CHAPTER 25 Rhinoviruses

Robert B. Couch

Rhinoviruses are the most commonly isolated viruses from persons experiencing mild upper respiratory illnesses (common colds). The name applied to this genus of *Picornaviridae* designates the primary site of infection with these viruses. In contrast to the enteroviruses, rhinoviruses do not appear to replicate in the intestinal tract. They also differ from enteroviruses in their greater species specificity and fastidious growth requirements.

HISTORY

The long association of colds with humans provided the basis for allusions to the malady in ancient history. Hippocrates believed therapeutic bleeding for common colds was a worthless treatment; and in the first century, Pliny the Younger recommended “kissing the hairy muzzle of a mouse” as therapy for colds. Benjamin Franklin spoke strongly against cold exposure and atmospheric dampness as being responsible for development of a cold; he believed that colds were acquired from other persons. Recordings of freedom from colds while at sea and occurrence of colds among voyagers and isolated populations when contact with continental populations was reestablished supported a belief in the contagious nature of colds.

In the early 1900s, colds were induced in volunteers by intranasal inoculations with filtrates of nasal secretions from other volunteers with colds. As a result of these various studies, colds were presumed to be caused by filterable agents (viruses).

Long-term studies of experimental colds in volunteers were begun by Andrews (5) in the 1940s at a Common Cold Research Unit in Salisbury, England. A great deal of understanding of the properties and spread of colds was provided by these studies and by similar studies at a later time by Jackson in Chicago (63,130,131). Andrews was able to propagate an agent in lung explants that later proved to be a rhinovirus; many of the nasal secretions used for inducing colds in volunteers at Salisbury and at Chicago also were subsequently shown to contain rhinoviruses. Long-term studies on the epidemiology of colds and other acute respiratory illnesses were begun by Dingle et al. (53) in the 1940s among families in Cleveland. These studies demonstrated the role of the family in the spread of colds and emphasized the greater incidence among children than adults.

The initial isolations of a rhinovirus were accomplished by Pelon et al. (175) and Price (188) using rhesus monkey kidney tissue cultures and nasopharyngeal washings from persons with colds. The initial isolates, strains 2060 and JH, were shown to be identical and were designated echovirus type 28; a subsequent definition of properties resulted in these strains being reclassified as rhinovirus type 1A. In 1960, Tyrrell and Parsons (228) at Salisbury isolated strain HGP by reducing the incubation temperature of cultures to 33°C, lowering the pH of tissue culture media to around 7.0, and gently rotating cultures during incubation. Use of these “conditions of the nose” and human tissue cultures then led to isolations of rhinoviruses in many locations. When the sensitive semicontinuous strains of human embryonic fibroblast tissue cultures described by Hayflick and Moorehead (117) and the conditions described by the Salisbury group were used routinely, a profusion of rhinovirus serotypes was detected.

Epidemiologic studies by Hamre et al. (111,112), Mogabgab (158), Gwaltney et al. (96,97 and 98,100,122), Monto et al. (160,161,162,163 and 164), Fox et al. (66,75,76,146), and others documented the major importance of rhinoviruses as a cause of mild acute respiratory illness and described many of the features of their occurrence in various human populations. Couch et al. (44) noted the surprisingly small amount of virus required to initiate experimental infections in

volunteers. Couch, Cate, and Douglas, with others (30,31,32 and 33,44,58,61,62), and Gwaltney, Hendley, and others (91,95,101,102,119,120) provided considerable information on the pathogenesis and immunology of rhinovirus infections.

The name “rhinovirus” was originally suggested by Andrews, and a description of the group was proposed by Tyrrell and Chanock in 1963 (227); this was adopted by a nomenclature committee. In 1967, a collaborative program (141) assigned numbers 1A through 55 to the known rhinovirus types. In 1971, a second phase added types 56 through 89 (142), and a third phase increased the number to 100 (106).

Both inactivated virus vaccines (60,177) and attenuated viruses (59) were tested in volunteers in the 1960s and 1970s, but the multiplicity of rhinovirus serotypes and lack of established methods for optimizing mucosal immunization soon led to a cessation of vaccine development. Efforts to develop antivirals has characterized research on control of the common cold for the past two decades. This effort was facilitated by the description of the three-dimensional structure of rhinovirus type 14 by Smith et al. (207), and of compounds capable of binding to the receptor site on the virion surface.

The introduction of molecular and structural biology into research led to identification and description of the cell receptors of rhinovirus and the structural biology of cell receptor and antibody interactions with the virion surface (Chapter 23). Recent epidemiologic studies, using nucleic acid amplification techniques for detecting rhinoviruses, have further increased the significance of rhinoviruses as causes of upper respiratory illnesses and documented a role for them in induction of serious disease in elderly persons and those with asthma and chronic lung disease.

INFECTIOUS AGENTS

Propagation and Assay in Cell Culture

Initial isolations were accomplished with rhesus monkey kidney tissue cultures (types 1A, 1B), but a clear superiority of human tissues for isolation and growth was shown later. Efficient growth of rhinoviruses occurs only in human and some primate cells; the presence of receptors on cell surfaces influences this tissue specificity (38). Three different cell-surface receptors are used by rhinoviruses (229). Type 87 alone uses a receptor other than the minor group receptor (low-density lipoprotein [LDL] receptor) used by 10 serotypes (1A, 1B, 2, 29, 30, 31, 44, 47, 49, and 62) and the major group receptor intercellular adhesion molecule 1 (ICAM-1)] used by the remaining described serotypes.

A variety of human cells are available for growth of rhinovirus. Those reported to be useful include human embryonic kidney, human amnion, diploid fibroblast lines from human embryonic lung, tonsil, liver, intestine, skin, adult fibroblast lines from aorta and gingiva, and the L132, KB, HEP-2, and HeLa continuous cell lines (94). Some strains may be detectable only with polymerase chain reaction (PCR) testing (140). Organ cultures of nasal and tracheal epithelium are required for growth of some fastidious strains (126), but whether strains detected only with PCR will all grow in organ culture is not known.

The most commonly used cells for rhinovirus growth are the WI-38 strain and the MRC-5 strain (133) of diploid fibroblasts (117), fetal tonsil cells (75), and rhinovirus-sensitive lines of HeLa cells (39). Comparative information on these different cell cultures for isolation of rhinoviruses from clinical specimens has indicated superiority of different cultures in different laboratories (10,43,150). Available data show that maximal isolation of rhinoviruses requires simultaneous use of several cell-culture systems.

Optimal conditions for growth of rhinoviruses include a concentration of bicarbonate in media of less than 0.35 g/L (pH 7.0–7.2), incubation temperature of 33°C, and slow rotation of cultures. Eagle's minimum essential medium is most commonly used for maintenance and is supplemented with 2% fetal calf serum and antibiotics. The low pH is less critical with use of HeLa and human fibroblast cultures than with monkey and human kidney cultures.

Growth of virus in cell monolayers is usually detected by appearance of cytopathic effects (CPEs); on rare occasions, interference with a second virus has been used. CPEs are similar to those produced by enteroviruses (Fig. 1). They initially occur in foci where cells become rounded, and some may swell; nuclei become disorganized, and the focus of the CPEs will contain cellular debris and both large and small rounded cells with pyknotic nuclei.

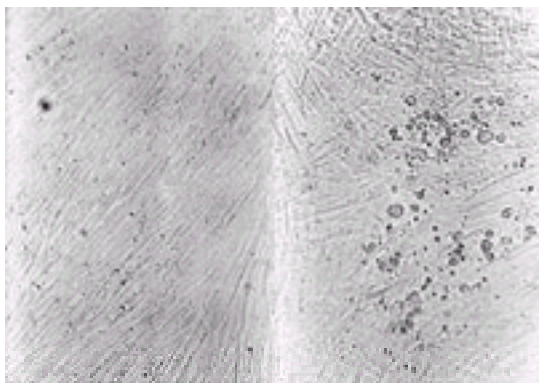

FIG. 1. Cytopathic effects in human fibroblast tissue cultures that are caused by a rhinovirus. **Left:** Normal WI-38 human embryonic lung fibroblast tissue culture. **Right:** A culture inoculated 2 days earlier with a rhinovirus. Note the variable cell size and numerous small, rounded cells.

Plaques can be obtained in a variety of cell lines with most described techniques by using purified agar or methyl

cellulose with diethylaminoethyl (DEAE)-dextran in the overlay (40,54,67). Different plaque sizes and appearances are a function of the overlay medium used. Added magnesium enhances plaque formation of many but not all rhinoviruses in HeLa cells (68).

Biologic, Chemical, and Physical Characteristics

The property used to distinguish rhinoviruses from enteroviruses is their acid lability. Inactivation occurs for all rhinoviruses below pH 6, and rapid and complete inactivation occurs at pH 3 (94).

In contrast to enteroviruses, most rhinoviruses are thermostable. Types 3 through 12, 15, 18, and 19 are relatively stable at 50°C for 1 hour; types 14, 16, and 17 are partially inactivated; type 13 is completely inactivated (147); and types 1A, 1B, and 2 are variable in their response. One molar magnesium chloride will stabilize most rhinoviruses but will not stabilize type 30. Rhinoviruses are relatively stable at 24°C to 37°C and will survive for hours to days on environmental surfaces (123); they are stable for years at –70°C.

Rhinoviruses are resistant to 20% ether, 5% chloroform, and sodium deoxycholate solutions; they are not destroyed by blending with fluorocarbon (94). A variety of disinfectants are virucidal (91,124). Types 3 through 6 and 14 were shown to be trypsin resistant, but types 1A, 1B, 13, 15, 16, 17, 32, and 33 were trypsin sensitive (148).

Description of Key Antigens

Rhinovirus infectivity can be neutralized by specific antisera. Structural analysis of a monoclonal neutralizing antibody indicated that bivalent binding by antibody is critical for strong neutralizing capacity and that both receptor-binding inhibition and capsid stabilization contribute to neutralization (208,209). Studies with neutralizing monoclonal antibodies against types 2 and 14 revealed three and possibly four or five sites on the contiguous halves of two icosahedral asymmetric units (7,202,203). One and possibly two sites are on VP1 toward the apex of fivefold symmetry, one spans the receptor canyon (see Chapter 23), and one and possibly two are near the base of the asymmetric unit and are on VP1 and 2. In recent studies, it has been shown that antibody may undergo conformational changes and actually penetrate the canyon (206). Although neutralization of virus in *in vitro* testing can occur with monovalent antibody binding, as well as binding away from the receptor canyon, bivalent binding that spans the canyon receptor site with high affinity characterizes the most potent neutralizing antibodies (35,125).

Designation of new serotypes is based on the neutralization reaction; absence of cross-reactivity of polyclonal antisera with established serotypes constitutes the criterion for a new serotype. These criteria resulted in acceptance of 100 serotypes (Table 1), but an unknown number of other serotypes exist. Work with hyperimmune rabbit sera revealed a number of cross-reactions between serotypes and led to the proposal that subgroups of rhinoviruses that share common epitopes must exist (42). The concept of shared epitopes is supported by occurrences of heterotypic antibody responses among humans infected with a number of rhinoviruses (70,159). Thus cross-reactions, some minor and some major, appear to be common among the different rhinovirus serotypes. Sequencing data on types 1A, 2, 14, 16, and 89 rhinoviruses indicate amino acid identity of capsid proteins between serotypes ranging from 41% to 83%; type 14 was least similar to the other four types (172). Sequencing of the genome region that included the major neutralizing antibody–binding site of 21 serotypes revealed at least 70% amino acid identity between serotypes with 84% identity between types 3, 14, and 72 (128).

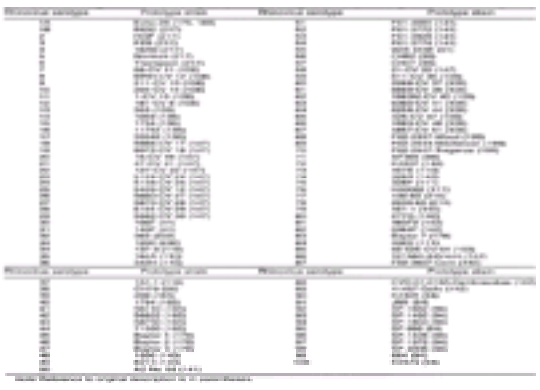

TABLE 1. *Rhinovirus prototypes*

Antigenic variants have been described for rhinovirus types 22 and 51 (200,216). Prime strains for a number of types also have been described (108,200). Prime strain antigenic variants of type 17 emerged from cell-culture passage in the presence of polyclonal antisera, but such variation did not occur for 15 other serotypes treated similarly (174). Description of intertypes further supports antigen variation as a property of rhinoviruses.

Treatment of rhinoviruses at pH 5 and 56°C produces particles that cross-react in immunodiffusion and complement-fixation tests with antisera to other rhinoviruses and with enteroviruses (94). Exposure of these common epitopes appears to result from a conformational alteration of the virus particle. This sharing of epitopes among picornaviruses is in keeping with the demonstration of nucleic acid homology between rhinoviruses and enteroviruses (204,212). Percentage homologies for the capsid proteins VP1 through 4 of type 2 rhinovirus and poliovirus type 1 are 17%, 45%, 49%, and 58%, respectively, whereas those for type 14 and polio 1 are 39%, 49%, 41%, and 58% (204).

Infection in Experimental Animals: Host Range

A major characteristic of human rhinoviruses is a high degree of species specificity, attributable for major group viruses primarily to presence of the receptor ICAM-1. Chimpanzees have been infected with types 14 and 43 and gibbons with types 1A, 2, and 14; no overt illnesses were observed in the infected animals (50,181). Inoculation of vervet and rhesus monkeys with M (monkey kidney grown) strains of virus did not produce infection. Infection was not produced in rabbits, guinea pigs, weanling mice, or 1-day-old mice injected with human rhinoviruses by the subcutaneous, intraperitoneal, or intravenous routes. Similarly, intracranial injections of monkeys, hamsters, or baby mice did not induce either infection or disease (108,148). Intranasal inoculation of ferrets, hamsters, and newborn mice also was without effect. One of the animal rhinoviruses, equine rhinovirus, can infect other species including humans (187); a hamster model for use in screening of antiviral compounds uses this virus. One of the human rhinoviruses, type 2, was adapted to grow in L cells and used in a mouse model of rhinovirus infection in which growth was demonstrated (236).

PATHOGENESIS AND PATHOLOGY

Elucidation of the pathogenesis and pathology of rhinovirus infections has been provided primarily through study of experimentally induced infections in normal adult volunteers. Descriptions of infections and illnesses are similar to those reported for natural colds.

Mechanisms and Route of Transmission

Rhinovirus infections are spread from person to person by means of virus-contaminated respiratory secretions. A clear demonstration of the feasibility of direct-contact transmission of rhinovirus infections was provided in studies using experimental infections (91,95,101,102). High concentrations of virus in nasal secretions and a propensity for ill persons to contaminate their hands and environmental objects with virus were demonstrated. Rhinovirus was recovered from 40% to 90% of hands of persons experiencing colds and from 6% to 15% of diverse environmental objects such as door knobs, dolls, coffee cups, and glasses (101,123). Rhinovirus exhibits good survival on many environmental surfaces for hours after contamination, and infection is readily transmitted by finger-to-finger contact and by finger to contaminated environmental surface if the newly contaminated finger is then used to rub an eye or touch the nasal mucosa (95). Hand transmission was interrupted experimentally by pretreatment of fingers with 2% aqueous iodine (102) or treatment of contaminated environmental surfaces with a phenol/alcohol disinfectant before finger contact (91). In separate observations, Hendley et al. (123) noted that frequent rubbing of the eye or “picking” at the nose represents normal human behavior. Thus there seems little doubt that rhinoviruses may be transmitted by direct contact.

Despite the availability of data supporting the possibility of direct-contact transmission, investigators have had difficulty demonstrating transmission by this route in natural circumstances (46,134). Indeed, one investigator (134) concluded that “spread of colds is unlikely to occur via objects contaminated by the hands of the virus-shedder.” Dick (52) suggested that failure to detect significant airborne transmission of rhinovirus was attributable to insufficient intensity of exposure. He developed a model exposure circumstance in which infected and ill volunteers slept and interacted closely, as in card games (156). There was a direct relationship between donor-hours of exposure and transmission rate to susceptible exposed volunteers in this model situation. Dick then restrained susceptible volunteers so they could not touch their faces (airborne exposure only) and found the transmission rate in this group to be the same as that among unrestrained volunteers (airborne and contact exposure). Exposure of another group to virus-contaminated playing cards did not lead to transmission. Thus airborne transmission of rhinoviruses can clearly occur.

A study of transmission of rhinovirus infection among childless couples, after one partner was artificially infected, showed that conditions associated with most transmissions were (a) presence of high titers of virus in nasal secretions, (b) presence of virus on hands and anterior nares, (c) presence of a moderately symptomatic illness, and (d) spending of many hours together (47).

The study of colds in Antarctica among persons completing 6 months of isolation and those just arrived from the United States has not shown differences in susceptibility of the two groups (231). Moreover, rhinovirus spread among susceptible persons has been slow and deliberate. The authors suggested that their experience supports effectiveness of good ventilation of buildings and proper disposal of nasal secretions in the prevention of spread of colds.

Infection and Illness

Infection can be initiated with less rhinovirus than is detectable in optimal assay systems. The 50% human infectious dose (HID_{50}) for antibody-free volunteers given rhinovirus type 15 by nasal drops corresponded to 0.032 median tissue culture infective dose ($TCID_{50}$) of virus when assayed in human embryonic fibroblast tissue cultures (44). Similar low HID_{50} values were obtained for rhinovirus type 13 (0.1 $TCID_{50}$) (55), type 16 (0.28 $TCID_{50}$) (46), and type 39 (0.4 $TCID_{50}$) (113), whereas the HID_{50} was 5.7 $TCID_{50}$ for a type 14 inoculum (120). The HID_{50} was increased if volunteers possessed prechallenge serum antibody (120). When the same type 15 inoculum referred to earlier was given by small-particle aerosol, the HID_{50} was increased to 0.68 $TCID_{50}$ (44); this 20-fold disparity in infectious dose between nose drops and inhaled particles suggests that the lower respiratory tract is less susceptible to rhinovirus infection than is the nasopharynx. Support for initiation of infection in the nasopharynx was provided by comparative 50% doses for infectious type 16 of 0.28, 1.39, 2,260, and 11,000 for the nasopharynx, anterior nares (internal), tongue, and anterior nares (external), respectively (46).

The incubation period to onset of virus shedding into nasal secretions is 1 to 4 days (58). Virus in secretions will increase rapidly to peak concentrations in most susceptible persons, and after a 2- or 3-day interval, titers will decrease to lower levels (Fig. 2); virus may remain detectable for 3 weeks. Persons with this early-onset high-concentration pattern of virus shedding are likely to develop respiratory illness, whereas persons who have a later onset tend to exhibit a slower increase in titer of virus in secretions and to remain clinically free of symptoms (58). Thus there is a direct correlation between titer of virus in secretions and occurrence, as well as severity of illness. Using biopsy and a method of

processing that ensured that detected virus was intracellular, Douglas et al. (56) also showed that the number of sites in the nasal mucosa where virus could be detected correlates with the titer of virus in nasal secretions at that time, indicating that the titer of virus in secretions is a reflection of the extent of mucosal involvement with infection.

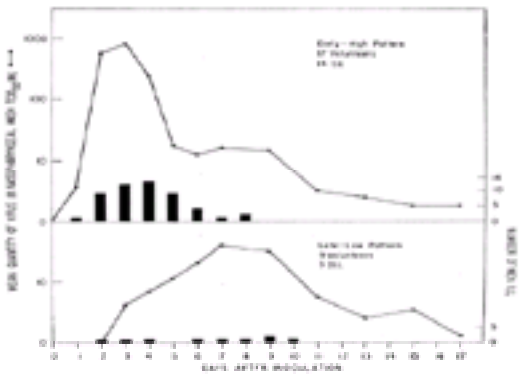

FIG. 2. Temporal quantitative virus shedding in nasopharyngeal wash specimens. Results are means for serum antibody–negative volunteers inoculated by the intranasal route with rhinovirus type 15. Volunteers in the early-high group began to shed virus on day 1 or 2; volunteers in the late-low group began to shed virus on day 3 or later. **Bars:** Number of men ill each day. From ref. 58, with permission.

Examination of nasal mucosa biopsy specimens that yielded virus and nasal polyp organ cultures in which virus replicated to high titers did not reveal histologic abnormalities (56,105,234,235). Nevertheless, virus recovery data (56), demonstrations of specific immunofluorescence and immunoperoxidase staining of columnar epithelial cells in nasal washings from infected volunteers (226), and replication of rhinovirus in ciliated epithelial cells detected by *in situ* hybridization (8,17) indicate that the primary site of infection is the epithelial surface of the nasal mucosa. Morphologic changes were noted in some but not all infected human tracheal organ cultures, but abnormalities were documented (192) in scanning electron microscopy of bovine tracheal epithelium infected with a bovine rhinovirus. Studies of the number of ciliated epithelial cells in nasal secretions from infected volunteers revealed a pattern of increase and decrease that paralleled symptom scores, but a correlation between number of cells in secretions and symptom score on the peak day of cellular shedding was not apparent (223). This absence of histopathology despite presence of virus in the nasal mucosa led to the postulate by Gwaltney et al. that chemical mediators of inflammation might be responsible for nasal symptoms (168).

Explant cultures inoculated with rhinovirus failed to develop CPEs, whereas those inoculated with influenza virus and adenovirus did (234). Full-thickness biopsies of the nasal mucosa during colds revealed marked edema of subepithelial connective tissue with sparse infiltration of inflammatory cells. Hyperemia, exudation of seromucinous fluid, and narrowing of nasal passages are known to accompany the histologic changes. During the height of illness, there is considerable transudation of serum proteins into nasal secretions (26), and this is accompanied by impaired mucociliary flow rates (198). An increase in kinins, enzymes with arginine esterase activity, albumin, and neutrophils has been detected in nasal washings from those who developed experimental or natural colds (168,190). There was no change in histamine levels in those studies. These studies supported the notion that kinins may induce the edema and transudation that partially accounts for the symptoms of the common cold. Nevertheless, a reduction in kinin levels that occurred during treatment of common colds with oral steroids was not accompanied by a reduction in symptoms (90). Search for other mediators of the pathophysiologic changes noted led to identification of elevated levels in nasal secretions of interleukin-1b (IL-1b), interleukin 6 and 8 (IL-6, IL-8), and tumor necrosis factor a (TNF-a) (218,221,225,237,238). IL-8 and other cytokines also have been detected in rhinovirus infection of primary and continuous bronchial epithelial cell lines (20,137,189,201,218,237). IL-8 is proposed as the mediator promoting neutrophil infiltrations into submucosal and epithelial sites, a finding in both nasal secretions and nasal biopsies of common cold patients. There is a correlation between IL-8 levels, neutrophils in nasal secretions, and severity of colds (225,234). Nevertheless, the relative importance of IL-8, other cytokines, neutrophils, other cells and kinins in the pathophysiology of common colds is yet to be determined, but the absence of histopathology in the nose strongly supports the notion that some constellation of mediators and neurogenic reflexes accounts for the physiologic abnormalities characterizing common colds.

Analysis of colds among experimentally infected subjects indicated that psychosocial factors influenced responses (37). Persons who had experienced stress and displayed mood alterations were more susceptible to infection and experienced more illnesses, whereas those with diverse social ties were more resistant. Such factors could influence symptom reporting as well as release and response to physiologic mediators.

Colds are more common in temperate climates during the colder months of the year, and a commonly held belief is that cold exposure and chilling will “cause a cold.” Early studies on the effect of “chilling” on causing colds and increasing susceptibility to virus challenge failed to detect evidence of an effect of cold (5). In a systematic approach to the question, Douglas et al. (61) examined the effect of chilling and transient lowering of body temperature on susceptibility to rhinovirus type 15 infection, on development and severity of illness, and on the pattern of recovery. No effect of either chilling or lowering of body temperature on the different phases of a rhinovirus cold was noted. Thus modern studies have failed to find an effect of cold and chilling on the development and course of colds.

The major site of symptoms, the nose, also is the major site of infection with rhinoviruses. Virus may be recovered from throat and oral secretions but never as frequently or in as high a concentration as in nasal secretions (30). A rare recovery of rhinovirus may be obtained from rectal swab or fecal specimens, but direct inoculation of the small intestine of volunteers with large doses of virus failed to result in establishment of infection (31). This finding indicates that the primary reason for the difference between rhinoviruses and enteroviruses in occurrence of intestinal infection does not

reside in destruction of rhinovirus during passage through the acid environment of the stomach. Viremia is not detected in healthy adults with colds, but viremia with a rhinovirus was reported in two infants who experienced unexpected crib deaths (230).

Rhinoviruses also can infect the lower respiratory tract and thereby account for lower respiratory symptoms. Rhinovirus inoculations of volunteers by small-particle aerosol has produced tracheobronchitis (29); rhinovirus is the only virus recovered from some infants with pneumonia; natural colds in healthy persons are often accompanied by lower respiratory symptoms and abnormal lung function (80); and colds may cause wheezing in asthmatic children (157) and exacerbations of chronic bronchitis in adults (213). These findings all suggested that infection of the lower respiratory tract can occur. Direct virologic evidence for growth in the lower tract was found recently in biopsy and bronchoalveolar specimens from infected volunteers (18,84) and immunocompromised patients (85).

Considerable effort has been devoted recently to defining the role of rhinovirus infection in lower respiratory disease and episodes of asthma and breathlessness in patients with chronic lung diseases. These studies have indicated that the majority of asthmatic attacks and a significant portion of exacerbations in patients with cystic fibrosis and chronic obstructive lung disease (COPD) occur in association with a viral respiratory infection; rhinovirus infections predominate in these episodes (15,25,138,139,171,191,210). Additionally, rhinovirus infections in elderly patients exhibit a high frequency of lower respiratory symptoms (169). Acute tracheobronchitis, a lower respiratory disease syndrome, was reported among healthy volunteers given rhinovirus 1A by small-particle aerosol in 1965, whereas similar inoculations with rhinovirus 15 did not exhibit this syndrome (44). The combination of clinical reports and evidence of infection of lower respiratory tract epithelium indicates that rhinovirus infection and disease in the lower respiratory tract can occur. Nevertheless, the infrequency of significant lower disease in healthy persons supports occurrence of this disease as primarily a complication experienced by certain populations. A possibility of risk for lower tract disease only accompanying certain strains was suggested by studies of comparative growth at 34°C and 37°C, in which some serotypes grew well at both temperatures, but others did not (173).

A major effort has been devoted to elucidating the pathogenesis of rhinovirus-induced attacks of asthma. Repeated demonstrations have been provided of enhanced responsiveness of the lower airways to histamine and acetyl choline analogs among rhinovirus-infected persons (36,71,78,82,89). In addition, inflammation in the lower airways, a cardinal feature of asthma (104), was documented in bronchial biopsies in rhinovirus-infected asthmatics (78). Notable in studies focused on detecting parameters of allergic disease (eosinophil infiltration, eosinophil cationic protein, evidence of an atopic state) has been their frequent identification in wheezing rhinovirus-infected asthmatics (78,81,88,136,186,191,219). An increase in neutrophils and IL-8 also has been noted in sputum of asthmatics (89,136,186). Thus evidence supports the notion that rhinovirus infection of the lower respiratory tract can lead to lower tract disease in persons with an increased risk for such an illness because of an underlying condition.

Rhinoviruses also have been recovered in pure culture from maxillary sinus fluids collected from persons with acute sinusitis (182), and Gwaltney et. al. (103) have demonstrated extensive abnormalities of the upper airways, including occlusion and abnormalities in sinus cavities during colds. Similarly, rhinoviruses have been recovered in pure culture from the middle ear of young children with otitis media (185). These findings have led to the proposal that rhinovirus infection can be described as a rhinosinusitis (93) and that otitis media in rhinovirus-infected children could result from rhinovirus infection of the middle ear (183).

Immune Responses

Neutralizing antibody to the infecting virus develops after infection in serum and secretions of the majority of persons. Among infected volunteers, detectable serum antibody usually developed between 7 and 14 days after inoculation, but in initially antibody-free volunteers, it might first be detected on day 21 (33). Reported frequencies of responses for natural infections have been as low as 37% and as high as 92%. With a sensitive assay using human tissues, Gwaltney et al. (97) documented an increase in serum antibody in 77% of persons from whom a rhinovirus was isolated. Fox et al. (75,76 and 77) indicated an effect of age on responsiveness because 59% of adults in their virus watch studies developed a response, whereas only 42% of children did so. Studies using experimental infections and low doses of virus in serologic tests usually documented a response in more than 90% of volunteers (30).

Using an enzyme-linked immunosorbent assay (ELISA), Carey et al. (28) indicated that the dominant serum antibody response to infection was in the immunoglobulin G1 (IgG1) subclass, followed by IgG3, IgG4, and IgG2; the dominant IgA antibody was IgA1. With blocking monoclonal antibodies, they showed that the serum antibody response was directed toward each of three separate sites. Neutralizing antibody responses in nasal secretions also develop in most persons infected with a rhinovirus, and the time of appearance parallels that for antibody in serum (33). Studies in experimentally infected volunteers have revealed such responses in 70% to 100% of infected persons (33,62). Antibody in secretions mostly sediments in the 9S to 14S region along with IgA, although 7S IgG and 19S IgM antibody may be detected (196).

During the illness phase of an acute rhinovirus infection, Butler et al. (26) documented a considerable transudation of serum proteins into secretions; if present before infection, this transudation will include specific IgG antibody. After the acute illness period, transudation ceases, and then the concentration of IgA progressively increases. By 7 days, this increase may be twice that detected in baseline specimens, even through specific antibody is not detectable for an additional 7 to 14 days. Douglas et al. (62) showed that neutralizing antibody also developed in tears and parotid saliva, even though no virus shedding in those secretions is detectable. Neutralizing antibody in serum and secretions may continue to increase in titer for 4 to 5 weeks after primary infection (33).

Serum antibody persists for at least 2 to 4 years after natural infections, but a decrease in titer of two- to 16-fold will occur in some persons; it is probable that antibody persists for many years. Measurements of nasal immunoglobulin and rhinovirus antibody among persons placed in Antarctic isolation revealed a decrease for a period of 5 months despite a stability of serum antibody titers during this time (127). Disparities in serum and secretion antibody ratios at the time of rhinovirus challenge (33) indicate that a disproportionate decrease in titer must have occurred for rhinovirus antibody in

secretions. Cate (33) reported a ratio of neutralizing antibody titer in nasal secretions to titer in serum of 1:2 after recent infection but a ratio of 1:16 remotely after infection. Nevertheless, the titer of antibody in serum always correlates with the titer in nasal secretions whether acquired by experimental or by natural infection. Other serologic methods have been used for detecting antibody to rhinoviruses, but none has been studied systematically.

Because of the late appearance of antibody in serum and secretions, it is believed that recovery from infection and illness is not dependent on its appearance (33). This belief is supported by the seemingly normal recovery exhibited by persons with isolated IgA deficiency and by those with hypogammaglobulinemia. Interferon is detectable in nasal secretions of one third of infected volunteers (32); it is usually present 1 or 2 days after the peak virus titer and therefore may play a role in recovery. However, it is detected only in those volunteers with highest titers of virus and most severe illness; for this reason, many believe other recovery mechanisms may be more important. Nevertheless, administration of interferon before challenge with rhinoviruses can prevent or reduce the intensity of infection (197). Cessation of virus shedding is directly related to time of first detection of neutralizing antibody in nasal secretions, suggesting that antibody accomplishes final clearance of infection (33).

Gern (83) isolated virus-specific clones of responsive lymphocytes and showed that cells from most persons are activated by a number of serotypes, indicating shared epitopes by different rhinoviruses. T cells from tonsils of children also responded to multiple serotypes; responses were by $CD4^+$ cells, and T_H1-type cytokines were released (233).

Immunity

Epidemiologic studies have revealed an increase in frequency of serotypes to which serum antibody is detectable with increasing age. Analysis of 184 sera from persons of various ages revealed an increase throughout childhood and early adult years, with a plateau after 35 to 40 years (107). This reduction corresponds to a decrease in infection rates among older persons. It seems likely that these findings are partly attributable to a reduced exposure to children in the home, but immunity to reinfection is probably operative as well.

Rates of rhinovirus infection and illness are lower among those with preexisting antibody than among those free of detectable antibody. In an early study among families in Wisconsin, the rhinovirus infection rate for the group with serum antibody was half that of the group with no antibody (46). About 20% of Seattle family members possessed preexisting serum antibody to the serotype producing infection in the family; the infection and illness rates were reduced by about 50% in this group (75,76). Similar reductions in infection frequency were noted among college students and military personnel with preexposure antibody.

A clear indication that homologous immunity develops after a rhinovirus infection was provided in studies using artificial challenge among volunteers. Increasing titer of preexisting serum antibody was accompanied by reduced frequency of infection and illness (30). When rechallenge was performed 1 month after infection, however, protection was greater than that seen with antibody acquired by a prior remote infection (30). This led to a serial evaluation of challenges with homotypic and heterotypic virus, which revealed a transient, nonspecific resistance to rechallenge that was manifested by a reduced frequency and magnitude of infection (69). Whether this represented transient cross-reacting antibody protection or a nonspecific effector mechanism was not determined. Nevertheless, protection against homologous reinfection was better early after infection than late after infection.

The probable natural history of antibody responses to rhinovirus infection is described in Fig. 3. As noted in the first panel, the titer of antibody in nasal secretions was about half that of serum antibody early after infection; at this time, immunity to homologous rechallenge had been complete. As indicated in panel 2, however, another group of volunteers with a similar serum antibody level but much lower nasal secretion antibody titer was reinfected. The third group of volunteers who resisted infection had higher serum antibody titers, and their nasal secretion antibody titers were similar to those seen early after infection in the primary infection group. The current prevailing concept of immunity is that both nasal secretion and serum antibody increase after primary infection, and in the first few months, antibody in secretions prevents reinfection. Antibody in secretions decreases with time, and renewed susceptibility results, so that reinfection occurs (panel 2). Eventually, sufficient antibody is present in both sites to prevent reinfection.

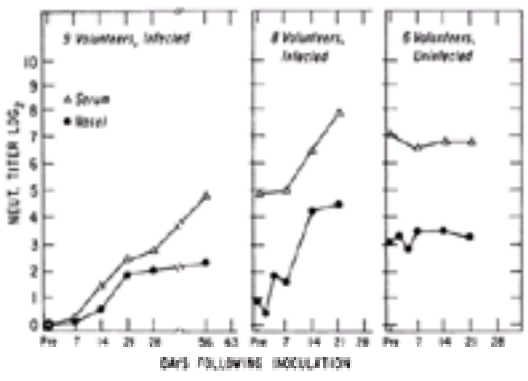

FIG. 3. Geometric mean neutralizing antibody titers against rhinovirus type 15 of nasal wash and serum specimens collected before and after inoculation with this rhinovirus. From ref. 33, with permission.

Attempts to prove that the IgA antibody in secretions is the mediator of resistance to infection have not produced clear results. Serum and nasal-secretion antibody titers correlate with each other, and both correlate with resistance to infection. To dissociate the two antibodies, volunteers were given intranasal or intramuscular vaccine with an inactivated rhinovirus type 13 vaccine and then challenged with infectious type 13 virus (176). A significant reduction in frequency of

illness and virus shedding was seen only among those given vaccine intranasally; in addition, antibody titers in secretions significantly related to occurrence of illness, whereas antibody in serum did not. A clear relation to prevention of infection was, however, not detected. Although quantitation of virus was not a part of that study, these results are best interpreted as showing partial but incomplete immunity attributable to IgA antibody.

Other data, however, support a primary role for IgA in resistance to rhinovirus infection. Studies on synthesis have indicated that more than 95% of this immunoglobulin is produced by local submucosal B lymphocytes. Concentrations of IgG in nasal secretions are only about one-tenth those of IgA, and about 50% of this IgG is produced locally. Thus although definitive data have not been provided, the primary mediator of resistance to rhinovirus is likely to be specific IgA antibody in nasal secretions. During acute illness, there is a considerable transudation of serum proteins, including serum IgG, into secretions, so a contribution of serum antibody to modifying an established infection and any accompanying illness is possible.

EPIDEMIOLOGY

Relation to Age, Sex, Season, and Location

Rhinovirus infection rates are highest among infants and children and decrease with increasing age. Actual virus isolation rates for a group of Seattle families and insurance company employees in Virginia are shown in Table 2. Such rates depend on sensitivity of methods used and reflect minimal estimates. Rates of rhinovirus infections among infants are thought to be highest because of the extreme susceptibility of this age group to any rhinovirus brought into the household. The mean rate for Seattle families was 0.68 infections per person-year (75); rates were intermediate among young children and lowest among mothers. Rates in Virginia for the same age group as mothers in Seattle were higher, although rates in that study also decreased with increasing age (96). Adjustment of the Seattle rates to reflect the Virginia rates would indicate that infants and small children average more than one rhinovirus infection per year. Rates for young women in Virginia and in a Tecumseh, Michigan, survey were higher than those for men of similar age (96,164). A greater exposure to young children is thought to account for this difference.

Population group	Age (yr)	Mean isolations per person-year	Mean illnesses per person-year[a]	
Seattle families (52)	0–1	0.84	0.75	
	1–2	0.64	0.87	
	2–5	0.64	0.74	
	6–9	0.64	0.31[b]	
	Mothers	0.25	0.54	
	Fathers	–	0.35	
			Males	Females
Charlottesville working adults (65)	18–25	0.56	0.47	0.60
	26–35	0.59	0.48	0.52
	36–45	0.57	0.69	0.53

TABLE 2. *Relation of age to rhinovirus isolation and illness rates*

Rhinovirus illness rates also are highest for small children and decrease with increasing age (see Table 2). Estimates of rates for Seattle families were near 0.8 per person-year for young children and 0.54 for mothers. The illness rates for mothers in Seattle and women of comparable age in Virginia were similar and were greater than those for young men. Compensation for this higher illness rate among young women in early adult years appears to ensue in later years, when illness rates are higher among men (96).

When compared with respiratory illnesses caused by other viruses, a general mildness of rhinovirus illness is reflected in a low percentage of persons seeking health care for illness. In the Michigan community surveillance, rhinoviruses represented 38.5% of viruses isolated from all acute respiratory illnesses but only 23.3% of illnesses that caused a person to consult a physician (164).

Rhinoviruses are isolated from persons experiencing respiratory illness in temperate climates in all months of the year. However, studies in a variety of populations in various parts of the U.S. indicate an increased frequency in early fall and late spring (75,76,96,162,164). Increased prevalence in the fall was noted in each of 4 surveillance years in Seattle, Washington, although an increase was noted during spring in only 2 of 4 years (75). The same fall and spring prominence was noted in Charlottesville, Virginia, but an increase during fall months was most common (96). Rhinovirus isolations may be prominent during winter months, but this appears to be uncommon; although present, prevalence rates are regularly lowest in summer.

Rhinoviruses have been clearly demonstrated as common causes of colds in the U.S. and in Western Europe. Although epidemiologic studies associating rhinoviruses with respiratory illness in other parts of the world are limited, serum antibody prevalence data have indicated that rhinovirus infections are widespread throughout the world (22). A 29-month surveillance of young children in an impoverished urban population in Brazil revealed a high incidence of respiratory illness and a dominance of rhinoviruses in specimens from the children (12).

Morbidity in Specific Population Groups

Families

The family unit is established as a major site for spread of rhinoviruses in contemporary society. Considering the index case as the introducer among families in Seattle led to a conclusion that the highest rate of introductions was attributable to young children and primarily to those younger than 2 years (75,76). Introductions, their rate, and the calculated relative risk for this event indicated that 50% of introductions were by children younger than 2 years old and about 75% were by preschool children. The basis for such a high frequency for infants and small children is uncertain but is believed to reflect their high degree of susceptibility, so that exposure to infected baby-sitters, friends of the family, and fomites contaminated by playmates or siblings results in a high infection rate. In a smaller group of working families in Virginia, the school-aged child was a more common introducer, and adults also were prominent. Family size is directly related to number of family episodes of rhinovirus infections (75).

Secondary infections within the family are most common among young children and mothers but occur in all members of the household; these infections appear at 2- to 5-day intervals, but most will appear within a few days of onset of illness in the index case (75,76). Secondary attack rates in the family have varied between 30% and 70%, but most studies have revealed rates of about 50%. When antibody-free (susceptible) members only are considered, secondary rates of 70% are common. Secondary infection rates in families decrease with increasing age and are higher among mothers than fathers, presumably because of their close exposure to children in the family.

Characteristics of the introducer influence the secondary attack rates in families. Among Seattle families, the secondary attack rate was 71% if the introducer was ill but only 27% if he or she was well, a finding similar to that noted for spread between spouses (75).

Schools

Efficient spread of rhinoviruses among children in a nursery school was demonstrated by Beem (19), who detected rhinovirus infections more commonly than all other respiratory virus infections combined. Rhinoviruses clearly spread among university students, medical students, boarding school populations, and probably other groups in dormitory-type situations who have little or no contact with children (100,111,112,158). The manner of spread of rhinoviruses and features of their epidemiologic behavior in these populations have not been described.

The simultaneous occurrence of respiratory illness peaks among children and adults, as well as among working adults with and without children, suggested that something other than opening of school accounted for the fall increase (122). Attempts to identify a correlative meteorologic event were not successful. Nevertheless, once infected, children were instrumental in introducing rhinoviruses into families.

Military

Rhinoviruses cause a major portion of afebrile respiratory disease in military populations. The season of peak occurrence has been more varied for this population (21,158). In a prospective study among marine and navy recruits for a 4-week period in November, Rosenbaum et al. (195) reported an attack rate of almost 90%, with many recruits experiencing two infections during this interval. Accompanying illness was typically an afebrile upper respiratory illness, and this occurred an average of 1.2 times per person during the 4-week period. This extraordinary attack rate has not been reported by others; relative frequencies of antibody to rhinoviruses were similar among university students and a population of young airmen, suggesting that rhinovirus infection rates relate better to age than to population group (158).

Epidemiology of Serotypes

Initial observations on serotyping of rhinovirus isolates indicated that a multiplicity of serotypes existed (95), that surveillance of a population for several months would result in isolation of several distinct types, and that prevalent serotypes would change from year to year. This multiplicity of serotypes of presumed medical significance provided the primary basis for the belief that conventional vaccination approaches for prevention of rhinovirus illness were not reasonable. Nevertheless, it was noted in early reports that a small number of the serotypes caused most of the illnesses. In the nursery school population described earlier, 14 serotypes were detected in a 10-month period, but only seven of the 14 spread to another child, and only three spread extensively. Studies in other populations also suggested a varying degree of transmissibility for the different serotypes. Mogabgab (159) noted that only eight of 37 serotypes recovered from military and university students accounted for 81% of 301 isolates. In New York families, 11 of 39 serotypes accounted for 55% of isolates; in Seattle families, 15 of 59 serotypes accounted for 57% of 456 isolates; and in Virginia industrial employees, 10 serotypes accounted for 53% of 197 isolates (74). Although an Antarctica population was equally susceptible to two different rhinoviruses, only one spread in the population (231). Characterization of rhinovirus serotypes in subsequent surveillance periods (76,160) has continued to show prevalence of a limited number of serotypes. However, only some of the prevalent types were prevalent in earlier surveillance periods, so that the number of serotypes producing most disease may still be large. Andries (6) systematically evaluated capsid-binding antivirals against all serotyped rhinoviruses and identified two cluster groups on the basis of antiviral sensitivity; one group contained 33 serotypes, and the other contained 67 serotypes. Viruses within a group exhibited sequence similarities for viral protein I (VPI) and the antiviral binding site. Published data for 1,018 isolates suggested a natural occurrence of infections with the 67-serotype group at 2.37 times the expected rate.

A change in distribution of serotypes recovered over a 7-year period in Virginia consisted of an increase in higher-numbered serotypes and in nontypeable strains with time (27). Analysis of serotypes occurring at New York, Seattle, and Michigan during this same period also suggested antigenic variation (74). Antigenic characterization of later isolates, however, indicated that rhinoviruses identified earlier were still prevalent. Antisera to types 1 through 89 identified 15 (94%) of 16 isolates in Boston in 1982 through 1983, 752 (95%) of 790 isolates in Seattle in 1975 through 1979, and 194 (93%) of 209 isolates in Tecumseh, Michigan, in 1976 through 1981 (108).

Prevalence

Illness induced by rhinoviruses probably represents the most common acute infectious illness of humans. National Health Survey data for the U.S. indicate that acute respiratory illness accounts for about half of all acute conditions on an annual basis. Of absenteeism among insurance companies at Charlottesville, Virginia, 36% was attributable to respiratory illness; in a group of Seattle families containing young children, 86% of all illnesses over a 4-year period were respiratory. The most commonly isolated viruses from persons experiencing acute respiratory illness are rhinoviruses. The prevalence of these viruses among persons in disparate populations in the U.S. who were experiencing acute respiratory illness indicates that a greater frequency of illness is caused by rhinoviruses than by other common viral respiratory pathogens. With conventional isolation tests, 42% to 77% of isolations were rhinoviruses (19,21,66,111,158,161,166). Estimates of the proportion of acute respiratory illnesses caused by rhinoviruses varied between 10% and 40% among various populations. These varying frequencies reflect the population studied, period of observation, and methods used. In recent reports, addition of the PCR for detecting rhinoviruses has increased the rhinovirus proportion from 20% to as much as fourfold (10,15,129,140,152). Because serology for rhinoviruses is not used in most surveillance studies, it is reasonable to suggest that one third to one half or more of all acute respiratory illnesses are caused by rhinoviruses.

CLINICAL FEATURES

Primary Illness

The typical illness accompanying rhinovirus infection is a common cold. Predominant symptoms are sneezing, nasal obstruction, nasal discharge, and sore throat, but other prominent symptoms are headache, cough, and malaise. The percentage of persons in a variety of different populations who reported various symptoms during a rhinovirus infection is shown in Table 3. Notable is the fact that, despite a prominence of symptoms in the upper respiratory tract, symptoms referable to the lower respiratory tract, gastrointestinal system, and other organ systems are not uncommon. Fever varies in frequency of occurrence but is generally seen in no more than 10% to 20% of persons (see Table 3). Physical examination usually confirms the presence of nasal obstruction and discharge and reveals a hyperemic or pale edematous nasal mucosa. Minimal erythema of the pharynx and tender cervical nodes also may be present, but otherwise abnormal findings are not usually detected (30). Nasal secretion weights in experimental colds averaged 8.5 g for the maximal period of rhinorrhea but varied between 0 and 85 g (30). An elevation in neutrophil and a decrease in lymphocyte counts are seen in peripheral blood leukocytes on the first day of illness, but counts return to normal in 1 or 2 days (30). About one third of experimentally infected volunteers developed a transient elevation in erythrocyte sedimentation rate.

Symptoms	Percentage reporting symptoms				
	Military recruits	Health care employees	English schoolboys	Industrial employees	Children OPD pts.

TABLE 3. *Symptoms associated with rhinovirus infections in persons from whom virus was isolated*

About two thirds of antibody-free volunteers will develop an illness with an experimentally induced infection (30,44,58), and similar percentages of naturally occurring infections will be accompanied by illness. Illness occurred in 63% and 60% of infected family members (75,146), 69% of infected employees of an insurance company (96), 88% of infected medical students (111), and 74% of infected military recruits (21). Frequency of colds among infected persons appears unrelated to age.

Illness is maximal for 2 or 3 days; then symptoms progressively improve. The median duration of illness in the insurance company population listed earlier was 7 days, with symptoms persisting for 2 weeks in 25% of persons and occasionally for as long as a month. In cigarette smokers, the frequency of cough was increased, and the duration of illness prolonged (97).

Complications

Colds are believed to predispose to development of sinusitis and otitis media because persons with these latter diseases frequently give a history of a simultaneous or preceding upper respiratory illness. Gwaltney (103) showed sinus disease as frequently present in persons with clinical colds only, with involvement of maxillary and ethmoid sinuses most common. For this reason, he considered rhinovirus colds to be cases of acute rhinosinusitis. Detection of rhinovirus in middle ear and sinus fluid and other studies associating rhinovirus with otitis media in children argue strongly for a role of rhinoviruses in this complication (182,184,185). Rhinovirus isolations were present in 6% to 8% of sinus aspirates of adults with acute sinusitis, but reverse transcription-PCR (RT-PCR) testing of sinus brushings in one study revealed a rhinovirus in 40% of specimens (183,186). Similarly, abnormalities in middle ear pressure are common in persons experiencing colds (24,64), and rhinovirus isolations have been obtained from middle ear fluid of children with clinical

otitis media (179). When RT-PCR testing was applied to such fluids, 19% and 24% of specimens were positive for rhinovirus (184,185).

Acute bacterial sinusitis or otitis media is presumed to result from obstruction of the orifice of the eustachian tube or of a sinus, owing to the local edema accompanying virus infection, a finding demonstrated among infected and ill volunteers (154). Specimens from persons with acute sinusitis or otitis have yielded virus only, bacteria only, and both (182,185). The role of each or both in disease is not yet clear.

Lower respiratory disease has been reported to occur more commonly among infected healthy infants and children than among infected adults (194), and rhinoviruses have been associated with atypical pneumonia in airmen (158) and recovered from the lung and lower respiratory tract of immunocompromised persons with pneumonia (45,85). Rhinoviruses are commonly isolated from young children experiencing serious lower respiratory disease, including pneumonia (2,155), and have been reported to occur in up to 40% of exacerbations of chronic bronchitis (213), and 16% to 18% of exacerbations in children with cystic fibrosis (183,210).

Special attention has been given recently to respiratory viral infection as a cause of exacerbations of asthma. Most cases are associated with a respiratory viral infection, and rhinovirus infections are detected most commonly (15,138,139,157,171,191). Asthmatic children also reportedly experience more rhinovirus infections than their siblings, and illnesses last longer. In a study of wheezing among children, rhinovirus infection was associated with 71% of episodes in children aged 2 to 16 years, and comparisons of wheezing children with contacts indicated a significant risk for wheezing if rhinovirus-positive cases also were positive in radioallergosorbent tests (RASTs) for allergen-specific IgE, demonstrated nasal eosinophilia, or elevations in eosinophil cationic protein (191).

DIAGNOSIS

Clinical

The typical constellation of signs and symptoms leading to diagnosis of a common cold is well known. Although many symptoms may be reported, nasal obstruction and/or nasal discharge must be present and be the dominant symptoms. When contrasted to colds caused by other viruses, no distinctive features of colds caused by rhinoviruses emerge that permit an etiologic diagnosis from clinical findings alone. The epidemiologic setting of the illness may, however, permit a presumptive diagnosis of rhinovirus common cold. Features suggesting a rhinovirus etiology are occurrence of a cold in early fall or late spring, particularly in an older child or adult while schoolmates, playmates, or family members are experiencing similar illnesses. Rhinoviruses may cause other acute respiratory illness syndromes, but the predominance of other viruses in these syndromes makes a rhinovirus etiology unlikely.

Laboratory

Viral Isolation and Identification

Specimens containing nasopharyngeal secretions are best for virus isolations. Oral secretions and sputum specimens (when available) are low-yield specimens. Rhinoviruses are rarely detected in rectal swab or stool specimens.

Studies in volunteers indicated virus was present in highest concentrations in nasal secretions, and maximal isolation frequencies were obtained on day 1 or 2 of illness (30,58). Virus was isolated from more than 50% of specimens obtained from persons with naturally occurring rhinovirus colds between the day before and 6 days after onset of illness, but maximal frequencies were on the first five illness days (75).

Isolation of rhinoviruses requires use of cell cultures. No experimental animal is suitable, and growth does not occur in embryonated hen's eggs. Cell cultures of human origin are preferred; human embryonic fibroblast cell cultures and rhinovirus-sensitive lines of HeLa cells have been used most extensively (see Propagation in Cell Culture). Organ cultures of nasal and tracheal epithelium are required for growth of some fastidious rhinovirus strains, but routine use of such cultures is impractical (126).

Comparisons of the rhinovirus-sensitive line of HeLa cells and various sources of human embryonic fibroblasts have not shown a clear superiority of a single tissue culture for isolations (10,43,150). Although the optimal tissue culture for rhinovirus isolation is unclear, most investigators use either the WI-38 or MRC-5 strains of human embryonic fibroblasts. Use of more than one type of cell culture is required for optimal isolation. Addition of antiinterferon antibody to 256 specimens obtained from children with respiratory illness led to isolation of a rhinovirus from 40 specimens, whereas only 19 were positive when this antibody was not present (79).

Tissue cultures are observed frequently for CPEs (see Propagation in Cell Culture). CPE is usually detected in the first week and is frequently detected the second or third day after inoculation of cultures. When a culture system such as WI-38 cells is used, observation beyond 10 to 14 days is not necessary.

Presumptive identification of an isolate as a rhinovirus may be made on the basis of the tissue cultures supporting growth, the pattern of CPE, and demonstration of lability at pH 3 (94). A PCR assay using specific primers is an acceptable alternative to an acid lability test for differentiating between rhinoviruses and enteroviruses (14). Definitive identification requires neutralization of 32 to 100 $TCID_{50}$ by specific antisera. Although described for only a few serotypes, typing was accomplished with PCR followed by restriction enzyme analysis of a 380-bp fragment from the 5' region and by hybridization with 3' region probes (73,220).

Direct Detection of Rhinoviruses

Dearden (49) described an ELISA assay using rabbit hyperimmune serum to type 2 and an untyped strain as both a capture and detecting antibody. A degree of cross-reactivity of antigen was present, suggesting that a single system could detect about two thirds of 57 different serotypes. Sensitivity appeared high, and amplification overnight in tissue culture appeared to provide some advantage. Use of the assay for direct detection of type 2 virus in secretions from infected volunteers revealed a sensitivity greater than virus isolation (3). The same group also described use of oligonucleotide probes for detecting rhinoviruses in clinical samples (23).

Reports from a number of sources have now documented the fact that use of RT-PCR for detecting rhinoviruses invariably leads to higher numbers of proven infections (13,15,129,140,170). The increased proportion attributable to PCR has varied considerably, presumably because of varying sensitivity of the culture and PCR methods used.

Serologic Diagnosis

The multiplicity of rhinovirus serotypes and the relative lack of cross-reacting antigens prevent routine use of serologic means for diagnosis of rhinovirus infection. A variety of serologic methods have been described, however, and may be used for a serologic diagnosis if the infecting serotype is known. Neutralization tests are sensitive for detecting a serologic response, provided low doses of virus (6–16 $TCID_{50}$) are used in the tests. Both macro- and microneutralization tests that use tissue cultures have been described (94). Plaque-reduction neutralization tests also have been described for the latter procedure; a purified agar or methyl cellulose overlay is needed for plaque formation, and size is enhanced by addition of magnesium and DEAE.

A description of hemagglutination of sheep erythrocytes by certain rhinoviruses led to the development of a hemagglutination-inhibition test for serum and nasal secretion antibody (193). Correlation of titers with those detected in neutralization tests was good, but seroconversion was detected in fewer than half of volunteers who shed virus. An indirect hemagglutination-inhibition test also has been described (94). Although complement-fixing (CF) rhinovirus antigens have been described, use of the CF tests for detecting antibody in humans resulted in frequent detection of responses to heterotypic rhinoviruses and detection of responses after enterovirus infections (94). Moreover, CF antibody did not parallel neutralizing antibody titers. A sensitive ELISA assay using antibody-captured rhinovirus as antigen can detect IgG and IgA in serum and IgA antibody in unconcentrated secretions (16).

PREVENTION AND CONTROL

There are no established methods for effective prevention or treatment of rhinovirus infections. A variety of approaches have been evaluated, most with little or no effectiveness. Nevertheless, certain principles emerging from these studies provide direction to development efforts.

Nonspecific Measures

The commonness of common colds accounts for the multitude of approaches suggested to prevent or treat colds by lay-persons, scientists, and physicians. These approaches include various medicaments, nutritional supplements, and recommendations of various types of human behavior that supposedly enhance host resistance. None of these is accepted as being of proven value for prevention or treatment of colds.

In the card-game exposure situation described earlier (see Transmission), transmission was completely prevented when citric acid/malic acid–impregnated tissues were used frequently, and donors were prompted to blow their noses gently and smother all coughs and sneezes. The need for the chemical impregnation was not established, so it is possible that attention to the hygienic measures alone would be effective for preventing spread. Similarly, the reduction in transmission in the home with use of iodine on fingers supports the view that hygienic measures would be beneficial (121).

A number of studies have been performed on the effect of various treatments for rhinovirus colds. Included have been analgesics, antiinflammatory compounds including oral and topical steroids (1,65), decongestants (205), anticholinergics (92), antihistamines (151), vitamin C (34,118), zinc lozenges (132), extracts of *Echinacea* (87), and inhalation of hot humidified air (119). Beneficial effects on symptoms have been described, and it is accepted that reductions in rhinorrhea, nasal obstruction, cough, and so on can be achieved with use of some of these medications.

Vaccines

Monovalent and multivalent inactivated vaccines have been evaluated against artificial challenge in volunteers (60,177). A problem with such vaccines appeared to be antigenic dose, because the systems used for preparation of viral antigen did not yield doses comparable to those used for poliovirus vaccines. Nevertheless, a few potent preparations induced titers comparable to those after natural infection (60,177); reductions in virus shedding and severity of illness resulted, but neither infection nor illness was prevented. These findings contributed to concepts of the relative significance of serum and nasal secretion antibody in immunity to rhinovirus infection and illness described earlier, because little or no secretion antibody appeared after intramuscular immunization.

A live-attenuated strain of rhinovirus type 15 was developed, and differing plaguing properties of the wild parent and the attenuated progeny were described (59). Use of attenuated viruses for immunization would require use of multivalent live preparations. Despite some promise, the live-virus vaccine approach has not been pursued.

Problems for all immunization approaches are the multiplicity of serotypes and the suggestion that most have epidemiologic significance (160).

Antivirals

Because of the problems with vaccination as an approach to control of rhinovirus infections, most effort has focused on development of effective antivirals. A great variety of compounds and types of compounds have exhibited *in vitro* activity, but few have demonstrated effectiveness at the clinical level (11).

Early studies using various interferon inducers demonstrated production of interferon in nasal secretions and a degree of prophylactic effectiveness that was related to the amount of interferon induced (57). The description of the three-dimensional structure of rhinoviruses permitted precise assessment of drug interaction with capsid proteins. A number of compounds were described that bind to the pocket at the floor of the canyon, displacing the floor so that receptor binding could not occur; some also inhibited a step during eclipse (207). Compounds exhibiting this mechanism of action include a variety of isoxazole derivatives, flavinoids, pyridazines, and others. These compounds have contributed to understanding the receptor-binding process through three-dimensional structure analyses, but testing for effectiveness in humans has been almost uniformly discouraging. Active compounds that were well absorbed after oral administration lacked a beneficial effect on infection or illness (180,222). The lack of effect was attributed to insufficient drug in nasal secretions, a finding for some other candidate antirhinoviral compounds. Topical administration of canyon inhibitors also has failed to provide a beneficial effect, but when incorporated into a cyclodextrin, a relatively insoluble compound, R61837, exerted some clinical effect (4). Pleconaril, another canyon inhibitor, had clinical benefit in one dosage group (114), whereas topical pirodavir, one of the most potent and broadly reactive canyon inhibitors, led to reduced viral shedding but no clinical benefit (115). Other antirhinoviral compounds with different mechanisms of action, such as the benzimidazide derivative enviroxime, have exhibited similar problems in demonstrating value (180). An ICAM-1 inhibitor (224) and a protease inhibitor were shown recently to be effective in volunteers challenged with a rhinovirus (9,144,149,167,224). Thus the problem in development of antivirals for rhinovirus infection is not in identifying potent and safe drugs but in developing methods for optimal administration to the nasal mucosal cells. Greenberg et al. (86) provided insight into the problem with a series of physiologically oriented studies using interferon. Structure, direction of air flow, chemical nature of secretions, and mucociliary clearance are all important factors in design of optimal approaches for topical administration of antivirals. Mechanisms of action that require constant presence of the antiviral in secretions can impair use. Other problems for antiviral use include development of resistant strains (9,48) and obtaining effectiveness for treatment as well as prevention because the peak viral shedding and illness periods are brief.

The availability of recombinant DNA–produced interferon led to evaluation of larger doses of interferon for prophylaxis of rhinovirus infection. Use of a 5-day schedule beginning before challenge resulted in a high degree of effectiveness (80%) in prevention of illness if intranasal doses were at least 10^7 units per day (197). When these doses were used for longer periods, however, local erosions, nasal stuffiness, and blood-tinged secretions occurred (197). Studies with interferon indicate a greater effectiveness for interferon a than interferon b for preventing rhinovirus infection (211). When used for short periods in contacts of a family member with a cold, effectiveness for prevention of rhinovirus infection was demonstrated (113). Although it is possible that practical ways to use this approach for prevention of rhinovirus infection might be developed, use of interferon has not been pursued. Administration of very high doses for therapy of established infection has not been effective (116).

PERSPECTIVE

The emergence of rhinovirus infections as the most common cause of common colds, a relatively minor illness in healthy persons, led to the belief that causing loss of time from work and school constituted their medical significance. In the past few years, they have emerged as infections also causing more severe disease. Currently they are the most common cause of episodes of asthma, are a cause of exacerbations of illness in persons with underlying lung disease, and convey a risk for lower respiratory disease in elderly persons. Moreover, they may directly and indirectly cause many cases of acute sinusitis and otitis media; a quantitative definition of the role of rhinoviruses, bacteria, and simultaneous virus and bacterial infection in causing sinusitis and otitis media is needed. However, developing effective control of rhinovirus infections constitutes the most important need for future disease-related research. Because conventional approaches for vaccine development do not appear reasonable for prevention of infection and clinically useful antivirals have not yet been identified, continued efforts to define more precisely the mediators and/or mechanisms for disease causation is desirable not only to understand better the pathogenesis of disease but also to permit design of inhibitors of disease. A reduction in disease among infected persons could have benefit at several levels: shortening the course of illness, reducing the risk of complications, contributing to relief of asthmatic episodes, and reducing spread of virus to susceptible persons. Although not specifically directed toward the infection, such a modality might also be useful for preventing illness in exposed persons' families and other population groups.

Continued efforts toward identifying antivirals effective against most rhinoviruses remains as an important effort. Although the record of the past is not encouraging, an antiviral useful for prevention of infection and/or illness in exposed persons would have value, and one that is safe and effective for both prevention and treatment would constitute a major medical accomplishment.

CHAPTER 26 Hepatitis A Virus

F. Blaine Hollinger and Suzanne U. Emerson

HISTORY

Ancient Chinese literature made reference to the occurrence of jaundice [reviewed by Zuckerman (455)], as did a letter from Pope Zacharias to Archbishop St. Boniface of Mainz during the 8th century AD (279). However, it was not until the 17th, 18th, and 19th centuries that scattered outbreaks of jaundice affecting diverse populations were recorded more frequently. The disease was especially common among the military and was called *campaign jaundice.* Although the prevailing view was that all types of jaundice were obstructive, an infectious etiology was suspected by a number of clinicians, especially for the milder, more contagious forms of jaundice called *epidemic catarrhal jaundice.*

An accurate accounting of epidemic jaundice was made by Cockayne (58) in 1912, who believed that the disease reached the liver through the blood, although the aerosol route was erroneously considered to be the principal mode of spread. Cockayne used the term *infectious hepatitis* to describe the epidemic form of the disease. McDonald (272) postulated that acute yellow atrophy of the liver may be caused by a virus acting on a “previously damaged liver.” Support for a viral etiology of infectious hepatitis gained favor from that point forward.

In 1923, Blumer (37) summarized the pattern of illness found in 63 outbreaks of epidemic jaundice reported in the United States between 1812 and 1922. Most infections occurred in children or young adults, developed 7 to 10 days after exposure to a jaundiced patient, showed a peak incidence in the fall and winter, and appeared to be transmitted largely by person-to-person contact. The relatively short incubation period seen in many cases probably reflected co-primary events, rather than secondary cases, or failed to take into account the period of communicability that precedes clinical disease. Nevertheless, these early observations established the existence of one of the major forms of viral hepatitis, now known as *viral hepatitis type A.*

Epidemiologic studies and human volunteer experiments performed during and after World War II confirmed the viral etiology of this disease and demonstrated its uniqueness from homologous serum jaundice, another form of hepatitis having a longer incubation period (38, 162, 163, 213, 249, 273, 276, 423). In 1947, MacCallum (246) introduced the terms *hepatitis A* and *hepatitis B* to categorize these diseases. These terms have been adopted by the World Health Organization (WHO) Committees on Viral Hepatitis (441, 442) to replace the myriad descriptions previously applied.

Between the late 1950s and early 1970s, the studies of Murray (289) and Krugman et al. (213) were instrumental in further defining the seroepidemiologic relationships between hepatitis A and B and eventually led to the evaluation of new methods for the immunoprophylaxis of these diseases (214). Two distinct types of hepatitis were differentiated at the Willowbrook State School for the Mentally Handicapped (see also Chapter 87). One of the hepatitis agents, designated *MS-1,* was transmitted primarily by the fecal–oral route but also could be spread by inoculation of blood obtained during a transient stage of viremia that occurred during the incubation period. The disease was highly infectious, had a relatively short incubation period of 4 ± 2 weeks, and closely resembled classic viral hepatitis type A. The MS-1 strain of hepatitis A virus (HAV) was used to infect adult volunteers in whom the disease was reproduced (38), and the virus was clearly identified for the first time by immune electron microscopy of their feces, as reported by Feinstone et al. in 1973 (108). Over the next 3-year period, highly sensitive immunoassays were developed for detecting the antigen and its antibody, culminating in the development of immunoglobulin M (IgM)-specific anti-HAV tests to distinguish recent HAV infection from a previous infection (reviewed in 172). In 1979, Provost and Hilleman (322) were successful in cultivating and serially passaging HAV in cell culture, an important step that contributed to the development of a vaccine.

INFECTIOUS AGENT

There has been a rapid expansion of knowledge pertaining to HAV since it was unequivocally identified in 1973 (108). A comprehensive summary was published by Gust and Feinstone in 1988 (146). In addition, several recent reviews pertain to the biology and replication of HAV (92, 223, 235, 338).

Biologic Characteristics

Classification and Comparison with Other Viruses

In the early 1980s, HAV was provisionally classified as enterovirus type 72 because its biophysical characteristics are like those of enteroviruses and cardioviruses, and its biochemical features resemble those of enteroviruses (see Table 1 and Chapter 23 and Chapter 24). However, later studies have demonstrated several characteristics that distinguish HAV from other picornaviruses: (a) HAV nucleotide and amino acid sequences are dissimilar from those of other picornaviruses, as are the predicted sizes of several HAV proteins; (b) HAV is difficult to adapt to growth in cell culture and usually replicates very slowly without cytopathic effect; (c) HAV is resistant to temperatures and drugs that inactivate many picornaviruses; (d) HAV is stable at pH 1 (350); (e) HAV has only one serotype, and one neutralization site is immunodominant; and (f) an enterovirus-specific monoclonal antibody does not react with HAV (449) (see also Table 1). It is concluded that HAV is a unique member of the family *Picornaviridae,* resulting in its classification into a new genus, Hepatovirus (Fig. 1) (280).

TABLE 1. *Viral characteristics: comparison of examples among the picornaviral genera*

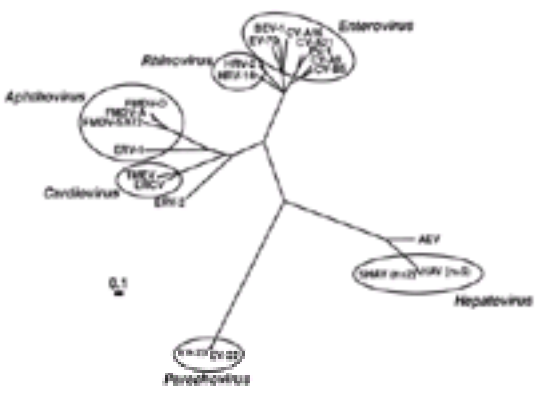

FIG. 1. Phylogenetic relationship of hepatitis A virus (HAV) and simian HAV (SHAV) to representative species of the mammalian picornavirus genera and to avian encephalomyelitis virus. The relationship was examined by the major-joining algorithm using amino acid similarities of the capsid precursor polypeptide P1. The bar represents distance as units of the expected fraction of amino acids changed. From ref. 261, with permission.

The knowledge that the antigens and nucleotide sequence of HAV are distinct from those of all other known viruses is especially relevant for clinical assays that detect evidence of infection. There is no serologic or hybridizing cross-reactivity between HAV and other agents of viral hepatitis, including hepatitis E virus (HEV), the other known agent of enterically transmitted hepatitis (see Chapter 89).

Strains and Genotypes

An HAV isolate that can be distinguished from other HAV isolates is defined as a *strain.* Viruses recovered from different locations often represent different strains, whereas viruses from individuals in the same outbreak usually represent the same strain. However, viruses from two or more locations may represent the same strain, or more than one strain may be present at a given location and time (334). Identical partial sequences for viruses from clinical specimens suggest an epidemiologic link (296).

The best-characterized HAV strains include HM175 (Australia, 1976), CR326 (Costa Rica, 1960), MS-1 (New York, 1964), SD11 (California, 1974), LA (California, 1976), HAS15 (Arizona, 1979), MBB (northern Africa, 1978), GBM (Germany, 1976), and H2 (China, 1982), all collected from humans, and PA21 (from an owl monkey, Panama, 1980) and AGM27 (from an African green monkey, Russia, 1985). These have been distinguished from each other on the basis of different growth characteristics (34,45,366) but are most reliably distinguished by genomic sequencing (47,63,141,292,293,308,334,417).

The identification of HAV and much of its initial characterization were done with strain MS-1 (108,212). Wild-type strain HM175 (63,72) has been adapted to yield the widest range of mutants in cell culture, including those with attenuated (61,200), persistently infecting (71,373), cytopathic (11,71,235), and neutralization-resistant (69,235,316,384) phenotypes.

Infectious cloned cDNA has been manipulated to yield mutants of HM175 with various phenotypes in cell culture and experimentally infected primates (60,83,92,93,95,118). Attenuated mutants of HM175, CR326, and H2 are the best characterized candidates for live virus vaccines, but variants of strains GBM and MBB (111,177,200,255,319) and chimeras between simian AGM27 (15) and human HM175 strains (329) also are being evaluated.

Sequence comparison of HAV isolates has been accomplished by using efficient methods for nucleic acid amplification [polymerase chain reaction after reverse transcription of RNA (RT-PCR) from virus purified by capture with monoclonal antibody] (334). Analysis of a 168-base region of 152 HAV strains resulted in the designation of seven *genotypes* (£85% sequence identity between genotypes and no more than 15% divergence within a genotype, a criterion used for polioviruses) (236,334). Two genotypes (I and III) were further divided into subgenotypes A and B (86–92.5% identity) (Fig. 2). The vast majority of human strains were genotype I. These included CR326, MS-1, SD11, HAS-15 (subgenotype IA), and HM175 and MBB (subgenotype IB). Genotype III represented most of the remaining human strains as well as the "simian" strain PA21 (subgenotype IIIA). The five other genotypes were each represented by only one strain, two from humans and three from monkeys. Clusters within genotypes predominate in certain geographic regions, such as a group of subgenotype IA strains with more than 97% identity that represented nearly all of the viruses from the U.S. Other regions, such as Europe and Japan, had a greater genetic mixture of viruses, suggesting regular introduction of strains by travelers returning from endemic regions.

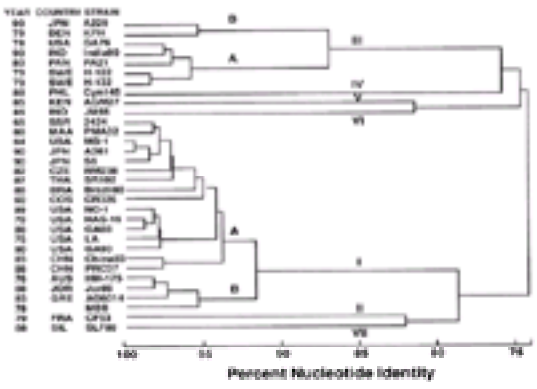

FIG. 2. Dendrogram depicting nucleotide sequence identity (relatedness) among 32 representative hepatitis A virus (HAV) strains. Identity was determined by pairwise comparison of sequences within a 168-nucleotide segment at the predicted junction of the 1D and 2A genes of HAV HM175/wild-type (nucleotide 3,024 to 3,191). A node connecting two strains indicates the approximate extent of identity between the strains. Genotypes (defined by £85% identity) are indicated by *roman numerals,* whereas subgenotypes (86–92.5% identity) of genotypes I and III are indicated by *A* and *B.* Genotype I (which represents most of the strains analyzed to date), and genotypes II and VII are known to include only human strains. Genotype III includes human strains and PA21, a strain that was collected from a New World monkey. The only known representatives of genotypes IV, V, and VI were collected from Old World monkeys. From ref. 236, with permission.

Several characteristics of HAV are common to strains collected from humans in widely separated geographic regions. These include the single serotype of HAV and similar reactivity of different strains with monoclonal anti-HAV antibodies (232,384). Nucleotide and amino acid sequences are highly conserved (>90% and >98% identity, respectively) throughout the genomes of strains HM175, LA, MBB, CR326, and HAS-15 in genotype I.

Strain PA21, recovered from a New World monkey, is biologically indistinguishable from human strains and has sequence similarity with genotype III human strains (334), suggesting that it may be a human rather than a simian strain. Strains that were recovered from Old World monkeys (genotypes IV, V, and VI) may be true simian strains: they have relatively distinct sequences and may have important biologic differences (see Fig. 2) (292,417). Some amino acid differences correspond to those that confer neutralization–resistance on experimentally selected mutants (236,316,334). Although the genotype V virus is not recognized by certain monoclonal antibodies that neutralize human HAV, the virus elicited an anti-HAV response in chimpanzees that protected against disease after challenge with the virulent human-derived HM175 strain (96). Because the simian virus did not cause hepatitis in chimpanzees, the experimental host most like humans, it is a candidate Jennerian vaccine. Chimeric recombinant viruses constructed by substituting a portion of a simian gene for the analogous region of the HM175 genome also may be promising vaccine candidates (329).

Morphology and Physicochemical Properties

Morphology

As first described by Feinstone et al. (108), HAV is a nonenveloped virus, 27 to 32 nm in diameter, that is morphologically indistinguishable from other picornaviruses (323). By electron microscopy (Fig. 3), "full" and "empty" particles appear to be spherical and featureless, but fine structural analysis has demonstrated icosahedral symmetry.

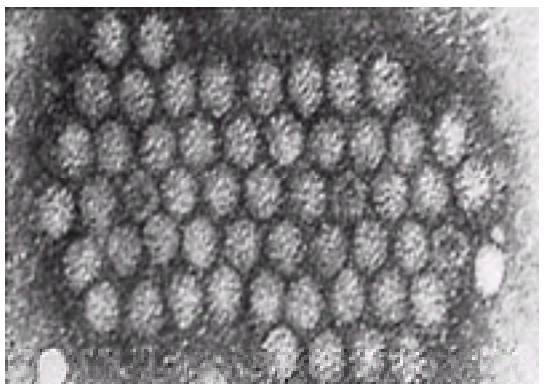

FIG. 3. Hepatitis A virus (HAV) particles observed by immune electron microscopy. Virus-like particles, 27 to 32 nm in diameter, are arranged in a crystalline array, with antibody coating their surfaces. These HAV particles appear to have cubic symmetry and have capsomeres measuring 8 to 12 nm (×130,650). From ref. 244 ×130,650, with permission.

Characteristics in Density Gradients

Hepatitis A virions have a primary buoyant density of 1.32 to 1.34 g/cc in CsCl and a sedimentation coefficient of 156S to 160S in neutral sucrose solutions (44,323,369). Additional populations of virus with different sedimentation characteristics have been isolated from human feces and cell culture. Empty particles (lacking RNA) have been detected at 1.20 and 1.29 to 1.31 g/cc, with sedimentation coefficients ranging from 50S to 90S, predominantly 70S. These are abundant in feces collected during early infection (44) or as a variable proportion of particles from cell culture (233) and are believed to represent procapsids (35) and perhaps other premature or defective particles. These alternative structures are morphologically indistinguishable from typical HAV and have the same major surface antigens (86), but their significance is unknown. Capsid-like structures have been produced by inserting the open reading frame of HAV into the genome of vaccinia virus (218) or baculovirus (337); these banded at 1.29 g/cc, sedimented at 70S, and were morphologically similar to empty HAV capsids.

Genome and Proteins

The virion is composed of a genome of linear, positive-strand RNA, approximately 7.5 kb in length, and a capsid containing multiple copies of three or four proteins (67,126,369). HAV RNA sediments at 33S and has a buoyant density of 1.64 g/cc (68,369). A 22S, double-stranded RNA form, closely resembling the replicative intermediate of other picornaviruses, also has been detected. Detailed genomic analysis has been accomplished with cloned or RT-PCR–amplified cDNA. Cultured cells can be infected with RNA transcribed from cloned HAV cDNA (62).

Genomic Organization

Like all picornaviral genomes, that of HAV can be divided into three parts: (a) a 5' noncoding region (NCR) that comprises approximately 10% of the genome, is uncapped, and is covalently linked at the 5' terminus to viral protein VPg; (b) a single open reading frame that appears to encode all of the viral proteins, with regions designated as *P1* for capsid proteins and *P2* and *P3* for nonstructural proteins; and (c) a short 3' NCR terminating in a poly(A) tract (Table 2 and Table 3; Fig. 4). Partial or complete sequences were determined for multiple HAV strains, including several mutants of strain HM175 (see GenBank listings). Complete sequence lengths range from 7,470 to 7,478 nucleotides, excluding a 3' poly(A) tail of 40 to 80 nucleotides. As noted earlier in the section on HAV strains, sequences for known human isolates are highly similar even when geographic and temporal origins are widely separated. This similarity suggests that genomic variation is constrained for HAV.

Region/Segment	Nucleotides	Comments
5' NCR	1–734	In other picornaviruses, this region stimulates synthesis of viral proteins and contains virulence and other phenotypic markers (6,186,307)
Stem-and-loop	1–40	Similar structures of different size predicted for picornaviruses; all have U(U) in first two nucleotide positions, required for HAV infectivity (163)
Pyrimidine-rich	88–138 (83%) 31–249 (68%)	Unique to HAV but may be structurally analogous to the poly(C) tract of cardio- and aphthoviruses; nucleotides 99–138 not required for growth in cell culture (3&63); highly variable in length and sequence between HAV strains
Hypervariable IRES	88–207 ~154–735	Mutations in this segment enhance HAV growth in cell culture Very inefficient for promoting translation; structure may be most similar to IRES of cardio- and aphthoviruses among picornavirus IRES
Conserved	88–95, 227–237, 483–731	Few mutations among HAV strains for which sequence is determined
Oligopyrimidine Translation initiation	712–728 720–744	Similar segment near initiation codons of other picornaviruses Approximates consensus sequence described for eukaryotic mRNAs (5,211)
3' NCR	7410–7478	High percentage of differences between strains, terminates in poly (A); poliovirus mutant in this region is temperature sensitive (246)

IRES, internal ribosome entry site; data from cultured cells; HAV, hepatitis A virus.

TABLE 2. *Genomic characteristics: noncoding regions (NCRs) of HAV strain HM175/Wild type*

Region encoding	Nucleotides	Length, in amino acids	C-terminal cleavage[a]	Proposed or known function	Comments (refs.)
Polyprotein	741–7413 or 735–7415	2226 or 2227			Most similar in length to PV polyprotein; downstream AUG codon at 741–743 preferred for translation initiation (402)
P1 (Capsid)					
1A	741–863 or 735–855	21 or 23	AG	Morphogenesis, VP4	Not myristylated (402); needed for capsid formation (316)
1B	864–1458	222	GAV	VP2	During maturation, precursor 1AB (VP2) may self-cleave to yield VP2 and VP4
1C	1470–2207	246	QG	VP3	Changes at Arg^{34} or Gln^{71} in neutralization-resistant mutants (316,318)
1D	2208–3029 or 3026 or 3023	274 or 275 or 277	SIM	VP1	Changes at Ser^{77}, Val^{111}, Ala^{170}, or Ser^{71} in neutralization-resistant mutants (318)
P2 (Nonstructural)					
2A	3030–3242	71	GA	Morphogenesis	Needed for particle formation (318); not a protease distinct from other 2A
2B	3243–3485	81	GS	?	Distinct from other 2B; mutations at nucleotide 3665 important for adaptation to cell culture (91)
2C	3536–5050	335	QG	RNA synthesis	Precedes NTP binding and RNA helicase activities (86,186); mutations important for adaptation to cell culture (34,318)
P3 (Nonstructural and VPg)					
3A	5051–5323	74	EG	Pre-VPg (ex 3AB)?	Distinct from other 3A
3B	5233–5291	23	QS	VPg	Tyr^{3} attached to 5′ termini of viral RNAs (109)
3C	5292–5948	219	QA	Protease	Cys^{172}-His^{44}, His^{172} or active site (3)
3D	5949–7413	488	—	RNA polymerase	Tyr^{273}-Gly^{274}-Asp^{275}-Asp^{276} in presumed active site (317)

[a] During polyprotein processing, cleavage is predicted to occur between the two residues indicated. The only known N-termini for native proteins are those of VP2 and VP1. All known cleavages in HAV except VP4/2A and VP4/VP1 are catalyzed by proteases 3C. The 2C/3A, 3B/3C, and 3C/3D cleavage sites have been determined by using in vitro synthesized proteins. Peptides representing VP2/VP3, VP3/VP1, and 2B/2C sites were efficiently processed by 3C produced in *E. coli* peptides representing 3B/3C and 3C/3D were inefficiently cleaved, and there was no detectable cleavage of a 2A/2B peptide. The C-terminus of VP1 is heterogeneous and could not be predicted by host proteases. Primary cleavage in P1 to yield 1B, at Pro-G four residues of 2A. Cleavage of P1/2A may be autocatalytic. See text for other details and references.

Source: (Revised from refs. 63, 236, and 406, with permission.)

TABLE 3. *Genomic characteristics: open reading frame of HAV strain HM 175/Wild type*

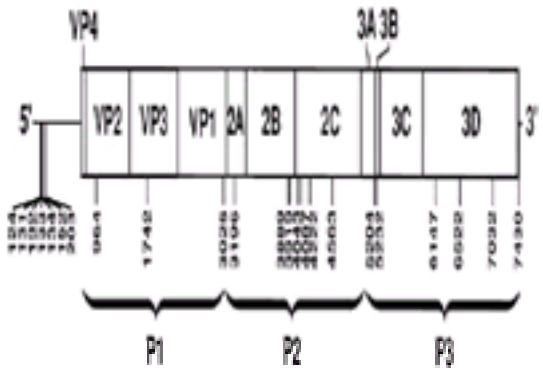

FIG. 4. Diagram of the hepatitis A virus (HAV) genome. Coding regions are in blocks. *Numbered vertical lines* indicate the nucleotide positions differentiating the virulent wild-type HM175 strain and the attenuated cell-culture–adapted variant HAV/7 (60).

Although the lengths of HAV genomic regions are most similar to those of enteroviruses (406), the HAV nucleotide sequence is not homologous with those of other picornaviruses (303). In addition, the low content of G + C (38%) in HAV is approximated only by that of rhinoviruses (39–40%). HAV and rhinoviruses have a preference for A or U in the third base position of codons (303).

Noncoding Regions

HAV NCRs have several notable features (236) (see Table 2). The 5' NCR appears to be the most conserved region of the genome (³89% nucleotide identity among seven strains representing genotypes I, II, and III) (45). A high proportion of C and U nucleotides is found near the 5' terminus (pyrimidines constitute 95% of nucleotides 99 to 138 and 68% of nucleotides 31 to 249; all numbering here refers to the HM175/wild-type sequence in ref. 63), as in cardiovirus and aphthovirus genomes. Deletion of the pyrimidine-rich tract spanning nucleotides 96 to 139 did not alter viral replication in cell culture (361) or decrease virulence for tamarins (362); however, deletions that also included nucleotides 140 to 144 yielded temperature-sensitive HAV, whereas deletion of nucleotides 93 to 134 was lethal (361). Nucleotides 99 to 207 are susceptible to naturally occurring mutations, particularly deletions (45). In contrast, nucleotides 66 to 95, 227 to 262, 681 to 721, and 712 to 720 are highly conserved among HAV strains. The latter is an oligopyrimidine tract near the translation initiation codons of HAV (nucleotides 735 to 737 or 741 to 743) and is similar to those in other picornaviral 5' NCRs (5,406). Some mutations in the 5' NCR enhance growth of HAV in cell culture (75,92,118) but do not appear to have a major role in determining virulence (60,119).

The 3' NCR has a high proportion of differences (up to 20%) between HAV strains and mutants. One study detected proteins in HAV-infected MRC5 or FRhK4 cells (47 kD and perhaps others £14 kD) that bound with nucleotides 7,430 to 7,452 or the corresponding bases from the 5' terminus of negative-strand HAV RNA (300). The onset of this interaction coincided with the establishment of persistent infection in culture. These data suggested that trans-acting cellular factors might participate in down-regulation of HAV RNA synthesis.

Little is known about the effects of 3' and 5' terminal sequences on picornaviral RNA synthesis, but they are thought to have important roles (5). All picornaviruses have putative stem-loops at the extreme 5' end, although these structures differ in size. The importance of this putative secondary structure was suggested by analysis of a poliovirus mutant with a nucleotide deletion that would disrupt such a structure; this mutant was deficient in RNA replication and translation (327). In addition, HAV RNAs were not infectious when they lacked nucleotides 1 to 2 or 2 to 3, which are thought to form part of a stem-and-loop (see Fig. 5, domain I) (159).

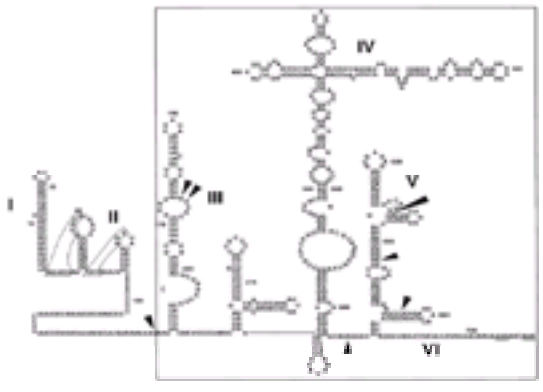

FIG. 5. Proposed secondary structure of the 5'8 noncoding region (NCR) of hepatitis A virus (HAV) RNA (strain HM175/wild-type). This model is based on a combination of phylogenetic comparisons, thermodynamic predictions, and nuclease digestions of synthetic RNA between nucleotides 300 and 735. Major structural domains are indicated by *roman numerals* beginning at the 5' terminus. Domains contributing to the HAV internal ribosome entry site (IRES; see text) are included in the box, although the boundaries are not precisely determined. Sites of mutations that appear to enhance HAV replication in cell culture are indicated (*arrows*). Two possible pseudoknots near the 5' terminus are outlined by *shaded interactions.* Two initiation codons for the open reading frame (nucleotides 735 to 737 and 741 to 743) are *underlined.* Several putative structures (pseudoknots, the single-stranded pyrimidine-rich tract between domains II and III, and the stem-and-loop near the top of domain V that also is predicted to form a pseudoknot) resemble structures predicted for the 5' NCR of encephalomyocarditis virus (EMCV). Modified from ref. 236, with permission.

Secondary structures and tertiary interactions in the complete HAV 5' NCR have been modeled by studying RNA digestion with single- or double-strand–specific RNases and by using computer programs to align sequences representing different strains and to predict thermodynamically stable base pairing (see Fig. 5) (45,219,361). These structures are most similar to those proposed for cardioviruses and aphthoviruses (5,185,219). In these models, pyrimidine-rich nucleotides 99 to 138 of HAV are not involved in stem-and-loop structures, but the presence of ordered structure in this region was indicated by the susceptibility to a double-strand–specific RNase (361). Nucleotides 705 to 726 of HAV RNA (overlapping with oligopyrimidine bases 712 to 720) may include sites of possible base pairing to 18S rRNA (219).

Translation

Significant advances have been made in understanding the role of 5' NCRs in translation. Structural models led to the recent identification of an internal ribosome entry site (IRES) in the HAV 5' NCR (46,48,133) that is somewhat similar to those previously recognized in other picornaviral 5' NCRs (5,185,312). Cis-acting picornaviral IRES are thought to interact with trans-acting cellular factors so that 40S ribosomal subunits bind and begin translation at the correct initiation codon and not at multiple AUG codons scattered throughout the 5' NCRs. This mechanism contrasts with typical eukaryotic translation, in which 40S subunits recognize the m7G-cap at the 5' mRNA terminus and then scan for the nearest AUG within an appropriate sequence motif (211). The HAV IRES was characterized *in vitro* and in cell culture by using bicistronic mRNAs in which translation of the second gene was dependent on the function of intact or altered versions of the HAV 5' NCR. *In vitro* studies suggested that the 5' IRES boundary was between nucleotides 151 and 257, and the 3' boundary was between nucleotides 695 and 735 (48), although more recent data suggested that it may extend an additional 66 to 114 nucleotides into the coding region (139). In HAV-permissive BS-C-1 cells, the boundaries, respectively, were downstream of nucleotide 45 and upstream of nucleotide 739 (133). Possible boundary discrepancies are not yet explained but could have resulted from differences between systems or 5' NCR alterations.

The HAV IRES was less efficient for directing translation than the EMCV IRES or nonpicornaviral leader sequences (capped or uncapped), in part because it competed poorly for cellular factors (48,133,432). Such competition almost certainly occurs in HAV-infected cells because the virus does not interfere with host protein synthesis. HAV replication may actually depend on continued synthesis of host factors. HAV IRES-directed translation in permissive cells was suppressed when cap-dependent translation of the cellular mRNAs was inhibited by poliovirus-encoded protease 2A (443). In contrast, poliovirus protease 2A stimulated EMCV IRES-directed translation (432). Picornaviral 5' NCRs appear to have negative-control elements for suppression of ribosomal scanning and an IRES for promotion of cap-independent translation (5,274); however, the HAV IRES appears to have been selected for low overall translational activity. The only report of increased HAV IRES activity in cells resulted from inserting four bases at position 633 (133).

Translation of HAV RNA in rabbit-reticulocyte lysates usually results in aberrant initiations within the open reading frame that can be corrected by replacing the HAV 5' NCR with that of EMCV, but not by adding extracts from HeLa cells (which improve translation of poliovirus RNA) or from BS-C-1 cells (which are permissive for HAV) (190). Recent efforts have attempted to identify cellular factors that could interact with the HAV IRES. Ribosome-associated proteins (30, 39, and 110 kD) from BS-C-1 and FRhK4 cells bound to several sites in the 5' NCRs of HAV and EMCV (54). *In vitro* the 57-kD protein, polypyrimidine tract-binding protein (PTB), and the 39-kD protein, glyceraldehyde 3-phosphate dehydrogenase (GAPDH), bind to overlapping sites in the 5' NCR. Local overexpression of GAPDH in transfected cells suppresses cap-independent translation directed by the HAV IRES, whereas local overexpression of PTB stimulates such translation. Thus it has been proposed that GAPDH suppresses translation by its ability to destabilize essential secondary RNA structures within the IRES (354), whereas PTB may reverse the inhibition by competing with GAPDH for binding or by stabilizing critical IRES structures (446). In support of this hypothesis, a naturally occurring mutation that enhances translation in African green monkey kidney cells (355) decreases the affinity of GAPDH for a stem-loop structure in the IRES (446). Another protein, identified as poly(rC) binding protein 2, is required *in vitro* for efficient translation of HAV (and of poliovirus) (138). Finally, an unidentified factor, presumably a protein, present in mouse liver cells but not BS-C-1 cells, also stimulates HAV translation *in vitro.* Evidence that accessory cellular proteins affect translation of HAV *in vivo* is indirect and is based on the discovery of host range mutations within the IRES (75,120,355). The HM175 strain of HAV

did not grow to detectable levels in MRC5 cells until serial passage resulted in the acquisition of a cluster of mutations in the region of the IRES preceding the initiation codon. These mutations selectively increased viral translation in MRC5 cells but were not required for growth or viral translation in FRhK4 cells (120).

There are two in-frame AUG codons at the beginning of the HAV open reading frame (nucleotides 735 to 737 and 741 to 743). Like other picornaviral initiation codons, both are within sequences that approximate, but do not match, the optimal context for scanning ribosomes (210). It has been suggested that suboptimal sequence context could contribute to poor translation and growth of HAV (5). Selective deletion demonstrated that the second AUG was preferentially used *in vitro* and in BS-C-1 cells, although either codon could function independently (403). It is not known why HAV has these two closely spaced initiation codons, but the simian AGM27 virus actually has a total of five in-frame AUG codons in this region (417).

The single open reading frame of picornaviruses is translated into one long precursor polypeptide, which is processed by a cascade of proteolytic cleavages to yield ultimately mature viral proteins (304). The primary cleavage, catalyzed by virally encoded protease 3C, takes place cotranslationally at the C-terminus of the P1/2A (capsid) precursor (see Table 3). All secondary cleavages, except VP1/2A and VP0, also are mediated by 3C (160,188,252,353). VP1 is apparently released from 2A by cellular proteases (142,260). Maturation cleavage involves the processing of VP0 (also designated 1AB) by an unknown, perhaps autocatalytic, mechanism to yield capsid proteins VP4 (or 1A) and VP2 (or 1B).

Detected Proteins

Nearly all of the viral proteins detected in HAV-infected cells are structural. Mature capsid proteins are the predominant form in virions: VP1 (or 1D; 30 to 33 kD by polyacrylamide gel electrophoresis), VP2 (or 1B; 24 to 30 kD), and VP3 (or 1C; 21 to 28 kD). Apparent molecular weights determined by electrophoresis often differ from those deduced by using amino acid sequences. A small protein, VPg (or 3B; predicted molecular mass of 2.5 kD), is covalently linked to the 5' genome terminus (428). Precursor polypeptides include VP0 (27 to 31 kD), which is a VP4/VP2 fusion protein; and PX (38 to 40 kD), which is a VP1/2A fusion protein. VPg and 2C have been detected among P2 and P3 proteins (418). Development of antibodies to P2 and P3 proteins was indirect evidence for their synthesis in HAV-infected primates (335,387), but concentrations of these nonstructural proteins appear to be very low in infected cells (418).

The 1A region of HAV encodes VP4, a polypeptide of 23 or fewer amino acids, with a maximal molecular mass of 2.5 kD (403). In other picornaviruses, VP4 is approximately 7 kD and is myristylated; myristyl-VP4 is found on the interior capsid surface of other picornaviruses and may contribute to particle assembly and stability or to binding and entry of virus into cells. Although the sequence of HAV VP4 includes a consensus sequence for myristylation (Gly-X-X-X-Ser/Thr), analysis of culture-adapted HAV and engineered mutants demonstrated that myristate was not incorporated (404). Efforts to detect mature VP4 in HAV particles have been unsuccessful.

Protein Processing

It was recently shown that the primary cleavage during HAV translation *in vitro* is mediated by viral protease 3C at a site approximately 40 amino acids beyond the P1-terminus, at the carboxy terminus of the 2A protein (192,261). This contrasts with primary cleavages for other picornaviruses (304). Enteroviruses and rhinoviruses produce a protease, encoded by the 2A region, that autocatalytically splits nascent 2A protein from the C-terminus of P1. An autocatalytic activity separates the 2A/2B junction of cardioviruses and aphthoviruses; 2A is subsequently cleaved from P1 by protease 3C. Protease activity has not been recognized for 2A of HAV, EMCV, or FMDV, or for HAV 2B (192,261). 2A/2B has virtually no amino acid similarity with the analogous portions of other picornaviral polyproteins. These observations are leading to revision of the VP1/2A/2B region of the HAV genomic map (see Table 3; Fig. 4). The C-terminus of 2A is now thought to be at amino acid 836 (from the first in-frame AUG codon), corresponding to the primary cleavage observed *in vitro.* Thus 2A is considerably smaller and 2B larger than previously predicted (see Table 3). Although dipeptide Gln/Ala (amino acids 836 to 837) is apparently the cleavage site (261), *in vitro* scission still occurred when this dipeptide was mutated to Asn/Ala or Ala/Ala. The capsid precursor would then be P1/2A, with a molecular mass of approximately 100 kD. A 100-kD protein that reacts with antibody to VP1 and VP2 has been identified in HAV-infected cells (39).

The C-terminus of VP1 is heterogeneous (142) and includes VP1-ser^{274} as the predominant form, along with minor forms that end at residue VP1 272 or 273. Similar proteins, including 42-kD (VP1/2A-like) and 98-kD (P1/2A-like) precursors, were produced in cells infected with a recombinant vaccinia virus that expressed the HAV polyprotein to yield virus-like particles (440).

The heterogeneity of the mature VP1 terminus and the multiple anti-VP1 reactive proteins in addition to PX (VP1/2A) in HAV-infected cells (192) contributed to the difficulty in identifying the terminus. Earlier, inaccurate predictions were based on comparisons with other picornaviruses and the apparently incorrect assumption that the 3C protease was involved. Generation of the majority species of VP1 requires a scission between Ser^{274}/Met^{275} that is not a known substrate for 3C protease (6). It has been proposed that, as for Mengo virus, cellular proteases probably trim 2A sequences from PX to generate intermediates and the mature VP1 protein (142,260).

HAV and Other Picornaviruses: Comparison of Proteins

Most HAV proteins are distinct from those of other picornaviruses, but regional amino acid sequence similarities exist. Proteins VP4, VP1, 2A, 2B, and 3A are particularly distinct. The predicted lengths of several HAV proteins are quite different from the analogous proteins of most other picornaviruses: VP4, VP2, and 3A are shorter, whereas VP3, 2B, 2C, 3C, and 3D are longer. Although the three major capsid proteins are thought to have the b-barrel structure common to other picornaviruses, alignment of amino acid sequences has been difficult because of minimal similarity. Unfortunately, it has not been possible to crystallize HAV for determination of its three-dimensional structure. Significant structural differences between HAV and other picornaviruses also are suggested by the resistance of HAV to acid, heat, and

disoxaril. However, studies of surface iodination (333), monoclonal antibody binding (179), peptide mapping (97,124), and digestion with trypsin and chymotrypsin (227) have identified HAV VP1 and VP2 as major surface proteins, as in other picornaviruses. The presence of VP1 and VP3 on the virion surface, or influencing surface structure, is implied by identification of important epitopes in these proteins (see Antigens and Antigenic Structure later). Overall, HAV has more sequence identity with encephalomyocarditis virus (EMCV) and rhinovirus type 2 than with other human picornaviruses. However, a recently characterized avian picornavirus, avian encephalomyelitis virus, is most similar to HAV (262). Similarity of HAV to human picornaviruses has been demonstrated in known or proposed functional regions of VP0, 2C, 3B, 3C, and 3D (see Table 3). Conserved sequences at the VP0 cleavage site and near the N-terminus of VP2 may participate in the maturation cleavage step (304). 2C probably functions in viral RNA replication (reviewed in 93), perhaps via RNA helicase activity (88), and has a putative guanosine triphosphate (GTP)-binding domain (136) and markers for guanidine resistance. Mutations in 2C and 2B were essential for adaptation of HAV HM175, and perhaps other strains, to growth in cell culture (see Propagation and Assay in Cell Culture later) (93,94,118). Mature 3B (VPg) is probably covalently linked through tyrosine residue 3 to the 5' terminus of viral RNA (428) (see Chapter 23). 3C has been crystallized and is a chymotrypsin-like serine protease (6) that generates secondary cleavages in cis and trans (125,160,252,353). The crystal structure indicates a strong preference for glutamine at the P1 cleavage site (6). 3D is assumed to be the viral RNA polymerase, although there are no direct data. Thus, although the function or specificity of certain HAV proteins (particularly VP4, 2A, 2B, 3A, and 3C) may differ from those of analogous proteins of other picornaviruses, other functions (capsid, genome-linked protein, major protease, and RNA polymerase) are conserved. The distinct characteristics of HAV proteins are contrasted by the high degree of sequence identity among HAV strains, particularly in the P1 region, which suggests a selective advantage for *in vivo* stability of HAV genotypes or constraints for replication in hepatocytes.

Capsid Assembly

A model for assembly of HAV capsids explains current observations of viral protein synthesis and processing in cells (12,35,39) and is consistent with data from other picornaviruses (see Chapter 23). In this model, primary cleavage of the HAV polyprotein by 3C yields a P1/2A precursor. The 2A portion of the precursor serves as the primary signal for five copies to assemble into a 13S pentamer (318), whereas this step is initiated by myristylated VP4 of poliovirus. Subsequently 3C catalyzes secondary VP2/VP3 and VP3/VP1 cleavages to produce 14S pentamers containing VP0, VP3, and VP1/2A (39). Twelve pentamers assemble to form empty capsids (procapsids) or incorporate virion RNA to form provirions. The assembly of HAV pentamers into empty capsids is very inefficient in the absence of VP4 (318). Processing of VP1/2A to yield VP1 begins after assembly of procapsids or provirions, but VP1/2A can be detected in provirions. Maturation cleavage of VP0 to release VP2 depends on RNA encapsidation, takes place at a linear rate over days, may be self-catalyzed, and is associated with an increase in sedimentation coefficient (implying conformational change) and infectivity (35). The fate of VP4 in this process is unknown.

Antigens and Antigenic Structure

As determined by neutralization assays, there is only one known serotype of HAV (96,229,232,451). The only naturally occurring antigenic variants are HAV strains collected from Old World monkeys (see Strains and Genotypes earlier).

Antigens of the intact virion appear to be conformational and generally different from those of isolated HAV proteins. Purified virus elicited neutralizing anti-HAV and antibodies to denatured capsid proteins in rabbits (not known to support HAV replication) (124). Mice developed neutralizing anti-HAV in response to 14S and 70S subviral particles that had been produced in recombinant vaccinia virus–infected cells (385). In contrast, antibodies to purified capsid proteins or to synthetic peptides have weak or no detectable neutralizing activity; only two peptides, representing sequences near the N-terminus of VP1 (residues 11 to 25) and amino acids 110 to 121 of VP3 (40), stimulated production of such antibody (97). Chimeric polioviruses that expressed HAV peptide sequences elicited weak neutralizing activity only when the peptide corresponded to VP1 residues 13 to 24 or 101 to 108 and only in a minority of the inoculated animals (228). It is unusual for neutralizing anti-HAV to develop in response to individual proteins, polypeptides, or uncleaved precursors produced by recombinant DNA techniques (23). Such proteins often react with rabbit anti-HAV or human convalescent-phase anti-HAV, and they sometimes elicit a priming response for anti-HAV (127,193,317). Priming amino acids appear to be located near the C-terminus of VP1 (158). It is likely that VP2 and perhaps VP3 also contain such helper T-cell epitopes (317). After inoculation with recombinant vaccinia virus expressing uncleaved HAV P1 precursor, two marmosets developed anti-HAV. The animals were not tested for neutralizing antibody, but were protected from challenge with virulent HAV (199).

Multiple epitopes have been detected on intact virions and on 14S pentameric subunits by using monoclonal anti-HAV. Most of these epitopes overlap as an immunodominant neutralization site, but there is evidence for a second, possibly independent, site (236,316,384). Monoclonal antibodies to HAV did not bind to isolated capsid proteins, but the Fab fragment of one such antibody was able to bind VP1 on intact virions (179). Later studies demonstrated three epitopes that overlap as part of an immunodominant site (224,384). Mutants selected by passage in the presence of a monoclonal antibody (291,316,384) became resistant to neutralization by that antibody. Among mutants selected against any one monoclonal, the number of amino acid positions with changes was limited: fewer than two positions for strain HM175 (at VP3 Asp^{70} and Gln^{74}, or at VP1 Ser^{102}, Val^{171}, Ala^{176}, and Lys^{221}), and only one amino acid was changed in each mutant (315,316). For strain HAS-15, there were only two patterns of change for mutants to each monoclonal, with mutations in one to three amino acid positions (at VP3 Pro^{65}, Asp^{70}, and Ser^{71} or at VP1 Asn^{104}, Lys^{105}, and Gln^{232}) (291). For both strains, all of the mutant residues appear to participate in the immunodominant site. Oligonucleotide-directed mutagenesis of VP1 Ser^{114}, and VP1 Lys^{221} also produced neutralization-escape mutants (69). Although most such studies have been performed with murine monoclonals, limited analysis of the human response to HAV infection has detected antibodies to VP3 Asp^{70} and to VP1 Ser^{102} and Ser^{114} (76). A recombinant human monoclonal anti-HAV appears to be directed against the immunodominant site (240). The immunogenic sites may be located within peptide loops that connect b-strands of the capsid proteins and project from the virion, analogous to immunogenic sites in other picornaviruses (236,316). Treatment of HAV with trypsin was reported to abolish reactivity and neutralization of the virus with a monoclonal antibody used to define the immunodominant site, without affecting infectivity (382). However, a similar study did not detect antigenic change after trypsin treatment but did observe cleavage of VP2 (which is not known to be

directly involved in this site) (227). This apparent discrepancy has not been resolved. A sequence near the N-terminus of VP1, which elicited weak neutralizing activity as a peptide or when inserted into a chimeric poliovirus (see earlier), is thought to be internally located in HAV capsids but externalized during virus attachment to cells (228). The finding of few amino acid changes among multiple neutralization-escape mutants suggests that there could be constraints to antigenic or structural variation of HAV. This notion is supported by the characteristics of HAV strains isolated from Old World monkeys (292,417). These HAV isolates have the antibody-binding phenotypes and amino acid changes of some of the neutralization-escape mutants. When one neutralization-escape mutant was inoculated into owl monkeys, revertant virus (with wild-type VP3 Asp^{70}) was selected, suggesting that there could be similar constraints *in vivo* (237) (see Strains and Genotypes earlier). Cytopathic mutants of HAV HM175 that spontaneously arise during persistent infection in cell culture also can develop, without selective pressure from antibody, a neutralization-escape phenotype with changes at some of the amino acid positions associated with the immunodominant site (235,316). It was suggested that a long period of persistent infection could reduce the pressure for maintaining structural features necessary for infecting new cells (235).

The nonstructural proteins of HAV also are immunogenic during natural and experimental infections. Antibodies were detected by immunoprecipitation of P2 and P3 proteins that had been synthesized *in vitro* (191,335) or by an ELISA specific for 3C protease expressed in *Escherichia coli* (387). However, chimpanzees did not develop anti-P2 or anti-3C antibodies after vaccination with inactivated HAV.

Stability

Unpurified, cell-adapted HAV retains most of its infectivity when subjected to pH 1.0 for 2 hours at room temperature, and is still infectious at 5 hours, whereas poliovirus type 1, coxsackieviruses types A9 and B1, and echovirus type 9 lose virtually all of their infectivity by 2 hours. Because it is a nonenveloped virus, HAV also is resistant to 20% ether, chloroform, dichlorodifluoromethane (Freon), and trichlorotrifluoroethane (Arklone, Genetron) (323,365,368).

HAV is relatively resistant to heat. Virus integrity or antigenicity is not affected when HAV is incubated at 60°C at neutral pH for 60 minutes and is only partially inactivated after 10 to 12 hours (306,372). The temperature at which 50% of HAV particles disintegrate and release their RNA in the absence of cations is 61°C after 10 minutes versus 43°C for poliovirus type 2 Lansing. When stabilized by 1 mol/L $MgCl_2$, disintegration occurs at 81°C and 61°C, respectively, with generation of empty capsids that retain antigenicity. Such reactivity is lost at 87°C for HAV and at 67°C for poliovirus. In human and animal experiments, HAV was inactivated within minutes at 98°C to 100°C (323).

Infectivity can be preserved for at least 1 month after drying and storage at 25°C with 42% humidity (271,380), or for years at –20°C or lower. HAV also was found to survive for days to months, and for longer periods than poliovirus, in experimentally contaminated fresh water, seawater, wastewater, soils, marine sediment, live oysters, and creme-filled cookies (380). Thermal treatment of oysters (60°C for 19 min), inoculated with HAV-containing feces and sealed in a can, failed to inactivate the virus totally (313).

Inactivation of HAV was reviewed by Coulepsis et al. (65). HAV is inactivated by autoclaving (121°C for 20 minutes), by ultraviolet radiation (1.1 W at a depth of 0.9 cm for 1 minute, or 197 µW/cm^2 for 4 minutes), by formalin (1:4,000 for 72 hours at 37°C, 3% for 5 minutes at 25°C, or 8% for 1 minute at 25°C), by b-propiolactone (0.03% for 72 hours at 4°C), by iodine (3 mg/L for 5 minutes), or by chlorine (10 to 15 ppm residual chlorine concentration after 30 minutes; free residual chlorine concentration of 2.0 to 2.5 mg/L for 15 minutes) or chlorine-containing compounds (sodium hypochlorite, 3 to 10 mg/L at 20°C for 5 to 15 minutes). Infectivity of HAV is substantially decreased by 70% ethanol at 25°C (2.25 and 5.5 log_{10} reductions in infectivity after exposure for 3 and 60 minutes, respectively).

Propagation and Assay in Cell Culture

Early attempts to isolate HAV in cell or organ cultures were generally unsuccessful. Five years passed between the discovery of HAV and the successful propagation by Provost and Hilleman (322) of marmoset-adapted HAV in primary explant cultures of marmoset (*Saguinus labiatus*) liver and in a fetal rhesus monkey kidney cell line (FRhK6). After incubation for weeks, cytopathic changes were not observed despite accumulation of viral antigen. Direct immunofluorescence analysis (264) was the key to demonstrating HAV replication. Many other laboratories have confirmed and extended these findings (for reviews, see refs. 146,236,339,406).

Various primary and continuous cells of primate origin will support HAV growth, although optimal replication often results from a particular combination of HAV strain, cell type, and temperature (24,34,366). Primary African green monkey kidney (AGMK) cells, primary human fibroblast cells, and continuous human diploid lung (MRC5) cells often have been used because of their suitability as potential vaccine substrates. Cell lines derived from AGMK (such as BS-C-1, Vero, and BGMK), fetal rhesus kidney (FRhK4, FRhK6, Frp/3), or human hepatoma (PLC/PRF/5) tissue also have been useful for studying replication and for propagating large amounts of virus (34,72,109,114,366). However, HAV is usually difficult to adapt and grow *in vitro.* Some wild-type strains have not been adapted to cell culture despite intensive efforts, and successful isolation from clinical specimens often requires several weeks and blind passages (34,72,322). Even when well adapted, HAV usually takes several days to weeks to reach maximal concentrations of propagated virus. Typical yields of 10^6 to 10^9 $TCID_{50}$/mL are usually recovered only by mechanical lysis because progeny of most HAV strains remain cell associated and spread to adjacent cells by an unknown mechanism.

HAV usually has few or no visible effects on the host cell, in contrast to many other picornaviruses (123; see Chapter 23). Some strains or mutants release progeny to the medium but usually without cytopathic effect. The only ultrastructural alterations observed in most infected cells are cytoplasmic accumulations of multilayered membranes as well as clusters of virus in vesicles (18,206,259). Cells infected with a cytopathic HAV mutant had similar changes; in addition, long polyribosomes were observed early in the infection, followed by degenerative changes in the rough endoplasmic reticulum. Thus detection of HAV multiplication usually requires an indirect method: (a) an immunologic assay for viral antigens (171,231,266,326), or (b) a hybridization assay for HAV RNA (186). A radioimmunofocus assay (231) can be

used for quantifying infectious HAV, selecting viral clones, and for measuring neutralizing anti-HAV. Cell culture is not useful for the diagnosis of typical hepatitis A.

Infectious cloned cDNA has made it possible to study the effects of mutations on the growth of HM175 in cell culture (60,93,94) and on virulence of HAV for primates (see Fig. 4) (60,91,92,95). As with other picornaviruses, particular phenotypes often represent contributions from multiple mutations. The different studies have used different assays (immunofluorescence microscopy for percentage of cells containing HAV antigens, immunoblot analysis of viral proteins, radioimmunofocus assay for number and size of viral growth foci, and hybridization for total HAV RNA), and these can alter the interpretation. However, several concepts have emerged about mutations selected during adaptation or passage: (a) those in gene 2B (particularly nucleotide 3889) or 2C (nucleotides 4043, 4087, 4222, and 4563) appear to be essential for the adaptation of HM175 (93), and perhaps other strains, to certain cells (140,141); (b) those in the 5' NCR (especially in the variable region near nucleotide 200) are not essential, but they enhance growth and alter the host range *in vitro* (75,118); and (c) other mutations throughout the genome also enhance growth (60,75,92,93 and 94,118,453).

Because HAV usually does not cause a cytopathic effect, persistent infection is readily established in many cell lines. Three phases of replicative events were identified in cells that became persistently infected with HAV under one-step growth conditions (77). From day 2 to day 8 after inoculation, negative- and positive-strand viral RNAs and the rate of infectious HAV synthesis reached their highest levels. During days 9 to 14, viral antigen production was maximal, and positive-strand HAV RNA and infectious HAV levels remained high, but negative-strand HAV RNA became undetectable. After day 14, there was minimal viral metabolic activity. Nearly all of the HAV remained cell associated.

Most HAV mutants attain maximal accumulation within 3 to 7 days but are not cytolytic. However, with some mutants, a cytopathic effect develops 2 to 14 days after inoculation (9,11,71,235,443). The development of a cytopathic effect depends on the interaction between particular HAV strains and cells at certain passage levels (71,235). In most cases, rapid cytolytic growth was selected by passaging HAV HM175 from persistently infected cells at intervals of 3 to 7 days. However, some strains of HAV were cytopathic within several passages after direct isolation from human feces (360,422,443).

Studies of chimeric infectious cDNAs indicate that multiple mutations outside of the P1 region, many of which are in 2C, are most likely to contribute to the cytopathic phenotype (235,282). Mutations in the P2 region of a cytopathogenic mutant enhanced replication, but additional mutations within the 5' NTR and P3 regions were required for the full cytopathogenic effect (453).

HAV RNA synthesis was detected 6 hours after inoculation of the cytopathic mutant HM175A (10,12,35,39) into BS-C-1 cells and reached maximal levels at approximately 12 to 27 hours during the logarithmic phase of HAV propagation. Cytopathic effect developed after 2 to 3 days, yielding 20 infectious doses of HAV per cell or approximately $10^{8.7}$ PFU/mL. Little negative-strand RNA was synthesized. Furthermore, nearly all positive-strand RNA was encapsidated at all times during the replication cycle.

Several mechanisms have been proposed to explain the typically slow cycle of HAV replication [reviewed by Lemon et al. (238)]. First, inefficient uncoating may limit the extent of replication. This may reflect incomplete maturation cleavage of VP0 (VP4/VP2) during the previous cycle (35,431). Second, replication is asynchronous in certain cells (reviewed in 57). Delayed uncoating could be a factor that contributes to asynchronous replication. Third, HAV does not shut off host-cell macromolecular synthesis, and HAV translation competes poorly with that of cellular mRNAs (133). Fourth, posttranslational processing may be inefficient, limited by low levels of protease 3C or perhaps activities responsible for maturation of VP1/2A (35,39). Fifth, viral RNA might be sequestered into nascent HAV capsids and thus be unavailable for translation or replication (10). Sixth, host-mediated HAV down-regulation may occur, as is suggested by binding of host proteins to the 3' NCR at the onset of persistent infection and the absence of such binding to the genome of a cytopathogenic mutant (300). Seventh, defective-interfering particles could inhibit HAV replication (122,299). It should be apparent that these mechanisms can be interdependent.

Receptor

Virtually nothing is known about the mechanism by which HAV enters susceptible cells. A study of virus attachment determined that HAS-15 was rapidly (within 20 minutes), but inefficiently (approximately 1% of the input virus), adsorbed to permissive FRhK4 cells (431). Attachment of an Italian strain to Frp/3 cells was abolished by treating the cells with trypsin, phospholipases, or b-galactosidase (360). More recently, HM175 attachment *in vitro* was shown to be calcium dependent. In one of these studies (452), attachment was maximal at 4°C, and HAV bound to both permissive and nonpermissive cells, whereas there was no temperature effect for permissive cells or binding to a nonpermissive cell type in the other study (381). Serum inhibited HAV attachment via high molecular-weight components perhaps related to b_2-macroglobulin (452). Arg-Gly-Asp (RGD) peptides did not interfere with attachment, even though that sequence corresponds to VP3 residues 112 to 114, and such peptides are involved in binding of FMDV and certain proteins to cells (381). Trypsin or chymotrypsin, respectively, digested HAV VP2 or VP1 and VP2 without affecting infectivity (see Genome and Proteins earlier) (227).

Recently a putative receptor for HAV was isolated from cultured cells by using recombinant technology in combination with an antibody that blocked binding of HAV to cells. A class I integral-membrane glycoprotein of unknown natural function was independently isolated by two groups from AGMK cells (197) and from a hybrid marmoset–Vero cell line (20), respectively. The receptor recovered from the two cultures differed slightly in size (451 versus 460 amino acids) and amino acid composition (95% similarity). Additional polymorphisms were found in different AGMK cell lines (106). Subsequently an even smaller receptor glycoprotein (359 amino acids) was isolated from human liver and kidney cells (107). The human homolog had only 79% identity with the AGMK receptor and was expressed in all organs analyzed (liver, small intestine, colon, spleen, kidney, testes), with higher levels in the kidneys and testes than in the liver. There

are no data on whether this molecule serves as the receptor for HAV *in vivo.*

Effects of Chemical Agents on Replication

Several agents that inhibit the growth of poliovirus and some other picornaviruses do not affect HAV, including arildone, disoxaril (formerly known as WIN 51711), 3'-methylquercetin, 2-amino-4,6-dichloropyrimidine, and 2-a-hydroxybenzyl) benzimidazole (78,367). Arildone and disoxaril represent a group of antivirals that, by filling the hydrophobic interior of VP1, stabilize the capsid and prevent uncoating of enteroviruses and rhinoviruses. The other agents interfere with intracellular replicative events: 3'-methylquercetin inhibits synthesis of poliovirus RNA, and 2-amino-4,6-dichloropyrimidine inhibits the morphogenesis of poliovirus (78).

Low concentrations (1 to 3 mmol/L) of guanidine reversibly inhibit replication of enteroviruses and rhinoviruses; effects vary with different combinations of virus strain and host cells (57). HAV strain MBB, adapted to growth in PLC/PRF/5 cells, was resistant to 2 mmol/L guanidine (366), whereas 3 mmol/L guanidine inhibited a cytolytic mutant of HM175 in FRhK4 cells (70). BS-C-1 cell-adapted HM175 was inhibited by 2 mmol/L guanidine, but replication was enhanced by 0.1 to 1 mmol/L guanidine.

Although there are no commercial antiviral drugs specifically licensed for treating HAV infection, ribavirin, amantadine, and 2-deoxy-D-glucose are among several antiviral substances known to interfere with HAV replication (the latter also inhibits poliovirus) (307,435). Amantadine (among several lipophilic amines) and monensin (an ionophore that raises intravesicular pH) are thought to prevent uncoating of HAV in endosomes or lysosomes. Monensin also may block HAV egress from cells by interfering with vesicular transport function; this is also observed with brefeldin A. The effects of 2-deoxy-D-glucose (an inhibitor of glycolysis) and dinitrophenol and sodium azide (inhibitors of oxidative phosphorylation) suggested that late, but not early, events of the HAV cycle are energy dependent. Similar results were obtained with colcemide, vinblastine, and cytocholasin D, which alter cytoskeletal structure.
Tricyclodecane-9-yl-xanthogenate, which inhibits a broad range of DNA and RNA viruses by an unknown mechanism, did not affect HAV or poliovirus (78). HAV propagation was enhanced, at least with particular combinations of virus and cells, by prostaglandin E_1, dexamethasone, or 5,6-dichloro-1-b-D-ribofuranosylbenzimidazole (123,434,435). The latter primarily inhibits transcription by cellular RNA polymerase II and does not enhance growth of poliovirus or echovirus type 6.

Host Range and Experimental Infection in Animals

Attempts to transmit HAV to experimental animals were generally unsuccessful until the 1960s. In 1962, Deinhardt et al. (80) described the development of biochemical and histopathologic changes of mild hepatitis in chimpanzees inoculated with acute-phase serum or feces. The significance of these results was minimized by expectations of jaundice (which rarely occurs in nonhuman primates) and by using assays for aspartate aminotransferase (AST) instead of more sensitive and specific assays for alanine aminotransferase (ALT). In 1967, Deinhardt et al. (81) serially transmitted agents of hepatitis in marmosets by using acute-phase sera from patients with disease that had the epidemiologic characteristics of hepatitis A. Interpretation was initially hampered by reactivation of a latent marmoset agent (or a human non-A, non-B hepatitis virus), which resulted in evidence of hepatitis (305). Transmission of HAV was confirmed when coded control and acute-phase sera from HAV-infected volunteers were correctly identified after inoculation of marmosets (175). Further evidence for transmission to marmosets soon followed, and HAV was subsequently transmitted to chimpanzees (84,269).

HAV is now known to produce disease in humans, chimpanzees (*Pan troglodytes*) (84,269), owl monkeys (*Aotus trivirgatus*) (221), stump-tailed monkeys (*Macaca speciosa*) (256), and several species of South American marmoset (tamarin), most notably *Saguinus mystax* and *S. labiatus* (24,81,175,246). Disease in nonhuman primates resembles that in humans but is usually milder (Fig. 6). After infecting these animals, HAV or viral antigen can usually be detected in serum, liver, bile, and feces. Other primate species are susceptible to infection but do not develop disease with human HAV strains; this limits their usefulness for studies of human strains. Cynomolgus monkeys (*Macaca fascicularis*) were found to have been infected with HAV in the wild (49). In the laboratory, hepatitis was induced in *M. fascicularis* and in *M. arctoides* by experimental inoculation with HAV YaM-55 (collected from cynomolgus monkeys) but not by human HAS-15 (16). The simian virus isolated from African green monkeys caused severe hepatitis in *Cereopithecus aethiops, S. mystax,* and *M. fascicularis,* but not in *P. troglodytes* (96). These data suggest that host species-specific variants may have been selected in certain nonhuman primates (232). This notion is supported by the demonstration of genomic and antigenic differences between HAV from Old World monkeys and humans (see Fig. 2, Strains and Genotypes, and Antigens and Antigenic Structure, earlier). In addition, it appears that a host-range alteration can be experimentally induced. After 20 passages in marmosets, HAV MS-1 was more virulent for marmosets but was attenuated for chimpanzees (45).

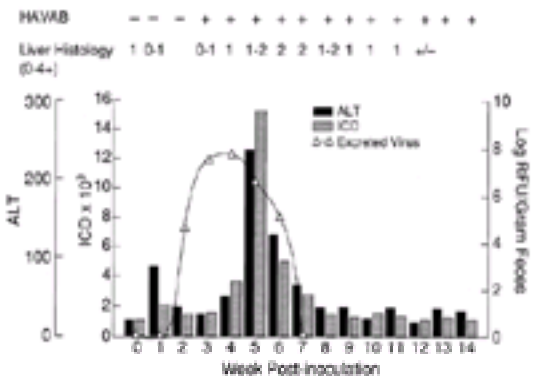

FIG. 6. Course of hepatitis A in an experimentally infected tamarin. A tamarin was inoculated intrahepatically with RNA transcribed from a cDNA clone encoding virulent HM175 virus. The isocitrate dehydrogenase (*ICD*) and alanine aminotransferase (*ALT*) levels in serum are shown, as are quantities of infectious virus [radioimmune focus units (RFUs)]

excreted in the feces. Results of the liver histology and serology tests are noted at the top of each graph. Modified from ref. 119, with permission.

PATHOGENESIS AND PATHOLOGY

Pathogenesis

Natural infection with HAV usually follows ingestion of virus from material contaminated with feces containing HAV. The sequence of events that begins with entry via the gastrointestinal tract and ultimately results in hepatitis has not been completely resolved. Although the primary site of replication for HAV is the hepatocyte, the factor that determines this tissue tropism has not been elucidated. The host-cell receptor used *in vivo* has not been identified, but *in vitro* studies suggest it may be a class I glycoprotein (20,107,197). During the incubation period, viremia is observed at about the same time that fecal shedding of HAV is occurring. It is believed that HAV reaches the intestinal tract in the bile (352,423). Viremia terminates shortly after hepatitis develops, whereas feces may remain infectious for another 1 to 2 weeks. In some situations, HAV may circulate in the blood enclosed in lipid-associated membrane fragments that may transiently protect the virus from neutralizing antibody (230). In this regard, vesicular structures containing virus have been observed in cell cultures (19) and in primate hepatocytes and Kupffer cells, where they appear to be released into the biliary system or the blood (363).

Although coproantibodies have been detected in acute hepatitis A (242,447), they apparently lack neutralizing activity (383). Nevertheless, immune complex formation between specific IgA antibodies and fecal HAV has been observed (198). This may explain why HAV can be detected by molecular hybridization long after HAV antigen becomes negative by immunoassays (399). Patients with relapsing type A hepatitis may continue to excrete detectable HAV, even though their serum remains positive for IgM anti-HAV (376). There is no evidence that defective secretory antibody production has anything to do with this phenomenon, which is simply not understood.

If a primary extrahepatic site of HAV replication exists, it has been difficult to demonstrate. In experimental infections in nonhuman primates, HAV viral antigen and/or genomic material have been observed in the spleen, kidneys, tonsils, and saliva, but have been inconsistently identified in the intestinal mucosa (59,198,212,264,267,401). A recent study in owl monkeys detected HAV antigen in the epithelial cells of the intestinal crypts and in cells of the lamina propria 3 days after inoculation and up to 5 weeks later, but RNA replication was not shown (18). Detection of HAV in tonsils and saliva, shortly after the appearance of virus in the blood, suggests that an early replicative event could occur in the oropharynx or salivary glands (59). In one human study, a saliva sample was about 10,000-fold less infectious than a serum sample, which was 100,000-fold less infectious than a stool sample collected on the same day (325).

Even though mature virions of other picornaviruses exit the cell by infection-mediated disintegration of the host cell, there is little evidence that HAV is directly cytotoxic to hepatocytes. Although some correlation has been seen between severity of disease and virus shedding in the stool (85,115), fecal excretion is, in most cases, greatest before the onset of liver injury, as manifested by an elevated ALT level (see Fig. 6). In addition, viral antigen is first detected in the liver parenchyma of experimentally infected primates 1 to 2 weeks after intravenous inoculation and may persist there throughout the acute phase (146,200,264). Cytopathology (by light microscopy) is unimpressive during this early phase of maximal viral replication, although organelle damage has been detected by electron microscopy (19). *In vitro,* cells persistently infected with HAV are not destroyed, and their metabolism is relatively unaffected (123). These findings suggest that virus-induced cytopathology may not be responsible for the pathologic changes seen in HAV infection and that liver disease may result primarily from immune mechanisms (reviewed in 371). *In vitro* studies have shown evidence of cell-mediated lysis of HAV-infected cells by natural killer cells and by human leukocyte antigen (HLA)-restricted, HAV-specific, $CD8^+$, cytotoxic T cells that were cloned from liver biopsies obtained during acute hepatitis A in patients with hepatocellular necrosis (217,419).

The juxtaposition of hepatitis with the appearance of IgM anti-HAV, immune complexes, and reduced levels of serum complement may be coincidental or relevant to the clinicopathologic changes (22,43,181,257,405). Analysis of the immune complexes has revealed IgM and IgG, HAV capsid proteins, and the C3d component of complement (257). However, patients with hepatitis A appear to lack complement-dependent cytotoxic antibodies (121,378). In addition to these host-mediated immunologic responses, increased levels of interferon have been detected in the serum of HAV-infected patients (74,239,450). Presumably, these biologic phenomena are responsible for the reduction in symptoms and in virus burden seen in patients after the onset of clinical disease.

Pathology

Needle biopsy of the liver is rarely indicated in acute viral hepatitis. In acute hepatitis A, both degenerative and regenerative parenchymal changes coexist with a diffuse and evenly distributed accumulation of mononuclear inflammatory cells, leading to lobular disarray (Fig. 7). Parenchymal cells undergo ballooning degeneration. These hepatocytes are swollen and have indistinct plasma membranes, enlarged nuclei, and a featureless cytoplasm, except for some cytoplasmic remnants condensed around the nuclei (Fig. 8). Disruption of bile canaliculi may lead to bile retention after liver cell enlargement or necrosis. Acidophilic degeneration (apoptosis) also occurs (Fig. 9). Cells become shriveled, angulated, and display increased eosinophilia. Both types of degeneration result in the migration of affected cells or cellular debris into the spaces of Disse and eventually into the sinusoids, where they are surrounded by reticuloendothelial cells (Kupffer cells) and undergo phagocytosis and digestion. Activation of Kupffer cells in the sinusoids and macrophages in the portal tracts results in marked hypertrophy and hyperplasia of these cells. The portal tracts are enlarged as a result of edema accompanied by a moderate-to-heavy infiltration of inflammatory cells, primarily lymphocytes, although neutrophils and eosinophils may be present (Fig. 10). Plasma cells are uncommon, however. Inflammatory cells may spill over into the adjacent parenchyma, a process called *piecemeal necrosis* or *interface*

hepatitis, but less than 25% of the limiting plate is involved. During the recovery stage, regeneration is prominent, as manifested by anisonucleosis, the presence of numerous bi- and trinucleated cells, and mitosis. The inflammatory response diminishes, but Kupffer cell hypertrophy persists for a few weeks. The damaged hepatic tissue is usually restored within 8 to 12 weeks.

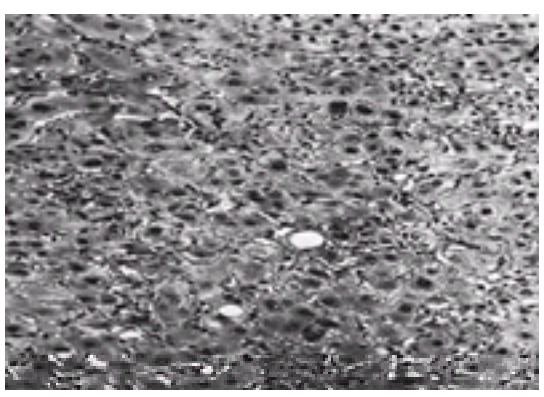

FIG. 7. Acute viral hepatitis. Lobular disarray characterized by anisocytosis, anisonucleosis, ballooning, and Kupffer cell hypertrophy (H&E, ×190). From ref. 183, with permission.

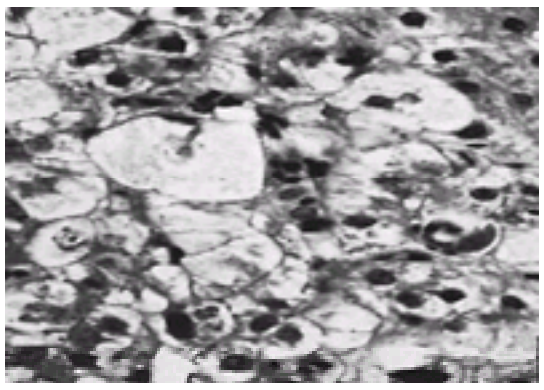

FIG. 8. Acute viral hepatitis. Ballooned hepatocytes show lysis of cell membranes and nuclei and an empty cytoplasm (H&E ×520). From ref. 183, with permission.

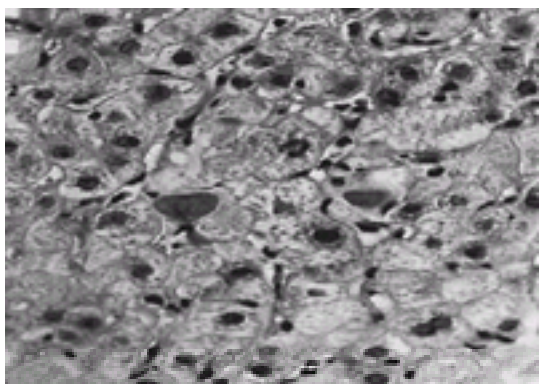

FIG. 9. Acute viral hepatitis. Two sinusoidal acidophilic (apoptotic) bodies can be seen in the center of the field (H&E ×490). From ref. 183, with permission.

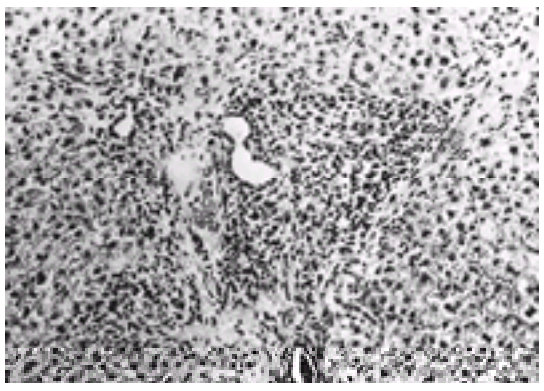

FIG. 10. Acute viral hepatitis. Portal area infiltrated with numerous inflammatory cells (H&E ×140). From ref. 183, with permission.

In 5% to 10% of patients, focal necrosis gives way to zones of necrosis that bridge portal tracts or join portal areas to

central veins (30,42). When this process of confluent (bridging) hepatic necrosis with impaired regeneration involves entire lobules or adjacent lobules, the terms *submassive* (involving the central and middle zones of lobules) or *massive* (involving entire lobules) are applied to the process (Fig. 11 and Fig. 12). The latter is characterized further by the proliferation of cholangioles in the periportal areas infiltrated by neutrophils. Confluent hepatic necrosis is potentially a progressive lesion that may lead to fulminant hepatitis and death in 30% to 60% of cases (42,426). Death appears to be inevitable when necrosis involves more than 65% to 80% of the total hepatocyte fraction (128,358). However, it is encouraging to note that neither functional nor pathologic sequelae are common in patients who survive an episode of acute fulminant hepatic failure despite previous widespread necrosis (176,201).

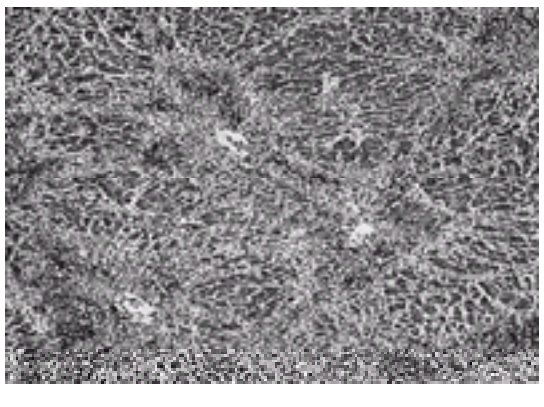

FIG. 11. Acute viral hepatitis with submassive necrosis. Zones of necrosis are linked together (bridging necrosis) (H&E ×43). From ref. 183, with permission.

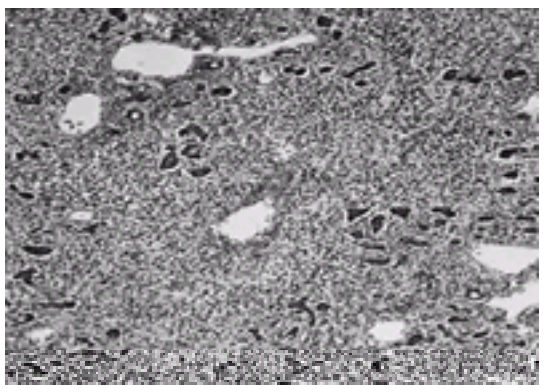

FIG. 12. Acute viral hepatitis with massive necrosis. All liver cells have “dropped out.” Note proliferating periportal cholangioles and infiltration of stroma and portal areas with inflammatory cells (H&E ×73). From ref. 183, with permission.

Rarely, patients with acute viral hepatitis A develop features of cholestasis (deep jaundice, acholic stools, pruritus) that may persist for 2 to 8 months (137). This appears to be more common in hepatitis A than in hepatitis B or C, but is less common than in acute hepatitis E (144,205,357,402). Histologically, there is severe centrilobular cholestasis associated with periportal inflammation that sometimes resembles chronic hepatitis, which never occurs in hepatitis A or E. Plasma cells are prominent throughout the inflammatory infiltrate.

Just as it is difficult to determine the etiology of acute hepatitis without serologic data, the pathologic changes in acute-phase liver tissue obtained from humans with different forms of viral hepatitis are qualitatively similar (30,31,183,250). In general, liver tissue from patients with acute hepatitis A has less conspicuous parenchymal changes (including focal necrosis, Kupffer cell proliferation, acidophilic bodies, and ballooning degeneration) and less occurrence of steatosis than does tissue from acute hepatitis C patients, but necrosis and mononuclear cell inflammation of the periportal region are more evident than in biopsies from patients with acute hepatitis B (2,216,314,402). In addition, the limiting plate is more likely to be disrupted in hepatitis A, and periportal inflammation often simulates chronic hepatitis.

CLINICAL FEATURES

The course of viral hepatitis may be extremely variable. Patients with inapparent or subclinical hepatitis have neither symptoms nor jaundice. These asymptomatic cases previously went unrecognized, but now can be identified by detecting biochemical or serologic alterations in the blood. In addition to the inapparent or subclinical cases, patients may develop anicteric or icteric hepatitis. The terms *inapparent* and *anicteric hepatitis* are often used interchangeably by physicians. However, anicteric hepatitis should be reserved for those patients who develop clinical symptoms but who are not jaundiced. Symptoms ranging from mild and transient to severe and prolonged may accompany anicteric or icteric hepatitis. Patients may recover completely or develop fulminant hepatitis and die (see Table 4).

Parameter	Predicted outcome	
	Children (<5 yr)	Adults
Inapparent infection	80–95%	10–25%
Anicteric or icteric disease	5–20%	75–90%
Complete recovery	99+%	98+%
Chronic disease	None	
Mortality rate		
≤14 yr	0.1%	
15–39 yr	0.3%	
≥40 yr	2.1%

TABLE 4. *Predicted outcome after an infection with hepatitis A virus*[a]

Signs and Symptoms

Regardless of etiology, the course of acute viral hepatitis is similar and can be divided into four clinical phases: (a) incubation or preclinical period (time between exposure and the first day of symptoms or jaundice; (b) prodromal or preicteric stage; (c) icteric phase; and (d) convalescent period (reviewed in 210).

Although the median incubation period for each type of viral hepatitis may be distinctly different, there is considerable overlap, so that knowledge of the incubation period is rarely useful in determining etiology for individual cases. In addition, the patient may not know the time of exposure. The incubation period for hepatitis A ranges from 10 to 50 days, with a mode of approximately 1 month, regardless of the route of infection (294,309,310). However, the greater the dose of virus inoculated, the shorter the incubation period (310). When two cases occur less than 14 days apart, they are more likely to be co-primary, rather than secondary cases. Correspondingly, cases occurring more than 60 days after a point source epidemic are presumably due to secondary spread of the infection (214,425). During the incubation phase, the patient remains asymptomatic despite active replication of the virus. It is in this preclinical phase that transmissibility is of greatest concern (see Epidemiology).

A short prodromal or preicteric phase, varying from several days to more than a week, precedes the onset of jaundice. In more than half of the patients, the prodromal state typically is characterized by anorexia, fever (usually <103°F), fatigue, malaise, myalgia, nausea, and vomiting. Many of these symptoms may be mediated by interferon induction. In hepatitis A, the transition from well-being to acutely ill occurs abruptly (within a period of 24 hours) in more than 60% of the cases, whereas the onset is more insidious in hepatitis B. Fever above 100.5°F is more common in acute hepatitis A than in hepatitis B (425). Diarrhea, nausea, and vomiting are more frequent in children than in adults (223). In some cases, the diarrhea may be secondary to another enteric infection acquired from the same source (263). Weight loss of 2 to 10 pounds is common as a result of the anorexia that accompanies disorders of taste and smell (166,379). Older children and adults often complain of right-upper-quadrant pain or discomfort as a consequence of hepatomegaly, which usually precedes jaundice by 1 to 2 weeks (425). Severe abdominal pain and protracted vomiting are unusual manifestations and should lead the clinician either to question the diagnosis or to suspect a more severe variant of the disease.

The icteric phase of acute viral hepatitis is ushered in by the appearance of dark, golden-brown urine due to bilirubinuria, followed 1 to several days later by pale stools and yellowish discoloration of the mucous membranes, conjunctivae, sclerae, and skin. This icteric phase begins within 10 days of the initial symptoms in more than 85% of HAV cases (281,454). Jaundice becomes clinically apparent when the total bilirubin level exceeds 2.0 to 4.0 mg/dL (155). Patients often seek medical attention at this stage of their illness. Fever, if present, usually subsides after the first few days of jaundice.

Atypical manifestations of hepatitis A (reviewed in 349) include the development of cholestasis, relapsing hepatitis, extrahepatic manifestations, and the possible induction of type 1 autoimmune chronic hepatitis. Patients with cholestatic hepatitis A initially have pruritus, fever, diarrhea, and weight loss. The serum bilirubin usually remains above 10 mg/dL for more than 12 weeks, whereas the ALT level is often under 500 International Units (IU)/L. Resolution of the disease is slow, but patient recovery is complete. HAV also has been associated with gallbladder wall thickening (409) and acalculous cholecystitis on rare occasions (287). Detection of HAV antigen in bile epithelium and the gallbladder suggests a possible pathogenetic role in HAV-associated cholestasis and gallbladder disease.

Relapsing hepatitis occurs in 3% to 20% of the cases of acute hepatitis A (134,188,376). A recrudescence of the disease, which may be more or less severe than the original episode, occurs 4 to 15 weeks after the initial symptoms have resolved. In some patients, only biochemical changes are observed. IgM anti-HAV either reappears or increases in titer, and HAV has been detected in feces and serum. More than one relapse can occur, and enzyme elevations may persist for 5 to 12 months, although chronic sequelae are not observed.

Extrahepatic manifestations of hepatitis A are unusual, although transient rashes are observed infrequently, as is arthralgia. Clinically apparent arthritis and leukocytoclastic vasculitis have been reported, and mild, membranoproliferative glomerulonephritis associated with immune complex deposits has been seen in a postmortem specimen (174).

Physical examination of the patient with acute disease reveals tenderness to palpation or percussion of the liver that may be enlarged. Measurement by percussion is essential, because reduced size in a deteriorating patient often heralds massive necrosis. Approximately 5% to 15% of patients have splenomegaly. Generalized adenopathy is not a component of viral hepatitis A, B, or C, but often is present with cytomegalovirus- or Epstein–Barr virus–related hepatitis. Palmar

erythema and spider angiomata may be observed.

Occasionally, more extensive necrosis of the liver occurs during acute viral hepatitis, leading to severe impairment of hepatic synthetic processes, excretory functions, and detoxifying mechanisms. This entity, designated fulminant hepatitis if it occurs during the first 6 to 8 weeks of illness, is characterized by the sudden onset of high fever, marked abdominal pain, vomiting, and jaundice followed by the development of hepatic encephalopathy associated with deep coma and seizures (4,347,412). Ascites, a bleeding diathesis, and decerebrate rigidity lead to death in 70% to 90% of the patients. Mortality is highly correlated with age, survival being uncommon among hospitalized patients younger than 10 years or older than 40 years (28,285,301,412,413). Clinical signs portending liver failure include a rapid decrease in the size of the liver, increasing prolongation of the prothrombin time, and a decrease in the aminotransferase levels as the bilirubin level continues to increase. Fortunately, this clinical pattern is rare, occurring in less than 1.5% of the icteric patients hospitalized for acute viral hepatitis.

Table 4 provides a summary of the predicted outcomes that might occur after an infection with HAV. As noted, the disease is milder in children than in adults, complete recovery is the rule, and chronic disease has not been observed (220). Hospitalization and death due to hepatitis A is age dependent. Whereas two thirds of the clinical cases occur in children and young adults, more than 70% of the deaths are observed in patients older than 49 years. The mortality rate is considerably higher among patients with chronic hepatitis B or C who are superinfected with HAV (150,203,445), especially if the underlying liver disease is advanced.

Laboratory Findings

The clinical diagnosis of acute viral hepatitis is made by biochemical assessment of liver function. The initial laboratory evaluation of the jaundiced patient should include a biochemical liver panel, complete blood count (CBC), and prothrombin time. Typically, total serum bilirubin usually remains below 10 mg/dL, but levels of 20 mg/dL may occasionally be observed (393). After reaching a peak in 1 to 2 weeks, the rate of decline is more gradual, with resolution occurring within 6 weeks of onset in most patients (341). Discordant findings between serum and urine bilirubin may occur during convalescence when elevated levels of serum bilirubin may not be accompanied by bilirubinuria (129). This is due to the presence of a conjugated form of bilirubin (delta bilirubin) that is irreversibly (covalently) bound to albumin (427), thereby impairing its excretion in the urine.

Serum ALT and AST concentrations are highly sensitive indicators of hepatocellular injury. They provide a quantitative assessment of acute damage sustained by the liver, although the eventual outcome cannot be predicted from the level attained. ALT is primarily localized to the liver. Within hepatocytes, AST is found in mitochondria (80%) and the cytosol (20%), whereas ALT is limited to the cytosol. This compartmentalization of enzymes may partially explain the aminotransferase patterns seen in many forms of liver disease. For example, during “classic” acute viral hepatitis, liver biopsy sections reveal ballooning degeneration throughout the lobule. This is characterized by swelling of hepatocytes, indistinct or lysed cell membranes, and cytoplasmic rarefaction (183). Ultrastructural studies reveal marked dilatation of the cisternae of the endoplasmic reticulum, loss of glycogen, and condensation of the inner compartments of mitochondria (415). These relatively mild and reversible changes may be induced by factors that damage the plasma membrane (416), leading to ionic and water shifts followed by leakage of enzymes from the cytosol. Consequently, ALT levels are significantly higher than AST levels in uncomplicated acute viral hepatitis, resulting in a high ALT/AST ratio (>1.4) in almost all cases. Exceptions include those situations in which severe tissue necrosis develops, resulting in the release of mitochondrial AST into the blood. In these situations, the lactic dehydrogenase enzyme (LDH) is significantly elevated.

Certain serum proteins, such as albumin, prothrombin, fibrinogen, and vitamin K–dependent coagulation factors, are synthesized exclusively or predominantly by the liver. Because the intravascular half-lives of the various plasma-clotting factors range from 5 hours (factor VII) to 5 days (fibrinogen), measurement of both the extrinsic clotting system (prothrombin time) and the intrinsic pathways (partial thromboplastin time) may more accurately reflect early and potentially serious derangements in liver function than does the measurement of serum albumin, which has a half-life of 3 weeks. Conversely, because albumin is the major secretory protein produced by the liver and is important for osmotic regulation, transport of various metals, and binding of other substances, its concentration is a useful guide to prognosis and therapy.

Generally, the patient with typical acute viral hepatitis has a normal or slightly reduced number of segmented leukocytes and a relative lymphocytosis (164). When the white blood count is more than 12,000/mm^3, a more serious form of the disease is anticipated. Although mild to moderate reduction in red blood cell survival is frequent in acute viral hepatitis, the hematocrit and hemoglobin remain within normal limits (64,202). Occasionally, hemolytic anemia occurs, often in association with glucose-6-phosphate dehydrogenase deficiency (55,56,180,207,345). Rarely agranulocytosis (290), thrombocytopenia (99,251), pancytopenia (207), red cell aplasia (408), or aplastic anemia (152,251,439) accompanies acute viral hepatitis.

DIAGNOSIS

Because the agents of viral hepatitis often cannot be distinguished clinically and HAV superinfection of hepatitis B and C carriers can occur, serologic means are required for their identification (172,173). To accomplish this, a variety of diagnostic profiles are offered to the clinician to ensure that a misdiagnosis does not occur, because this may impinge on immunoprophylaxis. The most favored acute viral hepatitis profile includes assays for IgM anti-HAV, HBsAg, IgM anti-HBc, and anti-HCV. However, idiosyncrasies of the assays make it desirable to perform ancillary tests that will confirm a positive response. In detection of HAV infection, this would include a measurement for total anti-HAV (IgG and IgM), because the detection of IgM anti-HAV always should be accompanied by a positive test in the assay that measures total specific antibody. The reader is directed to the diagnosis section in Chapter 87 for an algorithm covering the serologic diagnosis of HAV, HBV, HCV, and HDV. HEV is discussed separately in Chapter 89.

Before the onset of clinical symptoms, HAV appears in the blood and stool (Fig. 13). Compared with the relatively high concentrations of virus shed in the feces (10^9 virions/g), virus concentrations found in blood are relatively low (10^5 virions/mL) (Fig. 14). Should preillness samples of blood or feces be available, HAV can be detected by experimental infection of nonhuman primates or cell cultures, immunoassays [enzyme imunoassay (EIA) and radioimmunoassay (RIA)], immune electron microscopy, hybridization assays, or the RT-PCR method (83,108,187,296,334,359,376,448) (see also Host Range and Experimental Infection in Animals , earlier). However, none of these methods is practical in a clinical setting; they are not necessary unless incontrovertible proof for the presence of infectious virus is needed.

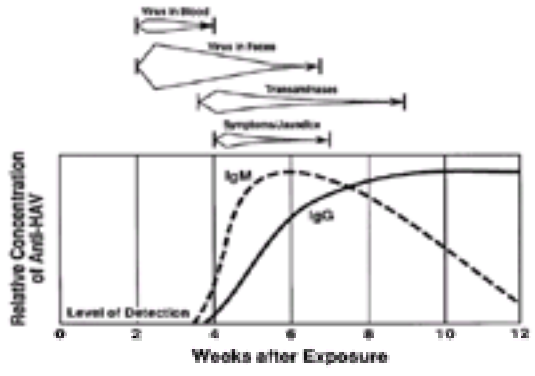

FIG. 13. Immunologic and clinically relevant biologic events associated with hepatitis A virus (HAV) infection in humans. Modified from ref. 172, with permission.

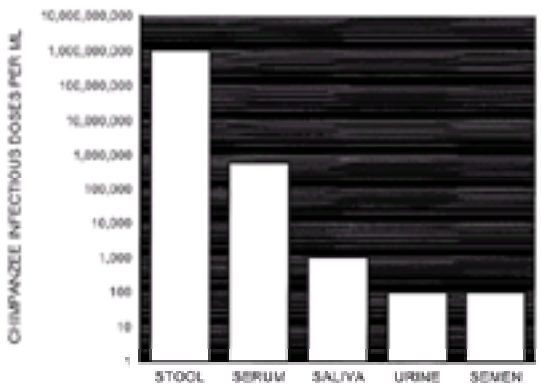

FIG. 14. Infectivity titers of body fluids and excretions.

To establish the diagnosis of acute or recent hepatitis A, blood samples are examined for the presence of IgM-specific anti-HAV (see Fig. 13) (43,79,243). This acute-phase antibody rapidly increases in titer over a period of 4 to 6 weeks, and then declines to nondetectable levels within 3 to 6 months in most patients (range of <30 to >420 days, with persistence for more than 200 days in 13.5%) (196). In more than 85% of the subjects, the liver enzymes will be normal before or at the time of disappearance of IgM anti-HAV. IgG anti-HAV can be detected simultaneously or within a week or 2 of the acute illness, and eventually replaces the IgM antibody. IgG antibody persists for years after infection (377).

The total anti-HAV assay is used primarily to determine the immune status of an individual after vaccination or infection or to assess risk in a person traveling to an endemic region or working in a high-risk area. In the absence of either IgM anti-HAV or an abnormal ALT level, clinicians can assume that the antibody being detected is of the IgG immunoglobulin type, indicating previous infection with HAV—or successful vaccination—and protection against future infection. These conclusions are valid only if passively acquired antibody from blood components, maternal antibodies crossing the placenta, or immune globulin immunoprophylaxis can be excluded. A more extensive review of the laboratory procedures and their interpretations can be found in reference 173.

Immunocytochemical staining has been used to identify HAV in the liver of infected primates from biopsies obtained early in the course of the disease (178,267,288,363). Viral antigen also has been localized to the cytosol–microsomal subcellular fraction (93%), with 4% in the nuclear fraction (204). Within the microsomal fraction, more than 85% was detected in the smooth microsomes. Studies of human liver have demonstrated HAV in cytoplasmic vesicles of hepatocytes and Kupffer cells and in the cytoplasm of epithelial cells of the biliary ducts (287).

MANAGEMENT OF ACUTE VIRAL HEPATITIS

There is no specific treatment for acute viral hepatitis, and liver biopsy is unnecessary. Therapy should be supportive and aimed at maintaining comfort and adequate nutritional balance. Although the disease is usually mild in children younger than 10 years, those who become clinically ill are more prone to develop fulminant hepatic failure compared with those who develop clinical HAV infection between the ages of 10 and 40 years. At older than 40 years, the severity of the liver disease intensifies. For most jaundiced patients, strict bed rest and prolonged confinement are probably not indicated (53). In one study, strenuous activity did not appear to have any adverse effect on the clinical course of acute viral hepatitis (330). Prudent therapy, however, seems to indicate a course of bed rest that is carefully tailored to the severity of the patient's illness and to his or her emotional well-being without insistence on prolonged inactivity.

Hospitalization is not ordinarily indicated.

The diet should conform to the patient's appetite and wishes; it must, however, supply adequate protein (1.0–1.5 g/kg) and calories (30 to 35 cal/kg). However, hospitalized patients may benefit from protein restriction, supplying all of the calories as an intravenous infusion of carbohydrate for a few days (see later). The use of oral, enteral, or intravenous amino acids in acute hepatitis has not been adequately evaluated. There is no good evidence that restriction of fats has any beneficial effect on the course of illness, and ingestion of fats in moderate amounts may help provide sufficient caloric intake. As a general rule, modest consumption of alcohol (<30 g/day for men and <15 g/day for women) during convalescence (6 to 24 weeks after symptoms develop) does not seem to be harmful when the ALT level has decreased to less than 1.5 times the upper limit of normal (410). Nevertheless, because of the direct hepatotoxic effect of ethanol, abstinence from alcoholic beverages during the acute phase of hepatitis seems prudent. Finally, women who are taking oral contraceptives need not discontinue their use during the course of hepatitis (356).

There is no indication for corticosteroids in the treatment of acute, uncomplicated hepatitis A. They have no effect on the rate of resolution of the underlying disease process and may increase the rate of relapse or result in death from fulminant hepatitis, especially if administered during the incubation or prodromal stage of infection (36,102,103,350). Conversely, a 4-week course of prednisone with tapering doses can hasten resolution in some patients who have developed prolonged, moderate-to-severe cholestasis, although complete recovery without therapy will eventually occur in all (349,438). Abruptly stopping the medication or shortening the interval of therapy can result in a relapse. Immune globulin or antibiotics also are of no value in acute viral hepatitis (101,131).

The treatment of confluent necrosis or fulminant hepatitis has been unsatisfactory, and mortality rates from these complications remain universally high. Nevertheless, intensive general supportive care and the management of complications are responsible for much of the recent improvement in survival rates. Although of no proven survival value in fulminant hepatitis, conventional treatment has included the reduction of protein intake and the use of cleansing (lactulose) enemas followed by the oral administration of neomycin or lactulose to decrease blood ammonia concentration, thereby alleviating hepatic encephalopathy. Clotting abnormalities should be corrected with the administration of fresh-frozen plasma. If the prothrombin time is prolonged, a single injection of vitamin K (10 mg) is justified. Seizures can be controlled with small, repeated doses of oxazepam (oral only) or lorazepam, because these drugs are conjugated by glucuronidation (which is not restricted to hepatic microsomes).

Because hypoglycemia is often prominent in critically ill, hospitalized patients, glucose levels should be monitored at least twice daily and caloric requirements maintained by the intravenous administration of glucose (16 cal/kg). It is recommended that 10% (rather than 5%) glucose be used, because patients with severe hepatitis sometimes have difficulties excreting a normal water load. Electrolyte disturbances also are common because of impaired sodium excretion and free water clearance, especially in patients receiving blood products for coagulation defects, osmotic diuretics for cerebral edema, or glucose in water for nutrition (437). Supplementation of the glucose with sodium and potassium chloride is recommended. In addition, vitamin B complex with thiamine is useful while intravenous therapy is being administered (340).

With regard to the treatment of fulminant and subfulminant liver failure with coma, a number of procedures designed to remove toxins temporarily (29,391) often improved the neurologic status of the patient, but survival was not improved, and complications often occurred. Massive doses of corticosteroids or adrenocorticotropic hormone (ACTH) also have not been effective and may be harmful (3,100,103,104). Recently the use of hybrid bioartificial liver systems to improve the metabolic status of patients with fulminant hepatitis until the liver tissue regenerates or orthotopic liver transplantation (OLT) can be arranged has yielded encouraging results. These systems use hollow-fiber membranes containing a human liver cell line or primary porcine hepatocytes (342,392). Primary hepatocytes are typically embedded in a collagen gel or attached to collagen-coated beads to maintain differentiated function and to allow cryopreservation (87). The addition of nonparenchymal cells to these support systems could stabilize the environment by contributing matrix protein for the control of morphogenesis and proliferation of the cells (390). They are being proposed for the treatment of liver failure in centers where the option of liver transplantation also exists. In the interim, acute liver failure is more successfully managed by the application of emergency OLT (total, auxiliary partial, or living-related partial), recognizing that the survival rate in fulminant hepatitis A ranges between 33% and 63% (29). Correspondingly, indications for emergency OLT in patients developing encephalopathy remain controversial. Selection is critical, because most patients with grade 4 encephalopathy (coma) will survive without a liver transplant and recover completely, whereas OLT results in survivors who require a lifetime of immunosuppression and medical management. By transplanting only those patients with a poor prognosis (reviewed in 301), 1-year survival rates of 80% for fulminant hepatitis A have been achieved.

EPIDEMIOLOGY

Hepatitis A is one of the most common causes of infectious jaundice in the world today. Recurrent epidemics are a prominent feature of the disease. In 1998, the total number of cases of viral hepatitis A reported to the National Notifiable Diseases Surveillance System operated by the Centers for Disease Control and Prevention was 23,229, yielding a rate of about 8.59 cases per 100,000 population (52). This preserves a downward trend seen in the hepatitis A rates since 1995.

Rates of disease are particularly high among children and young adults and in American Indians/Alaskan Natives and Hispanics (Fig. 15) (50). The rate in male subjects is approximately 1.6 times higher than that in female subjects, and the rate in the western United States is more than 2.5 times the average rate in the other regions of the country. The actual incidence of disease is much higher because many persons contract such a mild form of hepatitis that they do not seek treatment and because physicians report fewer than 12% of the hospitalized cases (209,258). It is estimated that 125,000 to 200,000 total infections occur annually, of which 84,000 to 134,000 are symptomatic. From 11% to 22% of those with overt hepatitis A are hospitalized, and approximately 100 die of fulminant hepatitis. Table 4 provides mortality data for HAV by age group. Based on the total number of viral hepatitis cases reported in 1998, 63% were due to hepatitis A, 28% to hepatitis B, and 9% to hepatitis C/non-A, non-B (Fig. 16) (52).

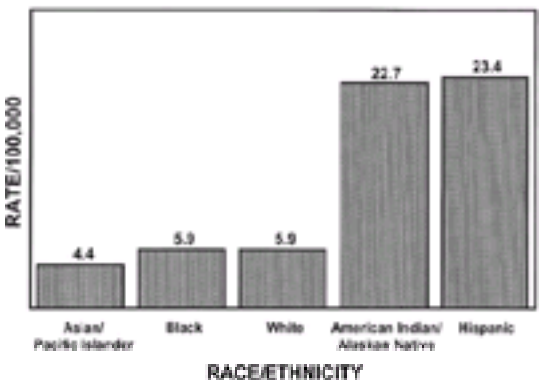

FIG. 15. Rates of reported hepatitis A cases (per 100,000 population) in the United States, by race/ethnicity, 1997. From ref. 50, with permission.

The level of sanitation or hygiene in the environment markedly influences the epidemiology of hepatitis A. In populations in which living conditions are crowded and sanitation is nonexistent or inadequate, prevalence studies reveal that infections occur at an early age and that close to 100% of children acquire immunity during the first decade of life (26,116,148,270,394,395). Transmission of HAV within crowded institutions, where the disease is hyperendemic, depends on length of institutionalization and is unrelated to the age of the individual at first admission (397). In contrast, in modern urban societies or in developing nations where improvements in sanitation and personal hygiene have delayed infection, a reduction in anti-HAV prevalence among younger persons has been found (149,184,270,348,395). Large segments of the population remain susceptible, and epidemics may occur after chance introduction of the virus to an area.

The principal mode of transmission for HAV is by the fecal–oral route, often resulting in community-wide outbreaks. Thus hepatitis A could be considered to be an enterically transmitted disease. Relatively high concentrations of HAV are shed in the feces 3 to 10 days before the onset of clinical symptoms or a few days before jaundice, near the time when the ALT level initially becomes elevated (see Fig. 13) (66,83,110,115,153,170,328). Communicability is apparently highest during this interval (27,82,328). Excretion of infectious HAV has been documented in stool specimens collected as early as 2 to 3 weeks before, and up to 8 days after, the onset of jaundice (Fig. 17) (161,215). Transmission is severely curtailed during the acute and early convalescent stages of the disease, requiring increasingly larger quantities of fecal material to elicit an infection (214,215,245,425). In adults, viral particles are more often detected in the stools of patients who become icteric, in contrast to patients who develop anicteric hepatitis or no clinical disease (85,115). In infants and young children, fecal excretion of HAV antigen and HAV RNA persist for a longer interval than is observed in adults (338,399). In one study (338), HAV RNA was detected by RT-PCR in three infants up to 4 to 5 months after they had been identified as being infected. Whether such excretion is biologically relevant has not been established.

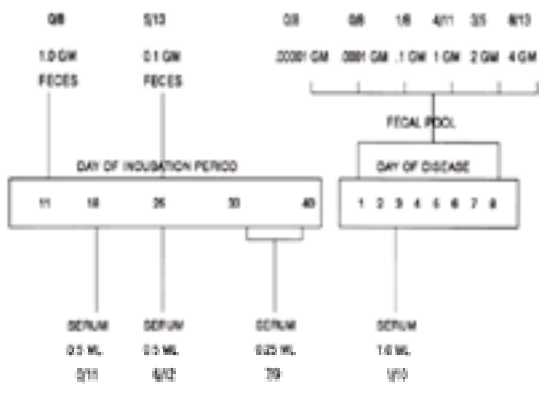

FIG. 17. Relative levels of infectivity observed for feces and serum samples collected during the incubation period and early stages of acute hepatitis A (215). The number of subjects tested versus the number developing clinical hepatitis A are provided for each quantity of sample evaluated. [In the absence of a diagnostic hepatitis A virus (HAV) assay in 1959 to determine susceptibility, the number tested is not necessarily equivalent to the number of susceptible subjects.]

Anti-HAV of the IgA class has been detected in stool specimens during the early stages of infection after the transaminase level has peaked and immunoglobulin-coated particles have been visualized (242,447). The appearance of immune complexes correlates with the abrupt reduction or absence of detectable particles of HAV seen in these preparations (44,83,85,110,170,328) and may account for the low rate of transmission to health care professionals exposed to hospitalized cases of hepatitis A (268).

The presence of virus in feces facilitates virus dissemination and accounts for the widespread outbreaks of hepatitis A that occur among household contacts or sexual contacts of a person who has hepatitis A (51). Other outbreaks have been observed in children and employees associated with day-care centers or with contacts of these individuals (151), in neonatal intensive care units (21,208,298,338), among the military, and in international travelers. Because clinical illness is uncommon in infants and young children, it is disease in their adult contacts that often calls attention to the problem in child-care centers and in neonatal intensive care units. In contrast to this person-to-person mode of spread, sudden, explosive epidemics of hepatitis A within communities or confined populations usually result from fecal contamination of a single source, such as drinking water, milk, or food prepared by persons in the incubation stage of their disease and served without further cooking (277,283,284,400,407).

Several outbreaks of hepatitis A have resulted from the consumption of raw or inadequately cooked oysters and clams obtained from water polluted with sewage (156,263,343). The largest outbreak in recent years occurred in Shanghai in 1988, when more than 300,000 reported cases of hepatitis A were identified, primarily in young adults who ingested uncooked clams from polluted water (445). A low case fatality rate of 0.015% was observed in this epidemic. The role of mollusks has been that of virus concentrators of water polluted by sewage rather than propagators of virus. During feeding, physiologically active bivalves (e.g., oysters or mussels) can filter up to 10 gallons of water per hour over a short period, during which HAV can be concentrated at least 100-fold and persist for about 7 days (98). The rate of uptake and depuration is slower without feeding. As expected, nonbivalve shellfish (e.g., lobsters, shrimp) do not impart the same risk.

Human transmission studies and molecular techniques have provided evidence that transient viremia occurs during infection from HAV (38,113,132,157,161,174,215,424,448). The viremia often precedes the development of symptoms by 7 to 14 days (see Fig. 13 and Fig. 17). By the time the patient seeks medical attention or the transaminases reach a peak, clinically relevant viremia has virtually disappeared. Rarely, viremia may be present during the early stages of jaundice (215). Studies using RT-PCR have shown that HAV RNA appears in the blood earlier than appreciated from the transmission studies, reaches its maximal concentration before peak ALT levels, and persists for 30 days or more from onset of symptoms (41,117,143,448). This discordance between detection of virus-specific nucleic acid and a capacity to transmit HAV is noteworthy, but not unexpected. However, the clinical relevance of these observations remains to be established.

HAV transmission through blood is a rare but potential cause of posttransfusion hepatitis (25,51,113,157,174,226). The problem is amplified in neonatal intensive care units where infants develop infection after receiving blood components from an infected donor, but do not develop symptoms of hepatitis. They subsequently transmit the virus to health care workers and family members, presumably by the fecal–oral route (21,208,298,338). The rarity of transfusion-associated hepatitis A probably can be attributed to several closely associated factors. First, the viremic stage is of short duration (see Fig. 13 and Fig. 17) (38,113,161,215), and the concentration of HAV in the blood is relatively low (171,174). The low incidence of HAV infection in the U.S. (52) and the absence of an HAV carrier state (214) also contribute to the rarity of HAV transmission through blood. For HAV transmission to occur, an infected donor would have to donate blood during a very restricted period. Even if this situation existed, the probability that the infectious unit would be given to an HAV-susceptible recipient diminishes with increasing age of the recipient (270,395). In addition, because most recipients are given more than one unit of blood, an anti–HAV-positive unit may be transfused with the HAV-positive unit, thereby neutralizing the virus. The last two scenarios often do not apply to neonates, which is why the risk is greater in this group. Current blood bank practices do not include specific screening of prospective donors for evidence of active HAV infection.

From 1989 to 1995, several outbreaks of hepatitis A occurred among hemophiliacs in Europe, South Africa, and the U.S. who received organic solvent- and detergent-treated factor VIII (253,332). Cases were dispersed geographically, were not associated with community outbreaks, and implicated lots contained HAV genomic material whose genetic sequence was identical to that obtained from patients. Subsequent experimental studies determined that 5.3 to 8.5 $\log_{10}$ $TCID_{50}$ of HAV would be inactivated during the processing of frozen plasma to cryoprecipitate (234). The solvent/detergent treatment had no effect on HAV infectivity, but could have been responsible for dispersing HAV in the product by releasing the virus from a nonneutralizable, lipid-associated environment. Older preparations of factor VIII contained substantial amounts of IgG that may have provided protection in this situation. However, the highly pure lots of factor VIII currently available were devoid of appreciable amounts of neutralizing anti-HAV. Thus the situation was favorable for factor-derived hepatitis A infections to occur when they did. Fortunately, effective heat-inactivation procedures now render these products safe.

There is little evidence for transmission of HAV by exposure to the urine or nasopharyngeal secretions of infected patients (163,248,295), although cases have been reported (1,132,194,248). Transmission of HAV by externally contaminated, coprophagous insects such as flies or cockroaches, or by biting insects, is conceivable but remains unconfirmed.

Other identified potential sources of exposure to HAV are nonhuman primates, usually chimpanzees, which have infected caretakers and other zoo personnel in close contact with them (73,167,168). In most instances, more than 3 months elapse between importation of the animals and appearance of the index case. Thus it is assumed that these animals

acquire the infection from humans or other primates shortly after arrival, and then transmit the disease to their caretakers.

PREVENTION AND CONTROL

Any decisions concerning the prevention of hepatitis A must consider the immunobiology of the disease and the principal routes of transmission (169). The most effective control measures must prevent fecal contamination of hands, food, water, or other sources by infected individuals before their clinical disease becomes apparent (51). Thus the most critical control measure is proper handwashing after bowel movements and before food preparation, and the avoidance of work practices that facilitate contamination of hands when taking care of children younger than 2 years. The importance of these measures cannot be overemphasized. Because the personal hygiene of young children is often difficult to control, they should be restrained from close contact with their susceptible playmates during the first 2 weeks of illness or for at least 1 week after the onset of jaundice.

Considering the low order of infectivity that is present during the icteric stage of disease in adults, many authorities have suggested that strict enteric precautions within the hospital are not necessary. Such precautions should be reserved for physicians and staff caring for newborn infants, young children, or fecally incontinent patients (105,298). Maynard (268) observed that physicians caring for most of the cases of hepatitis A had anti-HAV prevalence rates no greater than those in other specialties. In another study, Mosley (286) reported that no cases of hospital-acquired hepatitis A could be documented among several thousand patients admitted to the hepatitis service of a large hospital of indigent patients, despite continuing surveillance. It is noteworthy that toilet facilities were shared in this environment, and the personnel were not routinely gowned and gloved.

Although nosocomial infections appear to be rare, there have been situations in which transmission has occurred (21,90,208,298,338). In one outbreak, 55 cases of HAV (64% symptomatic) occurred among physicians, staff, parents, and relatives having direct contact with 11 neonates who were given blood from a single infected donor (298). The attack rate was 25% for susceptible relatives, 16% for nurses, and 4% for physicians. Transmission by aerosol or by contact with urine is highly improbable, regardless of the stage of infection. In general, universal precautions should be adequate when caring for patients with hepatitis A. Extraordinarily conservative measures, such as isolation of patients in private rooms and the use of gowns or masks, are unnecessary unless direct and excessive exposure to feces or fecally contaminated items is anticipated. More responsibility for preventing nosocomial hepatitis A can often be transferred to the patient unless that patient is a young child.

Although viremia also precedes clinical disease and could represent an additional potential source of infection (38,161,174,214,215), chronic viremia does not occur. Thus the potential for infection by inadvertent percutaneous transmission is very low, as corroborated by HAV prevalence studies in patients and staff of hemodialysis centers where parenteral exposure is common (396).

Immune Globulin Immunoprophylaxis

Current lots of conventional intramuscular immune globulin (IGIM) are sterile preparations of concentrated antibodies that have tested negative for HBsAg, anti-human immunodeficiency virus (HIV), and anti-HCV. No cases of HBV, HIV, or HCV have occurred after the administration of this product, in contradistinction to intravenous immune globulin (IGIV), which has been associated with the transmission of HCV in at least one IGIV preparation (135).

Prevention of clinical manifestations of hepatitis A through the administration of IGIM was documented initially by Stokes and Neefe (389) in 1944 during a common-source outbreak at a summer camp near Philadelphia. Among 53 persons who received IGIM, clinical hepatitis occurred only during the first 10 days in 11 (21%), and icterus was observed in only one of these early cases. In contrast, new cases of hepatitis continued to occur for 32 days in 67% of the 278 exposed controls, and 45% of these were icteric. This represents an 87% reduction in the attack rate observed among those receiving IGIM. Similar immunoprophylaxis studies were carried out simultaneously in military personnel and institutionalized children (130,165). In each instance, IGIM was capable of preventing anicteric or icteric hepatitis A in 80% to 90% of the participants. IGIM was effective when given up to 6 days before the onset of illness, and doses as low as 0.01 to 0.02 mL/kg were found to be protective. IG collected from any geographic region should be protective against HAV infection because only a single human HAV serotype exists.

Studies performed in institutions (Table 5) and those conducted during community outbreaks of hepatitis A indicate that passive immunization with IG can either completely suppress or modify the infection in HAV-susceptible persons, depending on the concentration of anti-HAV administered and the interval from exposure to treatment (89,154,388). As shown, larger doses of IG provide protection lasting a few more weeks, but passive–active responses are curtailed, leaving a larger percentage of susceptible persons available for infection after another exposure. IG is unlikely to be effective if given more than 3 weeks after exposure. The theoretic concern, that individuals might acquire HAV from persons who develop subclinical hepatitis after IG treatment, has not been borne out by epidemiologic investigations (302,388). Rigid isolation or compulsive cleanliness within a household is not necessary once the occupants have received adequate prophylactic treatment.

IG dose (mL/kg)	No. of susceptibles	No. with infection: Clinical	No. with infection: Subclinical	Seroconversion only	% Remaining susceptible
None	19	8	4	4	16
0.04	15	1	3	3	53
0.10	10	0	0	2	80

Source: Modified from ref. 154, with permission.

TABLE 5. *Effect of immune globulin (IG) on HAV infection among exposed residents of a custodial institution*

After the administration of IG, commercial assays for anti-HAV are unable to detect this antibody in the blood unless the procedure is optimized (8). However, low-level neutralizing antibody has been found to persist for at least 55 days when sera were evaluated with a sensitive neutralization assay. Because a direct correlation exists between antibodies detected by commercial immunoassay and the neutralization assay, it can be assumed that very low levels of anti-HAV are sufficient to prevent infection.

Vaccines

Until 1995, passive immunization with IG was the only option available for preventing HAV infection. However, IG is impractical when repeated exposure is anticipated. In 1978, Provost and Hilleman (321) produced the first prototype HAV vaccine, a formalin-treated homogenate of liver from an HAV-infected marmoset. The vaccine was used to inoculate susceptible marmosets, all of which developed anti-HAV and were protected against an intravenous dose of live HAV. These promising results, along with the successful propagation of HAV in cell culture (322), stimulated additional experimentation with HAV with approaches similar to those successful for poliovirus vaccines.

With the development and subsequent evaluation of hepatitis A vaccines, the potential for long-term immunity has become a reality. As nations develop public sanitation, the age at which individuals will become infected is delayed until adulthood, at which time the likelihood of developing symptomatic illness is considerably higher. The large outbreak of hepatitis A that occurred in Shanghai during 1988 was a recent example of this trend (445). HAV infection has become a public health problem elsewhere in Asia (Korea, Singapore), Europe (Greece, Italy, Portugal), and the Americas (Cuba, Chile) (145,195). HAV also causes up to 63% of the clinical hepatitis reported in industrialized nations (52,112,386). A review of the various products available for active immunization follows, concluding with strategies for immunoprophylaxis.

Inactivated Vaccines

Several laboratories have produced candidate killed virus vaccines by inactivating cell culture–derived HAV with formalin or b-propiolactone (14,225,324,370). Binn et al. (33) and Sjogren et al. (374) extensively characterized formalin-inactivated HAV HM175 that was propagated in human diploid MRC5 cells. Inoculated owl monkeys developed antibody that neutralized six HAV strains of wide geographic origin, and they were protected against challenge with live virus. Forty-two male volunteers were given three or four doses of vaccine over a 6-month interval; 86% developed neutralizing antibody 2 months after the last dose (374).

SmithKline Beecham (SKB) conducted large safety and efficacy trials using the HM175 strain adapted to MRC5 cells (147). HAV is extracted from the cells by freezing and thawing. This crude harvest is tested for the absence of extraneous agents, microbiologic sterility, and identity of the antigen. The harvest is then purified and concentrated by sterile filtration, ultrafiltration, and column chromatography (311). The purified virus is assayed for antigen, total protein, and bovine albumin concentration. Residual MRC5 cellular protein (<5 µg/adult dose) and traces of formalin (<0.1 mg/mL) are present. In addition, less than 8 µg of bovine albumin per adult dose remains in the vaccine. Virus particles with a buoyant density of 1.32 to 1.34 g/mL and a mean diameter of 27 nm are observed. Sterile-filtered virus is inactivated with formaldehyde for 15 days at 37°C. Separate sterile filtrations are done on day 6 and at the end of the inactivation period. Preclinical trials of this vaccine in chimpanzees have demonstrated safety and efficacy. There was no detectable excretion of HAV during the vaccination or challenge periods.

The licensed SKB adult vaccine (Havrix) contains 1,440 ELISA units (EL.U.) of viral antigen per milliliter (determined by a standardized ELISA), 0.5 mg aluminum as $Al(OH)_3$, and 5.0 mg 2-phenoxyethanol as a preservative. Primary immunization consists of a single dose of vaccine with a booster dose 6 to 12 months later to obtain a more durable immunity. Children (2 through 18 years of age) receive one half or one fourth of these amounts in 0.5 mL. The smaller amount is administered twice at 1-month intervals, whereas the 720 EL.U. is given once. For both pediatric schedules, a booster dose is recommended 6 to 12 months after the primary course. The vaccine should be administered by the intramuscular route, preferably in the deltoid region in adults. Suboptimal responses may result if the vaccine is administered in the gluteal region. Accelerated stability tests at 37°C for up to 3 weeks and after 15 months at 2°C to 8°C have revealed no loss of immunogenicity in mouse potency tests. Similar results were observed in humans. As has been discovered with the hepatitis B vaccine, freezing may be deleterious to the product.

Another licensed formalin-inactivated hepatitis A vaccine is VAQTA, distributed by Merck & Co., Inc. This vaccine also is prepared from MRC5 cell monolayers infected with an attenuated HAV, CR326F'. The original CR326 was isolated from a fecal sample that was inoculated directly into a FRhK6 culture (241,319). After 15 passages in these cells, it was adapted to MRC5 cells for an additional 16 passages, which led to its attenuation for marmosets and chimpanzees (319). Further

serial passage yielded highly productive replication of HAV sufficient for commercial development. Antigen is extracted by lysis of infected cells, and then concentrated and purified to greater than 90% protein purity. The purified preparation is free of detectable MRC5 protein and contains less than 0.1 µg of nonviral protein, less than 4×10^{-6} µg of DNA, 10^{-4} µg bovine albumin, and less than 0.8 µg of formaldehyde per 50-unit (U) dose. The antigen is composed of monodispersed, full and empty, HAV particles. Formalin inactivation proceeds for 5 days at 37°C, after which the product is adsorbed to aluminum hydroxide. The 50-U adult dose contains 450 µg aluminum, whereas a 25-U pediatric/adolescent dose, for ages 2 through 17 years, contains half as much. The vaccination regimen consists of one primary dose followed 6 to 18 months later with a booster dose. The vaccine was preclinically tested in chimpanzees, which developed neutralizing antibody within 2 weeks and were protected after intravenous challenge with infectious HAV.

Both of these vaccines have proven to be safe and immunogenic in humans (13,297). Reactions have been mild and clinically insignificant, with soreness at the injection site (generally mild and transient) being the most commonly elicited symptom. Hypersensitivity to components of the vaccine has not been observed. Of some 4 million doses of Havrix administered as of December 1993, only 353 adverse events (0.009%) have been reported to SKB, of which only six serious events (0.00015% or 1.5 per million doses) were believed by a physician to be related to the vaccine (13). These complications, and other postlicensure reports of serious adverse events received by the manufacturer or the Food and Drug Administration, without regard to causality, have included Guillain–Barré syndrome, neuropathy, myelitis, multiple sclerosis, encephalopathy, erythema multiforme, convulsions, anaphylaxis, anaphylactoid reactions, vasculitis, thrombocytopenia, diabetes mellitus, pancreatitis, rhabdomyolysis, allergic reactions (such as a rash), and paresthesia. In those situations in which background incidence data are available, rates in vaccine recipients are not higher than they are in an unvaccinated population.

Immunogenicity in adults, adolescents, and children aged 2 years or older is excellent, with protective levels of antibody (^{3}20 mIU/mL) being achieved in virtually all subjects after the basic immunization series. Development of IgM anti-HAV after vaccination is rare (364,374), and the ALT level remains normal, so confusion with recent viral hepatitis should not be an issue. Immunogenicity data for infants is sparse, but initial studies indicated excellent responses in seronegative infants without the development of serious adverse events (414). In contrast, responses in infants with preexisting maternal antibody have been impaired. Other factors associated with reduced immunogenicity include immunosuppression from disease or drugs and advanced age.

The administration of hepatitis A vaccine with other vaccines, such as diphtheria, poliovirus (oral or inactivated), tetanus, hepatitis B, yellow fever, typhoid, rabies, and Japanese encephalitis, has failed to modify the immune response to the hepatitis A vaccine or to increase the frequency of adverse events (7,32). Durability of immunity cannot be accurately assessed because the current vaccines have been under evaluation for only 7 to 8 years. However, estimates using kinetic models suggest that protective levels could persist in a majority of vaccinees for 20 years or more (420,436).

The simultaneous administration of inactivated hepatitis A vaccine with 3 to 5 mL IGIM should provide both immediate and long-term protection in adults (222). However, the anti-HAV titers are about twofold lower when compared with those observed when vaccine alone is administered, but more than 100-fold higher than levels considered to be protective. Although IG may not interfere with the immune response to oral poliovirus or yellow fever vaccine, or to inactivated vaccines, it may interfere with the response to live, attenuated vaccines such as measles, mumps, rubella, and varicella. Therefore IG should be delayed at least 2 weeks after such immunizations, or if IG is administered initially, at least 5 months should pass before these other vaccines are administered.

Two large efficacy trials have been conducted with the Merck and SKB vaccines. In the first, 505 evaluable children between the ages of 2 and 16 years received one injection of inactivated hepatitis A vaccine produced by Merck & Co., Inc. (430). An additional 508 children received a placebo. From day 21 after the initial injection, no clinical cases of hepatitis A occurred in the vaccine group compared with 34 cases among the placebo group for an estimated efficacy of 100% [95% confidence interval (CI) lower bound, 87%; $p < 0.0001$] (Fig. 18). Subclinical infection was not evaluated in this study. Because the only cases of hepatitis A that were observed in the vaccine group occurred during the first 16 days, these cases presumably represented persons who had been infected with HAV before, or shortly after, the initial injection of the vaccine. This assessment is based on results from previous immunogenicity trials conducted by Merck and SKB, in which a detectable level of anti-HAV is not observed until 1 to 2 weeks after injection in most vaccine recipients. During 6 years of follow-up, no vaccine recipient has developed hepatitis A despite continuing community exposure (429).

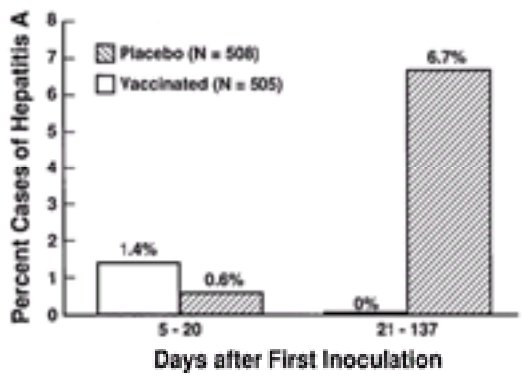

FIG. 18. Results of controlled efficacy trial of inactivated hepatitis A vaccine (VAQTA; Merck & Co., Inc., West Point, PA) in healthy children. From ref. 429, with permission.

A second clinical trial was conducted in Thailand, in which 19,037 children between the ages of 1 and 16 years received two injections of the SKB inactivated hepatitis A vaccine 1 month apart (182). An additional 19,120 children were given hepatitis B vaccine. Adverse reactions were mild and self-limited. During the surveillance period (days 138 to 386), two clinical cases of hepatitis A (based on clinical symptoms, an ALT >45 IU/L, and a positive IgM anti-HAV test) were documented in the vaccine group compared with 31 cases in the control group, for a vaccine efficacy of 94% (95% CI, 79–99%; $p < 0.0001$) (Fig. 19). A booster dose was administered at 12 months, and an additional 6 months of surveillance identified no new cases in the vaccine group compared with six cases in the control group. The cumulative efficacy rate for the entire study was 95% [two (0.01%) of 19,037 among vaccine recipients compared with 37 (0.19%) of 19,120 in the control group; 95% CI, 82–99%; $p < 0.0001$]. The two cases that occurred in the vaccine group were comparatively mild as manifested by (a) ALT levels <70 IU/L versus a mean of 827 IU/L in the HAV-infected control population (range, <8–3,310 IU/L); (b) no fever versus 42% prevalence among the controls; (c) a mean bilirubin of 1.8 versus 4.2 mg/dL; and (d) a delayed IgM anti-HAV response in the vaccinated cases.

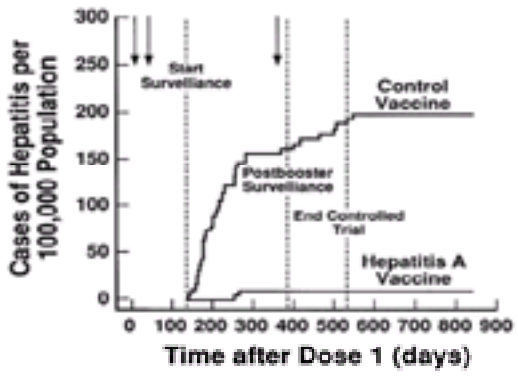

FIG. 19. Cumulative rates of symptomatic infection with hepatitis A virus (HAV) in healthy children receiving HBsAg vaccine (control group) and hepatitis A vaccine (Havrix; SmithKline Beecham, Philadelphia, PA). Timing of vaccine administrations is represented (*arrows*). From ref. 182, with permission.

Attenuated Vaccines

During the development of live poliovirus vaccines, some strains became attenuated during adaptation to growth in cell culture (344). Similarly, some HAV mutants induced an immune response in certain primates without causing hepatitis. These vaccine strains have been propagated in cells certified for vaccine production (AGMK, MRC5, or other human diploid fibroblasts) after direct isolation from human feces or after multiple passages in marmosets. They were shown to be free of, or to have diminished, residual virulence for marmosets and chimpanzees and to prevent infection after challenge with wild-type HAV.

Provost et al. (319,320) evaluated many mutants of HAV strain CR326. Initially, these were derived from virus passaged 31 times in marmosets and then in cell culture at 32°C or 35°C. Despite attenuation for chimpanzees, these mutants remained virulent for marmosets. Passage at 32°C appeared to result in highly attenuated variants that lacked immunogenicity or protective properties. Several mutants that were avirulent in nonhuman primates were not immunogenic when administered subcutaneously to humans. Emphasis then shifted to the evaluation of CR326 mutants that were directly isolated in cell culture from human feces because these appeared to be less virulent for marmosets. The most promising mutants were designated F and F'. Mutant F was immunogenic in 17 of 20 subcutaneously inoculated humans, but five individuals had biochemical evidence of mild hepatitis. Mutant F' was even more attenuated. At the highest dose used in a dose-escalating trial ($10^{7.3}$, $TCID_{50}$), neutralizing antibody was detected at 3 and 6 months after vaccination in all 10 recipients (278). The vaccine was well tolerated, and HAV was not recovered from stool or blood specimens.

Purcell et al. (60,324,375) obtained analogous results with HAV strain HM175 isolated directly from human feces into AGMK cells and then propagated at 35°C. Selection of HAV that was attenuated for chimpanzees occurred after only 10 passages in AGMK cells. However, the virus remained virulent for marmosets through 21 passages (200) but was substantially attenuated after 32 passages. All animals inoculated with passage 21 or passage 32 virus developed high levels of neutralizing anti-HAV. After challenge with live HAV, nearly all of the chimpanzees and marmosets were protected. Comparison of wild-type and cell-culture–adapted HM175 virus indicates that multiple mutations in the 2A/2B/2C region and the 5' non-coding region are essential for cell-culture adaptation and for attenuation of virulence for marmosets (60,91,92,95,119).

Mao et al. (254,255) developed an attenuated hepatitis A vaccine that has been reported to be safe, immunogenic, and efficacious. The H2 strain of HAV was serially passaged in newborn monkey kidney cells and adapted for growth in human lung fibroblast (KMB17) cell culture. More than 20 million people in China have received this vaccine. In one study, 6,298 children in 11 schools were immunized over a 4-year interval. No cases of clinical hepatitis A were reported in that group. Among a nonvaccine control group from the same schools and from other primary schools where immunization was not offered, more than 495 cases of hepatitis A occurred for a morbidity rate of 204/100,000 person-years of observation ($p < 0.001$). In another city in China, the mean rate of HAV infection averaged 32 cases/year (morbidity of 214/100,000). After 5 years of a successful immunization program that reached almost 90% of the population, hepatitis A declined to six cases, none of whom were vaccine recipients. No cases have occurred in the last 2 years of the project. There is no evidence that the vaccine virus is shed in the feces or that it causes vaccine-associated infections. Correspondingly, reversion to a more virulent strain has not occurred. Unfortunately, oral inoculation has been

unsuccessful, even when higher doses of vaccine were administered.

Strategies for the Use of Hepatitis A Vaccine and Intramuscular Immune Globulin

Anti-HAV Responses After Passive and Active Immunization

Figure 20 compares anti-HAV responses in the following situations (223):

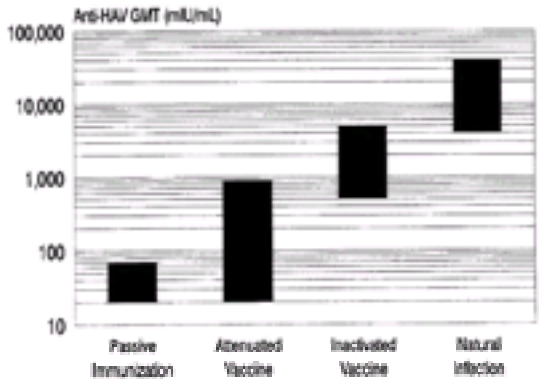

FIG. 20. Hepatitis A virus (HAV) antibody concentrations (mIU/mL) observed in persons after passive and active immunization and after natural HAV infection. Adapted from ref. 224, with permission.

1. At 3 to 5 days after receiving 5 mL of IGIM (passive immunization);
2. At 6 to 12 months after one injection of live-attenuated HAV vaccine;
3. At 6 to 12 months after two injections of inactivated hepatitis A vaccine; and
4. At 10 to 20 years after a natural infection.

Preexposure Prophylaxis

Although universal childhood immunization for hepatitis A is a worthy goal, it is unlikely that such a recommendation will be issued by policymakers in developing countries or regions with transitional economies, given the economic and political realities of global immunization programs. Even in developed countries, the integration of hepatitis A vaccination into routine childhood immunization schedules is unlikely to be recommended in the near future. In the interim, several high- and intermediate-risk groups will be targeted to receive the vaccine (see Table 6), with IGIM being relegated to more specific indications. Nevertheless, the greatest impact on the incidence of hepatitis A will be realized only when the vaccine is included in the routine childhood immunization schedule, and successive cohorts of children are vaccinated.

• Travelers to or workers in foreign countries (including the military) where the risk of acquiring hepatitis A is enhanced because of living conditions, the prevalence of HAV in the area, and the length of stay
• American Indians/Alaskan natives
• Men who have sex with men
• Illegal drug users, injecting or noninjecting
• Persons who work with HAV or with nonhuman primates
• Persons with chronic liver disease
• Persons who have clotting factor disorders
• Persons residing in areas where extended community outbreaks exist or children living in states that have high and intermediate rates of disease (e.g., approximately twice the national average rate per 100,000 population)
• Refugees residing in temporary camps after catastrophes

HAV, hepatitis A virus.

TABLE 6. *High-risk groups potentially targeted for preexposure prophylaxis*

As shown in Table 6, immunization should be offered to persons traveling from industrialized countries to regions of the world where HAV is endemic (Asia, Africa, Latin America, eastern Europe, the Middle East, and the Commonwealth of Independent States). For most travelers, vaccine alone will suffice if administered at least 4 weeks before travel. When time is a factor, both IGIM and the initial dose of vaccine should be administered at different anatomic sites. At-risk individuals who are allergic to components in the vaccine or who do not elect to receive the vaccine can be given small doses of IG (0.02 to 0.04 mL/kg or 2.0 mL for adults) if the anticipated period of exposure is 2 to 3 months (Table 7). Larger doses (0.05 to 0.06 mL/kg or 5.0 mL for adults) should be administered every 4 to 6 months for more prolonged exposure. The incidence of symptomatic hepatitis A for a 1-month trip to a developing country is three to six cases per 1,000 susceptible travelers (386). The incidence rate is sixfold higher (20 cases per 1,000) in vagabonds or other persons whose travel arrangements or personal hygiene place them in jeopardy of acquiring an infection. In making a recommendation for vaccination, it is important to recognize that hepatitis A is contracted at least 100 times more frequently than is typhoid fever or cholera (386).

Person's weight (lb)	IG dose (mL)	
	Routine	High risk[a] (prolonged exposure)
<50	0.5	1.0
50–100	1.0	2.5
>100	2.0	5.0

[a]Within limits, larger doses of IG provide longer-lasting, but not necessarily greater, protection. Therefore, a higher dose of IG is prescribed in high-risk situations where continuous exposure is anticipated (institutional contacts; traveling to foreign countries where HAV is endemic). Hepatitis A vaccination is recommended for most of these situations.

TABLE 7. *Guidelines for immune globulin (IG) prophylaxis against hepatitis A*

Because HAV infection is uncommon among U.S. military personnel except during peace-keeping missions or military campaigns, routine immunization could be reserved for those who regularly travel to endemic areas, such as shipboard personnel, or those in rapid-deployment units. For other soldiers, typical reassignment or deployment times of several weeks would be sufficient for generating a protective response to vaccination. Vaccines should be offered to staff and residents of institutions for the mentally disabled or to members of other relatively closed communities, such as American Indians or Alaskan Natives, who are at high risk of acquiring hepatitis A. It also should be offered to preschool children attending day-care centers, the staff, parents, and siblings, and to any other group whose life style, occupation, or behavior places them in the high-risk category (e.g., illegal drug users and men who have sex with other men). Other groups that have been targeted for possible immunization for hepatitis A are listed in Table 6.

One of the more controversial recommendations concerns the administration of hepatitis A vaccine to patients with chronic liver disease, especially those with hepatitis B or C. Several reports have suggested that the occurrence of hepatitis A in these patients is associated with a higher frequency of severe illness or fulminant hepatic failure, leading to substantially higher case fatality rates (203,421). Other investigators, however, reported conflicting data on the clinical course and outcome of hepatitis A in chronic liver disease (275,398). In the interim, it seems prudent to offer vaccination to all patients with chronic liver disease as recommended by the Advisory Committee on Immunization Practices (ACIP).

Postexposure Prophylaxis

The need for immediate protection after exposure mandates that IG be administered as soon as possible, but not more than 2 weeks after an incident. The recommended dose of IG for postexposure prophylaxis is 0.02 to 0.04 mL/kg or use “Routine” dosing schedule from Table 7.

Postexposure prophylaxis with IGIM has been recommended for household and sexual contacts of hepatitis A cases, for staff and attendees of day-care centers where a case has been identified, for residential facilities experiencing an outbreak, or for the military where one or more cases are recognized. Similarly, postexposure prophylaxis should be considered for potential common-source exposure (e.g., a foodhandler with hepatitis A) if exposure is recognized before cases have begun to occur or if consumers can be identified and treated within 2 weeks of exposure. Day-care centers with children in diapers present the greatest risk to employees. Within the hospital, prophylaxis should be reserved for those situations in which health-care personnel are unknowingly exposed to a case of hepatitis A. Examples of this type of exposure include late recognition of a case in a newborn nursery or pediatric intensive care unit. Accidental needle-sticks should be managed as described in the section, Guidelines to Postexposure Immunoprophylaxis, in Chapter 87. IG is not routinely recommended for casual school or work contacts; however, playmates of children with hepatitis A should receive IGIM (Table 8).

Close personal contact: all household and sexual contacts of persons with hepatitis A
Day-care centers: staff, attendees, and all members of households whose diapered children attend
Schools, preschools, and institutions for custodial care: not generally warranted unless an institutional or classroom-centered outbreak is identified
Hospitals: not routinely indicated for hospital personnel. Instead, sound hygienic practices should be emphasized
Offices and factories: not indicated under usual working conditions for persons exposed to a fellow worker with hepatitis A
Common-source exposure: not warranted once cases have begun to appear. When a food handler with hepatitis A is identified, IGIM should be given to other kitchen employees and may be considered for patrons if (a) the infected person is directly involved in handling foods that are not to be cooked or with cooked foods before they are eaten; (b) the hygienic practices of the worker are deficient; and (c) consumers can be identified and treated within 2 weeks of exposure

HAV, hepatitis A virus

TABLE 8. *Recommendations for the use of postexposure prophylaxis with IGIM after exposure to HAV*

Data are limited regarding hepatitis A vaccine for postexposure prophylaxis. Efficacy may depend on the interval between exposure and vaccination—a longer delay would favor the use of IG (or simultaneous administration of the two products). An exception may be in the management of extended community outbreaks in which vaccination holds greater promise for permanent success. In these situations, at least 70% coverage is recommended and should be achieved as rapidly as possible.

Perspectives

To provide higher antigen mass and possibly reduce the number of doses and costs for immunization in the future, it may be advantageous to use specialized equipment such as cell factories or microcarriers and to identify cell-culture parameters that would increase virus yields (336,366,433). A better understanding of HAV virulence mechanisms and identification of possible extrahepatic sites of HAV replication will be important for the development of safe and effective live vaccines.

CHAPTER 27 Human Caliciviruses

Kim Y. Green, Robert M. Chanock, and Albert Z. Kapikian

The family *Caliciviridae* is composed of small (27 to 40 nm), nonenveloped, icosahedral viruses that possess a linear, positive-sense, single-stranded RNA genome. Caliciviruses have a broad host range and can cause various disease syndromes, including respiratory disease in cats caused by feline calicivirus (FCV), an often-fatal hemorrhagic disease in rabbits associated with rabbit hemorrhagic disease virus (RHDV), and epidemic gastroenteritis in humans caused by the Norwalk group of viruses. This chapter will focus predominantly on the caliciviruses associated with epidemic gastroenteritis in humans, but several features of the caliciviruses associated with disease in animals will also be addressed because important information has come from the study of animal caliciviruses that grow in cell culture.

Norwalk virus is the prototype strain of a group of related, noncultivatable human caliciviruses associated with epidemic gastroenteritis. This “Norwalk group” of human caliciviruses has recently been assigned to a new genus (tentatively named the “Norwalk-like viruses”) in the *Caliciviridae.* The “Norwalk-like viruses” are the major cause of nonbacterial epidemic gastroenteritis, a disease that usually occurs in family or community-wide outbreaks (11,98,173). In a recent study, “Norwalk-like viruses” were detected in 86 (96%) of 90 nonbacterial gastroenteritis outbreaks that occurred over an 18-month period in the United States; an item of food was implicated in at least 37% of the outbreaks (89). In addition to the “Norwalk-like viruses,” a second distinct group of human caliciviruses is associated with diarrheal disease. These viruses, previously called the classical caliciviruses because their distinct morphologic appearance is similar to that of known animal caliciviruses, belong to a new genus in the *Caliciviridae*, tentatively designated the “Sapporo-like viruses.” The impact of the “Sapporo-like viruses” has not been fully established, but they do not appear to share the predominant role of the “Norwalk-like viruses” in epidemic gastroenteritis. It should be noted that neither group of human caliciviruses has been commonly associated with severe gastroenteritis in infants and young children (33,188). The predominant etiologic agent of severe diarrheal illness in this young age group is the 70-nm rotavirus in the family *Reoviridae* (described in Chapter 55).

HISTORY

Volunteer Studies

Bacteriologic and parasitologic discoveries made during the past century identified the etiology of only a small proportion of diarrheal illnesses, leaving a major segment that could not be associated with any known agent (138,296). During the 1940s and 1950s, it was assumed by exclusion that viruses were responsible for the major portion of these illnesses of unknown cause. Because these presumed viral etiologic agents could not be recovered and propagated *in vitro*, volunteer studies were carried out in the 1940s and 1950s in the United States and Japan (92,99,100,101,162,186,297,372). These studies showed that bacteria-free stool filtrates derived from outbreaks of gastroenteritis were capable of reproducing the illness, demonstrating that viruses were the likely cause. Many of these fecal specimens were analyzed intensively in the laboratory for an etiologic agent, but without success. A second generation of human volunteer studies was initiated in the 1970s, and specimens collected during a gastroenteritis

outbreak in Norwalk, Ohio, proved to be important (50,76,77,241,369).

The Norwalk outbreak, which was investigated by the Centers for Disease Control (CDC), began in October, 1968 (1). During a 2-day period, acute gastrointestinal illness developed in 50% of 232 students and teachers of an elementary school, and a secondary attack rate of 32% was observed among family contacts of primary cases. The disease lasted about 24 hours, with an incubation period of approximately 48 hours, and was designated winter vomiting disease because it resembled this syndrome first described by Zahorsky in 1929 (375). Although some of the patients had diarrhea, the predominant clinical manifestations were vomiting and nausea. An intensive laboratory study of clinical specimens from the Norwalk outbreak failed to yield an etiologic agent (1). Subsequently, a bacteria-free filtrate prepared from a rectal swab specimen obtained from a secondary case of gastroenteritis in the Norwalk outbreak was fed to three volunteers (76). Two of these individuals developed acute gastroenteritis. The agent was passaged serially in other volunteers and induced an acute gastroenteric illness in approximately 50% of these individuals (77). Although stool filtrates that contained an infectious agent were now identified, attempts to cultivate the agent in cell or organ culture or to transmit it to various experimental animals were unsuccessful (29,76,77).

Discovery of Norwalk Virus

In 1972, Kapikian et al. discovered virus particles in human-passaged fecal material derived from the Norwalk outbreak (170). These particles, described as 27 nm in their shortest diameter and 32 nm in their longest diameter (Fig. 1A), were the first viruses associated with gastroenteritis to be visualized and identified. This was accomplished by the technique of immune electron microscopy (IEM), first used in studies of tobacco mosaic virus in 1941, which involves the direct observation of antigen–antibody complexes by electron microscopy (EM) (3,5,13). Specific antibody molecules aggregate virus particles, concentrating them for easier detection, and in addition, they form a characteristic “fuzzy” layer by binding to the surface of the virion (167). The technique of IEM would prove important in the characterization of Norwalk virus, and other fastidious viruses as well, by an approach that became known as “particle” or “direct” virology (reviewed in ref. 165).

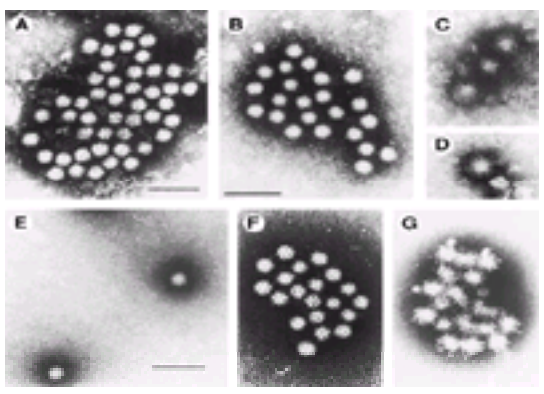

FIG. 1. Norwalk virus and Sapporo virus in stool material. **A:** Norwalk virus particles in a stool filtrate visualized by immune electron microscopy (IEM). (From ref. 170, with permission.) **B, C,** and **D** demonstrate an antibody response to Norwalk virus by IEM (from ref. 167, with permission). **B:** An aggregate observed after incubation of Norwalk virus stool filtrate with a 1:5 dilution of a volunteer's prechallenge serum. Particles have a light coating of antibody molecules. The amount of antibody present was given an overall rating of 1–2 to 2+, and the serum was given an overall rating of 1–2+ on a scale of 0 to 4+. **C,D:** Three single particles **(C)** and one individual particle **(D)** observed after incubation of the Norwalk virus stool filtrate with a 1:5 dilution of the same volunteer's postchallenge convalescent serum. Particles are heavily coated with antibody molecules. The amount of antibody was given a rating of 4+ and the serum was given an overall rating of 4+. **E, F,** and **G** demonstrate an antibody response to Sapporo virus by IEM (from ref. 252 and S. Nakata, personal communication). **E:** Sapporo virus particles partially purified from stool material and incubated with guinea pig preimmune serum that was given a rating of 0 on a scale of 0 to 4+. The distinct, hollow cup-like structures are apparent. **F** and **G** show Sapporo virus particles following incubation with a low **(F)** or high **(G)** concentration of hyperimmune serum from the same guinea pig. **F:** The amount of antibody coating the aggregate of particles was given a rating of 1+. **G:** An aggregate of particles heavily coated with antibody. The amount of antibody was given a rating of 4+.

The spherical 27-nm Norwalk virus particles were visualized in a fecal filtrate that had been shown to induce acute gastroenteritis in volunteers, but additional evidence was needed to establish the association of these particles with infection and disease (170). The IEM technique was adapted for this purpose. The fecal filtrate was incubated with prechallenge or convalescent-phase serum from a volunteer who had become ill following ingestion of the filtrate. After centrifugation of the mixtures, the reconstituted sediments were examined by EM. Figure 1 shows the striking difference between the appearance of the particles after incubation with the prechallenge serum (part B) and after incubation with convalescent-phase serum (parts C and D). In contrast to the virus particles that were exposed to the prechallenge serum, the particles incubated with convalescent serum were coated with a thick layer of antibody molecules, indicating that the volunteer had developed a specific serologic response. Four volunteers who ingested the virus, as well as naturally infected individuals who became ill during the original Norwalk outbreak, also developed a serologic response to the 27-nm particle by IEM. From this and other evidence, it was suggested that the 27-nm particle was the etiologic agent of the Norwalk outbreak (170).

The discovery of Norwalk virus in stool material, and soon after, the human rotavirus in duodenal mucosa by Bishop et al. (23), stimulated the search for new enteric viruses associated with gastroenteritis. In 1976, Madeley and Cosgrove (217) reported the presence of “typical” caliciviruses in the stools of infants and young children (2 to 18 months of age), and these viruses showed a striking morphologic similarity to previously characterized animal caliciviruses that were known to exhibit “classical” distinct cuplike depressions on the surface of the virion. That same year, Flewett and Davies (90)

observed similar calicivirus particles in a sample from the intestinal lumen of a child at autopsy, and in the feces of a child with gastroenteritis. Chiba et al. (48) described a typical calicivirus, associated with gastroenteritis, in infants and young children living in an infant home in Sapporo, Japan, in 1977. Another virus (later designated Sapporo/82/Japan) that exhibited classical calicivirus morphology was subsequently detected from this same infant home (see Fig. 1E) and was found to be antigenically distinct from Norwalk virus by IEM (252). Hyperimmune serum was raised in guinea pigs against Sapporo/82/Japan virus particles purified from stool material, and the technique of IEM was used to establish its antigenic characteristics (see Fig. 1F and Fig. 1G, respectively).

Numerous descriptions of small, round, predominantly noncultivatable viruses in feces in the 1970s and 1980s led to the development of an interim system to classify these agents on a morphologic and physicochemical basis (42). Two main morphologic groups were discerned: the “featureless” and the “structured.” The featureless group included those viruses with a smooth outer edge and without a defined surface structure. Representative members included two picornaviruses (Coxsackie virus B5 and hepatitis A virus), as well as several parvoviruses, including mink enteritis virus and certain agents detected in various gastroenteritis outbreaks (Ditchling and cockle agents). The structured group was further subdivided into three groups: astrovirus (now classified in a distinct family, *Astroviridae*, described in Chapter 28); classical caliciviruses (represented by Sapporo virus); and small round structured viruses, or SRSVs (represented by Norwalk virus), which consisted of those viruses with a defined surface structure and/or a ragged edge.

Virus-positive stools provided a source of antigen for the development of diagnostic tests such as IEM, immune adherence hemagglutination (IAHA), and immunoassays for the detection of Norwalk virus, Sapporo virus, and a number of emerging reference strains such as Hawaii virus (from a family outbreak of gastroenteritis that occurred in Honolulu in 1971) (346) and Snow Mountain virus (from an outbreak in a Colorado resort camp in 1976) (80,81,117,137,169,241,247,307,349). These assays enabled the first epidemiologic studies that established the importance of Norwalk virus and other SRSVs in epidemic gastroenteritis, as well as limited characterization of the Norwalk virus in regard to its density, antigenic characterization, and tentative classification as a calicivirus (119,120,168). However, the limited availability of virus-positive stool specimens for these assays limited such studies primarily to only a few laboratories. Progress continued to be hampered by the absence of a cell culture system, and by the late 1980s, the relationships, epidemiology, and classification of many of these viruses remained uncertain.

Molecular Advances

In the late 1980s, the stool filtrate derived from the Norwalk, Ohio, outbreak was fed to adults in volunteer studies to obtain adequate quantities of virus particles for characterization of the viral genome (148). Using Norwalk virions partially purified from human stool material in this study, Jiang et al. (148) accomplished the cloning and initial characterization of the RNA genome of Norwalk virus in 1990, which firmly established its identity as a member of the *Caliciviridae.* A second, independent report followed, describing the isolation of a cDNA clone of the Norwalk virus genome encoding an immunoreactive region (227). Subsequently, the genomes of other “Norwalk-like” human caliciviruses associated with infectious gastroenteritis were successfully cloned using reverse transcriptase-polymerase chain reaction (RT-PCR) and primers designed from the Norwalk virus sequence (7,59,107,113,194,195,204,205 and 206,226,238). It soon became apparent that Norwalk virus was representative of a large, genetically and antigenically diverse group of viruses associated with epidemic gastroenteritis. These “Norwalk-like viruses” segregated into two major phylogenetic groups that were designated genogroups I (GI) and II (GII), with Norwalk virus belonging to GI and the Hawaii and Snow Mountain viruses belonging to GII (107,205,356). Nearly full-length genomic sequences were first reported independently in 1993 for Norwalk virus and the Southampton virus, an SRSV that was obtained from a 2-year-old child during a family outbreak of gastroenteritis that occurred in Southampton, United Kingdom, in 1991 (155,194). Subsequent studies reported the presence of 12 additional nucleotides at the 5´-end of the Southampton and Norwalk viruses (130,196).

As described in detail later, the RNA genomes of the Norwalk and Southampton viruses are organized into three major open reading frames (ORF1, -2, and -3) with a polyadenylated 3´-end, similar to that found in FCV (38). Furthermore, the ORF1 encodes a large polyprotein, with three regions containing nonstructural protein motifs similar to those of the picornavirus 2C helicase, 3C proteinase, and 3D polymerase that had previously been identified in the ORF1 of FCV (254). The ORF2 encodes the major capsid protein and ORF3 encodes a predicted basic protein with no homology to other known proteins. Recently, the cloning and characterization of Norwalk virus–related caliciviruses associated with infection in large animals such as swine (SW43 virus) and cattle (Jena virus) have been described, indicating a broader host range for this group of viruses (66,213,336,350).

The cloning and initial genetic characterization of a genome of a classical human calicivirus (the Plymouth virus, associated with acute gastroenteritis in a 16-month-old child in the United Kingdom in 1992), followed by the cloning of Sapporo/82/Japan, confirmed that viruses in this group were members of the *Caliciviridae* (195,226). Comparison of the classical human calicivirus sequence with others available at that time for the family *Caliciviridae* indicated that these viruses shared higher sequence identity to known animal caliciviruses than to Norwalk virus. The striking genetic diversity between Norwalk virus and the human caliciviruses with classical morphology validated the previous division of these viruses into two distinct groups (SRSVs and classical caliciviruses) that had been based primarily on differences in virion morphology (42). The initial cloning of the classical group was based on low temperature amplification using RT-PCR primers derived from the Norwalk virus sequence; the availability of sequence information allowed the design of more efficient primers (146,226,260). “Sapporo-like viruses” have subsequently been detected in sporadic and outbreak cases of gastroenteritis that occur predominantly in younger age groups (47,146,252,352). As was seen for the “Norwalk-like viruses,” there is evidence for genetic diversity within the Sapporo-like group (146,260,352). The genomic sequence of Manchester virus, which is closely related to Sapporo virus, and which was obtained from an infant with acute vomiting and diarrhea in Manchester, England, in 1993, was reported by Liu et al. in 1995 (212). The organization of the RNA genome of Manchester virus shows a striking difference from the Norwalk and Southampton viruses in that the predicted capsid-encoding sequence is in frame with the large nonstructural polyprotein, making the genome organization of this virus more similar to that of RHDV than to FCV (235). Subsequently, the molecular characterization of porcine enteric calicivirus (PEC), an agent associated with diarrheal disease in pigs, showed that viruses related to the classical or Sapporo-like group are found also in large animals (126).

INFECTIOUS AGENT

Classification

The two major groups of human caliciviruses have been classified into distinct genera within the family *Caliciviridae*, and they have been provisionally named the “Norwalk-like viruses” and the “Sapporo-like viruses” (reviewed in ref. 110). Although all caliciviruses share a common ancestor in phylogenetic analyses, the “Norwalk-like viruses” and “Sapporo-like viruses” form distinct genetic clades within the *Caliciviridae* (22,260). In addition, certain features of their RNA genome organization distinguish them from each other and from other genera in the *Caliciviridae* (Fig. 2). The family has two additional genera, *Lagovirus* and *Vesivirus*, each of which includes caliciviruses of veterinary importance such as RHDV and FCV, respectively. The taxonomic structure of the *Caliciviridae* and representative viruses in each of the four genera are shown in Table 1. A cryptogram is useful for identification of calicivirus strains and is organized as follows: host species from which the virus was obtained/genus abbreviation/species abbreviation/strain name/year of occurrence/country of origin. A comparison of the deduced amino acid sequences from the capsid proteins of selected viruses from each of the four genera illustrates the considerable genetic diversity among strains within and between calicivirus genera (Table 2).

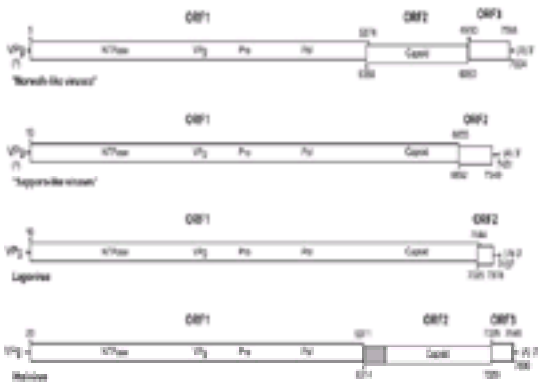

FIG. 2. Calicivirus genome organizations. The genomic organization and reading frame usage (numbers indicate nucleotide position) are shown for representative strains in the genera “Norwalk-like viruses” (Hu/NLV/I/Norwalk/1968/US, GenBank Accession Number M87661), “Sapporo-like viruses” (Hu/SLV/Manchester/1993/UK, GenBank Accession Number X86560), *Lagovirus* (Ra/LV/RHDV/GH/1988/GE, GenBank Accession Number M67473), and *Vesivirus* (Fe/VV/FCV/F9/1958/US, GenBank Accession Number M86379). *Arrows* denote the location of the first AUG in each predicted open reading frame (ORF) and the termination codon is included in the nucleotide numbering for the ORF. The predicted “2C-like” nucleoside triphosphatase (NTPase), VPg, proteinase (Pro), and polymerase (Pol) regions present in all calicivirus genomes are indicated. The *shaded region* of the ORF2 of the representative member of the genus *Vesivirus* illustrates the leader sequence (approximately 125 amino acids in length) of the capsid precursor protein.

TABLE 1. *Taxonomic structure of the Caliciviridae*

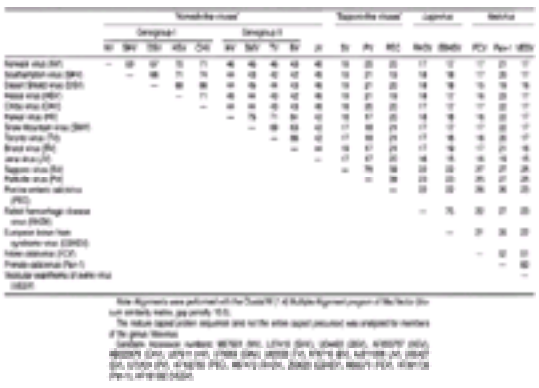

TABLE 2. *Overall amino acid identities between capsid proteins from viruses representing the four genera of the Caliciviridae*

Propagation in Cell Culture

Although some animal caliciviruses such as FCV and other members of the genus *Vesivirus* grow efficiently in cell culture, the human caliciviruses have not been propagated in cell culture or in human embryonic intestinal organ culture (56,77,171). PEC, a member of the genus "Sapporo-like viruses," can be propagated in cell culture, but optimal replication requires the use of a growth medium that contains an intestinal content preparation derived from an uninfected, germ-free pig (281).

Biologic Characteristics

The human "Norwalk-like viruses" associated with epidemic gastroenteritis share certain characteristics. These viruses (a) are shed into feces of patients with gastroenteritis, (b) have a polyadenylated positive-sense single-stranded RNA genome with three major ORFs (155,194), (c) have a buoyant density of 1.33 to 1.41 g/cm^3 in cesium chloride (CsCl) (42,168,219,346), (d) usually lack distinctive calicivirus cuplike morphology when viewed by EM (170), and (e) form a distinct phylogenetic clade within the *Caliciviridae* (22,260).

The Norwalk virus retains infectivity for volunteers following (a) exposure of the stool filtrate to pH 2.7 for 3 hours at room temperature, (b) treatment with 20% ether at 4°C for 18 hours, or (c) incubation at 60°C for 30 minutes (77). Norwalk virus is resistant to inactivation following treatment with 3.75 to 6.25 mg/L of chlorine (free residual chlorine of 0.5 to 1.0 mg/L), a chlorine concentration consistent with that found in a drinking water distribution system (177). However, Norwalk virus is inactivated following treatment with 10 mg/L of chlorine, a concentration that is used to treat water supply systems after contamination has been detected. Norwalk virus is more resistant to inactivation by chlorine than poliovirus type 1, human rotavirus (Wa), simian rotavirus (SA11), or f2 bacteriophage (177).

The human "Sapporo-like viruses" associated with gastroenteritis (a) are shed into feces of patients with gastroenteritis, (b) have a polyadenylated positive-sense single-stranded RNA genome with two (or three) major ORFs (212), (c) have a buoyant density of 1.37 to 1.38 g/cm^3 in CsCl (343), (d) often possess distinctive calicivirus cuplike morphology when viewed by EM (217), and (e) form a distinct phylogenetic clade within the *Caliciviridae* (22,260).

Description of Key Antigens

Norwalk virus capsid protein and soluble antigen were initially identified in fecal specimens obtained from infected volunteers (120). Convalescent-phase serum antibodies immunoprecipitated the major virion-associated capsid protein and a soluble protein with estimated molecular masses of 59,000 and 30,000 daltons, respectively (120). A 32,000-dalton soluble protein observed in Norwalk virus stool material was subsequently shown to be a proteolytic cleavage product derived from the C-terminal part of the capsid protein (133). The recognized cleavage site (K227/T) was consistent with cleavage by trypsin or a trypsin-like enzyme.

Further evidence that the Norwalk virus capsid protein contains major antigenic sites has been found in recombinant protein expression studies. When the genes encoding the Norwalk virus capsid protein (ORF2) and the terminal ORF3 product are transferred into a recombinant baculovirus and the proteins are expressed in insect cells, the capsid protein spontaneously self-assembles into recombinant virus-like particles (rVLPs) (154). When studied by negative-stain EM, Norwalk rVLPs exhibit a morphology similar to that of the native Norwalk virus, although they appear empty because the RNA genome is not present (Fig. 3A).

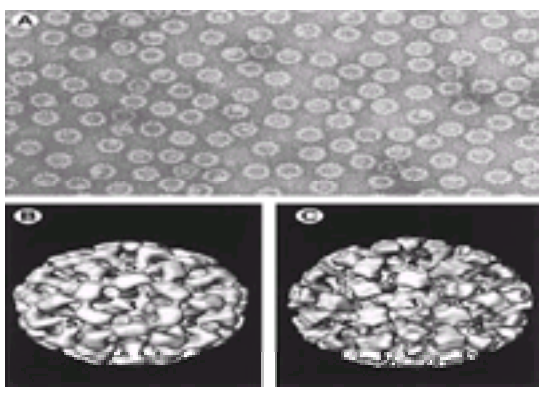

FIG. 3. The structure of Norwalk virus particles. **A:** Norwalk virus recombinant virus-like particles (rVLPs) prepared as described by Jiang et al. (154) and visualized by direct EM. **B:** Three-dimensional structure of Norwalk virus rVLPs viewed along the icosahedral threefold axis at 22Å (291). The Norwalk virus rVLPs have a distinct architecture, and they exhibit T=3 icosahedral symmetry; the twofold, threefold, and fivefold axes of symmetry are shown, and the cuplike depressions are evident at the threefold and fivefold axes. **C:** Three-dimensional structure of primate calicivirus Pan-1, viewed along the icosahedral threefold axis at 22Å (290). The architecture and symmetry are similar to that of Norwalk virus, but the edges of the cuplike depressions are more defined. (**A**) provided courtesy of M. K. Estes; (**B,C**) provided courtesy of B. V. V. Prasad.

The rVLPs are similar in antigenic and biochemical properties to native virus and can be used as an antigen in enzyme-linked immunosorbent assays (ELISAs) and IEM (105,112,154,239,276). Volunteers infected with Norwalk virus develop specific antibodies to this protein (112,276). Furthermore, the rVLPs are immunogenic when used to prepare hyperimmune sera in laboratory animals (154) or when given orally to mice or adult volunteers (17,18). Virus-like

particles have been generated for several other “Norwalk-like viruses” (with and without the ORF3 protein), and these reagents have been important tools in epidemiologic and antigenic studies of the “Norwalk-like viruses” (73,111,150,156,182,183,201,286).

Structural Studies

The Norwalk rVLPs have been important also for structural studies of the viral capsid (289,291). The Norwalk virus capsid is formed predominantly from a single major capsid protein that does not require packaging of the RNA genome for assembly into VLPs. Analysis of Norwalk rVLPs by electron cryomicroscopy and computer image processing shows that the particles (38 nm in diameter by this technique) have a distinct architecture and exhibit T=3 icosahedral symmetry (see Fig. 3B). The capsid contains 90 dimers of the capsid protein that form a shell from which 90 archlike capsomeres protrude at the local and strict twofold axes. These arches are arranged in such a way that there are large hollows at the icosahedral five- and threefold positions, and these hollows are seen as cuplike structures on the surface of caliciviruses (*calici* is derived from the Latin word *calyx*, or cup). The three-dimensional structure of a morphologically classical animal calicivirus (primate calicivirus, strain Pan-1 in the genus *Vesivirus*) has been determined (see Fig. 3C); it differs from that of Norwalk virus in that its protruding, archlike domains are longer in length and also differ in shape, consistent with the difference observed by negative-stain EM described previously (290). The shape of the top of the arch also differs in such a way that the Norwalk virus exhibits a feathery appearance by negative-stain EM, whereas the primate calicivirus has sharply defined edges (290). The Norwalk virus recombinant capsid protein can also self-assemble into smaller VLPs (23 nm) with suspected T=1 symmetry that is thought to be composed of 60 copies of the capsid protein (361). Smaller corelike particles of 25 to 27 nm have been observed in liver tissue of rabbits infected with RHDV, and these are composed of an approximately 30,000-dalton protein derived from the capsid protein (103).

The structure of the Norwalk rVLPs has been resolved to the atomic level by x-ray crystallography, so that the precise location of the primary amino acid sequence is now known (289). The electron cryomicroscopy studies had defined two major domains in the capsid—the shell (S) and the protruding arm (P) (Fig. 4A). The S domain forms the inner part of the capsid that surrounds the RNA genome, and the P domain forms the archlike capsomeres that protrude from the virion. The amino acid residues that correspond to these domains are diagrammed in Figure 4C. A ribbon model of the capsomere derived from the crystallography data (see Fig. 4B) shows a more detailed view of these domains. The NH_2-terminal (N) arm, located within the S domain, consists of residues 10 to 49 and faces the interior of the capsid. The part of the S domain that forms a beta-barrel consists of amino acids 50 to 225. The entire S domain (amino acids 1 to 225) corresponds to the N-terminal region of the capsid protein that is relatively conserved among “Norwalk-like viruses” in sequence comparisons (region 1, residues 1 to 280 for Norwalk virus) (diagrammed in Fig. 4D). In addition, the N-terminal region of the capsid protein is highly conserved among other caliciviruses within a related group, such as the B region described in a comparison of selected animal caliciviruses in the genus *Vesivirus* (255) (diagrammed in Fig. 4E). The P domain corresponds to the C-terminal half of the capsid protein, which is more variable in sequence. The P domain is divided into the P1 subdomain, encompassing amino acids 226 to 278 and 406 to 520, and the P2 subdomain, encompassing amino acids 279 to 405. The P2 subdomain corresponds to a region (region 2, residues 281 to 404 for Norwalk virus) of the capsid protein that shows the highest sequence variability among “Norwalk-like viruses.” The P1 subdomains form the sides of the arch of the capsomeres and position the P2 subdomain at the top of the arch. The exposure of the capsid variable region on the surface of the virion is consistent with its suspected role in the formation of a major antigenic site and in receptor binding (132,289,360). This observation may also explain the observed specificity of IEM, in which antibody molecules bind efficiently to the surface of the infecting virion (166). The variable region 2 among the capsid proteins of the “Norwalk-like viruses” corresponds to the E variable region of the *Vesivirus* capsid proteins, which was also proposed to be involved in the antigenic structure (255). Sequence analysis of monoclonal antibody neutralization-resistant variants has identified the E region of FCV as part of a major neutralization antigenic site (347). Additional evidence that the E region of FCV is involved in the formation of the antigenic structure of the virus has been found in studies of chimeric viruses in which the exchange of this region between FCV strains can alter neutralization specificity (257).

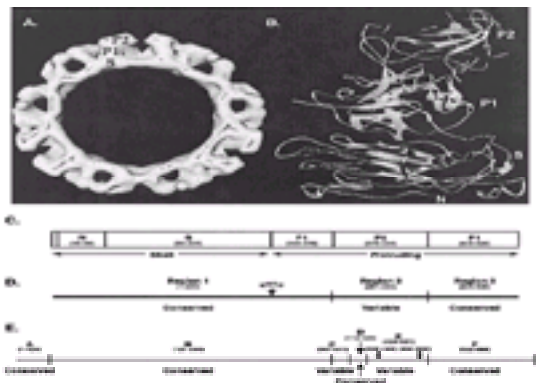

FIG. 4. Detailed view of Norwalk virus capsid protein. The Norwalk virus capsid structure is made up of 90 dimers of a single protein, which form a shell domain from which archlike capsomeres protrude (291). **A:** A central section of the Norwalk virus rVLPs perpendicular to the icosahedral threefold axis. The arch is composed of the protruding (*P*) domain (divided into subdomains P1 and P2) and the shell (*S*) domain (291). **B:** Three-dimensional ribbon representation of an individual subunit from the rNV capsomere derived from x-ray crystallography studies of Norwalk rVLPs at 3.4Å (289). **C:** Regions 1, 2, and 3 of the Norwalk virus capsid protein primary amino acid sequence (amino acid residue boundaries shown in *parentheses*), which correspond to the P1, P2, and S domains (291), respectively, are indicated. **D:** Regions of conserved and variable amino acid sequence (amino acid boundaries shown in *parentheses*) defined in a comparative analysis of human “Norwalk-like viruses” (M. K. Estes, personal communication). The location of the trypsin cleavage site between amino acid residues lysine and threonine (K227/T) that was mapped in *in vitro* studies of Norwalk rVLPs is shown (133). **E:** Regions of conserved and variable capsid precursor protein amino acid sequence in the genus *Vesivirus* (255). Amino acid changes in monoclonal antibody neutralization-resistant variants of FCV are located in two discrete regions of variable sequence (residues 426 to 460 and 490 to 520) within the “E” region ( ); they include amino acid

substitutions at residues 441, 448, 449, 455, 493, and 494 (347).

Antigenic Relationships of "Norwalk-like Viruses"

Antigenic relationships among the "Norwalk-like viruses" have been evaluated primarily by (a) cross-challenge studies in volunteers, (b) IEM or solid phase IEM (SPIEM), employing sera from infected individuals and antigens present in fecal suspensions, and (c) ELISAs or IEM using rVLPs (112,170,208,209,258,268). Initially, IEM was used to establish evidence for at least four distinct antigenic serotypes (proposed as serotypes 1 to 4), of which the prototype strains were the Norwalk, Hawaii, Snow Mountain, and Taunton viruses, respectively (80,167,170,174,208,209,369). Norwalk virus and Hawaii virus were shown further to be antigenically distinct in cross-challenge studies (369). An IEM analysis of SRSVs derived from outbreaks of acute gastroenteritis in Japan identified nine distinct antigenic types (designated S1 to S9) (268). Several of these viruses were similar by IEM to Norwalk virus, Hawaii virus, or the Otofuke virus (associated with a mild gastroenteritis outbreak in adolescents and adults in Japan) (267,268,341). A third typing system based on SPIEM was proposed in England in which three antigenic types and a possible fourth antigenic type of SRSVs (designated SRSV UK1 to UK4) were defined (208). The prototype strains for this system were Taunton (SRSV UK1), Norwalk virus (SRSV UK2), Hawaii virus (SRSV UK3), and Snow Mountain virus (SRSV UK4?). Comparative sequence analyses of the capsid protein from the Norwalk, Hawaii, and Snow Mountain viruses (with Taunton virus not available for this analysis) found marked genetic diversity (75% amino acid identity or less in pair-wise comparisons) that was consistent with the antigenic differences observed by IEM and SPIEM (131,155,179,205) (see Table 2). Comparison of the Norwalk, Hawaii, and Snow Mountain virus capsid sequences with those from other human "Norwalk-like viruses" indicates that several genetic clusters (or genotypes) of capsid proteins are circulating worldwide (8,258,353) (Table 3).

TABLE 3. *Grouping of human "Norwalk-like viruses" (NLVs) by genetic relatedness in the complete major capsid protein*

A unified system for serotyping based on neutralization is not available because of the fastidious nature of these viruses, so it is not yet clear whether each genetic cluster within a genogroup represents a distinct serotype. However, it is likely that distinct serotypes of the "Norwalk-like viruses" do exist, in view of the evidence for antigenic differences in the cross-challenge studies, IEM and SPIEM, and rVLP-based ELISAs described earlier. The continued generation of rVLPs and hyperimmune sera specific for viruses from the different genetic groups will be needed to develop a unifying interim antigenic grouping system.

Antigenic Relationships of "Sapporo-like Viruses"

The key antigens of the "Sapporo-like viruses" are associated also with the major capsid protein. Five distinct antigenic types of human caliciviruses (designated independently from the SRSV system described previously, as UK1 to UK4, and a fifth from Japan, also called human calicivirus Japan) were initially identified by IEM (57). These morphologically classical caliciviruses appeared to be related to Norwalk virus when studied by radioimmunoassay (RIA); however, these relationships were not evident by IEM (57). Sequence analyses later revealed that certain caliciviruses with classical morphology in these studies may have been "Norwalk-like viruses" (59). As found in the "Norwalk-like viruses," there is evidence for several distinct genetic groups of "Sapporo-like viruses" capsid protein sequences (Table 4). Expression of the capsid protein from Sapporo virus and "Sapporo-like viruses" in the baculovirus system yields rVLPs that will be useful for the study of antigenic relationships, until a neutralization assay is available (157,261).

Reference virus[a]	GenBank Accession number	Viruses with >80% amino acid identity with corresponding reference virus (GenBank Accession number)
Manchester/1993/UK	X86560	Sapporo/1982/JP (U65427); Plymouth/1995/UK (L23828); Houston/1998/US (J04940)
Parkville/1994/US	U73124	Houston 27/1998/US (J88644); Pelindaba/2000/GE (AF354738)
London 28845/1992/UK	U95645	
Stockholm 318/1997/SE	AF194182	

[a]Reference viruses share 79% amino acid identity or less in pair-wise comparisons of the capsid protein sequence with those of other reference viruses and are listed in order of historical precedence based on date of deposition of the full-length capsid gene sequence into GenBank.

References for the original description and the genetic characterization of the viruses shown are Wallchester virus (212), Sapporo virus (248,261), Plymouth virus (185), Houston/86 virus (148), Parkville virus (280), Houston/90 virus (148), Pelindaba virus (unpublished GenBank submission), London virus (148), Stockholm virus (352).

Country abbreviations: GE, Germany; JP, Japan; SE, Sweden; UK, United Kingdom; US, United States.

TABLE 4. *Grouping of human "Sapporo-like viruses" (SLVs) by genetic relatedness in the complete major capsid protein*

Infection of Experimental Animals, and Host Range

Numerous attempts have been made to induce illness in experimental animals. The Norwalk virus failed to induce illness following introduction into the alimentary tract of mice, guinea pigs, rabbits, kittens, calves, baboons, rhesus monkeys, marmosets, owl monkeys, patas monkeys, and cebus monkeys (29,76,77,370,371) (R. G. Wyatt et al., unpublished studies). Chimpanzees inoculated with Norwalk virus developed a serologic response as detected by IEM and RIA, but they did not develop illness (123,370). In addition, inoculated chimpanzees shed a soluble Norwalk virus antigen in their stools (123).

Caliciviruses infect a broad range of animal species (34,56,305,367). As noted previously, viruses in the genera "Norwalk-like viruses" and "Sapporo-like viruses" have recently been found in both humans and animals and are predominantly associated with infection and disease of the enteric tract. Viruses in the genus *Vesivirus* have been associated with infection in a wide variety of hosts, including cats, dogs, cattle, swine, marine mammals, skunks, mink, reptiles, fish, amphibians, birds, and nonhuman primates. A disease of veterinary importance in this genus is FCV, which causes an acute respiratory illness in kittens (reviewed in ref. 141). Thus far, members of the genus *Lagovirus* have been found only in rabbits and hares and are associated with a generalized viremic infection in which massive liver necrosis can trigger disseminated intravascular coagulation and rapid death (265).

Information concerning the frequency of interspecies transmission among caliciviruses is limited. The recent finding of genetically related human and animal enteric caliciviruses in the same phylogenetic clade suggests that such transmission might have occurred at some point in the evolution of these viruses (reviewed in ref. 350). However, the human and animal enteric caliciviruses are sufficiently divergent to suggest that they have undergone host species adaptation for some time. There are reported cases of calicivirus interspecies transmission in settings where the ecologic niche of the virus has been altered. These include the transmission of marine caliciviruses in the genus *Vesivirus* to domesticated swine in the United States in the 1930s in uncooked garbage (reviewed in ref. 325) and the infection of a laboratory worker handling San Miguel sea lion virus (324).

Molecular Biology of the Caliciviruses

The inability to grow human caliciviruses in cultured cells has hampered many aspects of research. However, considerable progress has been made by the analysis of cDNA clones generated from the genomic RNA of virions in stool material. In addition, information gained by the study of caliciviruses that grow efficiently in cell culture [such as FCV and vesicular exanthema of swine virus (VESV)] or that have an animal model and a limited cell culture system (such as RHDV), has been important for the identification of features that are likely to be shared among members of the *Caliciviridae*.

All caliciviruses have a linear, single-stranded, positive-sense RNA genome. Two major themes are observed in the organization of their major ORFs. Members of the genera "Norwalk-like viruses" and *Vesivirus* encode the capsid structural protein in a separate ORF (ORF2), whereas viruses in the genera "Sapporo-like viruses" and *Lagovirus* encode the capsid protein contiguous with the large nonstructural polyprotein (ORF1) (see Fig. 2). As a result, viruses in the genera "Sapporo-like viruses" and *Lagovirus* have at least two major ORFs (ORF1 and ORF2). In the genus "Sapporo-like viruses," the ORF1/2 junction consists of a one- or four-nucleotide (nt) overlap between the stop codon of ORF1 and the first AUG codon of ORF2. This creates a –1 frameshift. A third ORF has been described in certain strains that "overlaps" the capsid protein gene in a +1 frameshift (49,212). In the genus *Lagovirus*, a longer overlap [20 nt in RHDV and 8 nt in European brown hare syndrome virus (EBHSV)] is present at the ORF1/2 junction that includes the stop codon of ORF1 and the first AUG of ORF2 that also creates a –1 frameshift. Viruses in the genera "Norwalk-like viruses" and *Vesivirus* have three major ORFs (ORF1, ORF2, and ORF3). In the "Norwalk-like viruses," the first and third ORFs are in the same reading frame. Two independent changes are responsible for this. First, there is an overlap of ORF1/2 (a 17-, 20-, and 14-nucleotide overlap in GI, GII, and the bovine "Norwalk-like" enteric strain Jena virus, respectively) that includes the stop codon of ORF1 and the first AUG of ORF2. This creates a –2 frameshift. Second, there is a 1-nt overlap between the ORF2 stop codon and the ORF 3 initiation codon that restores the original reading frame. The *Vesivirus* genome is organized so that ORF1 and ORF2 do not overlap. There is either a 2- or 5-nt spacer sequence that results in a –1 frameshift for FCV and VESV, respectively. However, canine calicivirus strain No. 48 has a 3 nt spacer region between the stop codon of ORF1 and the initiation codon of ORF2, making the capsid gene coding sequence in-frame with that of the nonstructural polyprotein (301).

Calicivirus RNA genomes range from 7.3 to 8.3 kilobases in length, excluding the poly(A) tract (Table 5). All genomes begin with a 5´-end terminal GU. This 5´-end sequence is repeated internally in the genome and most likely corresponds to the beginning of a subgenomic-sized RNA transcript that is co-terminal with the 3´ end of the genome and that has been observed in FCV- and RHDV-infected cells as well as packaged into virions (135,236,256). A comparison of the 5´-end sequences of representative viruses within each of the four genera and the corresponding repeated internal sequence suggests that this is a feature that is characteristic of the caliciviruses (Fig. 5). The first in-frame AUG of ORF1 is relatively close to the 5´ end of the genome (ranging from 4 to 21 nucleotides), and the first in-frame AUG of the subgenomic RNA is also relatively close to the 5´ end. The synthesis of a subgenomic RNA in calicivirus-infected cells is a major difference between the replication strategy of caliciviruses and picornaviruses (85), although several of the replicative enzymes share distant homology (189). It is not known whether caliciviruses have a picornavirus-like internal ribosomal entry site (IRES) (145) for the initiation of translation, but it has been proposed as unlikely (at least for the calicivirus subgenomic RNA) because translation of the FCV capsid precursor protein begins at the first AUG of the subgenomic RNA (329).

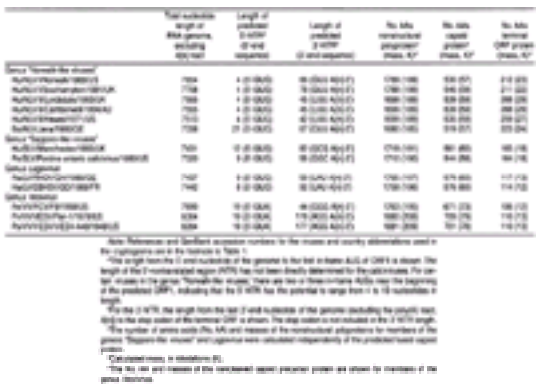

TABLE 5. *Comparison of the full-length genomes of representative caliciviruses*

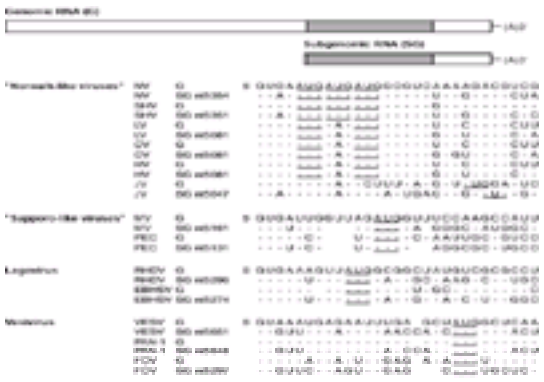

FIG. 5. Conserved sequences at the 5' ends of genomic and subgenomic RNA transcripts from viruses representing the four genera of the *Caliciviridae*. The genomic (*G*) sequence for each virus begins at the precise 5' end of the genomic RNA, and the subgenomic (*SG*) sequence begins at the internal nucleotide (*nt*) position, where similarity is shared with the 5'-end. The 5' end of the FCV and RHDV SG RNA has been mapped directly (135,236). The in-frame AUGs in the G and SG RNA that could be potential initiation codons are *underlined.* Strain abbreviations are NV, Norwalk virus; SHV, Southampton virus; LV, Lordsdale virus; CV, Camberwell virus; HV, Hawaii virus; JV, Jena virus; MV, Manchester virus; PEC, porcine enteric calicivirus; RHDV, rabbit hemorrhagic disease virus; EBHSV, European brown hare syndrome virus; VESV, vesicular exanthema of swine virus; PAN-1, primate calicivirus; FCV, feline calicivirus. The GenBank accession numbers for these viruses are shown in the footnote to Table 1. Identical nucleotides between the “reference” 5'-end genomic sequence in each genus and the selected viruses within that genus are indicated (–). Alignments were performed with the Clustal W (1.4) Multiple Alignment program of MacVector (blosum similarity matrix, gap penalty 10.0), and gaps are indicated by an *open space.*

The length of the 3´-end nontranslated region (NTR) of the representative full-length calicivirus genomes in Table 5 ranges from 42 to 178 nucleotides and is followed by a poly(A) tract. A longer 3´ NTR (235 nt) has been reported for the canine calicivirus (301). In contrast to the globally conserved pGpU of the 5´-end, the precise 3´ end just upstream of the poly(A) tract varies in sequence. A stable stem-loop structure has been predicted for the 3´ NTR of FCV and RHDV, and three stem-loops have been predicted for the longer primate calicivirus (Pan-1) 3´ NTR (300,319).

The predicted numbers of amino acids and calculated molecular masses of the proteins encoded in the different reading frames of representative viruses from each of the four genera are summarized in Table 5. Members of the genus *Vesivirus* are apparently unique among the caliciviruses in that the ORF2 encodes a capsid precursor protein (ranging from 73,000 to 78,000 daltons) that is proteolytically processed by the viral proteinase to yield the mature capsid protein of approximately 60,000 daltons that is found in virions (39,329). The protein encoded by the terminal ORF is most variable in size among caliciviruses (12,000 to 29,000 daltons) and is also divergent in sequence among viruses within certain groups (40,317).

Caliciviruses derive their mature nonstructural proteins by proteolytic cleavage from a large polyprotein encoded in ORF1. The length of the polyprotein encoding calicivirus nonstructural proteins ranges from 1680 (Jena virus) to 1881 amino acids (VESV), and the predicted noncleaved precursor of the nonstructural proteins is approximately 200,000 daltons (excluding the in-frame capsid protein sequences for the genera *Lagovirus* and “Sapporo-like viruses”). This large precursor has never been observed in *in vivo* or *in vitro* studies (24,329), most likely because proteolytic processing is rapid and cotranslational (211,330). The proteolytic cleavages are mediated by a virus-encoded “3C-like” cysteine proteinase that maps just upstream of the RNA-dependent RNA polymerase in the genome (211,330,364,365). Studies with RHDV have given insight into the likely proteolytic processing strategy of caliciviruses in infected cells (Fig. 6). A genomic-sized transcript (7.4 kilobases) serves as a template for translation of the polyprotein encoded in ORF1. Intermediate-sized proteins of 16,000, 60,000, 41,000, and 72,000 daltons that correspond to the nonstructural region of ORF1 have been detected both *in vitro* and in infected cells (187,237). Evidence for additional proteolytic processing into the putative “mature” nonstructural proteins has been found. The functions of these cleavage products were first inferred based on analogous sequences in the picornaviruses and included a “2C-like” helicase [with a predicted nucleoside triphosphate (NTP)-binding domain], a “3C-like” proteinase, and a “3D-like” RNA dependent RNA polymerase (254). Recent studies have confirmed that the RHDV “2C-like” protein binds ATP and has ATPase activity (221). Mutagenesis studies have confirmed the identity of the RHDV proteinase (364), and expression of the putative mature RHDV polymerase region in bacteria has verified that it is an RNA-dependent RNA polymerase (351). The genomic location of the protein covalently linked to the viral RNA (designated VPg, for virus protein, genome) of RHDV was determined using region-specific antisera (365). The functions of the N-terminal ORF1 cleavage product and the protein encoded just

upstream of the VPg are not known for the caliciviruses, and these proteins do not share significant homology with other known proteins. Several cleavage sites utilized by the virus-encoded “3C-like” cysteine proteinase have been identified for RHDV in bacterial expression studies (364,365). The cleavage sites are E/G and E/T dipeptides, similar to those recognized by the picornavirus 3C proteinase (reviewed in ref. 198). Recently, E/D and Q/G cleavage sites have also been identified in the RHDV polyprotein (237).

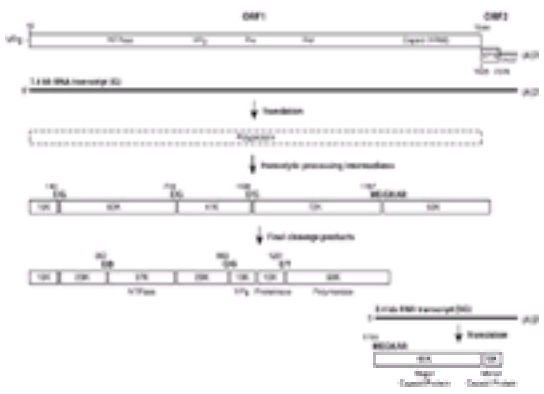

FIG. 6. Schematic diagram of the proposed replication strategy of rabbit hemorrhagic disease virus (RHDV) relating to protein translation and proteolytic processing. Two major RNA transcripts have been detected in RHDV-infected liver cells (236). The 7.4-kb genomic-length (*G*) RNA serves as a template for translation of the nonstructural polyprotein that is processed into intermediate and mature forms by the virus-encoded cysteine “3C-like” proteinase. The 2.4-kb subgenomic-length (*SG*) RNA serves as a template for translation of the major structural capsid protein (VP60) and the minor structural protein, VP10. (The RHDV ORF1 proteolytic cleavage map was modified from ref. 187,237.)

A cleavage map has been generated for the Southampton virus using cDNA clones derived from the large ORF (ORF1) encoding the nonstructural polyprotein (Fig. 7) (211,214). The cleavage map shares several similarities with RHDV. At least five cleavage sites (Q399/G, Q762/G, E961/G, E1099/A, and E1280/G) have been identified that would generate six proteins with masses of 48,000, 41,000, 22,000, 16,000, 19,000, and 57,000 daltons. The 41,000-, 16,000-, 19,000-, and 57,000-dalton proteins would correspond to the “2C-like” helicase (or NTPase), VPg, “3C-like” proteinase, and “3D-like” RNA dependent–RNA polymerase, respectively. Mutagenesis of the cysteine in the predicted active site of the Southampton virus proteinase region abrogates *in vitro* cleavage, confirming its identity as the proteinase (211). The cleavage sites identified in the Southampton virus polyprotein are conserved in the sequences of Norwalk virus, Lordsdale virus, Camberwell virus, Hawaii virus, and Chiba virus (287a,318,326a).

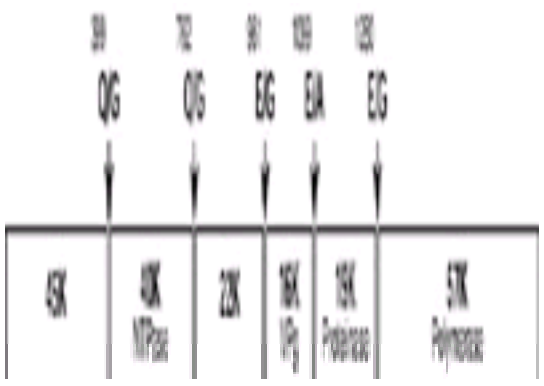

FIG. 7. Predicted proteolytic cleavage map of the nonstructural polyprotein of Southampton virus. Cleavage at the indicated dipeptide cleavage sites by the viral cysteine proteinase would result in the generation of six mature nonstructural proteins with the calculated mass (expressed in kilodaltons, K) (211,214). The predicted function (if known) is indicated.

A common characteristic among caliciviruses is the presence of the VPg covalently linked to the 5´-end region of the positive-strand RNA genome (36,309). The VPg of RHDV is linked also to the 5´-end region of the subgenomic RNA that is packaged into virions (236). The VPg of the caliciviruses (approximately 15,000 daltons) is larger than that of the picornaviruses (approximately 8,000 daltons) and has been reported as essential for the infectivity of RNA purified from virions (36). The function of the calicivirus VPg is not yet known, but it has been proposed that it plays a role in translation because proteolytic removal of the FCV VPg from RNA transcripts purified from FCV-infected cells leads to a decrease in translation efficiency *in vitro* (136). RNA transcripts derived from a full-length cDNA clone of FCV are infectious without the physical association of VPg, and it has been proposed that the 5´ terminal cap structure on the transcripts might compensate for the absence of the VPg in the initiation of translation (327).

Another general theme among caliciviruses is the presence of a 3´-end terminal ORF that encodes a basic (pI >8.0) protein. This protein has recently been identified as a minor structural protein in RHDV (designated as VP10), Norwalk virus (designated as the ORF3 protein), and FCV (designated as VP2) (97,328,365). The subgenomic RNA serves as a template for translation of both the capsid and terminal ORF proteins (see Fig. 6) (135,236,256). It has been suggested that the generation of a subgenomic RNA facilitates efficient synthesis of the major structural capsid protein during infection, similar to the replication strategy used by the alphaviruses (256). The ratio of the calicivirus terminal ORF protein to the capsid protein is much lower in virions, and the frameshift between the terminal ORF protein gene and the

capsid gene may serve as a mechanism to regulate translation of the terminal ORF product (135,256,365). The presence of the terminal ORF protein is not required for the self-assembly of the capsid protein, because recombinant capsid protein will self-assemble into VLPs without inclusion of the terminal ORF in the expression vector (197,201). One proposed function for this protein is that it interacts with RNA (because of its highly basic properties) and may be involved in packaging the genome into virions.

PATHOGENESIS AND PATHOLOGY

Incubation Period

Based on volunteer studies with the Norwalk virus, the incubation period ranges from 10 to 51 hours, with a mean of 24 hours (29,76,77,332,369). Illness usually lasts about 24 to 48 hours. The incubation period recorded in 22 naturally occurring outbreaks of Norwalk virus gastroenteritis was between 24 and 48 hours in 20 of the outbreaks, and the range was from 4 to 77 hours (173). During experimental infection of volunteers, virus shedding as detected by IEM coincided with the onset of illness and usually did not extend more than 72 hours after the first symptoms (345). However, the shedding has been detected for up to at least 7 days when analyzed by RT-PCR (102). The incubation period of experimentally induced Snow Mountain virus illness ranged from 19 to 41 hours, with a mean of 27 hours (80).

Entry and Site of Primary Replication

Human caliciviruses enter the body predominantly via the oral route. Virions are acid stable, consistent with an ability to survive passage through the stomach. Indirect evidence from epidemiologic studies suggests that viruses may enter also via aerosols, such as in those generated from the explosive vomiting that often occurs during illness (41,44).

The site of primary replication for the human caliciviruses has not been established, but it is assumed that they replicate in the upper intestinal tract. Biopsies of the jejunum of volunteers who develop gastrointestinal illness following oral administration of the Norwalk or Hawaii virus exhibit histopathologic lesions (2,78,311,312). There is broadening and blunting of the villi of the proximal small intestine, although the mucosa itself remains histologically intact (Fig. 8).

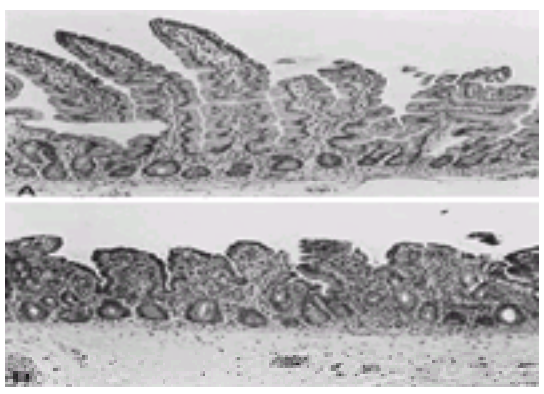

FIG. 8. A: Normal-appearing jejunal tissue from biopsy of a volunteer prior to challenge with Norwalk agent (H&E, ×390). **B:** Broadened and flattened villi in jejunal biopsy tissue from same volunteer during illness with Norwalk-induced gastroenteritis (H&E, ×390). (From ref. 2, with permission.)

Infiltration with mononuclear cells and cytoplasmic vacuolization is also observed. When viewed by transmission EM, the epithelial cells are intact, but there is shortening of the microvilli. Biopsies obtained during the convalescent phase of illness are normal. Virus has not been detected by EM in epithelial cells of the mucosa. It is of interest that the characteristic jejunal lesion has also been observed in volunteers who were fed Norwalk or Hawaii virus but who did not become ill (234,311,312). Histologic lesions are not observed in the gastric fundus, antrum, or rectal mucosa of volunteers with Norwalk virus–induced illness (362).

A transient malabsorption of fat, D-xylose, and lactose is observed during experimentally induced Norwalk virus illness (29,311). Levels of small intestinal brush-border enzymes (trehalase and alkaline phosphatase) are significantly decreased when compared to baseline and convalescent-phase values, whereas adenylate cyclase activity in the jejunum is not elevated following Norwalk or Hawaii virus-induced illness (2,203). In addition, interferon was not detected in serum, jejunal aspirates, or jejunal biopsies of Norwalk or Hawaii virus-infected volunteers (75). Gastric secretion of hydrochloric acid, pepsin, and intrinsic factor did not appear to be altered during Norwalk virus illness (234).

A marked delay in gastric emptying was observed in infected volunteers who became ill and developed the typical jejunal mucosal lesion (234). It has been proposed that abnormal gastric motor function is responsible for the nausea and vomiting associated with these viral agents (234).

Cell Tropism and Release

Information about the cell and tissue tropisms of human caliciviruses is limited. Radiolabeled Norwalk rVLPs bind to a variety of cell types, and in certain cells, they are apparently internalized with a low efficiency (360).

Human caliciviruses are released from the enteric tract of the host in feces. Norwalk virus and “Norwalk-like viruses” have been detected also in vomitus by IEM and RT-PCR (109,122,178,231).

Animal Models

Animal models for calicivirus diarrheal disease are in development with the recent discovery that enteric caliciviruses genetically related to the “Norwalk-like” and “Sapporo-like” viruses infect swine and cattle (66,126,213,336,350). Pathologic studies of the intestinal mucosa of pigs infected with PEC (a Sapporo-like virus) showed blunting of the small intestinal villi, similar to that observed during Norwalk virus infection (91). Immunofluorescence staining in this study indicated that villous epithelial cells throughout the small intestine were infected, with the greatest number of infected cells in the duodenum (upper small intestine).

Virulence

Little is known about human calicivirus virulence. The factors (host or viral) responsible for the emergence of an “epidemic” strain are not known. There are descriptions of strains that vary in pathogenicity among other groups in the *Caliciviridae*. Rabbit hemorrhagic disease virus generally causes a highly fatal hemorrhagic disease in rabbits, but a nonpathogenic variant has been identified in wild rabbits (37). Feline calicivirus strains have been described that appear to vary in virulence and disease manifestations (140), but the reproducibility of these observations could not be demonstrated in a challenge study (344), and sequence analysis of the capsid gene could not identify potential genetic determinants in this protein (95).

Persistence

Analysis of stool specimens from adult volunteers who were administered Norwalk virus by the oral route has shown that shedding of virus can continue for up to 2 weeks after the symptomatic phase of illness and that some volunteers undergo an asymptomatic infection (102,269). This observation suggests that infected individuals recovering from a “Norwalk-like” viral illness may continue to shed virus beyond the symptomatic period, a finding that has implications in the management of outbreaks caused by ill infected food-handlers (65,275,295,359). The “Sapporo-like viruses” have been associated with asymptomatic infection and prolonged shedding in children attending day care centers (124,226).

There is little evidence that the “Norwalk-like viruses” and “Sapporo-like viruses” cause chronic infection in a normal host. However, one study reported evidence for chronic infection in immunocompromised infants and young children, with one patient shedding the “Norwalk-like” virus GII strain for at least 8 months (202). Certain viruses in the genus *Vesivirus* have been associated with long-term, persistent infection in animals (70,161,285,294,326,357).

EPIDEMIOLOGY

Prevalence

Following the development of IAHA and RIA-blocking (BL) tests for detection of antibodies to the Norwalk virus, seroepidemiologic surveys were conducted for the prevalence of these antibodies in different populations and age groups (123). The prevalence of Norwalk virus antibodies measured by IAHA was compared with that of rotavirus antibodies in infants, children, and adults (169). The pattern of acquisition of antibodies in various groups in the United States differs for these two viruses. Norwalk virus antibodies are acquired gradually in childhood, and acquisition accelerates during the adult years so that 50% of individuals have such antibodies by the fifth decade. In contrast, antibodies to rotavirus are acquired rapidly during infancy and early childhood so that over 90% of individuals have such antibodies by 36 months of age. This pattern of acquisition of Norwalk virus antibodies was similar to that described for hepatitis A and certain rhinovirus serotypes, which suggested that the Norwalk virus was not an important cause of illness in infants and young children, at least in the United States (127,339).

The acquisition of antibodies to Norwalk virus in pediatric populations in various parts of the world was also evaluated by RIA-BL (26,62,83,118,164,304). The pattern deviates from the U.S. experience, as antibodies to Norwalk virus are acquired more rapidly in developing countries than in the United States, Taiwan, or Yugoslavia. For example, in two Matlab villages in Bangladesh, 43% of infants and children 2 to 49 months of age possessed Norwalk virus serum antibodies. The prevalence of antibodies was only 7% in the 2- to 7-month-old age group but increased to 100% in 4-year-old children (26).

When studied by RIA-BL, a majority of adults in both developed and developing countries were found to possess Norwalk virus antibodies (118). Male and female homosexuals in the United States had a prevalence of Norwalk virus antibody comparable to nonhomosexual adults (118).

Many, but not all, of the observations in these early studies of Norwalk virus in developing countries have been confirmed in recent studies that used more sensitive diagnostic ELISAs based on Norwalk rVLPs (93,105,262,283,293,322,342). For example, in Ga-Rankuwa, South Africa, antibodies to Norwalk virus were acquired early, reaching 100% by 2 years of age (323). However, in contrast to the early studies, in a developed country such as Finland, 73% of 154 infants and young children examined developed antibodies to Norwalk virus by approximately 2 years of age, indicating that these viruses had a wider distribution than considered earlier (207). As shown in Figure 9, recent studies enabled by the development of more sensitive assays using rVLPs for the detection of antibodies to not only Norwalk virus (GI) but also one or two GII viruses, demonstrate that the prevalence of antibodies to either genogroup characteristically increased more gradually by age in developed than in developing countries (156). However, a majority of individuals in both developed and developing countries are infected before adulthood. Antibodies to GI and GII “Norwalk-like viruses” have been detected on every continent (26,58,62,83,93,113,118,119,121,123,158,169,175,264,278,286,304,322,323). The prevalence of antibody to the GII viruses (Mexico, Hawaii, or Lordsdale) appears to be greater than that of the GI viruses in most studies (58,71,156,264,277,322). For example, in Italy, the acquisition of antibodies occurred earlier in life to the Lordsdale virus (GII) than to the Southampton virus (GI) and, in addition, the antibody prevalence in adults was 91.2% and 50.5% for the two viruses, respectively (286). This is not a consistent pattern, as in Japan and Southeast Asia,

antibodies to the Mexico virus (GII) were low in the younger age groups and increased gradually, a pattern similar to that described previously for the Norwalk virus in earlier studies in the United States (139). It is not known whether the overall higher infection rate with the GII viruses reflects a consistently higher prevalence or is merely a cyclical occurrence.

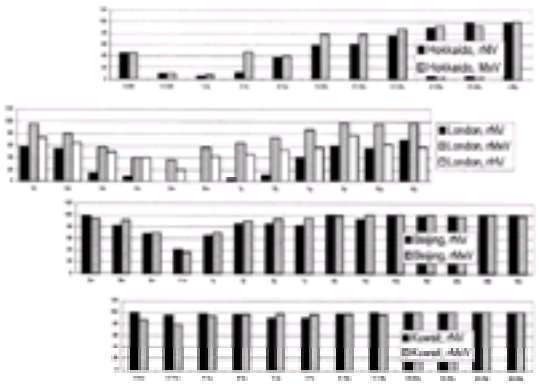

FIG. 9. Prevalence of antibody by age (m, month; y, year) to “Norwalk-like viruses” in Japan, United Kingdom, China, and Kuwait as measured by ELISAs that employed rVLPs from Norwalk virus (*NV*), Mexico virus (*Mx*), or Hawaii virus (*HV*) as antigen. (From ref. 156, with permission.)

In an attempt to determine if Norwalk virus is associated with serious diseases of unknown etiology with a gastroenteritic component, the prevalence of antibodies was evaluated in selected patients with such illness. Significant differences in the prevalence of Norwalk virus antibody or in Norwalk virus antibody titers were not demonstrated between patients with Crohn's disease and controls (116). Furthermore, exacerbations of either Crohn's disease or ulcerative colitis were only rarely associated with Norwalk virus infection (94). The prevalence of Norwalk virus antibody was also similar in patients with cystic fibrosis and controls (61). In additional studies aimed at determining if Norwalk virus was associated with gastroenteritis in human immunodeficiency virus (HIV)-positive patients, infection with Norwalk virus was comparable in HIV-infected and control patients (64,163). The role, if any, of other “Norwalk-like viruses” in such diseases has not been examined.

The “Sapporo-like viruses” have a worldwide distribution (47,252). The Sapporo virus antibody prevalence rates for adults in Japan, Canada, United States, China, Singapore, Indonesia, and Papua New Guinea ranged from 70% to 100% (252). The acquisition of antibodies to Sapporo virus begins early in life (250,252). In the developing country setting, such as Kenya, antibodies to the Sapporo virus were acquired by 1 to 2 years of age, as observed for the “Norwalk-like viruses” in such areas (250).

Incidence

Specific incidence data for illness caused by the “Norwalk-like” and “Sapporo-like” viruses are not available in the United States. However, the importance of viral agents is suggested from data on the incidence of enteric illnesses of any etiology in family studies, which indicate, that on average, each family member experiences more than one such illness per year (72,240). With the advent of sensitive detection systems, in the Netherlands it was possible to establish that 18% of the community cases of gastroenteritis over a single winter season and at least 5% of gastroenteritis cases that resulted in a visit to a physician were associated with the “Norwalk-like viruses” (191).

Predominant Role of the “Norwalk-like Viruses” in Epidemic Gastroenteritis

Although the prevalence of antibodies to the “Norwalk-like viruses” establishes that these viruses are distributed globally and in all age groups, it does not shed light on the prominent disease-causing potential of the “Norwalk-like viruses” in epidemic gastroenteritis. It is clear that the “Norwalk-like viruses” are the single most important cause of nonbacterial gastroenteritis outbreaks that occur in communities, schools, institutions, camps, cruise ships, nursing homes, universities, and families (119). This might have been anticipated, as viruses of this group were detected initially in specimens derived from gastroenteritis outbreaks in a school (Norwalk), in families (Hawaii, Montgomery County in Maryland, and Southampton), in a resort camp (Snow Mountain), and in a hospital (Taunton) (1,241,287,346). Outbreaks can vary in size, involving small family groups to hundreds of individuals (144). It is striking that one recent outbreak involved an estimated 5 million school children in Japan (228).

The important role of the Norwalk virus in the etiology of gastroenteritis outbreaks was established in early studies, when by RIA-BL it was found that 24 (34%) of 70 nonbacterial gastroenteritis outbreaks examined were associated with Norwalk virus infection (119). These outbreaks occurred in camps, recreational areas, elementary schools, cruise ships, nursing homes, colleges, restaurants, small families, and community settings. It is striking that more recently, with the availability of more sensitive diagnostic techniques, “Norwalk-like viruses” were detected by RT-PCR in 86 (96%) of 90 nonbacterial gastroenteritis outbreaks reported to the CDC from January 1996 to June 1997 (89) (Fig. 10). The major role of the “Norwalk-like viruses” as agents of epidemic gastroenteritis has now been reported in numerous locations throughout the world (67,144,354). Especially noteworthy is the frequent association of the “Norwalk-like viruses” with food-related outbreaks of gastroenteritis. It is estimated that food-borne diseases cause approximately 76 million illnesses, 325,000 hospitalizations, and 5,000 deaths in the United States each year the Norwalk-like viruses and bacterial agents assuming special importance in the overall etiology of food-borne illnesses, most of which still defy an etiologic agent (233), with bacteria such as *Salmonella* cited as the major cause (at least 75%) of food-borne disease outbreaks (270). However, improved detection methods for the “Norwalk-like viruses” suggest that their role in the etiology of food-borne illnesses has been grossly underestimated (51,270,334). The various common-source food-borne vehicles that have been implicated in “Norwalk-like viruses” outbreaks include bakery products (frosting), salad, celery,

melon, potato salad, vermicelli consommé, fruit salad, cole slaw, tossed salad, cold foods, sandwiches, lettuce, cold cooked ham, commercial ice, and water (reviewed in ref. 164). In addition, the “Norwalk-like viruses” are the most frequent cause of outbreaks of acute gastroenteritis following ingestion of raw shellfish (9,21,82,96,125,185,200,242,244,245,266,271,337). A relatively high rate of acute gastroenteritis was also observed following ingestion of cooked shellfish (10,180,230,242). The impact of these viruses on food-related disease is highlighted by the observation that in the United Kingdom, SRSVs were reported as the major cause (90%) of food-related gastroenteritis outbreaks (292). In Japan, 26 of 38 nonbacterial gastroenteritis outbreaks in which an SRSV was found were considered to be food-borne; it was striking that in 92% of the food-borne outbreaks, the vehicle of transmission was considered to be oysters (268). Finally, in Minnesota, food-borne outbreaks that are associated with the Norwalk and related viruses occurred more frequently (41%) than those associated with any single bacterial agent (69,193).

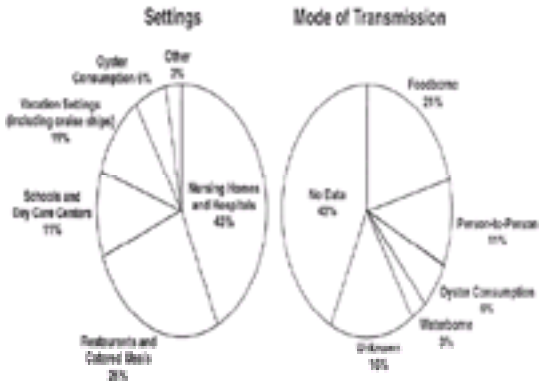

FIG. 10. Settings and presumptive modes of transmission for 90 outbreaks of nonbacterial gastroenteritis in the United States from January 1996 to June 1997. “Norwalk-like viruses” were detected in 86 (96%) of the 90 outbreaks by RT-PCR (range of detection within outbreaks 11% to 100%). (From ref. 89,98, with permission.)

“Norwalk-like viruses” have also been documented as important agents of gastroenteritis in military populations in several different areas of the world (12,14,31,52,142,143,229). Among U.S. military personnel deployed to South America or West Africa, Norwalk virus infection was detected in 10% of ill personnel, second in importance to enterotoxigenic *Escherichia coli*, which was the most frequently encountered pathogen (17%). In addition, large-scale outbreaks of gastroenteritis have been attributed to the “Norwalk-like viruses” on ships such as aircraft carriers on which hundreds of crew members became ill (53,272,320).

Norwalk virus does not appear to be an important cause of traveler's diarrhea. Its estimated role in different settings ranged from 0% to 15% (25,84,176,253,303). However, it is possible that the role of human caliciviruses in traveler's diarrhea has been underestimated because few studies have examined this possibility (98).

Importance of Human Caliciviruses in Different Age Groups

The “Norwalk-like viruses” have been associated with infection and disease in all age groups, although the majority of gastroenteritis outbreaks occur in settings that involve older, school-aged children and adults. The precise role of human caliciviruses in pediatric populations is not known, but several studies have indicated that the role of the “Norwalk-like viruses” in pediatric gastroenteritis deserves further evaluation. An early study in Bangladesh (26) found that children who had a serologic response to Norwalk virus (measured by RIA) experienced an excess incidence of 0.3 diarrheal episodes per 100 days. Thus, 1% to 2% of the diarrheal episodes in these children (who averaged 5.6 episodes per year) were estimated to be caused by Norwalk virus. This study provided the first evidence that the Norwalk virus might cause diarrhea in infants and young children by comparing the incidence of diarrhea not associated with other pathogens during periods when Norwalk virus infection did or did not occur. However, it should be noted that Norwalk virus infection was not identified as an important cause of dehydrating diarrheal illness in Bangladesh. For example, only 1 of 31 children under 10 years of age who were treated for dehydrating diarrhea in a hospital and who did not have rotavirus, enterotoxigenic *E. coli*, *Salmonella*, *Shigella*, or *Vibrio cholerae* in their stools had a serologic response to Norwalk virus (26).

Several EM studies have shown that viruses morphologically similar to Norwalk virus are observed only infrequently in stool specimens of infants and young children with gastroenteritis (33,169,190,284,335). For example, in an 8-year study conducted at the Children's Hospital National Medical Center in Washington, D.C., particles that were Norwalk virus–like in morphology were detected in stools by IEM in only 1.6% of 1,537 patients hospitalized with gastroenteritis (33,169). In addition, in Japan, in a cross-sectional study of pediatric patients hospitalized with gastroenteritis that spanned more than 6 years, caliciviruses or small round viruses were detected by EM in only 0.9% of 1,910 patients (188).

With the development of newer, more sensitive diagnostic techniques, studies in pediatric patients indicate that the “Norwalk-like viruses” may indeed be associated with an as yet undetermined portion of gastroenteric illness. For example, in a recent survey of 214 cases of gastroenteritis associated with SRSVs that occurred over the 1997 to 1998 winter season in Japan, 50% of the patients were 1 year of age or under (144). In Finland, 49% of 154 infants and young children exhibited evidence of Norwalk virus infection during a period of almost 2 years when studied by an ELISA using rVLPs as antigen, indicating that infections with “Norwalk-like viruses” may occur frequently in this age group (207). In this regard, “Norwalk-like” caliciviruses are considered to be the second most common cause of diarrhea in Finnish children, after rotavirus (273,274). The “Norwalk-like viruses” have been detected in the stools of pediatric patients with gastroenteritis in several different settings (30,202,206,222,251,263,279).

The “Norwalk-like viruses” have frequently been associated with gastroenteritis in the elderly, especially those living in institutional settings such as nursing homes (16,67,134,151,302,333). An estimated 43% of 90 nonbacterial gastroenteritis outbreaks reported to the CDC from January 1996 to June 1997 occurred in the hospital or nursing home setting (see Fig. 10).

Caliciviruses that are putatively in the genus “Sapporo-like viruses” have been considered to be primarily associated with pediatric gastroenteritis, but only infrequently with severe infantile gastroenteritis requiring hospitalization (48,55,90,217,232,246,249,250,252,338). In contrast to the “Norwalk-like viruses,” these viruses are not characteristically associated with outbreaks in adults and older children. Analysis of a collection of 59 stool specimens that were positive for caliciviruses with classical morphology and that were obtained over a 10-year period (1988 to 1998) in Europe and Scandinavia, demonstrated that 55 (93%) were “Sapporo-like viruses” by RT-PCR, and 51 of these were obtained from children less than 5 years of age (352). However, in a large study that included 1,273 sporadic cases of acute gastroenteritis in children in Sapporo, Japan, over a 3-year period, only 23 (1.8%) stool specimens reacted with a cDNA probe derived from Sapporo/82/Japan (184). The contribution of these agents to pediatric gastroenteritis was studied further in Finland using “Sapporo-like viruses” RT-PCR primers, and 44 (5.7%) of 775 cases of pediatric gastroenteritis were positive for “Sapporo-like viruses” (273).

The “Sapporo-like viruses” do not appear to be important agents of food-borne gastroenteritis outbreaks, although one such outbreak has been documented in adults (260).

Transmission

Studies in volunteers demonstrated that the Norwalk, Hawaii, Montgomery County, and Snow Mountain viruses induced gastroenteritis when administered by the oral route, with an average incubation period of 24 hours (76,77,160,203,241,332,369). Transmission via the respiratory route has not been established for this group of agents, although it has been suggested from epidemiologic observations in selected settings (45,308). The virus was detected by IEM in vomitus obtained from infected volunteers; vomitus has been considered to be a source of transmission in certain settings (122). Nasopharyngeal washings from a volunteer with experimentally induced Norwalk gastroenteritis did not induce illness in three volunteers (77). There is evidence that the human caliciviruses are stable in the environment and that contamination of water, food, and surfaces by infected individuals can lead to inadvertent exposure (46,109,138,202,215,282,316).

The explosive nature of some Norwalk virus outbreaks, in which a large number of persons become ill within 24 to 48 hours, suggests that infection is often acquired from a common source. This was suggested in the original Norwalk virus outbreak, but a common-source exposure could not be identified (1). Later, a review of 38 Norwalk virus–associated outbreaks suggested that a common source of infection was likely in 31 (82%) (173). The vehicle of transmission could be identified in 17 of the 31 outbreaks, including water in 13 instances and food in four others. Waterborne infection was attributed to a municipal water system (twice), semipublic water supply (seven times), stored water on a cruise ship (twice), and recreational swimming (twice). The food-borne outbreaks were associated with the ingestion of oysters or salad. A large outbreak of gastroenteritis in Minnesota was traced to contamination of cake frosting by Norwalk virus (192). Primary person-to-person transmission occurred in 7 of the 38 outbreaks (173). Sufficient data were available from 26 of the outbreaks to permit estimation of secondary attack rates (173). In 20 of 23 common-source outbreaks and in each of three person-to-person outbreaks, secondary transmission was observed, with attack rates ranging from 4% to 32%. In a large outbreak for which age data were available, the secondary attack rate was highest in children under 10 years of age. The median duration of the 38 outbreaks was 7 days (ranging from 1 day to 3 months). The number of individuals who became ill ranged from 2 to 2,000, with the attack rate being higher in common-source outbreaks (median 60%, range 23% to 93%) than in primary person-to-person outbreaks (median 39%, range 31% to 42%) (173). Recent studies have confirmed, for the most part, the various means of transmission of the “Norwalk-like viruses” (see Fig. 10) (89).

In the Colorado outbreak caused by the Snow Mountain virus, 61% of the 418 illnesses began on a single day (80,241). A waterborne source was suggested as the etiologic agent because the attack rate was directly related to the amount of water or ice-containing beverages consumed. In addition, the water supply was contaminated by a leaking septic tank and was inadequately chlorinated.

The efficient transmission of human caliciviruses by contaminated food and water vehicles has raised concerns about public safety in a global market economy (310). A recent example of an international outbreak of gastroenteritis occurred with the widespread distribution of contaminated raspberries from a single source in eastern Europe (288).

Molecular Epidemiology

Molecular epidemiologic studies have demonstrated a marked genetic diversity among circulating “Norwalk-like viruses.” As described earlier, two major genogroups within the “Norwalk-like viruses” have been identified as GI and GII. Genogroup I strains include Norwalk virus, Southampton virus, Desert Shield virus, Chiba 407 virus, Musgrove virus, Hesse virus, and Winchester virus, whereas genogroup II strains include Hawaii virus, Melksham virus (and the closely related Snow Mountain virus), Toronto virus (and the closely related Mexico virus), Bristol virus (and the closely related Lordsdale and Camberwell viruses), Hillingdon virus, Seacroft virus, Leeds virus, and Amsterdam virus (see Table 3). These viruses represent branches, or genetic clusters, of closely related viruses within their corresponding genogroups that have been designated in some studies as genotypes or subtypes (7,8,107,113,195,204,205 and 206,226,238,353). A numbering system has recently been proposed for the identification of “Norwalk-like viruses” in which the capsid sequence of a candidate virus would be compared to those of reference viruses (8), and the new virus would then be assigned both a genogroup and genetic cluster number (see Table 3). Most viruses in the genus analyzed thus far fall within the two major genogroups, although it has recently been proposed that the Jena bovine enteric calicivirus represents a third genogroup (GIII) within the “Norwalk-like viruses” (8). There is evidence also for genetic diversity

within the “Sapporo-like viruses” (see Table 4), but a numbering system for genetic groups has not been established. The biologic and epidemiologic significance of genetic diversity among the caliciviruses will require further study.

Large-scale molecular epidemiologic studies have given insights into important genetic features of the “Norwalk-like viruses.” First, viruses appear to be genetically stable over time (152,356). For example, the KY-89 virus, associated with illness in Japan in 1989, showed an overall amino acid identity of 96% in its capsid protein with Norwalk virus, which was associated with disease in the United States in 1968. Second, genogroup II viruses, particularly those related to the Bristol and Lordsdale viruses, have been the predominant viruses circulating globally in the last few years (8,20,30,106,114,178,202,220,238,274,282,306,314,331,354,366,368,373). Third, there is evidence for the widespread distribution of a global “common” strain during certain time periods, illustrating an efficient transmission of these viruses in the human population (89,259). Finally, evidence for mixed infections within the same individual or within the same outbreak has been reported (6,35,104,128,215,337), and such infections may allow recombination between RNA genomes, a possibility recently suggested from sequence analyses of naturally occurring viruses (131,147).

Geographic and Temporal Distribution

Human caliciviruses have a worldwide distribution (see preceding section, Prevalence). In a survey of outbreaks from eight countries, sporadic cases and outbreaks of “Norwalk-like viruses” gastroenteritis occurred in all age groups throughout the year, with a seasonal peak during the cooler months in 11 of the 12 studies (243). During a 1-year prospective study in Bangladesh, a serologic response to Norwalk virus was most frequent in the cool, dry periods of the year (26). In Australia, SRSVs were detected throughout the year, but most were detected from late winter to early summer (368). Moreover, in Japan, cases of gastroenteritis in pediatric patients that were associated with SRSVs peaked during the cooler months but somewhat earlier than the cool-weather rotavirus peak (144).

CLINICAL FEATURES

Viral gastroenteritis is generally considered to be mild and self-limiting, although the illness can be incapacitating during the symptomatic phase that usually lasts 24 to 48 hours. Illness induced by “Norwalk-like viruses” has occasionally been severe enough to require medical intervention (12,14,173,274,320).

Clinical manifestations observed in 38 outbreaks associated with Norwalk virus included the following (expressed as the median percentage of patients): nausea (79%), vomiting (69%), diarrhea (66%), abdominal cramps (30%), headache (22%), fever (subjective) (37%), chills (32%), myalgias (26%), and sore throat (18%) (173). Bloody stools were not reported. Vomiting occurred more frequently than diarrhea in children, whereas in adults the reverse was observed. The duration of illness in 28 outbreaks ranged from 2 hours to several days, with a mean or median of between 12 and 60 hours in 26 of the 28 outbreaks. In six outbreaks, illness lasted more than 3 days in up to 15% of the affected individuals. The attack rates did not differ significantly with age or sex in six outbreaks in which this was analyzed (173).

The spectrum of clinical manifestations observed in two volunteers who developed illness following Norwalk virus challenge is shown in Figure 11 (76). Although both individuals received the same inoculum, one volunteer developed an illness characterized by vomiting without diarrhea, whereas the other had diarrhea without vomiting. Clinical manifestations observed in 31 experimentally infected volunteers who became ill included the following: fever above 99.4°F (45%), diarrhea (81%), vomiting (65%), abdominal discomfort (68%), anorexia (90%), headache (81%), and myalgias (58%) (369). The illnesses were characteristically mild and usually lasted 24 to 48 hours; however, one volunteer was given parenteral fluid because he vomited 20 times within a 24-hour period. Fourteen of 16 volunteers who developed illness following Norwalk or Hawaii virus infection developed transient lymphopenia which affected T-, B-, and null-cell lymphocyte subpopulations (79). This was attributed to a redistribution of circulating lymphocytes to the site of viral infection in the small intestine. The lymphocytes remaining in the circulation responded normally or exhibited an exaggerated response to mitogenic stimuli.

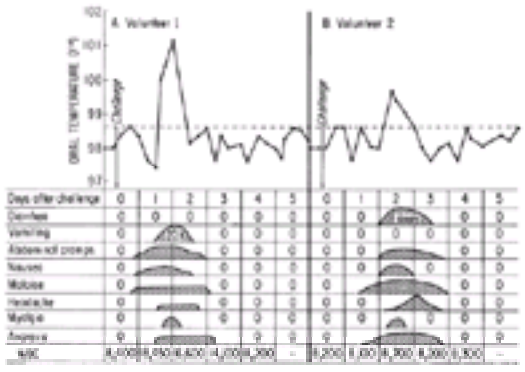

FIG. 11. Response of two volunteers to oral administration of stool filtrate derived from volunteer who received original Norwalk rectal swab specimen. The height of each curve is directly proportional to the severity of the sign or symptom. Volunteer 1 had severe vomiting without diarrhea, whereas volunteer 2 had diarrhea without vomiting, although both received the same inoculum. (From ref. 76, with permission.)

Illnesses induced by the Hawaii, Montgomery County, and Snow Mountain viruses in volunteers cannot be distinguished clinically from those caused by the Norwalk virus (50,80,369). Subclinical infections with Norwalk or Hawaii virus have been observed under experimental as well as natural conditions. Of interest, the characteristic jejunal lesions can develop in the absence of symptoms (173,234,311,312,332).

A comparison of the clinical features of gastroenteritis caused by the “Norwalk-like viruses” or “Sapporo-like viruses” in Finnish infants and young children showed that the “Norwalk-like viruses” induced vomiting as the predominant clinical feature, whereas the “Sapporo-like viruses” usually caused diarrhea (273).

IMMUNITY

Immunity to Norwalk virus is poorly understood but it does not appear to resemble the pattern observed with most other viruses. Because serum or intestinal secretory neutralizing antibodies cannot be measured in tissue culture, most of the information on immunity comes from volunteer studies. Adults consistently demonstrate a high degree of susceptibility to both naturally occurring and experimentally induced Norwalk illness. In some outbreaks, more than 80% of adults became ill (173). In addition, approximately 50% of unselected adult volunteers consistently developed illness following challenge with Norwalk virus (29,77,332,369).

Volunteer challenge studies have established that there are two forms of resistance to Norwalk virus: One is short term and the other is long-term (77,280,369). Short-term immunity, which follows the traditional pattern, is apparently serotype specific. Thus, volunteers who become ill following Norwalk virus challenge are usually resistant to rechallenge with this virus 6 to 14 weeks later. However, challenge of such volunteers with the heterotypic Hawaii virus induces illness. Similarly, volunteers who recently became ill following infection with Hawaii virus are susceptible to challenge with the Norwalk virus (369). Long-term immunity, however, deviates from the traditional pattern. Twelve volunteers who were challenged with the Norwalk virus on two occasions, 27 to 42 months apart, exhibited two different patterns of resistance to sequential challenge (280). Six volunteers developed gastrointestinal illness following the initial challenge, and they developed it again following rechallenge 27 to 42 months later. In contrast, the other six individuals failed to become ill following the initial challenge and were also resistant after rechallenge 31 to 34 months later. Serologic studies in which prechallenge serum antibodies to Norwalk virus were measured by IEM and RIA failed to provide an explanation for the difference in susceptibility (63,121,280). Paradoxically, volunteers who did not become ill had little, if any, antibody to Norwalk virus measurable by IEM in either prechallenge serum specimen (280). Also, they failed to develop a significant serologic response following each challenge. However, volunteers who became ill following each challenge, and who were evaluated serologically, developed a serologic response after each challenge. The observation that serum antibody to Norwalk virus does not correlate with resistance to illness has been reproduced in more recent volunteer studies (102,160).

Additional evidence for nonimmunologic factors in resistance was obtained when prechallenge serum and local jejunal antibody levels were determined in 23 additional volunteers who were challenged with Norwalk virus (121). The geometric mean Norwalk antibody titer (by RIA-BL) in serum or jejunal fluid did not correlate directly with resistance to illness. On the contrary, individuals who developed illness had a mean prechallenge jejunal fluid antibody titer that was significantly higher than that of volunteers who did not become ill. They also tended to have a serum antibody titer that was higher than that of volunteers who did not develop illness. These findings were confirmed in subsequent volunteer studies and during natural outbreaks of disease (19,28,159,160,218).

Several explanations for these observations have been suggested (27,60,280). For example, it has been proposed that a genetically determined variation in virus receptors in the intestinal tract is responsible for long-term resistance in the absence of appreciable Norwalk virus antibodies (19,27,60,280). Clustering of susceptibility to Norwalk virus illness in families exposed to contaminated water supports this explanation and suggests that genetic susceptibility operates under natural as well as experimental conditions (190). On the other hand, persons who become infected with the virus do develop specific antibodies and exhibit short-term homologous immunity. However, it is not clear why adults with various levels of Norwalk virus antibodies do not exhibit long-term homologous resistance to experimental challenge. In studies performed in a natural setting in developing countries such as Bangladesh or Panama, the presence of serum antibodies to the Norwalk virus was found to correlate with resistance to Norwalk virus infection (26,304). Perhaps a clearer understanding of immune mechanisms involved in protection will emerge when assays become available for examining the role of neutralizing antibodies to individual serotypes.

The “Sapporo-like” human caliciviruses have not been studied in volunteers, so even less is known about immunity to this group of viruses. There are suggestive data that antibodies may be important in immunity because antibodies measured by RIA to the Sapporo virus exhibited a correlation with resistance to illness in infants and young children (247,248).

DIAGNOSIS

Differentiation of illness caused by Norwalk virus from that caused by other members of the genus “Norwalk-like viruses” cannot be made on clinical grounds. However, an analysis of the common features of 38 Norwalk virus outbreaks (173) indicate that a provisional diagnosis of illness by this group can be made during an outbreak if the following criteria are met: (a) bacterial or parasitic pathogens are not detected; (b) vomiting occurs in more than 50% of the cases; (c) the mean or median duration of illness ranges from 12 to 60 hours; and (d) the incubation period is 24 to 48 hours (172).

Electron Microscopy

Electron microscopy continues to be a valuable diagnostic tool for viral gastroenteritis because it is rapid and requires minimal sample preparation. For acute gastroenteritis that occurs in an infant or young child from 6 months to 2 years of age, rotavirus should be the primary etiologic suspect and it can often be readily diagnosed by EM because the virus is shed in high titer in stool material (32). However, direct examination of unconcentrated stool material from gastroenteritis outbreaks (which usually occur in older children and adults) is of limited value as a routine diagnostic tool for the “Norwalk-like viruses,” because particles are usually present in low concentration (32,43,166,171,287,299). Furthermore, the significance of particles that are visualized directly cannot be established without other tests because stools contain many small, round objects of a size similar to that of viruses of this group. For this reason, putative “Norwalk-like viruses”

should be identified in stools by the technique of IEM or SPIEM (72,166,170,171,181,210,299). The time of stool collection is critical to success in virus detection. For example, Norwalk virus was detected in the stools of 11 of 23 volunteers who developed illness following challenge (345). Virus was detected in 26 of 54 specimens collected during the first 72 hours after onset of illness but in only 2 of 11 specimens collected after this interval.

Detection of the “Sapporo-like viruses” in stool material by EM may be less difficult because of their distinct morphology. The virions have been described as having a feathery edge, a six-pointed star with a dark hollow in the center (a Star-of-David) appearance, and distinct surface hollows that appear round or oval (216). However, caliciviruses can exhibit variable appearances (56) and morphology alone should not be used to conclusively distinguish between the “Sapporo-like viruses” and “Norwalk-like viruses” (59,184,206).

Reverse Transcriptase-Polymerase Chain Reaction

RT-PCR is currently the most widely used technique for detection of human caliciviruses. Several primer pairs have been described that were deduced from highly conserved regions of the RNA genome (usually the polymerase region) (reviewed in ref. 8). With this method, human caliciviruses can be detected in clinical specimens (feces or vomitus) and contaminated food, water, or fomites (15,68,128,153,200,315,316,321,363). RT-PCR has been used extensively to detect and characterize “Norwalk-like viruses” in various outbreaks (see preceding section, Molecular Epidemiology). One requirement for successful application of RT-PCR for outbreak investigation is the choice of primers, because considerable genetic diversity exists among circulating strains. Recently, a primer pair has been described that detects both “Norwalk-like” and “Sapporo-like” viruses (149).

Immunoassays

The development of rVLPs has had a major impact on the development of antibody-based diagnostic assays such as ELISAs (reviewed in ref. 156). Human calicivirus rVLPs are antigenically similar to native virions in stool and can be produced in large quantity. Immunoassays for the detection of several viruses from both the “Norwalk-like viruses” and “Sapporo-like viruses” groups have been developed that employ hyperimmune antisera prepared against recombinant VLPs. However, although sensitive, these assays are often highly specific for the immunizing VLP (102,152). The expression of calicivirus capsid proteins in bacteria has been explored as an approach to generate cross-reactive antigens for the development of diagnostic reagents (374). Efforts are in progress to develop broadly reactive polyclonal or monoclonal antibodies (129,132) for use in ELISAs that can detect viral antigen in clinical specimens.

ELISAs that use rVLPs as antigen are specific, sensitive, and efficient for detecting infection with the human caliciviruses and have been used in several large-scale sero-epidemiologic studies (see preceding section, Prevalence). The Norwalk rVLP ELISA has been shown to detect broadly reactive antibody responses in volunteers given Norwalk virus, Hawaii virus, or Snow Mountain virus, although the maximal response was observed in volunteers challenged with the Norwalk virus (102,239,348). It is impossible to identify the antigenic type of the infecting strain by serologic analysis because of the cross-reactive antibodies detected by ELISA (258). However, the demonstration of an antibody response in 50% or more of the individuals involved (or examined) in an outbreak to a calicivirus antigen is strong evidence linking the virus with the outbreak (173).

TREATMENT

As noted earlier, the Norwalk group of viruses characteristically induces a mild, self-limited gastroenteritis that normally resolves without complications (29,74,76,77,160,332,369). Oral fluid and electrolyte replacement therapy is usually sufficient to replace fluid loss (4,54). However, parenteral administration of fluids may be necessary if severe vomiting or diarrhea occurs. As noted earlier, hospitalization for severe dehydration, although rare, can occur with Norwalk virus gastroenteritis. In addition, deaths from Norwalk virus gastroenteritis in debilitated elderly patients and in immunocompromised children infected with human caliciviruses have been reported (88,173); however, these fatalities were considered to be caused, in large part, by an underlying disease. Oral rehydration therapy should not be administered to patients with depressed consciousness because of the possibility of fluid aspiration.

Oral administration of bismuth subsalicylate after onset of symptoms significantly reduced the severity and duration of abdominal cramps during experimentally induced Norwalk virus illness in adults (332). In addition, the median duration of gastrointestinal symptoms was reduced from 20 to 14 hours. The number, weight, and water content of stools, as well as the extent of virus excretion, were not significantly affected by treatment. The use of various medications for symptomatic treatment of acute diarrhea in infants and young children in the 1 month to 5 years age group was reviewed: bismuth subsalicylate, loperamide, anticholinergic agents, adsorbents, or *Lactobacillus*-containing compounds, was not recommended by the American Academy of Pediatrics, and in addition, the use of opiates as well as opiate and atropine combination drugs was contraindicated (4).

CONTROL AND PREVENTION

Specific methods are not available for the prevention or control of human calicivirus infection or illness. Because these viruses are highly infectious, effective hand washing and disposal or disinfection of contaminated material may decrease transmission within a family or an institution. Special care must also be given to the hygienic processing of food in view of the frequent occurrence of food-borne outbreaks. Depuration of oysters does not adequately clear tissues of Norwalk virus (9,125,315), so precaution must be taken to prevent contamination of oyster beds with feces or vomitus. Measures that increase the purity of drinking water or swimming pool water should also decrease the frequency of outbreaks (215).

One of the major obstacles to the formulation of a strategy for immunization against Norwalk virus and its related viruses is that the basis for immunity is not understood (reviewed in ref. 87). The inability to cultivate these viruses in cell culture has prevented an analysis of the role of neutralizing antibodies. Furthermore, the viruses themselves cannot be propagated as a source for live or inactivated vaccine. However, this latter problem may be circumvented by the present

availability of rVLPs, which are a replenishable and abundant source of capsid antigen (86). In phase I studies of Norwalk rVLPs as vaccines, they were safe and immunogenic when administered to adult volunteers by the oral route (17). Furthermore, expression of the Norwalk virus capsid in plants yielded VLPs that were immunogenic in laboratory animals and volunteers (224,298,340). If the mechanism of immunity is elucidated and antibodies are found to play a relevant role in prevention, the rVLPs may prove to have potential as a subunit vaccine. A safe and effective vaccine could reduce the incidence of epidemic viral gastroenteritis. An effective vaccine, if feasible, would be of special importance to college students, military personnel, nursing home residents, and individuals in various institutional settings. In addition, it might reduce the number of episodes of gastroenteritis in infants and children, especially those who live in developing countries. Although Norwalk virus gastroenteritis tends to be a mild illness, a reduction in diarrheal episodes may be important in the debilitated, malnourished infant, because it has been suggested that repeated diarrheal episodes may be a precipitating factor in the development of malnutrition through sequential damage to the intestinal mucosa (224).

CHAPTER 28 Astroviruses

Suzanne M. Matsui and Harry B. Greenberg

The family *Astroviridae* includes human and animal astroviruses that share a characteristic starlike surface structure when viewed by electron microscopy (EM). These small icosahedral viruses comprise a third family of nonenveloped human and animal viruses whose genome is composed of plus-sense, single-stranded RNA. As described later, they have several important features that distinguish them from the two other families of such viruses, the *Picornaviridae* and the *Caliciviridae.*

Astroviruses have been isolated from humans as well as numerous animal species. In most species, astroviruses are found in association with gastroenteritis. In avian species, however, both intestinal and extraintestinal manifestations of disease have been observed. The medical importance of astrovirus in humans was established initially in studies conducted in Thailand and Guatemala, where astroviruses were found to be the second most common cause (after rotavirus) of viral diarrhea in young children. Improved detection techniques and increased awareness of astrovirus infection have helped to define the epidemiology of this illness.

HISTORY

The term *astrovirus* was coined by Madeley and Cosgrove in 1975 (106) to describe small round viruses (SRVs) with a distinctive five- or six-pointed starlike appearance (astron, “star” in Greek) by direct EM (Fig. 1). They observed these small, 28-nm-diameter, round viral particles in the stools of infants hospitalized with diarrhea and in outbreaks of gastroenteritis in newborn nurseries (105). Ironically, the first astroviruses described in the literature did not display the characteristic astrovirus surface features. A few months prior to the naming of astroviruses, Appleton and Higgins (4) reported an outbreak of mild diarrhea and vomiting among infants in a maternity ward. SRVs that were 29 to 30 nm in diameter and without defining features were shed in large numbers in fecal samples from 8 of the 14 infants in this outbreak. By EM evaluation, these viruses differed in size and morphology from the previously identified Norwalk virus and rotavirus, but it was not until years later when specific immunologic reagents became available that these viruses were demonstrated to be astroviruses (26).

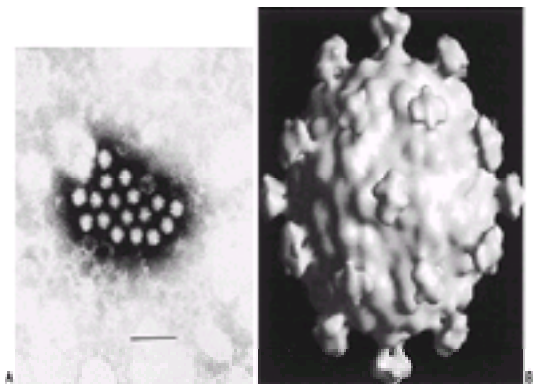

FIG. 1. A: Electron micrograph of human astrovirus in a fecal specimen. Bar = 100 nm. (Courtesy of T. W. Lee and J. B. Kurtz.) **B:** Surface-shaded views of the three dimensional reconstruction of human astrovirus, along the twofold axis of symmetry. (Courtesy of M. Yeager.) Cell culture–adapted human astrovirus serotype 1 (Oxford strain) was purified by isopycnic centrifugation and imaged by cryoelectron microscopy (193). External diameter (including spikes) is approximately 430 Å.

Subsequently, viral particles that were of similar size and had characteristic starlike surface features were identified in association with gastroenteritis in a wide variety of young mammals and birds, including lambs (162), calves (189), deer (171), piglets (23,159), kittens (61), mice (76), dogs (112,184), and turkey poults (118,150). Ducklings infected with astrovirus-like particles developed a rapidly fatal hepatitis (46), and viral particles were found in liver as well as feces. Astrovirus appears to cause infection in a species-specific manner (88), and at present there is no animal model to study human astrovirus infection.

An important milestone was achieved in 1981 when Lee and Kurtz (94) reported the isolation and passage of human astrovirus in cell culture. That astroviruses could be propagated in cell culture clearly distinguished them from Norwalk virus and other human caliciviruses that remain refractory to growth in such systems. This achievement also led to the recognition of five serotypes of human astrovirus in 1984 (87), development in the late 1980s of an enzyme immunoassay (EIA) that detects viral antigen (58,59), confirmation of its medical importance in 1991 (60), and cloning and sequencing of the astrovirus genome (67,99,176).

INFECTIOUS AGENT

Propagation of Human Astroviruses

Two years after astroviruses were identified by direct EM of human feces, Lee and Kurtz (93) demonstrated by immunofluorescence the infection of primary human embryonic kidney (HEK) cells with fecal extracts containing human astrovirus. It was not until 1981, however, that serial passage of astrovirus in primary HEK cells was made possible by incorporating trypsin in the serum-free growth media (94). The optimal trypsin concentration of 10 µg/mL yielded viral titers of 10^4 to 10^7/mL at approximately 48 hr after infection. The concentration of trypsin required in the medium was significantly higher than that required for propagation of rotavirus. After six passages in HEK cells, primary baboon kidney (PBK) cells and a continuous line of rhesus monkey kidney epithelial (LLCMK2) cells could be infected. The requirement for trypsin in the media remained unchanged. The first five serotypes of human astrovirus described (87) were adapted to growth in LLCMK2 cells. Attempts to establish serial passage by direct inoculation of PBK or LLCMK2 cells with fecally derived astrovirus were not successful. Although infected LLCMK2 cells do not display distinguishable cytopathic effects (CPEs), a plaque assay for at least three serotypes was developed to investigate viral neutralization and determine viral titer (63).

Willcocks et al. (179) directly infected a continuous line of human colon carcinoma (CaCo-2) cells with a fecal extract containing astrovirus serotype 1 from a 1988 outbreak of gastroenteritis in the United Kingdom. The optimal trypsin concentration in this system was determined to be 5 µg/mL, and CPE was apparent beginning 2 days after infection. Astrovirus serotypes 6, 7, and 8, the types identified most recently, have been successfully propagated in CaCo-2 cells (16,96). This is a promising technique that may allow more rapid isolation and subsequent propagation of wild-type astroviruses (148). Growth in CaCo-2 cells may be a way to distinguish astrovirus from calicivirus infection. In addition, the ability to achieve higher viral titers in CaCo-2 cells facilitates studies of astroviruses in cell culture.

Human astroviruses isolated in HEK cells, but not in Caco-2 cells, undergo a deletion of 15 partially repetitive amino acids, approximately 120 amino acids upstream of the carboxyl terminus of the open reading frame (ORF) 1a product (174). It was suggested that this deletion may improve the efficiency of adaptation to certain cells, but its significance is not well understood.

A hepatoma cell line (PLC/PRF/5) was found to support propagation of cell culture–adapted reference strains of human astrovirus (167). This cell line can also be used to isolate human astrovirus directly from fecal samples.

Propagation of Animal Astroviruses

Adaptation to growth in cell culture has been attempted for nearly every animal astrovirus identified by EM. Bovine (6) and porcine (159) astroviruses have been propagated in cell culture. Two factors appear to be important in achieving serial passage of animal astroviruses: (a) the use of host cells from the animal species in which the astrovirus infection was originally detected, and (b) the use of trypsin in the media of infected cells.

In the original description of bovine astrovirus, experiments aimed at adapting and maintaining these viruses in cell

culture were described (189). Primary calf kidney and testicular cell cultures were infected with a bacteria-free fecal preparation or the intestinal contents of infected gnotobiotic calves. Immunofluorescence could be demonstrated in the initial infection but was lost after a single passage. Several years later, passage of bovine astrovirus was attempted in primary, secondary, and tertiary bovine embryo kidney (BEK) cells (191) and this, too, was unsuccessful. It was speculated that either relatively fewer susceptible cells were present in secondary and tertiary BEK cells or that trypsin may be required for successful passage. In 1989, Aroonprasert et al. (6) demonstrated passage of bovine astrovirus in primary neonatal bovine kidney (NBK) cells in medium containing 50 µg/mL trypsin. Trypsin was necessary both for serial passage of virus and the release of infectious virus. Both NBK and primary BEK cells were infectable with bovine astrovirus derived from feces and cell culture. This system was used subsequently to study viral infection *in vitro* (see Pathogenesis section, later).

A porcine astrovirus was isolated from an outbreak of acute gastroenteritis at a pig farm in Japan (159). A fecal filtrate containing porcine astrovirus was used to infect embryonic swine kidney cells in media with 0.5 µg/mL trypsin. Maximal CPE was evident 4 to 5 days after inoculation of cell monolayers in trypsin-containing media. CPE was not produced if trypsin was removed from the medium or if the virus inoculum was mixed with convalescent phase serum.

Astroviruses from lambs (162), red deer (171), kittens (61), dogs (112,184), turkeys (118), and ducks (46) also were inoculated into cell cultures, but serial passage has not been established. Trypsin was not used in any of these experiments and in some cases (112,118,171), cells from the same species as the host were not used.

Physical Features

In 1982, Caul and Appleton (26) proposed an interim scheme to classify the SRVs based on their physical and EM features. The viruses considered in this scheme were first differentiated by whether the virion surface was featureless or structured. The featureless viruses included the enterovirus, parvovirus, and parvovirus-like particles that tended to be smaller in diameter than the structured viruses. Astroviruses were one of three groups of SRVs with surface structure. Astroviruses, shown in Fig. 1A, were described as 28- to 30-nm particles with a smooth margin and a characteristic five- to six-pointed star on the surface. They differed from the two other categories of structured SRVs: calicivirus, with its “Star of David” pattern with cuplike surface hollows and a ragged outline; and the small, round-structured viruses (SRSVs), including Norwalk and Norwalk-like viruses, that had an amorphous surface and a ragged outline. Although the surface star of astrovirus is its most striking feature, it is important to note that this may be discernible on only 10% of the viruses in a given preparation (106).

Antibody coating of viral aggregates in stool or in preparations of immune EM (IEM) may further obscure some of the surface features (8,85,88). In some preparations, “bridging structures” that may be surface extensions of the virus have been observed between adjacent astrovirus particles (61,104,106). The significance of these structures remains to be elucidated.

Astroviruses were described generally to have a diameter of 28 nm, based on the systematic measurement of over 1,000 negatively stained (phosphotungstic acid) astroviruses from infected infant stools by Madeley (104). The diameter of astrovirus particles may vary, however, depending on the source of virus and the method of preparation for EM. For example, bovine astrovirus serotype 2 (US2) propagated in primary NBK cells had an average diameter of 34 nm (range, 30 to 37 nm) after fixation in glutaraldehyde plus 1% osmium tetroxide and staining with uranyl acetate (6). Similarly fixed and stained sections of infected gnotobiotic calf ileum revealed bovine astroviruses that had an average diameter of 30 nm (range, 27 to 35 nm) (191).

More detailed ultrastructural analysis of human astrovirus serotype 2 grown in LLCMK2 cells in the presence of trypsin revealed particles with icosahedral symmetry and an array of spikes emanating from the surface (152). These particles had an external diameter on negatively stained preparations of 41 nm (including spikes). They did not display the starlike surface appearance characteristically found on fecally shed virus. The starlike morphology was inducible after alkaline treatment (pH 10), and the particles were found to disassemble rapidly when exposed to more alkaline solutions (pH 10.5).

Purified preparations of cell culture–adapted human astrovirus serotype 1 [Oxford strain from Kurtz and Lee (87)] particles evaluated by electron cryomicroscopy and image analysis demonstrated a rippled solid capsid shell (330 Å in diameter) decorated with 30 dimeric spikes extending 50 Å from the surface (Fig. 1B) (193).

Astrovirus particles were shown to be stable at pH 3 and resistant to chloroform, a variety of detergents (nonionic, anionic, and zwitterionic) and lipid solvents (88). Human astrovirus retains activity after 5, but not 10, minutes at 60°C. Viral particles appear to be stable when stored at ultralow temperatures (–70°C to –85°C) for 6 to 10 years (185), but they may be disrupted with repeated freezing and thawing.

A range of buoyant densities in cesium chloride (CsCl) was reported for human and animal astroviruses. Intact human astrovirus particles typically band at densities of 1.35 to 1.37 g/mL (26,88,114,179). Buoyant densities of 1.39 to 1.40 were observed for astrovirus particles from an outbreak of gastroenteritis at a school in Japan (78) and from a volunteer inoculated with astrovirus derived from an outbreak of gastroenteritis at a convalescent home in California (121).

Human astrovirus propagated in CaCo-2 cells produced two visible light-scattering bands at buoyant densities of 1.35 and 1.32 g/mL (179). The polypeptide profiles of both bands were identical, suggesting that the higher-density band very likely contained complete viral particles and the lower-density band empty virions. This speculation was not proven, as the RNA content of each of these fractions was not assessed. Evaluation of another human astrovirus serotype 1, propagated in LLCMK2 cells, yielded similar results (114). Fractions from the CsCl gradient were tested for the presence of astrovirus antigen by EIA (58,59), and two peaks were identified. The major peak at density 1.37 g/mL was demonstrated to contain RNA that hybridized with probes from two different regions of the astrovirus genome. Nucleic acid extracts from the minor peak at density 1.33 g/mL did not hybridize with either probe, suggesting that astrovirus

particles devoid of viral nucleic acid were present in this fraction. In addition, these results suggest that the lower-density band was not composed of encapsidated subgenomic RNA (see later), as has been described for the calicivirus rabbit hemorrhagic disease virus (RHDV) (119).

The buoyant density of canine (184) and porcine (159) astroviruses was found to be in the range of 1.34 to 1.35 g/mL. The buoyant density of ovine astrovirus from two sources, intraluminal contents and infected intestinal tissues, was determined as well (55). Viral aggregates in intraluminal contents banded at 1.39 g/mL, whereas single particles banded at 1.365 g/mL. Most of the viral RNA was observed in the higher-density fraction. Intracytoplasmic ovine astrovirus obtained from infected intestinal tissues was found in fractions with densities of 1.38 to 1.40 g/mL.

Although most of the data regarding the buoyant density of astrovirus particles were collected using CsCl density gradients, it was observed that separation of fecal SRVs (including astrovirus) in this medium and further concentration by pelleting disrupts virus morphology (7). Highly purified viral particles, requiring a CsCl purification step, are needed for evaluation by electron cryomicroscopy. The inclusion of divalent cations (Ca^{2+} and Mg^{2+}) in the purification solutions was found to stabilize viral particles undergoing isopycnic centrifugation in CsCl (193). An alternative gradient used to purify enveloped viruses and subviral structures (27,139) was proposed by Ashley and Caul (7). Potassium tartrate progressively diluted with glycerol yielded a positive-density, negative-viscosity gradient in which virus morphology was maintained and from which viral particles could be pelleted without deleterious effects. Peak density for astroviruses in this medium was observed to be 1.32 g/mL.

Genome Composition, Molecular Biology, and Viral Proteins

Astroviruses have a plus-sense, single-stranded RNA genome that is approximately 6,800 nucleotides (nt) in length, excluding the poly(A) tail at the 3'-end. RNA extracted from virions is infectious (41). Infectious RNA also can be transcribed from a full-length cDNA clone of human astrovirus serotype 1 (AVIC) (41). BHK cells, previously thought not infectable with astrovirus (94), were shown to support astrovirus replication and maturation when transfected with RNA extracted from virions or transcribed from AVIC. Astrovirus produced in these BHK cells can infect monolayers of CaCo-2 cells in trypsin-containing media.

Complete nucleotide sequences of five strains of human astrovirus are currently available: (a) the serotype 1 Oxford reference strain propagated in LLCMK2 cells (99), (b) a serotype 1 Newcastle strain isolated and maintained in CaCo-2 cells (176,177 and 178), (c) the serotype 2 Oxford reference strain propagated in LLCMK2 cells (67), (d) a serotype 3 strain (GenBank accession AF141381), and (e) a serotype 8 strain (GenBank accession AF260508). Genomic sequences also are available for avian astroviruses [avian nephritis virus (64) and turkey astrovirus (77) and sheep astrovirus (GenBank accession NC002469)].

During infection of susceptible cells, it was noted that both the full genomic (6.8 kb) and a subgenomic (2.4 kb) RNA are produced (114,132). The viral genome comprises three ORFs. The two ORFs at the 5'-end of the genome, designated ORF-1a and ORF-1b by the International Committee on the Taxonomy of Viruses (129), encode nonstructural proteins. The third ORF, designated ORF-2, encodes a structural protein and is found at the 3'-end of the genome (99,131,178). This ORF is common to both the genomic and the subgenomic RNA. Sequences of the capsid-encoding ORF-2 are available in GenBank for human serotypes 1 through 6 and 8, and for feline, porcine, chicken, and turkey astroviruses.

Sequence Analysis

A schematic representation of the astrovirus genome is shown in Figure 2. A 5'-untranslated region of 80 (serotype 8), 82 (serotype 2), or 85 (serotypes 1 and 3) nt precedes ORF-1a. ORF-1a is 2,763 nt in length for the Oxford reference serotypes 1 and 2 that were first isolated in HEK cells, and it is 45 nt longer in the Newcastle serotype 1 strain that was directly isolated in CaCo-2 cells. ORF-1a of the human astrovirus serotype 3 is 2,784 nt (GenBank accession AF141381) and that of serotype 8 is 2,766 nt in length. A 73-nt overlap exists between ORF-1a and ORF-1b in astrovirus serotype 1 and 2 strains, but it is 61 nt for serotype 3, and 70 for serotype 8. ORF-1b is 1,560 nt in length for serotypes 1 and 2 strains, 1,557 nt for serotype 8, and 1,548 nt for serotype 3. The overlap between the stop codon of ORF-1b and the start codon of ORF-2 is 8 nt for serotypes 1 through 3 and 8. ORF-2 varies in length among human astroviruses from 2,316 nt for a serotype 4 strain, to 2,391 nt in the Oxford serotype 2 strain (67). An 80-nt (serotype 1 strains), 82-nt (serotypes 2 and 3), or 85-nt (serotype 8) 3'-untranslated region is found between ORF-2 and the poly(A) tail at the extreme 3'-end of the genome.

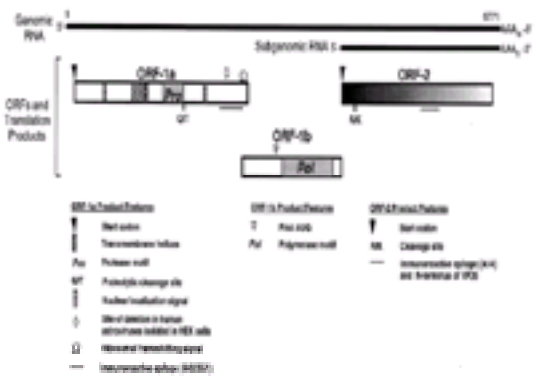

FIG. 2. Genome organization of human astrovirus serotype 1. Genomic and subgenomic RNA are indicated in the upper panel. ORFs and translation products are depicted in the middle panel. Features shown for each ORF are summarized in the lower panel. The ORF-1a product features transmembrane helices (*diagonally shaded boxes*), protease motif (*PRO, shaded*), a putative protease-dependent cleavage site (*Q/T*) (73), a nuclear localization signal (*box with horizontal lines*), a ribosomal frameshifting signal (W), and an immunoreactive epitope [A43/35/1 (114), *thin horizontal line*). The site at which a 45-nt (15-amino-acid) deletion occurs in human astroviruses isolated in HEK cells is indicated (à) (174). In

ORF-1b, the first in-frame AUG is found at the *open arrowhead.* ORF-1b encodes an RNA-dependent RNA polymerase motif (POL, shaded). ORF-2 encodes a capsid protein precursor that appears to be cleaved at amino acid 70/71 (*R/K*) before capsid assembly (10). The N-terminal half of the ORF-2 product is highly conserved (*darker shading*) in contrast to the majority of the C-terminal half, which is quite variable (*lighter shading*) among human astrovirus strains and serotypes. Immunoreactive epitope A14 (114) overlaps the N-terminus of capsid protein VP26 as shown (*thin horizontal line*). VP26 is recognized by a neutralizing monoclonal antibody (154).

The length of the astrovirus 3'-untranslated region and its predicted secondary structure are reminiscent of certain picornaviruses (177), but direct sequence comparisons disclose minimal sequence identity between these two viral groups. In a separate study, the terminal 19 nt of ORF-2 and the adjacent 3'-untranslated region were found to be highly conserved among all 8 serotypes (128). Of note, similarities in sequence and folding of the 3'-untranslated region of human, sheep, pig, and turkey astroviruses, avian infectious bronchitis virus (a coronavirus), and equine rhinovirus serotype 2 (a picornavirus) were observed (68); the investigators suggested that this homology arose from recombination events.

The polypeptide sequences of ORFs 1a and 1b indicate that nonstructural proteins are likely to be encoded by these ORFs. The polypeptide encoded by ORF-1a is 920 (67,99), 921, 927, and 935 (176) amino acids in length for serotypes 1, 8, 3, and 2, respectively, and it contains a viral serine protease motif. The protease motif of astrovirus has features consistent with chymotrypsin-like proteases of other plus-stranded RNA viruses, including RHDV and feline calicivirus (67). An important difference found when comparing the astrovirus protease motif with that of the caliciviruses is the substitution of a serine for a cysteine at the third catalytic amino acid residue. This substitution is seen in several viruses, sobemoviruses, luteoviruses, and arteriviruses, but the putative astrovirus protease bears stronger overall resemblance to the calicivirus protease.

Sequence analysis also demonstrates a bipartite nuclear localization signal encoded downstream of the viral protease motif in ORF-1a (67,176). Recent studies of human astrovirus serotype 1 have indicated that this signal is functional and directs ORF-1a-encoded proteins to the nucleus (175). Of note, bovine astrovirus proteins were found previously in the nucleus of infected cells by immunofluorescence (6). Further investigation is required to determine the significance of nuclear localization in the astrovirus life cycle.

Analysis of ORF-1a sequences of reference serotypes 1 to 7 indicates two distinct genogroups that correlate with serotype (13). Types 1 to 5 (13) and 8 (16) are found in one genogroup (A), and types 6 and 7 fall into a separate genogroup (B). These phylogenetic associations for ORF-1a sequence are different from that observed for ORF-1b or ORF-2, in which nearly equidistant clustering of serotypes is found with unrooted phylogenetic trees. Whether these differences are attributable to recombination remains to be studied.

ORF-1b encodes a polypeptide of 515 (serotype 3), 518 (serotype 8), or 519 amino acids (serotypes 1 and 2) (67,99,176) that contains motifs suggestive of an RNA-dependent RNA polymerase. The polymerase motifs are highly conserved among astrovirus serotypes 1 to 8 (13,99). In one analysis, serotypes 1 and 2 appear to be the most closely related, and serotypes 4 and 5 are the least related in this region (99). The astrovirus polymerase motifs are most similar to those of plant viruses Bymovirus and Potyvirus, and they can be aligned with other polymerases of Koonin's supergroup I (79), which includes picornaviruses, caliciviruses, and certain plant viruses (67). It has been suggested that the similarities between astrovirus and plant viruses in this region do not necessarily indicate a common origin (67).

Regions that may encode an RNA helicase, a methyltransferase, or a papain-like protease have not been identified in the astrovirus sequences that are currently available. It is unusual for a plus-strand RNA virus with a genome length of more than 6,000 nt to lack a helicase domain (67,71). It has been suggested that astrovirus encodes a VPg, based on the absence of a methyltransferase-encoding region and the similarity of its RNA-dependent RNA polymerase with primarily VPg-containing viruses. A convincing VPg domain has not been identified, but it may be located between the putative protease motif and upstream transmembrane alpha-helices, where a serine at amino acid position 420 that could link the VPg to genomic RNA is found. ORF-1a also encodes an immunoreactive epitope (amino acids 757 to 899) identified by antisera produced to purified viral particles, but its significance is not known.

The greatest sequence variability is found in ORF-2, the ORF that encodes a viral structural protein that varies in length from 782 amino acids for serotype 8 (assuming translation begins at the third in-frame methionine, as for serotype 1), to 786 amino acids (176) to 787 amino acids (99) for serotype 1, to 796 amino acids (67) for serotype 2, to 794 amino acids for serotype 3 (see later). Complete capsid sequences are also available for feline (GenBank accession AF056197; 816 amino acids), porcine (AB037272; 776 amino acids), sheep (NC002469; 762 amino acids), turkey (724 amino acids) (77), and chicken (683 amino acids) (64) astroviruses. Alignments of capsid polypeptide sequences indicates a high degree of conservation of the N-terminal 415 (or so) amino acids among the human serotypes (182). In this region, the amino acid sequence for the feline, porcine, and sheep strains share certain conserved stretches of amino acid residues with human strains and can be aligned with minimal gaps, whereas the avian strains vary considerably from the human and other mammalian strains. Beyond this region, there is considerable variability in sequence among the serotypes, requiring gaps to be introduced for optimal alignment. The C-terminal eight amino acids are highly conserved, particularly among the human strains.

Translation Strategies

The mechanism of ORF-1b translation is not readily apparent by routine sequence analysis. The first AUG codon occurs over 400 nt into ORF-1b (shown in Fig. 2) and is in a suboptimal context for initiation according to Kozak's rules (82). The overlap region between ORF-1a and ORF-1b is highly conserved among serotypes and displays a heptameric shift sequence (A AAA AAC) and the potential for the formation of a downstream stem-loop structure with possible pseudoknot

that strongly suggests that a (–1) ribosomal frameshifting mechanism is involved in ORF-1b translation (67,99,176). These elements resemble those required for frameshifting events that are used to translate the retrovirus protease and polymerase (28,65,66,187), and coronavirus polymerase (25). The astrovirus heptameric shift sequence and stem-loop structure were shown to be critical for ribosomal frameshifting to occur (101,102,110). However, unlike retroviruses and coronavirus, the potential pseudoknot-forming sequences were not required for frameshifting (101,102). Nucleotide sequences that can be aligned with the shifty heptamer and stem-loop motifs of human astrovirus also were identified in avian astroviruses (64,77).

As noted, ORF-2 is found in both the genomic and the subgenomic RNA. It has been suggested that the role of the subgenomic RNA is the production of viral structural proteins (131,132). Other viruses, such as the enveloped alphaviruses, use their subgenomic RNA to synthesize large amounts of structural proteins that are used to assemble intact progeny viruses efficiently (155). Proof to support such a role of the astrovirus subgenomic RNA was provided by expression of ORF-2 in an *in vitro* transcription and translation system, followed by immunoprecipitation of the 87-kd product by antibodies produced to purified astrovirus particles (99). This protein is the precursor to the smaller, 20- to 40-kd, structural proteins that have been identified in human and animal astroviruses (10,15,99,132). Production of monoclonal antibodies directed at a neutralization epitope in the 26-kd fragment of the 87-kd protein corroborates these data (11,154). The exact length of the 5' noncoding region of the subgenomic RNA has not been resolved. The length of this region in astrovirus serotype 1 [Newcastle (178)] is reported to be 3 to 19 nt longer than the comparable region in astrovirus serotype 2 [Oxford (131)].

In summary, the general organization of the astrovirus genome places the ORFs encoding the nonstructural proteins (ORF-1a and ORF-1b) at the 5' end and the ORF encoding a structural protein (ORF-2) at the 3' end. This arrangement resembles the genome organization of caliciviruses (165). However, several features serve to distinguish astroviruses from caliciviruses. These include differences in the size, number, and possible processing of structural proteins, the lack of a helicase domain in astroviruses, the use of ribosomal frameshifting to translate the RNA-dependent RNA polymerase, and distinctive morphologic features described previously. Basic features that distinguish astroviruses from picornaviruses include differences in genome organization, lack of a helicase domain, and use of translational strategies such as ribosomal frameshifting and subgenomic RNA. Astroviruses appear to incorporate specific features of a number of different viruses without strictly resembling any one group and therefore are assigned to a separate viral family, the *Astroviridae* (129).

Nonstructural Proteins

Information regarding processing of the nonstructural proteins is limited. A preliminary report by Gibson et al. (42) noted a “lack of processing” *in vitro* of ORF-1a and ORF-1a/1b translation products containing the 3C-like serine protease motif. By contrast, Willcocks et al. (175) found no full-length (101 kd) ORF-1a product, but they detected proteins of 74, 34, 20, 6.5, and 5.5 kd in astrovirus-infected CaCo-2 cells by Western blot analysis with antisera specific to the C-terminal 298 amino acids of the ORF-1a product. Using antisera to a recombinant ORF-1b-Baculovirus protein, products of 160 kd (most likely corresponding to the ORF-1a/1b fusion product) and 59 kd (ORF-1b product) were detected, suggesting that cleavage occurs near the boundary between ORF-1a and ORF-1b.

In other studies (73), ORF-1a was transcribed and translated in a cell-free system and products were immunoprecipitated by antibodies specific to N- and C-terminal epitopes. ORF-1a products identified were the full-length 101-kd protein (p101), an N-terminal cleavage product (p64), and a C-terminal cleavage product (p38). Mutation and deletion analyses indicated the important role of the catalytic triad of the viral 3C-like serine protease (Ser-551, Asp-489, and His-461) in processing of p101.

Structural Proteins

The polypeptide profiles of ovine, porcine, and several serotypes of human astrovirus have been examined. These studies did not fully concur on the size and number of structural proteins that comprise astrovirus particles. Examination of astrovirus particles shed by experimentally infected lambs revealed two polypeptides that migrated at about 33 kd (55). For porcine astrovirus, five proteins that range in mass from 13 to 39 kd have been described (159). Most of the studies of human astrovirus polypeptide composition were performed on cell culture–adapted viruses. Four proteins (36.5 kd, 34 kd, 33 kd, and 32 kd) were identified in astrovirus serotype 4 that was propagated in cell culture in the presence of trypsin (88). It was postulated that the faint 36.5-kd band may represent a precursor protein that undergoes subsequent processing, in a manner similar to the VP0 protein of enterovirus (157), to yield one of the more abundant, smaller proteins. Two additional proteins of 24 kd and 5.2 kd were found by Kurtz (84) in cells infected with astrovirus serotype 1. In contrast, CaCo-2 cells infected with astrovirus serotype 1 yielded three astrovirus-specific polypeptides (33.5 kd, 31.5 kd, and 24 kd), as determined by reactivity with astrovirus serotype 1–specific antiserum (179). In some preparations, a 27-kd polypeptide was also noted, and it was hypothesized that this may be derived from one of the larger proteins by proteolytic digestion. In studies of human serotype 5 isolated from volunteer fecal specimens, a single 30-kd structural protein was immunoprecipitated (121).

When protein synthesis was studied in astrovirus-infected LLCMK2 cells in the absence of trypsin, a single, approximately 90-kd protein was immunoprecipitated from infected cell lysates with hyperimmune antiserum to purified human astrovirus serotype 2 (132). Pretreatment of the lysates with trypsin resulted in immunoprecipitation of three proteins, a predominant 29-kd protein as well as a 31-kd and a 20-kd protein. These results suggested that the (about) 90-kd protein may be proteolytically cleaved to yield at least three smaller proteins. In cells infected with human astrovirus serotype 2, grown in trypsin-containing media, Sanchez-Fauquier et al. (154) used a neutralizing monoclonal antibody (PL-2) to determine that an 86-kd protein (P86) is the precursor to VP26, a major component of viral particles. VP29, a minor component of virions and the product of alternative processing of P86, and intermediate proteins ranging from P74 to P35 also were identified in infected cells by PL-2. Although these results suggest that processing of P86 to P26 and/or P29 occurs within infected cells, the presence of trypsin in the medium impairs optimal interpretation of the

data.

Belliot et al. (15) examined the capsid protein composition of partially purified preparations of astrovirus reference strains (serotypes 1 to 7) grown in cell culture. Human astrovirus reference types 1 to 4 consisted of three proteins, P1 (about 33 kd), P2 (about 33 kd), and P3 (25 to 28 kd, depending on serotype), that were immunoprecipitated with homologous rabbit antisera. For reference types 5 to 7, three infection-specific proteins were observed in radiolabeled samples, but only P2 and P3 reacted with type-specific rabbit serum. N-terminal sequencing of the P3 protein of serotype 1 virus indicated it is equivalent to the VP26 protein of serotype 2 (154). The P2 protein appears to contain at least one group-reactive epitope.

Recent studies by Bass and Qiu (10) suggest that assembly of astrovirus particles requires cleavage of 70 N-terminal amino acids of the 87-kd capsid precursor protein. The resultant 79-kd protein forms the viral capsid within astrovirus-infected CaCo-2 cells grown in the absence of trypsin. These particles are virtually noninfectious, but they can be made infectious with trypsin treatment, which also cleaves the 79-kd protein to three smaller proteins (34 kd, 29 kd, and 26 kd).

Serotypes of Human Astrovirus

Initially, five serotypes of human astrovirus were identified by immunofluorescence, neutralization, and IEM in the 1980s (63,87,95). Each of these reference strains was isolated from natural infections in the United Kingdom and adapted to growth in cell culture (94). Serotypes 6 and 7 originally were identified in the United Kingdom in 1989 and 1991 to 1992, respectively (33,96). Astrovirus serotypes 6 and 7 were indistinguishable from serotypes 1 to 5 by EM, cultivated in CaCo-2 cells in media supplemented with trypsin, and recognized by the group-reactive monoclonal antibody (see later). An eighth serotype was identified by immunofluorescence assay (16). Capsid sequence for the ORF-2 product of a serotype 8 virus is available (GenBank accession no. Z66541).

A limited number of serotyping studies using various methods were done, but the reference reagents used in these studies were all provided by the Oxford group (87,95). In general, astrovirus serotype 1 is the most common type found (40,70,87,88,96,133,135,137,138,143,153,186), but the predominant serotype may vary depending on location (52). The community-acquired astroviruses were monitored in Oxford, United Kingdom, between 1975 and 1987 (88). In this population, 72% of the astroviruses encountered were serotype 1. Serotypes 2, 3, 4, and 5 each accounted for 6% to 8% of the astrovirus strains. A more recent survey by Lee and Kurtz (96) examined the astrovirus serotypes found in the Oxford region between 1976 and 1992. Once again, serotype 1 was found most frequently and accounted for an average of 65% of the cases. If the astrovirus-positive cases were divided between those from pediatric wards and those submitted by community physicians, serotype 1 strains were found in 77% and 60%, respectively. Serotypes 2 to 7 accounted for 11%, 9%, 11%, 2%, 0.3%, and 0.7%, respectively. In all the years studied, there was only one year, 1991, in which the number of serotype 2 cases exceeded serotype 1 cases. A biennial peak of serotype 1 prevalence was noted over the last 5 years of the survey. A third study from the United Kingdom found a similar predominance of astrovirus serotype 1 (186). Serotype 1 was found by IEM in 55% of 40 astrovirus-containing stools. By contrast, a longitudinal study of diarrhea in a cohort of Mexican children found that astrovirus serotype 2 was most common (35%) and serotypes 1 and 5 were least common (4% each) (52).

Antiserum derived from animals hyperimmunized with each of the human astrovirus serotypes 1 to 7 appears to behave in a serotype-specific manner in immunofluorescence tests and IEM (58,88,96). In addition, rabbit polyclonal antiserum neutralizes astrovirus in a serotype-specific manner in a plaque assay (58). All eight serotypes of human astrovirus are recognized by a single monoclonal antibody produced by Herrmann et al. (59,96). This monoclonal antibody, which does not neutralize virus, is directed at a viral structural protein (70), most likely an epitope of the highly conserved N-terminal half of the ORF-2 product (16, and Geigenmüller and Matsui, unpublished data, 2000). An EIA in which the monoclonal antibody serves as a capture antibody and polyclonal antiserum is used as a detector antibody has been developed (59) and employed in large-scale seroepidemiologic studies (described later). A typing enzyme immunoassay (TYPE-EIA) that uses serotype-specific reference antisera for capture and the group-reactive monoclonal antibody as detector has been developed to assess the antigenic types of astroviruses found in clinical samples (138). Alternatively, molecular methods for genotyping clinical isolates by reverse transcriptase polymerase chain reaction (RT-PCR) with primers from the more conserved N- or C-terminal regions of ORF-2 may be used (113,138). A high concordance between results of genotyping and serotyping was observed. A rapid latex agglutination test to detect astrovirus serotypes 1 to 4 also was developed, but it has not yet been extensively tested (5).

Serotypes of Animal Astrovirus

Human, lamb, piglet, red deer, kitten, and calf astroviruses were shown to be antigenically unrelated to one another (54,95,171,191). Bovine astroviruses are the only nonhuman astroviruses that have been analyzed for serotypic variation. Three strains of bovine astrovirus have been described. The first reported (called UK) was found in the feces of calves with diarrhea in the United Kingdom in 1978 (189). Two U.S. strains of bovine astrovirus (US1 and US2) were described as well. The three isolates shared common antigens that were detectable by immunofluorescence (190). Antisera to each of the three bovine astroviruses did not cross-neutralize either the US1 or the US2 astrovirus, indicating that there are at least two serotypes of bovine astrovirus. Whether a third serotype exists can be determined only if the antisera are tested for cross-neutralization against the UK isolate.

Species Specificity of Infection

In all cases where antigenic relationships among astroviruses of different animal species have been examined, there has been no evidence for cross-reactivity between species (23,54,95,171,191). Thus, as an example, convalescent sera from lambs infected with astroviruses react only with lamb astrovirus and will not recognize calf or piglet astrovirus. In general, infection of animals and cell culture is also species specific. Astrovirus isolated from red deer has been shown to infect BEK cells, but serial propagation was not achievable (171). Furthermore, convalescent sera from red deer did not

recognize lamb astrovirus antigens in infected lamb intestinal tissue or bovine astrovirus propagated in bovine cell culture.

PATHOGENESIS AND PATHOLOGY

Transmission

Astroviruses can be transmitted through the fecal–oral route, as shown by human volunteer studies (89,121). In these studies, however, few of the adult volunteers developed a diarrheal illness with fecal shedding of virus and/or production of antibody to the virus in the inoculum. Person-to-person spread was deemed responsible for a protracted outbreak of gastroenteritis in Marin County, California, in 1978 (142). Although astrovirus diarrhea does not usually develop in adults, it was observed that adult caregivers of infected children, including parents, teachers, and medical personnel, did become ill (3,85,88,140). An outbreak among military troops was also described (14). This suggested that the ill adults were exposed to a larger dose of astrovirus or through a variable route (e.g., fomites, contaminated food or water). This pattern also was found with rotavirus illness (62). In addition, astrovirus was detected in water from an area where an outbreak of astrovirus gastroenteritis occurred (147), and 93% of surfers in the United Kingdom had antibodies to human astrovirus serotype 4, compared to 22% of age-matched controls (134). A study of sewage and environmental samples from a water treatment facility in the United Kingdom failed to detect astrovirus RNA by RT-PCR (37). A case of astrovirus gastroenteritis was diagnosed at the end of the sampling period, but it occurred outside the surveyed area. Using an integrated cell culture RT-PCR method coupled with nested PCR to detect enteric viruses in surface water samples, astrovirus was identified in 15 of 29 samples and eight samples contained infectious virus (29). In Japan, astrovirus was found in naturally grown oysters (15 of 112 samples) most often during winter months. For comparison, SRSVs (genogroup II) were detected in 28 and hepatitis A virus in two of the samples (74).

Viral Pathogenesis

Pathogenesis of astrovirus infections in humans has not been well studied. A brief report of two children with diarrhea correlated fecal shedding of astrovirus with identification of astrovirus particles in intestinal epithelial cells, suggesting that virus replication occurs in intestinal tissue in humans (146). Astrovirus particles in the biopsy specimen were localized to the epithelial cells in the lower regions of the villus in a patient with sucrase isomaltase deficiency and in the “exposed surface epithelium” of a second patient who had a severe enteropathy caused by sensitivity to cow's milk formula. The significance of astrovirus infection was difficult to assess in these patients because of their underlying gastrointestinal problems and fecal shedding of *E. coli* 086 or rotavirus prior to astrovirus. Studies on human volunteers have not examined the histologic effects of human astrovirus–related diarrhea (89,121).

Viral pathogenesis has been studied more extensively in animals. Classic experiments in which gnotobiotic lambs were administered an outbreak strain of ovine astrovirus revealed that mild transient diarrhea was caused by infection of mature enterocytes in the apical two thirds of villi and subepithelial macrophages, followed by transient villus atrophy and crypt hypertrophy. Infected lambs developed loose stools, then diarrhea on days 2 to 4, and they shed astrovirus on days 2 to 9 after inoculation (161,162). Infected intestinal cells were detected by immunofluorescence between 14 and 70 hours after inoculation. The largest number of infected cells was found in the incubation period from 14 to 38 hours after inoculation (161). During this time, virus particles were observed by EM in aggregates along the microvilli or in lysosomes and autophagic vacuoles. In some enterocytes, indirect evidence of infection, including intracytoplasmic inclusions, vacuoles, and degenerate nuclei, was seen (47). Histologic features of astrovirus infection resolved by the fifth day after inoculation (161).

In contrast to lamb astroviruses that cause symptomatic infection, bovine astroviruses are considered nonpathogenic, as inoculation of gnotobiotic calves with bovine astrovirus alone does not result in diarrhea (24,191). Bovine astrovirus appeared to cause infection by a different mechanism—namely, the infection of M cells and absorptive enterocytes overlying the dome villi of Peyer's patches in the small bowel (53,191). Infected cells were sloughed and replaced by cuboidal cells, and they formed an exudate with inflammatory mononuclear and eosinophilic cells above the dome villi. The dome epithelium contained similar inflammatory cells and was observed to fuse at times with the epithelium of an adjacent villus. The lamina propria was infiltrated with neutrophils and contained cells with degenerate nuclei. Lymphoid cell depletion was noted in the central region of germinal centers beneath infected dome villi.

Turkey poults inoculated orally with turkey astrovirus developed postinfection diarrhea on day 2 that persisted through day 10 (169). In the intestines, mild crypt hyperplasia was observed by light microscopy in the proximal jejunum on postinfection day 1, in the distal jejunum and ileum on day 3, and in the duodenum on day 5. Intracytoplasmic aggregates of astrovirus were found by EM in enterocytes on the sides and base of villi in the ileum and distal jejunum on day 3. Specific maltase activity, a reflection of intestinal disaccharidase activity, was monitored in other studies (170). During acute astrovirus infection (days 3 to 7 after infection), maltase activity decreased transiently and significantly, compared to controls, and was associated with disaccharide malabsorption, maldigestion, and osmotic diarrhea. Maltase activity returned to normal with resolution of symptoms.

A strain of turkey astrovirus (TAstV) also was isolated from birds with poult enteritis mortality syndrome (PEMS), an emerging infectious disease of young turkeys in which enteritis, growth depression, lymphoid atrophy and immunosuppression, and high rates of mortality are prominent features (77,156). TAstV was observed in the intestines, thymus, and bursa of affected turkeys. PEMS-like illness was induced in naive turkey poults who were given independently filtrates of intestine and thymus from infected poults (156).

Studies of Viral Pathogenesis in Cell Culture

These observations suggest that astroviruses are likely to enter cells through the apical surface. In polarized CaCo-2 cells, however, human astroviruses isolated from wild-type infections appear to enter through the basolateral surface (179). This result may be an artifact of the cell culture system and may not reflect the arrangement of astrovirus receptors

in differentiated intestinal epithelial cells *in vivo* (180).

The mechanism by which astroviruses enter cells was studied using Graham 293 cells, a transformed line of primary HEK cells (36). The effects on astrovirus infection of lysosomotropic agents (ammonium chloride, methylamine, and dansylcadaverine) and the ionophore monensin were investigated. All of the chemicals, used at nontoxic levels, inhibited viral infection. These results imply that a functional endocytic pathway is necessary for delivery of infectious astrovirus into the cytoplasm. This impression was supported by ultrastructural analysis, which showed viral particles being internalized by invagination of the cell membrane at coated pits approximately 10 minutes after attachment to the cell surface. Other studies have shown that flavanoids also inhibit astrovirus antigen synthesis in LLCMK2 cells in a dose-dependent fashion (166). Flavanoids have been shown to inhibit early steps in picornavirus replication, but their precise mechanism of action is not known.

A system to study bovine astrovirus infection in cell culture was developed as well. Bovine astrovirus was propagated in primary NBK cells in serum-free media containing 50 µg/mL of trypsin (6), and the expression of viral antigens was followed by fluorescent antibody probes. In a typical infection, less than 2% of the cells were infected, but occasionally infection could be detected in 10% to 20% of the cells. Immunofluorescence was first detected at 7 hours after infection in the cytoplasm of infected cells. Shortly thereafter, several brilliant immunofluorescent granules were identified in the nucleus, in a pattern suggesting nucleolar involvement. This was followed by dense immunofluorescent granules appearing in the perinuclear region and diffuse staining of the cytoplasm. The role of the nuclei and/or nucleoli in astrovirus replication is not known, but actinomycin D, an inhibitor of DNA transcription, did not inhibit astrovirus infection in this system.

CLINICAL FEATURES

Characteristics of Human Illness

Gastroenteritis caused by human astrovirus infection primarily affects young children, many under 6 months of age (135), throughout the world. Although its medical importance has been questioned in the past, studies demonstrated that it is the second most common viral agent found in young children with diarrhea evaluated in outpatient settings (17,37). A population-based cohort study from Egypt indicated that in children under the age of 3 years, the overall incidence of diarrhea caused by astrovirus was the same as for that caused by rotavirus (135). Astrovirus serotype 1 appears to be the most prevalent strain (88,96,143,186). Severe infections have been noted in young adults infected with astrovirus serotype 4 (33). Astrovirus infections have been recognized in elderly, institutionalized patients (48,100,115,186) and immunocompromised individuals (see later).

Adult human volunteer studies (see later) established the incubation period to be 3 to 4 days (89,121). A shorter incubation period of 24 to 36 hours was calculated from the secondary spread characteristics during an outbreak of gastroenteritis in a Japanese kindergarten (78). Human astrovirus infection induces a mild, watery diarrhea that typically lasts for 2 to 3 days, associated with vomiting, fever, anorexia, abdominal pain, and various constitutional symptoms that last for less than 4 days (21,49,85,88,92,144). Protracted diarrhea and viral shedding was observed in some studies (20,30,88). In children, it may be difficult to distinguish diarrhea caused by astrovirus from that caused by rotavirus on clinical grounds alone (32,60,88). In general, astrovirus diarrhea is milder and does not lead to significant dehydration or hospitalization (52,60,91,98,116,125,136,144). However, studies of hospitalized children found astrovirus to be the second most common viral pathogen, after rotavirus (40,143, and R. I. Glass, personal communication, 2000). Severe dehydration was an associated symptom in 17% of rural Egyptian children with astrovirus gastroenteritis (135). Improved assays for astrovirus detection have helped to identify the small subgroup of patients with astrovirus infection severe enough to require hospitalization (143,149,158). The role of astrovirus in persistent diarrhea remains to be established (172). Prolonged lactose intolerance and, less commonly, sensitivity to cow's milk have been a problem for some patients (38,91,136). Deaths associated with astrovirus infection are extremely rare but have been reported (115,160).

Volunteer Studies

Adult volunteer studies facilitated assessment of astrovirus pathogenicity. In one study, fecal extracts containing astrovirus from an infected child were administered to eight adult volunteers in the United Kingdom (89). It was established that these volunteers had little or no detectable astrovirus-specific antibody at entry. Only one of the volunteers developed overt illness, characterized by vomiting on days 3 and 4, constitutional symptoms on days 4 to 6, and copious, watery diarrhea on day 6 with shedding of large numbers of viral particles. Symptoms resolved rapidly, and the volunteer was completely well on day 7. One other volunteer had constitutional symptoms and mild abdominal discomfort but no vomiting or diarrhea. An inoculum was prepared from the fecal specimen of the overtly ill volunteer and administered to nine others, five of whom developed mild symptoms without vomiting or diarrhea. Of 17 volunteers in this two-phase study, viral shedding was observed in four and appeared to be proportional to the severity of the illness. Seroconversion was demonstrated in 13 of 16 by immunofluorescence testing, and in 10 of 16 by IEM.

Astrovirus serotype 5 from an outbreak of gastroenteritis at a nursing home in Marin County, California, was administered to 19 adult volunteers in the United States (121). Because none of the first 17 volunteers became ill after receiving a 1-mL inoculum, a 20-mL inoculum was given to the last two volunteers. One of the two developed nausea, vomiting, diarrhea, and malaise, beginning 5 days after infection, and symptoms lasted for 36 to 48 hours. Large numbers of 27-nm virus particles were detected in the feces of this individual by IEM. This volunteer developed an antibody response to not only the Marin County virus, but to all of the five available reference strains of astrovirus (serotypes 1 to 5). A total of nine volunteers developed a serologic response, as documented by radioimmunoassay and/or biotin–avidin immunoassay. In general, those who had negligible preinfection antibody were more likely to develop an immune response to the virus challenge. These studies indicate that astrovirus, unlike Norwalk virus, is of relatively low pathogenicity in adults.

Disease Spectrum in Animals

Astrovirus has been identified in association with diarrhea in several animal species. Direct correlation of astrovirus identified in stool to disease in animals was complicated by the fact that multiple viruses may be found concurrently in diarrheic feces. In most of the animals listed previously, astroviruses were separated from other viruses and shown to cause illness. However, attenuated illness was observed when astrovirus alone was administered to pigs (159) and cats (54), and bovine astrovirus (189,190 and 191) does not appear to cause illness in gnotobiotic calves inoculated with this virus alone, as noted before. On the other hand, coinfection of gnotobiotic calves with bovine astrovirus and either Breda virus or rotavirus resulted in severe diarrhea and more severe infection of dome epithelial cells overlying jejunal and ileal Peyer's patches (191).

Astrovirus infection caused a rapidly fatal hepatitis in ducklings (46). In 1983, an epidemic of hepatitis among ducks less than 6 weeks of age occurred at a commercial farm. Mortality rates of up to 50% were observed. Histologic examination of the liver revealed widespread hepatitis with hepatocellular necrosis and bile duct hyperplasia. Viral particles with characteristic astrovirus features were found by EM in the liver and feces of these animals. In addition, a reovirus-like agent was isolated in embryonating duck eggs and tissue cultures, but inoculation of ducklings with this agent did not result in disease. By contrast, the subcutaneous injection of a 20% (w/v) suspension of infected livers into twenty 2- to 3-day-old ducklings recapitulated the hepatitis with all of the histologic features of the original outbreak and death within 2 to 4 days in 25% of the ducklings. Serial passage of this agent resulted in mortality rates of 25% to 55%. This agent was shown to be serologically distinct from duck virus hepatitis type I virus. These results strongly suggest that the astrovirus-like agent was responsible for disease in ducklings. This conclusion could not be confirmed, however, because the astrovirus-like agent could not be propagated in tissue culture.

Intestinal and extraintestinal illness was noted in other avian species. Cloning and sequencing of avian nephritis virus (64) confirmed that it is an astrovirus that infects chickens and causes growth retardation and acute interstitial nephritis, as its name suggests. TAstV (see the previous section, Pathogenesis) was found in the intestines, thymus, and bursa of turkey poults with PEMS, a highly pathogenic multisystem disease (77,156).

Immunity

The determinants of immunity to astrovirus are not well understood. Symptomatic astrovirus infection is found in primarily two age groups: young children and elderly, institutionalized patients. This biphasic distribution of symptomatic infection suggests that antibody acquired early in life provides protection from illness through most of one's adult life and that immunity to astrovirus wanes late in life. Volunteer studies indicated that those with detectable serum antibody to astrovirus did not develop diarrhea after virus challenge (89). In other studies, a volunteer infected with the Marin County virus, a serotype 5 astrovirus, developed both IgM and IgG responses to serotype 1 astrovirus. The anamnestic response observed in this volunteer was postulated to be the result of earlier infection with astrovirus serotype 1 and antigenic relatedness between these two serotypes. Studies of a birth cohort in Egypt provide evidence for homotypic, but not heterotypic, immunity (135). Of note, subsequent astrovirus infections were observed to be milder.

The normal mucosal immune system plays an important role in protecting individuals from repeated infections with human astrovirus (127). T cells that recognize astrovirus antigens in a human leukocyte antigen (HLA)-restricted manner were found to reside in the intestinal lamina propria of adults. These human astrovirus–specific CD4+ T cells produced helper T-cell subtype 1 (T_H1)-type cytokines, interferon gamma and tumor necrosis factor, when activated.

Role in Immunocompromised Hosts

It has been suggested that astrovirus plays an important role in causing diarrhea in immunocompromised patients. Astrovirus was found in 13 of 109 (12%) fecal specimens from 65 human immunodeficiency virus (HIV)-infected individuals with diarrhea, whereas only 2 of 113 (2%) fecal specimens from 65 HIV-infected patients without diarrhea (controls) were astrovirus positive (51). In this study, seven different types of viruses were identified in 35% of the patients with diarrhea. In most cases, single agents were isolated, and detection of bacteria and parasites were less common. A study from Argentina failed to demonstrate an association between astrovirus and diarrhea in HIV-infected patients (43). One study from Venezuela found viruses in 10% of patients with acquired immunodeficiency syndrome, and in 14% of those with symptoms. However, no astrovirus, Norwalk virus, or rotavirus was detected (45). In contrast, another study from Venezuela found that infection with astrovirus and enterovirus occurs frequently in HIV-infected children, but in general, enteric viruses do not cause the type of diarrhea that often plagues these children (103).

A study to evaluate the role of enteric pathogens in the diarrhea that develops among bone marrow transplant recipients found an enteric pathogen in 13% of cases (31). Among these, astrovirus was most frequently implicated, accounting for 7 of 150 episodes (4.7%) of diarrhea. Diarrhea due to astrovirus infection developed between hospital days 21 and 65 and had a duration of 2 to 31 days. In a separate case (88), a child who had undergone bone marrow transplantation for combined immunodeficiency developed chronic astrovirus diarrhea with viral shedding, which persisted until his death. No antibodies to astrovirus were detected in the patient's serum. These findings were confirmed by a larger investigation of an outbreak caused by human astrovirus serotype 1 in a pediatric bone marrow transplantation unit in the United Kingdom (34). When EM, EIA, and RT-PCR were compared, RT-PCR was found capable of detecting astrovirus shedding earlier in the course of infection and for a prolonged period of time after EM and EIA studies no longer detected virus. In a region of the capsid sequence that is markedly variable among serotypes, the outbreak virus shared 92.5% homology with a serotype 1 strain that was isolated in the United Kingdom 9 years prior (174). Persistent diarrhea with shedding of rotavirus for more than 450 days and concurrent infection with astrovirus for at least 225 days also has been reported in a child with congenital T-cell immunodeficiency (188).

The important role of CD4+ T cells is further suggested by case reports in which patients developed prolonged diarrhea caused by astrovirus after treatment with fludarabine, which is known to deplete CD4+ T cells (18). In one case (30), a middle-aged patient with chronic lymphocytic leukemia developed protracted diarrhea after the fifth course of chemotherapy with fludarabine monophosphate. On hospital admission, after 10 days of profuse diarrhea (20 stools per

day), the patient's CD4+ lymphocytes were noted to be disproportionately depressed (0.28×10^9/L) compared to the neutrophil count (1.48×10^9/L). The patient's diarrhea resolved after 6 days of supportive care in the hospital. Four weeks later, astrovirus antigen was detected in stool by EIA, but viral shedding was not detected by EM, and the patient was without symptoms. In another report (20), an elderly patient with Waldenstrom's macroglobulinemia and chronic peptic ulcer disease, intermittently treated with acid-suppressing medications, developed watery diarrhea containing large numbers of astrovirus particles, nausea, and vomiting 3 weeks after the third course of fludarabine. This patient's condition worsened while on symptomatic treatment for 3 weeks. The patient then received high-dose intravenous immunoglobulin (0.4 g/kg) for 4 days, with resolution of the diarrhea within 24 hours. Astrovirus remained detectable by EM in the stool 2 weeks (but not 4 weeks) later. The integrity of other T cells may also be important in modulating infection. Cubitt et al. (34) observed that production of CD16+ and CD8+ T cells in a patient, who shed virus for a long period of time, was correlated with decreased levels of viral shedding (detectable only by RT-PCR).

The role of immunoglobulin in treating immunocompromised patients requires further study. Timing, route of administration, patient age, and other factors may be important variables. Limited numbers of cases receiving this treatment have been reported and outcomes have varied. The elderly patient with Waldenstrom's macroglobulinemia (described previously) had a rapid and dramatic clinical response after receiving intravenous immunoglobulin (20). Similarly, a young adult bone marrow transplant recipient, who developed astrovirus diarrhea 7 days after transplantation, was successfully treated with intravenous and oral gammaglobulin (194). By contrast, oral administration of high-titer hyperimmune gammaglobulin to pediatric bone marrow transplant recipients with diarrhea caused by astrovirus serotype 1 resulted in the shedding of large viral aggregates in the stool, but it did not prevent viral replication (34).

DIAGNOSIS

Electron Microscopy

Viruses traditionally were detected in fecal specimens by direct EM with negative staining. In contrast to patients with Norwalk and Norwalk-like virus infections, those with diarrhea caused by astrovirus frequently shed large numbers of viral particles (£1×10^{10}/mL, or 10^8 viable particles/mL) (88). In those patients who may be excreting fewer viral particles or in situations where immune response to astrovirus necessitates measurement, IEM techniques are useful (19,75,78). The sensitivity of EM has been estimated to be 10^6 to 10^7 virus particles per gram of stool.

In spite of the characteristic surface features described for astroviruses, accurate interpretation of electron micrographs may require an experienced microscopist (108). Generally, only 10% of the particles in a given specimen will display the distinctive astrovirus surface star (106). Oliver and Phillips conducted a retrospective analysis of fecal viruses that were originally identified as small, round, featureless viruses by EM alone (141). Of note, they found that many of these viruses, particularly astroviruses, had been misclassified. When complementary immunologic techniques were applied to careful reexamination of the specimens by direct EM, 14 of the 53 samples (26%) first classified as small, round, featureless viruses were shown to be astrovirus. Two caliciviruses and a Norwalk-like virus were also found to be misclassified. Another example of how difficult it can be to classify these viruses solely based on morphology by EM is the case of the Marin County virus, isolated in 1978 from an outbreak of gastroenteritis in a California convalescent home. The initial impression was that this was a Norwalk-like virus (142). Subsequent analyses, however, proved that the Marin County virus was an astrovirus serotype 5 (56,57).

Enzyme Immunoassay

Herrmann et al. (58,59) developed an EIA that relies on a group-reactive monoclonal antibody (8E7) to capture viral antigen and polyclonal antiserum as the detector antibody. A modification of this EIA uses a biotinylated detector antibody (126). Both EIAs are of comparable sensitivity (91%) and specificity (98%) to IEM. EIAs have been useful for rapid detection of astrovirus antigen in studies where a large number of samples must be assayed (32,60,98,126,158). EIA- and RT-PCR-based methods to type human astroviruses found in clinical samples have been described recently (138; see preceding). An astrovirus antigen EIA that uses a group-reactive monoclonal antibody [8G4 (158)] for both capture and detection (biotinylated) has also been developed. The sensitivity of EIA is estimated to be 10^5 to 10^6 viral particles per gram of stool (59,126).

Although not currently available in the United States, a commercial EIA based on group-reactive monoclonal antibody 8E7 (59) is available elsewhere for the detection of astrovirus antigen in clinical specimens (IDEIA Astrovirus EIA, DAKO Diagnostics, U.K.). In one survey from Australia, this qualitative assay was found to have a sensitivity of 100% and a specificity of 98.6% (116).

Reverse Transcriptase Polymerase Chain Reaction

As more information regarding the sequence of human astrovirus genomes became available, detection techniques that employ molecular probes and RT-PCR were developed (69,126,181,183). The sensitivity of RNA probes is similar to EIA (126,181). By contrast, the sensitivity of RT-PCR is estimated to be 10 to 100 particles per gram of stool (153). Investigation of an outbreak of astrovirus gastroenteritis at a day care center (124) found that the prevalence of astroviruses, determined by EIA, varied from 50% in affected rooms to 20% in rooms with older children. Analysis by RT-PCR indicated that nearly all children were infected and viral shedding was detectable for weeks despite resolution of symptoms. In addition, RT-PCR detected astrovirus in 32% of the samples tested, compared to EIA which had a detection rate of 10%.

At present, the complete sequence of five strains of astrovirus (two serotype 1, one serotype 2, one serotype 3, and one serotype 8) are available (see previous section, Molecular Biology). It was reported that oligonucleotide primers selected from sequences at the 3' end of the genome can successfully amplify astrovirus-specific products from all five reference serotypes (131). Primers derived from the highly conserved RNA-dependent RNA polymerase motif may also be suitable

candidates for amplification of different human astrovirus serotypes by RT-PCR (99). RT-PCR also was used to confirm astrovirus-positive samples detected by EIA (31,51,109,125). Good correlation was observed between these two detection assays (44).

Regions that encode immunoreactive viral epitopes may play an important role in the development of recombinant antigens and more specifically targeted antibodies that can be produced on a large scale in the future. Although tests that detect astrovirus antibody are useful for epidemiologic investigations (80,83,121,122,134), tests that rapidly and accurately identify astrovirus antigen are likely to be preferable in the clinical setting.

TREATMENT

Gastroenteritis caused by astrovirus is generally a mild, self-limiting illness that may disrupt an individual's activities for a few days but does not require specific therapy. In the young child or rare adult patient who becomes dehydrated, oral or intravenous fluid resuscitation may be necessary. Complications such as dehydration may develop in patients with underlying gastrointestinal disease, poor nutritional status, severe mixed infection, immunodeficiency, or protracted illness (32,88). Intravenous immunoglobulin may be a useful adjunct in severely immunodeficient patients who fail to respond to conservative measures (20,194), but larger studies are needed to determine efficacy and establish indications.

EPIDEMIOLOGY

Astrovirus infections have been found worldwide, primarily, but not exclusively, in young children with diarrhea (4,8,9,12,31,32,34,35,38,39,44,48,50,51,60,78,81,91,97,98,100,105,111,117,120,125,123,126,130,135,136,141,142,145,146,160,163,164,172,192). Sporadic outbreaks of gastroenteritis caused by astrovirus have been reported among elderly patients (48,100,115,142) and military recruits (14). Several studies associate astroviruses with diarrhea in immunocompromised adults (20,30,31,51). Large, food-borne outbreaks, affecting thousands of individuals in Japan, have occurred among otherwise normal school-age children and adults as well (140,173).

Most astrovirus infections are detected in the winter months in temperate regions and in the rainy season in more tropical climates, a pattern that resembles rotavirus infections (32,88,92). As noted, infection is transmitted by the fecal–oral route. Both community-acquired (60,81,107,117,136,158,168) and nosocomial (4,8,17,38,39,81,91,105,120,136,151,158,172) infections have been described.

Role in Disease

It is difficult to ascertain the true incidence of astrovirus gastroenteritis and its role in disease. Gastroenteritis caused by astrovirus is usually a mild, self-limiting illness that does not require hospitalization, extensive outpatient evaluation, or clinic visits. The virus may be difficult to detect by direct EM, as only 10% of the particles display the distinctive surface star, and this may lead to misclassification of astroviruses that are present in fecal samples. Even in humans, astrovirus may be found together with other potential gastroenteritis agents in diarrheic feces (136). Determining which of these viruses is the etiologic agent is a clinical challenge. Detection methods such as those described previously helped to define the epidemiology of human astroviruses, but the true disease burden caused by these viruses is not known (44). Prevalence of astrovirus among children with sporadic diarrhea was found by EIA to range between 2.5% and 10% (22,32,44,52,60,81,98,164,173).

Herrmann et al. (58,59) developed an EIA that is capable of detecting human astrovirus serotypes 1 to 8 in fecal specimens. They used this EIA in two separate studies (32,60) to address the medical importance of astroviruses. Controlled studies done in Thailand (60) examined the incidence of astrovirus gastroenteritis in pediatric outpatients compared to illness due to rotavirus and enteric adenovirus. As expected, rotavirus was the most frequently detected viral pathogen, found in 19% of patients with gastroenteritis. An unexpected result was that astrovirus was second to rotavirus, accounting for diarrhea in 8.6% of patients, and enteric adenovirus was a distant third, found in only 2.6% of the patients with diarrhea. A similar study was conducted on rural Guatemalan children (32). In this population, astrovirus was found in 7.3% of those with diarrhea and was again second to rotavirus. These findings were unexpected because hospital-based EM studies indicated that enteric adenovirus is the second most common cause of viral diarrhea in young children, and astrovirus incidence rates did not exceed 4% (72).

In Australia, astrovirus was found to be the second most common cause of gastroenteritis in children, after rotavirus (143). Infection with serotype 1 predominated, particularly in the winter months when gastroenteritis is common (40,116,143). A biennial winter peak of astrovirus infection among hospitalized children was observed (133). Serotype 4 strains were associated with infection in summer and autumn months (116). Among hospitalized patients, the incidence of astrovirus infection was 4.2%, far lower than rotavirus (63.2%), equivalent to all bacterial infections, and slightly higher than adenovirus (3.7%), suggesting that severe infection with astrovirus is seen in a subgroup of infected patients.

In a population of Mayan infants, astrovirus was the most common enteric pathogen identified in stool samples collected during a prospective study of oral poliovirus immunogenicity (109). The prevalence of astrovirus was compared with that of rotavirus, adenovirus 40/41, *Salmonella*, *Shigella*, and *Campylobacter* species. In 61% of the infants, astrovirus was detected by EIA from at least one stool sample over the 18-week period each infant was followed. Twenty-six percent of 305 diarrheal episodes reported at study visits were associated with astrovirus. The EIA results were confirmed by RT-PCR in a subset of EIA-positive and -negative samples. The reason for the high prevalence of astrovirus infection and the low rate of rotavirus infection (4% detected by a commercial EIA) in this semiclosed community is not known, but it may be related to temperature, rainfall, humidity, or other environmental factors.

In the group child care setting, astroviruses were shown to be an important cause of outbreaks of diarrhea. Children up to 36 months old attending child care centers were at greatest risk of developing diarrhea (98,125). An investigation of eight outbreaks of astrovirus diarrhea (five human astrovirus serotype 1 and three serotype 2) in six child care centers showed

that 20% of the children with diarrhea shed astrovirus (123). Although each outbreak was associated with a single astrovirus serotype, two distinct serotypes were identified in sequential outbreaks during one winter diarrhea season.

Antibody Acquisition and Prevalence

Human infection is common, as evidenced by the presence of antibody to human astrovirus in gammaglobulin pools from the United States (92), Japan (78), and other areas of the world (44,186). In U.S. gammaglobulin pools, antibodies to all five of the originally identified serotypes of astrovirus are detectable (92). It is not known at this time whether antibodies to the more recently described serotypes 6, 7, and 8 (16,96) are present in these preparations. Using an EIA based on recombinant Baculovirus-expressed capsid protein (83), Cubitt et al. (34) determined the IgG titer to astrovirus serotype 1 to be 1:128,000 in a gammaglobulin preparation given to a patient.

Antibodies to astrovirus tend to be acquired in early childhood. A survey of 87 children less than 10 years old in the Oxford region of the United Kingdom revealed that antibody prevalence rises rapidly from 7% in 6- to 12-month-old infants, to 70% by school age (86). Astrovirus antibodies could be detected in 75% of the 10-year-old children studied. As a point of reference, young adults (nursing students) were also surveyed, and 77% were found to have such antibodies.

One study of seroprevalence among children treated at a hospital in the United Kingdom found rates of 86% for serotype 1, 1% for serotype 2, 8% for serotype 3, and 6% for serotype 4 (137). In an age-stratified sample from Utrecht Province in The Netherlands, seroprevalence of neutralizing antibodies was found to be 91% for serotype 1, 31% for serotype 2, 69% for serotype 3, 56% for serotype 4, 36% for serotype 5, 16% for serotype 6, and 10% for serotype 7 (80). Of those that were seropositive for types 1 to 4, serotype 5 antibody acquisition was observed to be more gradual and suggested a different epidemiologic niche for astrovirus serotype 5. A separate study examined the prevalence of antibodies to astrovirus types 1 and 3 in children and adolescents in the United States (122). Peak prevalence of antibody to human astrovirus was found in children 6 to 9 years old: 94% for serotype 1 and 42% for serotype 3.

PREVENTION AND CONTROL

Interruption of transmission is the key factor in preventing astrovirus infection. This is especially important in hospitals and other institutions, day care centers, and families, where person-to-person transmission is likely to occur. Universal hygienic procedures must be enforced in these settings. Astrovirus is quite resistant to alcohol disinfection (90). Methanol has been shown to be more effective in reducing astrovirus infectivity than equivalent concentrations of isopropanol or ethanol. Whereas 70% methanol was found to decrease astrovirus infectivity by 3 $\log_{10}$, 90% methanol limited viral titers to less than 10 infective units per milliliter.

Astrovirus survival in dechlorinated drinking water was comparable to rotavirus serotype 3 and enteric adenovirus 40/41, both of which can be transmitted through the waterborne route (2). Astrovirus and adenovirus were more resistant than poliovirus to inactivation by the addition of free chlorine to the water, but less resistant than human rotavirus or hepatitis A virus (1).

Those in the business of handling or preparing food should be mindful that shedding of astrovirus in the feces may continue for several days after diarrhea resolves. In immunocompromised individuals, viral shedding may last for weeks after resolution of symptoms (20,30). In addition, foods such as shellfish that have been implicated in outbreaks of astrovirus gastroenteritis should be carefully selected and prepared.

Potential for Vaccines

A better understanding of the fundamentals of immunity to astrovirus and estimates of the disease burden caused by astrovirus are required before vaccine development can be initiated. Evidence that astrovirus is a medically important pathogen (32,60), coupled with the fact that astroviruses primarily cause infection in the same age group as rotaviruses, makes it tempting to consider designing a vaccine that will protect young children against both viruses. Because astroviral diarrhea develops largely in infants less than a year old (with an age-specific incidence of 0.38 for infants less than 6 months old and 0.40 for infants 6 to 11 months old), a basic requirement of any vaccine candidate would be the ability to induce immunity in very young children (135).

CHAPTER 29 *Togaviridae:* The Viruses and Their Replication

Sondra Schlesinger and Milton J. Schlesinger

TOGAVIRUSES

The *Togaviridae* were among the first well-characterized viruses containing a lipid envelope. Initially this family included a wide spectrum of viruses associated with different diseases (166). The relatively early recognition that they had a “coat” led to their being classified as Togaviruses (from the Latin *toga,* a Roman mantle or cloak). Many of the original members are now in different families, and the *Togaviridae* consists of only two genera: alphaviruses and rubivirus. Both are small, lipid-enveloped, spherical particles with a single-stranded positive RNA genome ranging in size from 9.7 for rubivirus to 11.8 kilobases for alphaviruses. Members of the alphavirus genus are grouped on the basis of genome homologies. In amino acid sequence, they share a minimum identity of about 60% in the nonstructural proteins and 40% in the structural proteins. From recent taxonomic data, the alphaviruses consist of 22 separate species, based on a combination of antigenic relationships and on divergence in genome sequence of greater than 23% and amino acid sequence of greater than 10% in the E1 gene (240). A phylogenetic relationship has been estimated based on the nsP1, nsp4, and E1 genes (240), and seven antigenic complexes can be grouped by serologic cross-reactivity (240). This number may increase, as salmon pancreas disease virus also appears to be a member of this genus (252).

The type-specific member of the alphaviruses is Sindbis virus, whose structure and replication have been studied in great detail. In addition, both Sindbis and Semliki Forest viruses have provided valuable models for examining the synthesis, posttranslational modifications, and localization of membrane glycoproteins. Most of the information presented in this chapter was obtained by studies with these two viruses, although other alphaviruses are beginning to contribute to our knowledge of the replication strategy and diversity of this genus.

Rubella virus, the sole member thus far of the rubivirus genus, is well known for its ability to cause disease in humans. Alphaviruses and rubella virus share many features, which originally suggested that they evolved from a common ancestor. A more detailed scrutiny of homologies, however, makes it difficult to propose a straightforward evolutionary relatedness.

Virion Structure

The dominant feature of alphavirus structure is a T=4 icosahedral nucleocapsid surrounded by a lipid envelope embedded with glycoprotein components also arranged in a T=4 icosahedral lattice. A clear picture of the organization of protein and lipid in the virion emerged from low-angle x-ray scattering (74), from negatively stained electron micrographs, and most recently from images obtained by cryoelectron microscopy (see later). Virions are about 70 nm in diameter, and the core or nucleocapsid is 40 nm in diameter. The molecular weight of the virion is about 52×10^6, with a density of 1.22 g/cc. The RNA genome is encapsidated in an icosahedral protein shell composed of a single species of protein (the capsid protein of 30–33 kd) and enveloped by a lipid bilayer derived from the host-cell plasma membrane. Lipid accounts for 30% of the dry weight of virions and is enriched in cholesterol and sphingolipid. Image reconstruction from cryoelectron micrographs has led to low-resolution structures for Semliki Forest, Sindbis, and Ross River viruses (25,45,58,157,158,213). These images (Fig. 1) reveal an arrangement of glycoprotein spikes distributed as 80 trimers, which project about 100 Å from the outer surface and are located at the local and strict three-fold axis of the icosahedral lattice. Each trimer contains three heterodimers consisting of the two viral glycoproteins E1 and E2. The heterodimers appear intertwined but flare out in a triangular, flower-like shape to form distinct bilobed petals. The most distal portion of the lobes contains domains of the E2 glycoprotein, which have epitopes recognized by monoclonal antibodies, and images with Fab fragments attached to either Sindbis or Ross River virus E2 have been obtained from cryoelectron micrographs (213). Each spike has a hollow cavity in its center, and the glycoproteins splay out to form a protein shell or skirt covering most of the outer surface of the membrane bilayer. Small holes in this shell appear at the two-fold and five-fold axis and at the base of each spike. Each spike is anchored in the membrane by three pairs of transmembrane domains, and each third of a trimeric spike interacts at the inner leaflet of the membrane with a different hexamer or pentamer of the nucleocapsid. Protein mass that is found immediately underlying the membrane is believed to represent the 33-amino-acid cytoplasmic domain of the E2 glycoprotein, which forms a binding site for nucleocapsids during the assembly process. A cryoelectron micrograph image of a mutant of Sindbis virus defective in cleavage of the precursor (PE2) to E2 and a small peptide, E3, revealed that the amino-terminus of PE2 is positioned as a bulge in the heterodimer localized midway between the center of the trimer and the tip of the spike (158). Analysis of a similar type of mutant of

Semliki Forest virus indicated that the PE2 form of the trimer was a more open arrangement of spikes when compared with the wild-type virus, and the E3, which is retained in the virion, is positioned at the distal portion of the mature spike (45).

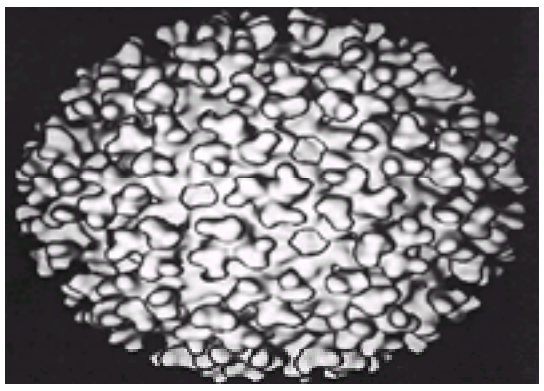

FIG. 1. Image reconstruction from cryoelectron micrographs of Ross River virus. The view is down the three-fold axis and shows the outer surface composed of flower-like projections of the E1/E2 heterodimers arranged as trimers and the interconnective portions that form a shell of protein. Very little of the lipid envelope is visible through three small openings of this shell. The resolution is about 20 Å. Courtesy of R.J. Kuhn, Purdue University, West Lafayette, IN.

The alphavirus nucleocapsid consists of 240 copies of the capsid protein (25,26,58,157,159). The Sindbis virus capsid protein was crystallized, and the atomic structure of the C-terminal half determined by x-ray diffraction to a resolution of 3 Å (Fig. 2) (26,224). Amino acids from positions 114 of the capsid sequence to the carboxy terminus at amino acid 264 were traced. The monomer fold was like mammalian serine proteases of the chymotrypsin family and closely related to the bacterial serine proteinases such as a-lytic proteinase, a result consistent with previous observations that alphavirus capsid proteins are autoproteases (5,68,132). The chain is folded into two Greek key b-barrel domains with the C-terminal tryptophan located between the domains and occupying the active proteinase site. The structure of the latter reveals the catalytic triad of serine, histidine, and aspartate (conserved among the serine proteinases) surrounding a hydrophobic pocket occupied by the tryptophan, which is the substrate for cleavage of the capsid from the nascent polypeptide (26,224). After cleavage, further catalytic activity is prevented by the tryptophan in the substrate-binding pocket. A structure of the Semliki Forest virus capsid protein, purified from virions, has been determined from crystals that diffracted to a resolution of 3 Å (28). The carboxyl-terminal 149 residues are folded like those of the Sindbis virus capsid in a chymotrypsin-like serine proteinase; however, a hydrophobic surface pocket that is occupied by amino acids from a neighboring molecule in the Sindbis virus capsid structure and may function as a binding site during assembly is empty. Several alphavirus capsid proteins have been produced as recombinant proteins in *Escherichia coli,* and the structure of the Sindbis virus capsid protein has been extended to residue 106, based on crystals that diffracted to a resolution of 2 Å (99).

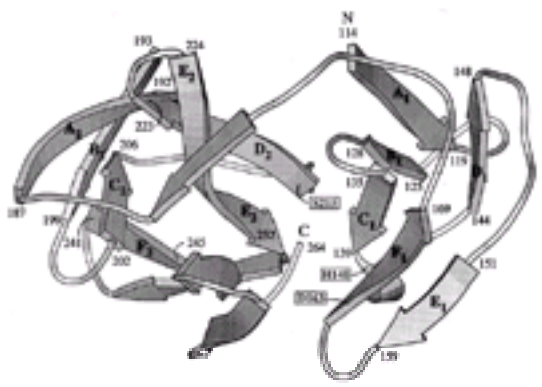

FIG. 2. Schematic drawing of the polypeptide chain of Sindbis virus capsid protein with secondary structure nomenclature based on x-ray diffraction analysis. The structure has since been extended toward the amino terminus to amino acid 106 (27). The catalytic triad of the active site serine-proteinase are in boxes. This picture was taken from Choi et al. (26), with permission, and was provided by M.G. Rossmann, Purdue University, West Lafayette, IN.

Genome Structure and Organization

The overall organization of the genomes of alphaviruses and rubella virus is shown in Fig. 3, where similarities and distinctions between them are noted. The genomes are arranged in two modules: the 5' two thirds codes for the nonstructural proteins (nsPs) required for transcription and replication of the RNA, and the 3' one third codes for the structural proteins. The 5' terminus is capped with a 7-methylguanosine, and the 3' terminus is polyadenylated. During replication, a discrete subgenomic mRNA species, identical in sequence to the 3' terminal one third of the genomic RNA, is synthesized (see also Fig. 4). This RNA also is capped and polyadenylated and serves as the mRNA for the synthesis of the viral structural proteins [reviewed in more detail in (219)]. An additional virus-specific RNA, detected in Sindbis virus–infected cells, contains the 5' two thirds of the genome; the 3' end maps to four nucleotides upstream of the start of the subgenomic RNA sequence. Its role in replication is not known; it is a minor species and may be the single-stranded version of one of the double-stranded replicative forms first identified almost 30 years ago in Sindbis virus–infected cells

after treatment of the RNA with RNase (257).

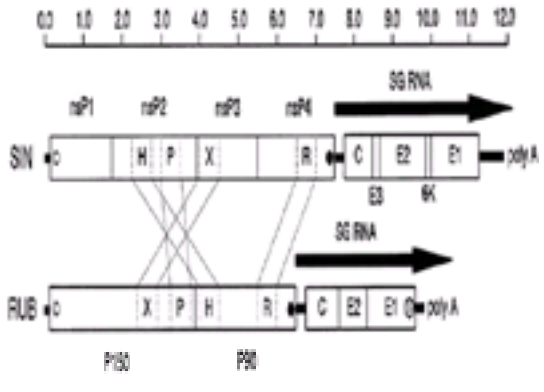

FIG. 3. Diagrams of the genomes of the alphavirus, Sindbis virus, and the rubivirus, rubella virus. The 5' two thirds of these genomes codes for the nonstructural proteins (nsPs), and the 3' one third codes for the structural proteins, translated from subgenomic (SG) RNAs. Untranslated regions are designated by *black lines*, and open reading frames, by *open boxes*. Designations are for individual proteins, which are processed from precursors. The scale at the top of the figure is in kilobases. The *open circles* near the 5' termini and the *closed circles* at the start of the subgenomic RNAs indicate conserved sequences in the alphavirus and rubella virus genomes. The location of the amino acid motifs for helicases (*H*), replicases (*R*) and cysteine proteases (*P*) are indicated. See text for more details. *X*, A small region of homology between the deduced amino acid sequences in the Sindbis virus nsP3 and the nsP of rubella virus. This figure was adapted from ref. 35 and 49, with permission, and was provided by T. Frey, Georgia State University, Atlanta, GA.

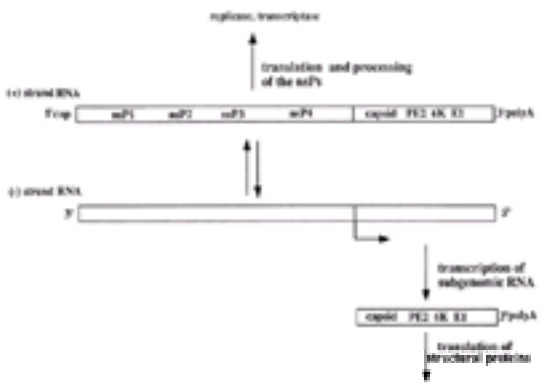

FIG. 4. Replication and transcription of alphavirus RNA. The first two thirds of the (+) strand genomic RNA serves as the mRNA for translation of the nsPs, which are eventually processed into four proteins (see text and Fig. 5). The (–) strand complementary strand is the template for the synthesis of both new genomic RNAs and the subgenomic 26S RNA, which codes for the structural proteins. The 5' terminus of the (–) strand has a polyU stretch that is assumed to be the template for the polyA tract at the 3' terminus of the genomic and subgenomic RNAs.

Sequence comparisons of different alphaviruses identified four regions of the genome that are highly conserved (149,150 and 151). These include (a) the 19 nucleotides at the 3' terminus, (b) 21 nucleotides that span the junction between the nonstructural and structural genes and include the start of the subgenomic RNA (the junction region), (c) 51 nucleotides near the 5' terminus, and (d) the 5' terminus, although this region appears to be conserved more in potential secondary structure than in sequence. The latter three regions also are conserved in rubella virus (35), and all four regions appear to be involved in the regulation of viral RNA synthesis. Sequence analyses also revealed similarities in the genome organization and in the sequences of the nonstructural proteins of alphaviruses and a number of plant viruses, some of which are quite distinct from alphaviruses in their overall structure [reviewed in (219)]. This suggested an evolutionary relatedness between the plant and alphaviruses and led to the definition of a Sindbis-like superfamily. It was this type of comparison that suggested that rubiviruses may be more distantly related to alphaviruses than are some of the plant viruses (35,49).

ALPHAVIRUSES

Attachment, Entry, and Uncoating

Alphaviruses have a wide host range and replicate in a variety of different species, as well as in many different cell types. Because attachment of a virion to a cell surface is one of the steps that can define host range, it seemed that these viruses must use a variety of different molecules for attachment or else use a ubiquitous surface molecule as a receptor. The high-affinity 67-kd laminin receptor is a receptor for Sindbis virus in baby hamster kidney (BHK) and several other mammalian cells (236) but not in chicken embryo fibroblasts (CEF), in which a 63-kd protein acts as the receptor (237). Mouse neuronal cells have other receptors: a 74-kd protein was detected on neuroblastoma cells that are loosely adherent, and a 110-kd protein was identified on firmly adherent cells (227). Recent studies have shown that heparan sulfate is an effective cell-surface ligand for binding of Sindbis virus to mammalian cells (19,90). A Chinese hamster ovary cell line selected for resistance to Sindbis virus infection is deficient in expression of sulfated glycosaminoglycans, heparan sulfate, and chondroitin sulfate (83). A strain of Sindbis virus composed of a consensus sequence derived from natural isolates does not bind to heparan sulfate; variants that do bind are rapidly selected by growth on cultured BHK cells (90). Thus heparan sulfate–like molecules may not function as natural receptors for Sindbis viruses, and

high-affinity binding of laboratory strains to this ligand appears to be a consequence of cultured-cell adaptation. Non–heparan-binding strains of Sindbis virus are more virulent in animals (90).

The viral glycoprotein E2 is the protein that interacts with these receptors. Antibodies directed primarily against the E2 protein neutralize viral infectivity, and amino acid changes in the E2 protein can affect both the efficiency of binding of the virus to neural cells and virulence in mice (81,105,199,226). Convincing evidence for the importance of E2 in binding virus to the cell surface came from experiments in which Sindbis virus mutants unable to bind to CEF were altered in the E2 protein (39).

Attachment of Sindbis virus to cells leads to the exposure on both glycoproteins of new transitional epitopes, which are indicative of conformational changes (46,135). These epitopes were detected also when purified virus was treated with heat, reducing agents, or low pH (134). Some of these changes may involve reduction of critical disulfide bonds in the glycoproteins, which may disrupt protein–protein associations in the envelope and be important for disassembly of the particle (1,7,8). Disulfide bond exchange had been proposed as a mechanism for allowing entry of virus at neutral pH at the cell surface, but further studies with both Semliki Forest and Sindbis virus failed to show significant inhibition of virus infection in the presence of thiol-blocking reagents (65).

In most cells, alphaviruses gain entry to the cell via the endocytic pathway, which normally functions for uptake of receptor–ligand complexes (33,128). Bound virus accumulates in coated pits, which are endocytosed to form coated vesicles. These vesicles are subsequently uncoated to form acidified endosomes, providing conditions that trigger fusion of the virus membrane with the vesicle membrane. The mechanism of receptor-mediated endocytosis for alphavirus penetration into cultured cells is supported by many studies, which include (a) the inability of bound Sindbis virus to effect antibody-mediated, complement-dependent cell lysis, indicating a rapid loss of virus glycoprotein from the cell surface (44); (b) the ability of lysosomotropic amines, which raise the pH of endocytic vesicles, to inhibit initiation of virus replication, demonstrating that acidified vesicles are required for early virus-replication events; (c) a requirement for a low pH (5–6) for fusogenic activity by Sindbis and Semliki Forest virus glycoproteins (230,254,255 and 256); (d) a block in fusion by concanamycin, a selective inhibitor of vacuolar proton–adenosine triphosphatase (ATPase) (80); and (e) the detection of virus in coated vesicles immediately after uptake from the cell surface, as revealed by electron micrographs of virus entry (256). Alternative pathways not involving acidified endosomes may exist, as a Chinese hamster ovary cell mutant defective in the endosome acidification was able to replicate Sindbis virus (41).

Studies with Semliki Forest and Sindbis viruses have demonstrated that the low-pH environment of the endosome leads to a dissociation of the E1/E2 heterodimer and a concomitant trimerization of the E1 subunits, which acquire new epitopes and become trypsin resistant (212,233,234). These alterations suggest that the E1 trimer is the fusion-active form of the protein, with a structure possibly analogous to the low pH–induced structure of the influenza virus HA2 protein (22,209). A highly conserved, hydrophobic sequence in the Semliki Forest virus E1 protein about 80 amino acids from the amino terminus is postulated to function as a fusion peptide, and mutations in this sequence shift the pH threshold for fusion to lower pH values (87), or block E1 homotrimer formation (89). Mutations in PE2 that prevent its cleavage to E2 also can affect fusion by controlling the formation and dissociation of the E1/E2 dimer (65,87).

Fusion of Semliki Forest and Sindbis viruses also requires the presence of cholesterol and sphingolipid in the target membrane (121,144,163,212). Dependence of Semliki Forest and Sindbis viruses on membrane cholesterol could be relieved by mutations in the E1 glycoprotein (121,231). One of these mutants, noted as srf-3, in which Pro^{226} in E1 was changed to Ser, was less dependent on cholesterol for trimer formation of E1 but retained the requirements for low-pH activation and sphingolipid exhibited by the wild-type virus (88).

Fusion leads to release of the nucleocapsid into the cytoplasm and must be followed by an uncoating event to permit the RNA to become accessible to ribosomes for initiation of translation. Several reports, based on *in vivo* and *in vitro* experiments, suggested that the binding of the nucleocapsid to ribosomes triggers the uncoating process (205,229,245,247,249,250). The capsid protein itself appears to have a ribosome-binding site between amino acids 94 and 106 of the capsid sequence (251), which is in the same region of the protein that interacts with viral RNA during encapsidation (64,152).

Transcription, Translation, and Replication of the Genome

The genomic RNA serves as the messenger RNA for translation of the viral nonstructural proteins and as a template for the synthesis of the complementary minus strand. The minus strand, in turn, provides the template for the synthesis of both new genomic RNA and subgenomic RNA [Fig. 4; for a more detailed review, see (219)]. Translation of the virion RNA is initiated at a single AUG near the 5' terminus of the RNA and proceeds uninterrupted for two thirds of the mRNA until encountering three termination codons located just downstream of the start of the sequences corresponding to the subgenomic RNA. The polyprotein is cleaved to four distinct polypeptides designated nsP1, nsP2, nsP3, and nsP4, according to their order in the genome. The protease responsible for these cleavages is encoded in sequences at the C-terminal domain of nsP2 (34,73,216). The genomes of Sindbis virus and several other alphaviruses have an opal termination codon a few codons before the nsP4 gene, and nsP4 is produced by read-through of the opal codon followed by proteolytic cleavage (218). Mutagenesis of the opal codon to one that encodes an amino acid or to the other two translation-termination codons adversely affects viral replication at low multiplicities of infection (109). An opal codon at this position in the genome of alphaviruses is common but not universal, and no termination codon exists at this position in Semliki Forest or O'Nyong-nyong virus genomes (217).

A number of activities must be carried out by the nsPs in their role as replicative enzymes. The isolation, characterization, and mapping of temperature-sensitive (*ts*) mutants defective in viral RNA synthesis at the nonpermissive temperature provided initial clues to identify the functions of each of the polypeptides (17,18,69,71). The RNA^{-} *ts* mutants fell into four complementation groups, which have been correlated with specific nsPs. The individual functions were predicted by gene-sequence homologies with known proteins [reviewed in (219)]. These include domains that are conserved among the alphavirus-like superfamily in three of the four nsPs. The nsP1 protein contains a

methyltransferase domain; the amino terminal region of nsP2 contains nucleotide-triphosphate binding motifs homologous to those found in bacterial helicases (see Fig. 3); and nsP4 has a GDD motif present in a number of viral RNA polymerases.

The predictions based on sequence homologies are being confirmed by functional tests. nsP1 has both guanine-7-methyltransferase and guanyltransferase activities (4,136,193). Mutagenic studies have defined amino acids essential for these activities (3,235). nsP1 also has been implicated in the synthesis of minus strand RNA (71,238). The protein is palmitoylated, and mutagenesis of the conserved cysteine residues, Cys ^{418}, Cys^{419}, and Cys^{420}, to alanine prevented the addition of palmitate and decreased the ability of nsP1 to bind to membranes (93). This protein appears to be involved in the association of the alphavirus replicase to membranes (4). Expression of nsP1 in cultured cells using a vaccinia virus expression system induced filopodia and rearrangement of actin filaments (94). These effects, also observed in virus-infected cells, indicate that nsP1 can affect the cytoskeleton.

nsP2 is involved in the regulation of minus strand RNA synthesis (189) and in the initiation of subgenomic RNA synthesis (222). As mentioned earlier, it also functions in proteolytic processing of the nsPs (34,73,216). The Semliki Forest virus nsp2, expressed in and purified from *E. coli,* is an RNA helicase (66). About half of the Sindbis and Semliki Forest virus nsP2 is associated with the nuclear fraction in virus-infected BHK cells, although its function there is not known (12,160). A pentapeptide in the carboxy-terminal region of the Semliki Forest virus nsP2 is required for nuclear localization (177). A mutant of Semliki Forest virus, in which the Arg ^{649} of the nuclear localization signal (P ^{648}RRV) in nsP2 was converted to Asp, was distinguished from the parental virus by two criteria: inhibition of host DNA synthesis was less than that seen in cells infected with the parental virus, and even more striking, its pathogenicity in mice was greatly diminished (176). Studies with Sindbis virus and Sindbis virus replicons (self-replicating genomes that lack the structural protein genes) have shown that mutations in nsP2, and specifically in Pro ^{726}, can lead to a significant reduction in viral RNA synthesis and permit the establishment of persistent infections in cultured BHK cells (38,50).

nsP3 does not have sequence motifs found in other RNA virus genomes, and its function remains unknown. It is phosphorylated (108,161), and mutants in this gene define an additional complementation group (96). nsP4 has been identified as the viral polymerase. Mutations in this gene affect the synthesis of all viral RNAs, and *in vitro* studies of Sindbis virus–infected cells establish nsP4 as the viral polymerase (13,69,100,188). All of the sequenced alphaviruses have a tyrosine at the amino terminus of nsP4. Shirako and Strauss (204) made a series of mutations to alter this amino acid and found that viable viruses were obtained only when the N-terminus was an aromatic amino acid or histidine.

Replication and transcription of alphavirus RNAs occur on cellular membranes (12,57). Studies with Sindbis virus have defined the proteolytic processing scheme for the nsPs and have led to an elegant model for the regulation of viral RNA synthesis. Proteolytic processing has been analyzed by translation of mRNAs *in vitro* (32,73), by expression of nsP genes in a vaccinia virus transient expression system (101,102 and 103), and by expression in cultured cells of Sindbis virus genomic RNAs containing site-directed mutations in the nsP genes (202,203). Each of these has provided important information for the proposed scheme illustrated in Fig. 5. The Sindbis virus nsPs are initially translated as two polyproteins, P123 and P1234, depending on whether the in-frame opal termination codon is suppressed. Cleavage of the latter at the 3/4 site occurs rapidly to form the complex P123 and nsP4, which is postulated to initiate minus-strand synthesis. Evidence for this is based on the result that nsP4 plus a P123, which is cleavage defective, but not a cleavage-defective P1234, can function efficiently in the synthesis of minus-strand RNAs (101,102 and 103,203). In the vaccinia expression system that leads to high levels of the nsPs, both plus- and minus-strand RNAs were synthesized, although minus stands were synthesized preferentially. In addition, in the vaccinia virus system, functional replication complexes were not formed when the nsPs were expressed as individual polypeptides or as different combinations of individual nsPs (101,102). The most convincing argument for a role for P123 in the synthesis of minus strands is based on studies in which the Asn^{614} of nsP2 was changed to Asp (103,216). This mutation leads to more efficient processing of P123 *in vitro,* but RNAs containing this mutation do not give rise to viable Sindbis virus in transfection assays (216). With the vaccinia virus expression system, minus-strand RNA synthesis could not be detected when this mutation was present in P123, but it was restored when the mutation was inserted into a P123 protein that was also cleavage defective (103).

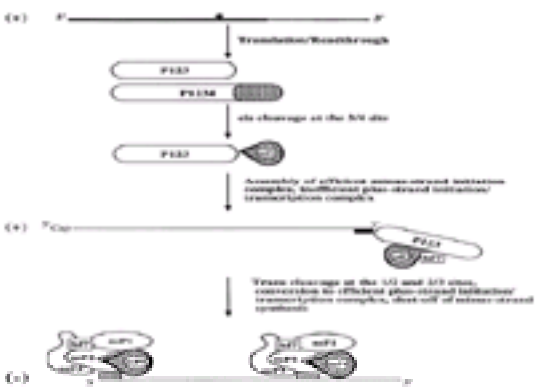

FIG. 5. A model for the temporal regulation of minus- and plus-strand RNA synthesis. The protein complex that initiates (–) strand RNA synthesis is composed of P123 and nsP4. This complex is also able to synthesize (+) strands, but inefficiently. Efficient synthesis of (+) strand genomic and subgenomic RNAs occurs after trans-cleavage at the 1/2 and 2/3 sites of the polyprotein; the latter cleavage results in the shut-off of (–) strand synthesis. Host factors (hf) are most likely involved in these reactions. From ref. 103, with permission, and provided by Drs. J. Lemm and C.M. Rice, Washington University, St. Louis, MO.

This model explains some aspects of the regulation of alphavirus RNA synthesis, in particular, the low level of minus strands synthesized by the replication complexes, the continued requirement for protein synthesis for production of minus

strands, and the cessation of minus-strand synthesis several hours after infection (190,191). *In vitro* translation studies show that processing of P123 occurs in trans and, in infected cells, the accumulation of P123 should accelerate its cleavage, leading to cessation of minus-strand synthesis. The partially and fully processed complexes carry out plus-strand RNA synthesis, which continues throughout the infection cycle. Not all of the earlier studies can be explained by this model, and there are mutations in both nsP4 and in nsP2 that permit continued synthesis of minus strands, even after cleavage of the proteins has occurred (188,189).

Attempts to study alphavirus RNA replication in cell-free extracts had been hindered by an inability to initiate viral RNA synthesis. Extracts prepared from alphavirus-infected cells would elongate endogenous RNA, but added templates were not functional (13). Based on the studies described earlier (and see Fig. 5), Lemm et al. (100) established an *in vitro* system that uses a Sindbis virus RNA template to initiate and elongate minus-strand RNAs. Extracts were prepared from cells infected with vaccinia virus recombinants: one expressing an nsP123 that had a defective protease so that the polyprotein would not be cleaved, and the other expressing nsP4. The addition of a plus-strand Sindbis virus RNA template led to the synthesis of the complementary minus stand. Furthermore, membrane fractions from extracts that expressed only the 123 polyprotein could synthesize genome-length minus-strand RNAs on addition of the appropriate template and solubilized nsP4, indicating that this system can be used to purify and characterize the nsP4 polymerase. In these studies, nsP4 by itself had no detectable polymerase activity. None of the extracts tested was able to synthesize plus strands.

The four conserved sequences, noted earlier, in the alphavirus genome were presumed to be replicase-binding sites and to function as promoter elements. Strauss et al. carried out extensive mutagenesis on three of these regions in the Sindbis virus genome: the 3' nontranslated region (91), the 51 nucleotides located between nucleotides 155 and 205 (143), and the 5' nontranslated 44 nucleotides (142). They show an important role for these sequences, as most of the mutations affect viral growth, frequently in a host cell–dependent manner, with strikingly different effects in chicken embryo fibroblasts and mosquito cells. These results support the contention that host proteins are involved in alphavirus RNA replication.

The fourth conserved region of the alphavirus genome surrounds the start of the subgenomic RNA. The minimal promoter region contains 19 nucleotides upstream and 5 nucleotides downstream of the start site for transcription of the subgenomic RNA, which coincides with the conserved region (107). Promoter activity is enhanced, however, when additional sequences in this region are included in the RNA (107,173). Additional studies of this promoter were carried out by the construction of Sindbis virus derivatives with two subgenomic RNA promoters: the wild-type promoter which was used for expression of the structural protein genes, and a second promoter, which was placed upstream of the chloramphenicol acetyltransferase gene and was subjected to modifications (173). Minimal promoters from other alphaviruses, but not from rubella virus, could be used by the Sindbis virus nonstructural proteins (77).

A role for host-cell proteins in alphavirus RNA synthesis was inferred from observations made in both vertebrate and invertebrate cells [reviewed in (219)]. Gel-retardation assays have been used to identify potential candidates (154,155) and led to the isolation from mosquito cells of a 50-kd protein that has a high affinity for the 3' terminus of the Sindbis virus minus-RNA strand and the identification of this protein as the mosquito homolog of the La autoantigen (156). The human La protein has been shown to interact with several other viral RNAs, suggesting that it may have a central role in viral RNA replication.

Expression of Virus Structural Protein Genes

Alphavirus structural proteins are translated from the subgenomic RNA early (2–3 hours after infection) in the replication cycle, probably as soon as the subgenomic mRNA is formed. Ribosomes initiate translation at a single site near the 5' end of this RNA and proceed uninterrupted for some 3,000 nucleotides to a termination site about 300 nucleotides from the 3' poly A terminus [reviewed in (219)]. The first sequences to be translated encode the viral capsid polypeptide, which folds to form a serine–protease catalytic site (see Fig. 2) that cleaves the capsid from the nascent polyprotein at a tryptophan–serine bond. Substitution of the C-terminal tryptophan by alanine, arginine, or phenylalanine showed that only tryptophan is an effective autoproteolytic substrate (210). Continued translation of the mRNA produces a signal sequence that facilitates translocation of the remaining polypeptide into the lumen of the endoplasmic reticulum (Fig. 6). As the protein emerges into this vesicle, it is modified by covalent attachment of oligosaccharides (201) and, later, by proteolytic cleavages carried out by host-cell signalase (110). The final products of translation are the capsid, two large (~45 kd) type I transmembrane glycoproteins, noted p62 or PE2 and E1, and a small (6 kd) membrane-embedded protein; the topology of these three membrane-bound proteins is shown in Fig. 7. Much of the data supporting this model derive from (a) assignments of domains with 22 hydrophobic amino acids in the sequences of the p62, 6K, and E1 as either signal- or stop-transfer sequences that span the membrane (see Fig. 6); (b) expression of cDNA constructs of Semliki Forest virus subgenomic RNA under the control of a heterologous promoter or expression of the Semliki Forest virus RNA genome, which show that the carboxy termini of either p62 or the 6-kd protein can function as a signal sequence for E1 (110,131); and (c) a change in the localization of the E2 carboxyl terminus to the inner leaflet of the bilayer during its transport to the cell surface (113). The p62, E1, and 6K proteins appear to move as a cohort through the secretory vesicles from their site of synthesis on the endoplasmic reticulum to their ultimate location at the plasma membrane of the cell (see Fig. 6). This process takes about 30 minutes at physiologic temperatures and leads to several posttranslational modifications. Among these are the trimming of and additions to the three oligosaccharides on Sindbis virus p62 and to the two on E1. Cellular enzymes localized to various compartments of the secretory system carry out these modifications in a manner resembling that found for cellular proteins destined for the plasma membrane or secretion to the extracellular fluid. Thus the precise composition of the oligosaccharides on the virus is dependent on the host cell in which the virus replicates (86).

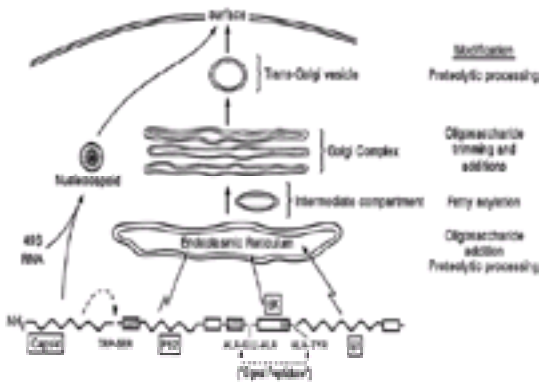

FIG. 6. Processing and modifications of the Sindbis virus structural proteins. Capsid is released co-translationally by autoproteolysis and assembles to encapsidate the 49S genomic RNA. The p62, 6K, and E1 proteins are modified during transport to the cell surface. Signal sequence, *shaded rectangle*; hydrophobic sequences, *open rectangle*.

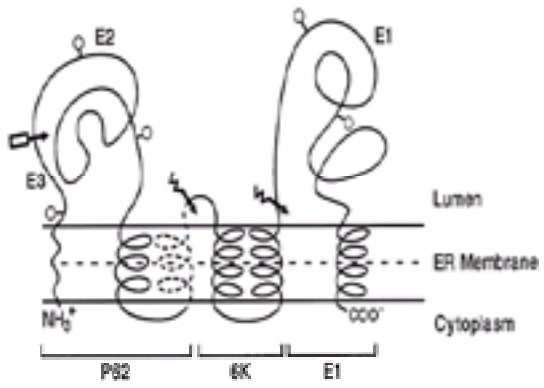

FIG. 7. Topology of the Sindbis virus p62 and E1 glycoproteins and the 6K protein in the endoplasmic reticulum membrane. The *dashed* part of p62 is removed from its transmembrane configuration and binds to the inner face of the lipid bilayer during transport to the cell surface. Host cell signalase activity, ; host cell furin-type protease, . Refer to text for detail.

A heterodimer of p62 and E1 forms very shortly after synthesis of the latter, and association is more effective when both proteins are expressed from the same genome instead of different RNAs (11). The folding of these proteins requires the formation of intrachain disulfide bonds and has been shown to involve a transient covalent interaction between the nascent and newly synthesized E1 and PE2 and the host-cell chaperones, protein disulfide isomerase and Erp57 (139). These disulfide-bonded intermediates could be detected by radioactive labeling, as the viral proteins are the only ones being synthesized in the infected cells. The folding pathway also includes noncovalent interactions with calnexin and calreticulin. In the absence of p62, E1 folds into disulfide-linked aggregates and fails to be exported from the endoplasmic reticulum (6,21), but p62 alone is capable of proper folding and transit to the plasma membrane. The newly synthesized E1 is not folded into its thermodynamically stable state but becomes trapped in a metastable conformation through the chaperone-like activity of p62 (6,36). The heterodimer complex trimerizes while still in the endoplasmic reticulum and is relatively stable to low-pH exposure. Continuous chaperoning by p62 and its proteolytically modified E2 maintains E1 in this metastable state in the virion spikes until low pH dissociates the dimers and leads to trimers of thermodynamically stable E1. The latter are distinguishable by new epitopes and rearrangement of disulfide bonds (140,197).

Palmitate acylation occurs at three sites on the Sindbis virus p62, four sites on the 6K protein, and one site on E1 during transport of the proteins after they have exited from the endoplasmic reticulum and before entrance into the Golgi complex [see Fig. 6 and (14,124,198)]. Cysteines oriented to the cytoplasmic face of the lipid bilayer are the sites of fatty acylation. The role of these fatty acids in glycoprotein function is unknown, but they probably affect interactions of the proteins with the lipid bilayer. Blocking their attachment by cerulenin (194) or by mutationally altering cysteine attachment sites (59,82) interferes with virus assembly and, in some cases, virus stability to heat and detergents (182).

A critical step in glycoprotein maturation is a proteolytic cleavage in p62 to form E3, which contains for Sindbis virus 64 amino acids of the amino terminus of p62, and the membrane-anchored E2. This cleavage occurs at a sequence enriched in arginines and lysines by a host cell furin-type enzyme localized to a trans-Golgi vesicle (138,186,239). Failure of the proteolytic cleavage does not interfere with assembly and budding of particles in vertebrate cells (167,181), but conversion of p62 to E2 is essential for particle formation in insect cells and in most cases is required for infectivity of the newly replicated particles in vertebrate cells (39,75,168,181,184). The failure of an alphavirus containing p62–E1 spikes to replicate in a cell may be due to the inability of the E1 to undergo the low pH–induced conformation required for its fusogenic activity (116,117). One variant of Sindbis virus, which has an uncleaved p62, contains an additional suppressor mutation in the E2 protein and is as infectious as the wild-type virus (76). A strain of Venezuelan equine encephalitis virus that was blocked in P62 cleavage gave rise to viable revertants containing suppressor mutations in either E2 or E1 (31). The E1 revertant grew normally in BHK cells but poorly in insect cells and was attenuated in adult mice.

Another important change occurs in the topology of the carboxy-terminal 33 amino acids of p62 as it transits from the endoplasmic reticulum to the Golgi vesicles. This domain is shifted from a transmembrane orientation (see Fig. 7) to one in which most of these amino acids are at the cytoplasmic face of the membrane (113). In its initial topology, p62 would

be unable to bind nucleocapsid, thus precluding premature assembly of particles at the endoplasmic reticulum membranes.

Assembly of Nucleocapsids and Enveloped Virions

The assembly of nucleocapsids includes both oligomerization of the capsid protein and selection of the genomic RNA for encapsidation. Although the subgenomic RNA is present in molar excess, it is the genomic RNA that is packaged into nucleocapsids and virions. The first evidence that selectivity was due to a packaging or encapsidation signal in the 5' region of the genome was the identification in the Sindbis virus genome of a 132-nucleotide fragment extending from nucleotide 945 to 1,076 in the nsP1 gene that interacts specifically with the capsid protein in binding assays and increases the encapsidation of an RNA in infected cells (56,241,242). Specificity appears to lie in the structure rather than in the sequence of the oligonucleotide (241). In contrast, the encapsidation signals for both Ross River and Semliki Forest virus are in the nsP2 gene (56,253). These two viruses are more closely related to each other than they are to Sindbis virus. It seems that as alphaviruses diverged from each other, the location and sequence of the encapsidation signal also diverged. Furthermore, although there could be similarities in structure, the Ross River virus capsid does not appear to recognize the Sindbis virus encapsidation signal (51,56).

The region of the Sindbis virus capsid protein that binds to the encapsidation signal is embedded in a 32-amino-acid region extending from amino acids 76 to 107 (64). This segment of the alphavirus capsid protein also interacts with ribosomal RNA and may be involved in uncoating of the RNA (251). Residues 97 to 106 are highly conserved among alphaviruses. Deletion of residues 97 through 106 from the capsid protein of Sindbis virus did not significantly inhibit particle assembly but reduced infectious titers more than 100-fold (152). ost of the particles contained the subgenomic RNA instead of the virus genome supporting the conclusion that these amino acids are important in packaging specificity.

Loss of discrimination in encapsidation also was observed with a Sindbis virus recombinant in which the capsid gene was replaced with the Ross River capsid gene (51). Furthermore, a deletion of amino acids 65 to 109 from this capsid protein did not reduce particle production, but they were almost completely devoid of viral genome RNA (51). This deletion eliminated most of the basic residues in the peptide chain and indicated that capsid–capsid interactions can occur in the absence of nucleic acid binding. The ability to form empty particles by removal of positively charged residues in the protein was first observed with icosahedral plant viruses (43,215).

Another exception to the strong selection of genomic over subgenomic RNA for encapsidation was described with Auravirus. This alphavirus packages both RNAs, although the ratio of genomic to subgenomic RNA is three- to 10-fold higher in virions than in infected cells (180). This result originally suggested that Auravirus subgenomic RNA contained an encapsidation signal; however, it is more likely that an encapsidation signal in the genomic RNA is not so efficient as that in other alphaviruses, resulting in less specificity in packaging. It appears that specific interactions between an RNA and an alphavirus capsid protein will favor encapsidation of that RNA, but in their absence, the capsid protein will interact with and package those RNAs that are most abundant.

In vitro assembly of nucleocapsids was carried out initially with capsid protein purified from virus (246,250), but recombinant capsid proteins expressed in *E. coli* have been used more recently (223). Both studies demonstrated that assembly can occur with a variety of nucleic acids, but in competition experiments, Sindbis virus RNA is preferentially packaged (196,223). Sindbis capsid proteins that lack the first 19 amino acids can assemble into nucleocapsids, but those deleted in the first 31 amino acids do not assemble by themselves (223). These and those missing the first 80 amino acids can be incorporated into nucleocapsids in the presence of competent capsid proteins. In mixed reactions with Sindbis and Ross River virus capsid proteins, only homologous nucleocapsids were detected (223).

The Sindbis capsid protein starting at amino acid 106 was crystallized, and the x-ray structure analysis showed that the amino terminal residues 108–111 of one chain associate with an adjacent molecule and that these residues bind into a hydrophobic pocket of the neighboring molecule (27). This finding, taken together with their mutational studies, led Lee et al. (99) to propose that residues 108 to 110 are important in the interactions between capsid monomers and also in the binding between the nucleocapsid and the C-terminal tail of the E2 glycoprotein (99).

The final stages in the replication of alphaviruses occur when nucleocapsids interact with the host-cell plasma membrane at sites occupied by viral transmembrane glycoproteins. This nucleation event leads to binding of additional virus glycoproteins and a bending of the membrane around the nucleocapsid until the bilayers meet and fuse to release the enveloped particle (20,62). Electron micrographs graphically illustrate this process (Fig. 8). Budding of alphaviruses requires the presence of both nucleocapsids and the heterodimeric complex of virus-encoded glycoproteins (10,220,263); however, mutations in the capsid protein that prevent the accumulation of stable nucleocapsids in the cytoplasm do not decrease the efficiency of Semliki Forest virus budding (48,211). This suggests that capsid–capsid interactions are stabilized by binding of spikes to the capsid protein, and in some cases, nucleocapsid assembly may occur concomitant with virus budding. The specific molecular interactions between alphavirus nucleocapsids and spike glycoproteins have not been identified; however, a motif at the carboxy terminus of E2 that is within a hydrophobic sequence localized to the cytoplasmic face of the membrane bilayer is essential for assembly. A tyrosine and a leucine residue near the amino-terminal portion of this sequence are highly conserved among the alphaviruses and are postulated to bind in a hydrophobic pocket containing a tyrosine and a tryptophan on the surface of the nucleocapsid (98,99,211). On association of E2 with the nucleocapsid, this pocket is hypothesized to undergo a conformational change that destabilizes and activates the core for eventual disassembly after virus entry into a host cell (98).

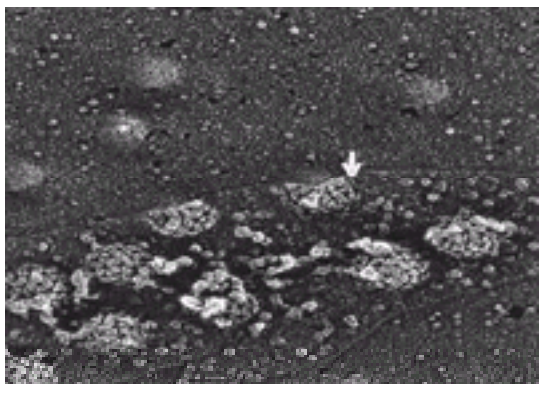

FIG. 8. Budding of Sindbis virions from infected chicken embryo fibroblasts. Cells were quick frozen and freeze fractured. The electron micrograph shows the fracture across the surface membrane of the cell (*white arrow*). On the bottom is the outer surface of the cell with clusters of virus glycoproteins at sites of budding. On the top is the inner leaflet of the surface lipid bilayer with viral nucleocapsids bound to the inner cytoplasmic side of the membrane. Sample preparation for electron microscopy was carried out by Dr. J. Heuser, Washington University School of Medicine, St. Louis, MO.

A number of studies using site-directed mutations in the E2 cytoplasmic domain and the capsid protein (60,82,97,153,211) provided further evidence for an interaction between the E2 cytoplasmic tail and the nucleocapsid, and mutations in the Sindbis virus capsid gene can partially suppress mutations in the E2 cytoplasmic domain that inhibit assembly (183). Capsid–E2 binding specificity also was demonstrated by experiments in which the gene for the Sindbis virus capsid protein was embedded in the Ross River virus genome (120). Virion particle production was greatly reduced with this chimera, but could be increased when seven amino acids of the Sindbis virus E2 cytoplasmic sequence were substituted for Ross River virus sequences. These results supported earlier studies in which a very hydrophobic six-amino-acid peptide corresponding to a conserved sequence within the E2 carboxy-terminal domain were shown to inhibit selectively Sindbis and Semliki Forest virus assembly and budding (30). Similar kinds of peptides with sequences identical to those in the E2 carboxyl terminus of Semliki Forest virus were reported to bind capsids (133). Not all chimeras, however, are defective; those in which the capsid protein gene was derived from either Semliki Forest virus or Ross River virus with the remaining genes from Sindbis virus assembled infectious virus at normal levels (51,214).

Effective budding also requires lateral interactions among the glycoprotein heterodimers, leading to trimeric and higher oligomeric forms such as the pentameric and hexameric structures that are positioned around the two-fold and five-fold axes of the virion. Hexagonal arrays of spikes were detected when membranes from Sindbis virions were examined by electron microscopy (232). These larger forms of the heterodimer would lead to polyvalent binding of the nucleocapsid to the E2 cytoplasmic ligands and could provide the force for membrane bending (62). Their formation also precludes insertion of host-cell proteins into the virus envelope. Defects in one of the glycoproteins (42) or its substitution by a chimeric form (i.e., E2 of Sindbis virus and E1 of Ross River virus) can interfere with the oligomerization process and decrease the amounts of secreted virus (262). In the latter case, heterodimers were formed, but no binding of nucleocapsids occurred at the plasma membrane. A series of suppressor mutations (five in Sindbis virus E2 and two in Ross River virus E1) increase progeny virus formation (260). The two adaptive changes in E1 were located adjacent to the membrane anchor domain of this protein. Based on cryoelectron microscopic reconstructions of Ross River virus (25), this region is part of the stalk that forms the spikes on the surface of the virion and consists of three entwined heterodimers; thus the mutations could affect trimer formation. Abnormal, multicored particles are released from cells infected with a Sindbis virus mutant containing the substitution of valine for alanine at position 344 in the E2 protein, and this phenotype can be partially corrected by a second, compensatory mutation in E1 (219).

The small, hydrophobic, fatty acylated membrane-associated 6K protein plays an important but still undefined role in alphavirus assembly and budding. Mutations in the 6K gene affect virus formation both quantitatively and qualitatively. Single-site mutations can lead to enhanced production of aberrant particles that contain multiple nucleocapsid cores, and a Semliki Forest virus mutant that totally lacks the 6K gene is highly defective in virus budding in BHK cells but much less so in insect cells (112,118). In the deletion mutant grown in BHK cells, virus cores align along the plasma membrane, and glycoproteins are not altered in their maturation and translocation. The 6K protein also interacts specifically with the E1/PE2 heterodimer, as shown by studies with a chimeric virus genome containing Sindbis virus glycoprotein sequences but a Ross River virus 6K virus sequence. This chimera was highly defective both in virus formation and in conformational changes occurring during maturation of the E1 glycoprotein (262). Mutations in the 6K Sindbis virus gene can be suppressed by mutations in the E2 glycoprotein, indicating a role for this protein in glycoprotein oligomerization during virus assembly (81). Because of its lipophilic properties, the 6K protein has been postulated to influence the selection of lipids that interact with the transmembrane domains of the glycoproteins, which, in turn, affect the deformability of the bilayer required for the extreme curvature that occurs as budding proceeds (20).

In most infected vertebrate cells, the plasma membrane is the site of alphavirus assembly; however, budding of Semliki Forest virus is selective in polarized epithelial cells, occurring only at the basal lateral surface (178,179) and, in cultured rat hippocampal neurons, this virus is secreted exclusively from membranes of the dendrites (37). In insect cells, budding occurs intracellularly, and virus-loaded vesicles are later disgorged to the extracellular fluid (137). In general, the lipid composition of alphaviruses closely resembles that of the membrane of the host cell (104). The ratio of cholesterol to phospholipid, however, is much higher in the membrane of alphaviruses than in the cellular membranes (175), and this may explain why Semliki Forest and Sindbis virus budding requires the presence of cholesterol in exiting the host-cell membrane (121,126). Virus membranes also are much more densely packed with protein and have a greater curvature than do the corresponding cellular membranes; thus their membranes are less fluid than are cellular membranes (200).

Alphaviruses as Vectors for the Expression of Heterologous Proteins

Sindbis virus, Semliki Forest virus, and Venezuelan equine encephalitis virus have all been genetically engineered to express heterologous proteins. Several different types of vectors have been described; the most versatile are those in which a heterologous gene replaces the structural protein genes (111,172,258). These vectors are self-replicating (replicons) but are not packaged and released from cells as virion particles. They can be complemented by defective "helper" RNAs that provide the structural proteins and allow replicons to be assembled into particles under conditions in which the helper itself is not packaged (15,111,172). Such particles are infectious but self-limiting, as they produce nsPs as well as genomic and subgenomic RNAs but, in the absence of structural proteins, do not form new particles.

Studies with replicons lacking the structural proteins led to the discovery of a translational enhancer in the viral subgenomic mRNA within the coding region of the capsid (54,208). The sequences that function as an enhancer are located about 25 nucleotides downstream of the AUG start codon and form a hairpin-like structure (55). Translation is stimulated about 10-fold, but only in infected cells (54,207). The existence and importance of this enhancer was clearly demonstrated for replicons derived from Sindbis and Semliki Forest virus but not for those from Venezuelan equine encephalitis virus (55,172).

A second type of expression vector contains two subgenomic RNA promoters; one controls the synthesis of the subgenomic mRNA that codes for the viral structural proteins, and the other controls the synthesis of the subgenomic RNA that codes for the heterologous protein (52). These vectors produce infectious virus particles able to spread throughout a culture.

Alphavirus vectors are being used for production of proteins in a variety of eukaryotic cells and have provided a useful tool for studies of protein expression and modification (52,63,122,195). They also are being developed as vaccines; for example, replicons expressing heterologous viral antigens, packaged into infectious particles or as DNA plasmids, have been introduced into animals. Initial studies in mice with DNA plasmids have been promising, as they induce an immune response at much lower doses than do conventional DNA plasmids.

A completely different approach to the use of alphaviruses as vectors had been to insert heterologous amino acid sequences into the viral structural proteins in such a way that the virus is still viable, but the heterologous epitope is expressed and can function as an immunogen. London et al. (119) made random insertions of an epitope from Rift Valley Fever virus into the structural protein genes of Sindbis virus. They then selected viable viruses containing the insert and found not only that the insertions were tolerated but also that the chimeric Sindbis virus could be used as a vaccine to make mice resistant to infection by Rift Valley Fever virus. Those initial studies and the subsequent isolation of Sindbis virus mutants that were defective in their ability to bind to vertebrate cells (39) served as a foundation for Ohno et al. (145), who devised a strategy to target Sindbis vector particles to specific cell types. They inserted the immunoglobulin G (IgG)-binding domain of protein A into the PE2 glycoprotein. This allowed them to target these Sindbis virus replicon particles to a particular cell type by adding monoclonal antibodies against a surface marker on those cells.

Recombination

Based on sequence comparisons, at least one alphavirus, western equine encephalitis virus, arose by recombination between eastern equine encephalitis virus and a Sindbis-like virus (67). Recombination also has been observed between replicons and defective helper RNAs. The latter events may arise more frequently than those between two virus genomes because crossovers do not have to be precise. Sequence analysis of these recombinant RNAs demonstrated that crossovers occurred within the defective modules (244). Recombinational events giving rise to infectious virion RNAs could create deletions, rearrangements, or insertions, as long as they occurred outside of each functional module (172,244).

More-detailed studies have been undertaken in efforts to define the mechanism and requirements for recombination (72,78,174). Surprisingly, recombination was detected with Sindbis virus RNA molecules that were unable to replicate because of deletions at the 5' or 3' terminus. Recombination events observed in laboratory studies usually take place under conditions in which high concentrations of RNAs are mixed together. Although these events are probably less likely to occur under conditions of natural infection, they do indicate that exchange between RNA molecules may play a role in the evolution of RNA viruses.

Effects of Alphavirus Infection on the Host Cell

Infection of vertebrate cells by most alphaviruses leads to inhibition of host-cell protein synthesis and cell death. Mechanisms that have been proposed for shut-off of host-cell protein synthesis include inhibition of host factors required for protein synthesis, with preferential translation of viral mRNAs, changes in the ionic environment of infected cells, which favors translation of viral RNAs, and direct inhibition by capsid protein [reviewed in (219)]. Infection of BHK cells with Sindbis virus replicons showed that inhibition of host-cell protein synthesis occurs at essentially the same rate under conditions in which no structural proteins or no viral subgenomic mRNA is synthesized (53). These data provide strong evidence that the structural proteins are not involved in mechanisms that inhibit host protein synthesis. Synthesis of the viral glycoproteins, however, leads to a much more rapid appearance of cytopathic effects than is seen in their absence (53). Furthermore, as mentioned later and in more detail (in Chapter 30), differences in the viral glycoprotein E2 can greatly affect how the cell responds to infection.

Cell death in alphavirus-infected vertebrate cells occurs by apoptosis (106,192), but in mosquito cells, the mechanism appears to be different and may more closely resemble necrosis (85). Infection of many *Aedes albopictus* (mosquito) cell clones leads to persistent infection (16), although it also may be cytopathic (84,187,225). In those cell cultures in which a persistent infection is established, the production of virus is comparable to that observed in most vertebrate cells during the first 24 hours, but then decreases several orders of magnitude during the persistent infection phase. The mechanism leading to persistence in mosquito cell lines is not known, although there have been reports that cells infected with

Sindbis virus produce an antiviral factor, and intracellular factors appear to restrict virus production (84).

It has been possible to establish persistent infections in some vertebrate cells. Two different types have been described. In one, essentially all of the cells are infected, but the synthesis of virus-specific RNA and protein in each cell is greatly reduced. This type of persistent infection was established in BHK cells by using defective interfering particles (243). The defective RNAs interfere with the replication of the genomic RNAs, leading to inhibition of viral RNA replication and virus production. The virus itself underwent a genetic change, converting it to a much less cytopathic mutant that was itself able to cause persistent infections in BHK cells. Several mutations were identified, but only one that converted the Pro ^{726} to Ser in the nsP2 protein was able to confer this phenotype on the virus (38). The decrease in cytopathic effects also was correlated with an eight- to 10-fold decrease in viral RNA synthesis.

A completely different approach to establishing this type of persistent infection in BHK cells was undertaken by using Sindbis virus replicons that express a gene (the *pac* gene) that codes for an enzyme that destroys puromycin. In the presence of puromycin, only cells that could eliminate this compound would survive, and only those cells that contained a Sindbis virus replicon that was not cytopathic could survive its replication and transcription, which would be required to express the *pac* gene. This selection procedure led to the isolation of several noncytopathic replicons (50). The one that has been analyzed in most detail has a single mutation, which led to the change of a single amino acid (Pro ^{726} to Leu) in nsP2, the same amino acid that was changed in the Sindbis virus mutant isolated from the persistent infection. The identification of several mutations in the nsP2 gene that lead to persistent infections and the localization of nsP2 in the nucleus suggest that this protein may have some as yet undefined functions affecting host-cell survival (176). These noncytopathic replicons are now being used as expression vectors in BHK cells (2).

A second type of persistent infection that has been described is one in which most of the cells are not infected, but the virus continues to persist because of a small fraction of cells that are susceptible and maintain the virus. In this case, the titer per culture is low, but those cells that do get infected may produce normal levels of virus and do not survive. An early example was the establishment of a persistent infection of mouse L929 cells by Semliki Forest virus. Only 1% to 20% of these cells expressed virus-specific antigens, and induction of interferon was the major factor in permitting the L cells to survive infection (130).

More recently the expression of other cellular genes has been shown to cause a significant decrease in virus replication and may lead to a persistent infection. The human MxA protein is a member of a family of guanosine triphosphatases (GTPases). When it was expressed in the human cell line Hep-2, the cells became almost completely resistant to infection by Semliki Forest virus: only 1% of the cells showed evidence of infection, but the virus was eventually cleared from the culture (95). Persistent infections by Sindbis virus and Semliki Forest virus could be established in a rat prostate carcinoma cell line (AT-3 cells) expressing the human *bcl-2* gene (106,192). The bcl-2 protein is a well-established antiapoptotic agent. In these cells, virus replication is severely restricted, with titers 10- to 100-fold lower in the AT-3 *bcl-2*–expressing cells than in the controls (192,228). As in the previous examples, only a small fraction of the AT-3 cells produced virus-specific antigens, indicating that the low titers were due to only a small number of the cells being productively infected. Further studies with Sindbis virus led to the discovery that the ability to establish this type of persistent infection was dependent on the strain used and was correlated with a single amino acid in the E2 glycoprotein (228) [and see Chapter 30].

Another restriction on Sindbis virus replication has been observed in mouse cells and is dependent on the class I major histocompatibility complex (MHC) haplotype. Sindbis virus replication was more than 100-fold higher in mouse cells that express the H-2^{k} haplotype than in cells expressing the H-2^{d} haplotype. The difference does not appear to be at binding or entry, but at the level of viral RNA synthesis (70). This difference also depends on the strain of Sindbis virus and specifically on the E2 glycoprotein.

RUBIVIRUSES

Rubella virus has long existed in the shadow of the alphaviruses. In the early studies of structure and replication of Togaviruses, it seemed that rubella virus was very similar to alphaviruses, but perhaps its replication was not so robust. This picture is gradually changing as we learn more about rubella virus—the properties of this virus and its interactions with its host cell have some special features. One major difference is the limited host range of rubella virus: it is found only in humans and does not grow in insect cells. Furthermore rubella virus grows slowly and to low titers in cultured vertebrate cells. Infection is much less cytopathic than that observed with alphaviruses, and persistent infections are readily established [reviewed in (49)]. It has been established that cell death in infected Vero cells occurs by apoptosis and involves a p53-dependent pathway (129,171). Chapter 31 describes these viruses in more detail.

Virion Structure and Entry

Rubella virions closely resemble alphaviruses in general morphology and physical characteristics; however, virion preparations are much more pleomorphic, and little is known about the icosahedral lattices and distribution of the glycoproteins on the virion surface. Two type 1 membrane glycoproteins form spikes projecting from the lipid membrane envelope; they are noted as E1 (282 amino acids) and E2 (481 amino acids) and are postulated to form heterodimers [reviewed in (49)]. Virion cores are similar to but somewhat smaller than alphavirus nucleocapsids and contain multiple copies of a single capsid protein about 290 to 300 amino acids in length that are present in virions as disulfide-linked dimers. The amino-terminal portion of the capsid is like that of the alphaviruses, enriched in arginines and containing a binding site for the genomic 40S RNA (115). Binding assays identified a 29-nucleotide region (nucleotides 347–375) in the rubella virus genome as the sequence required for specific interaction of RNA with the capsid protein. Studies to determine if this sequence is essential for or enhances encapsidation of the RNA have not yet been done.

In cultured Vero cells, rubella virus infection but not transfection of RNA was inhibited by lysosomotropic agents (162); thus this virus appears to enter the cell by receptor-mediated endocytosis and after membrane fusion in an acidified

endosome delivers its RNA to the infected cell cytoplasm.

Transcription, Translation, and Replication of the Genome

The replication of rubella virus does follow the same strategy as that of alphaviruses: the genomic RNA is first translated to produce the nonstructural proteins that are required for the synthesis of the complementary minus-strand RNA, the genomic RNA, and the subgenomic RNA [reviewed in (49)]. The subgenomic RNA is the mRNA for the viral structural proteins. Amino acid sequence homologies between rubella virus and the alphaviruses exist only within the nsPs (see Fig. 3), but proteolytic processing of the rubella virus nsP is distinct from that of alphaviruses. The 5' two thirds of the rubella virus genome is translated to a polyprotein of 240 kd that is posttranslationally cleaved into two polypeptides, one 150 and the other 90 kd. Region-specific antibodies located the 150-kd protein at the amino terminus, and the 90-kd protein at the carboxyl terminus of the polyprotein (47). Mutation of the cysteine at residue 1151 led to the accumulation of the largest protein at the expense of the two smaller proteins, providing evidence that the larger protein was the precursor of the smaller and that the cysteine was essential for protease activity (127). The protease responsible for cleavage is located at the C-terminus of p150 and is a papain-type cysteine protease. It requires divalent cations, contains zinc binding domains required for activity, and functions both in cis and trans (114,261). A histidine at position 1273 also is critical for activity. The site of cleavage is a gly-gly-gly sequence at positions 1299 through 1301 (23).

The first cDNA clone of rubella virus able to be transcribed into infectious RNA was derived from a strain (w-Therien) that forms opaque plaques on Vero cells. cDNA fragments obtained from a different strain (f-Therien) of rubella virus that gives clear plaques were used to replace equivalent segments in the clone (169). A swap of the 3' half of the genome led to an increase in specific infectivity, but the exchange of the 5' fragments resulted in clear plaques. The exchange of a region near the most 5' terminal fragment had the strongest effect on cytopathogenicity. The more cytopathic viruses produced more nonstructural proteins, and because the levels of the viral RNA species were similar, this result suggests that the amounts of the rubella virus nonstructural proteins can affect cell killing.

The 3'-terminal 305 nucleotides of rubella RNA has four stem–loop structures, two of which (SL1 and SL2) are located in the coding region of the E1 glycoprotein gene and two in the 59-nucleotide untranslated region. Nakhashi et al. (141) first showed by UV light–induced covalent cross-linking and gel-retardation assays that the 3' terminus of the genomic plus-strand RNA bound three cellular proteins of molecular masses 61, 63, and 68 kd. The 61-kd protein was identified as calreticulin, a calcium-binding protein usually found in the endoplasmic reticulum of eukaryotic cells (206). SL2 is the binding site for calreticulin, and binding is localized to the N-terminal domain of the protein (9). Site-directed mutagenesis of SL2 led to loss of binding of calreticulin, in particular for those mutations that destabilized the stem structure (24). Decreased binding of calreticulin did not correlate with inhibition of virus growth. Although this suggests that calreticulin binding is not required for virus viability, it was proposed that local intracellular concentrations of the protein might be high enough to allow binding to occur. Alternatively, the binding of calreticulin may have some role in human infections in which innate and immune responses can affect virus replication.

Extensive mutagenesis of SL3 and SL4 indicated that most of these regions were required for virus replication. In addition, further studies demonstrated the formation of three RNA–protein complexes with the 3' untranslated region, and UV cross-linking detected host proteins with molecular masses of 120, 80, 66, 55, 48, and 36 kd bound to this region of the RNA (24).

A very detailed mutagenesis analysis also was carried out for the 5' terminus of rubella virus RNA (170). Although many of these mutations had an effect on virus growth, most were not lethal. Mutations that were lethal included all of those that removed the two As at nucleotides 2 and 3, either by mutation or by deletion. Two cellular proteins, one 59 and the other 52 kd, when bound to the 5' terminus, were immunoprecipitated with a Ro-type human polyclonal serum obtained from patients with autoimmune disorders (164,165). A subset of sera recognized the La autoantigen or both the La and Ro autoantigens. The La autoantigen binds to the 5' stem–loop of rubella virus genomic RNA with relatively high specificity both *in vivo* and *in vitro* and affects the expression of the RNA (40). It is not yet possible to interpret the significance of the binding of these proteins to rubella virus RNA. The finding that these proteins are autoantigens has led to the speculations that their involvement in infection may lead to the arthritic symptoms associated with rubella virus infections. As mentioned previously, the La autoantigen is now implicated in the replication of a number of different RNA viruses, but how it is involved remains to be discovered.

Some headway on rubella viral RNA replication is being made. Virus replication complexes in Vero-infected cells have been localized to vacuoles of endolysosomal origin and tubular membranes with antibodies directed against the p150 replicase (92). Colocalization of lysosomal markers with double-stranded RNA antibodies was found by confocal microscopy, supporting the proposal that replication occurred on virus-modified lysosomes (125).

Synthesis of Structural Proteins and Virus Assembly

Translation of the rubella subgenomic mRNA produces a polyprotein that is proteolytically processed by a pathway different from that of the alphaviruses (29,146,147 and 148). The rubella virus capsid protein lacks an autoprotease activity. Stretches of 23 and 20 hydrophobic amino acids precede the amino termini of the E2 and E1 glycoproteins and act as signals for the translocation of the glycoproteins into the lumen of the endoplasmic reticulum. Cleavages between the capsid and E2 and between E2 and E1 are catalyzed by the host-cell signalase. After cleavage, the E2 signal sequence remains attached to the capsid protein, which becomes anchored to the membrane (79,221). The latter interaction is probably important in targeting the assembly of the virus nucleocapsid to intracellular membranes. There is no small hydrophobic “linker” protein between the two glycoproteins nor is there a precursor form of E2.

The two rubella virus glycoproteins resemble those of the alphaviruses in name, but their structure and synthesis are distinct [(29,146,147 and 148) and reviewed in (49)]. Both rubella virus glycoproteins contain N-linked oligosaccharides, and E2 also contains O-linked glycans (123,185). These proteins are retained in the Golgi organelle, and only a small fraction reach the plasma membrane. The transmembrane domain of E2 has a Golgi retention signal in contrast to E1,

which contains a retention signal for the endoplasmic reticulum in its transmembrane and cytoplasmic domain. The latter is overridden in the heterodimer, but both are required for virus particles to be secreted from infected cells (61). Site-directed mutagenesis studies indicate that a 29-amino-acid sequence in E1 may be the fusion peptide for the heterodimer complex of this virus (259). The accumulation of the viral glycoproteins in the Golgi complex may explain why virus assembly appears to occur mainly at this site. Nucleocapsids of rubella virus become visible only during the budding process and apparently do not assemble independent of an association with the glycoproteins.

PERSPECTIVES

Togaviruses and, in particular, alphaviruses are among the best-characterized RNA enveloped viruses. This chapter has documented much of our knowledge of the structure and replication of these viruses, but many questions remain unanswered. Progress on determining the three-dimensional structure of the virus continues to be made by using cryoelectron microscopy, and a structure for the E1 glycoprotein is being determined (248). These and other structural studies should provide a clearer picture of assembly and disassembly of these viruses. In the last few years, several functions of the individual alphavirus nonstructural proteins have been identified, but little progress has been made on how these proteins work in concert to replicate and transcribe viral RNA. Proteolytic cleavage of the nsP complex plays an essential role in the regulation of viral RNA synthesis, but the details have not yet been worked out. It will be important to learn if this type of regulation extends to the synthesis of rubella virus RNAs. Several different host-cell proteins that bind to viral RNAs have been identified, but there are no models for how these proteins might be involved in viral RNA synthesis. The ability to initiate alphavirus RNA synthesis in cellular extracts represents an important first step in uncovering the details of viral RNA synthesis (100).

There is at least one unsolved puzzle that stems from studies on the requirements for alphavirus RNA synthesis in cultured cells. Studies with both Sindbis and Semliki Forest virus replicons have demonstrated that viral RNA replication and the shut-off of host-cell protein synthesis occur in the absence of any of the viral structural proteins. Based on those results, it would seem that neither the viral glycoproteins nor the capsid protein plays a role in viral RNA replication nor in the inhibition of host-cell protein synthesis. In contrast, several publications proposed that the Sindbis virus glycoproteins are involved in regulating viral RNA synthesis. Relatively few changes in these viral glycoproteins can lead to extensive differences in the outcome of infection, as was reported for a rat prostate carcinoma cell line expressing *bcl-2* (228) and for mouse cells depending on their class I MHC molecules (70). In these examples, as for Semliki Forest virus in Hep-2 cells expressing the human MxA protein (95), the block in replication occurs at a very early step, but it has not yet been established to be a direct inhibition of viral RNA synthesis. One explanation to resolve this apparent discrepancy would be that the interaction of certain alphavirus glycoproteins with cellular membranes can interfere with the binding of the nsP complex to these membranes; this and other alternatives should be explored. An important future goal will be to correlate these observations in cultured cells with pathogenesis in humans and animals.

CHAPTER 30 Alphaviruses

Diane E. Griffin

The genus Alphavirus includes 25 viruses (Table 1). All are transmitted by arthropods, share a common replication strategy, and are geographically restricted in their distributions. Alphaviruses have been found on all continents except Antarctica and on many islands. In general, the pathogenic alphaviruses are divided into the viruses that cause human diseases characterized by rash and arthritis, primarily found in the Old World, and viruses that cause encephalitis, primarily found in the New World. For many alphaviruses, no human or veterinary disease has been recognized. Alphaviruses cycle primarily between mosquitoes and small mammals or birds. Larger mammals, such as humans and horses, that tend to develop severe or fatal disease are often dead-end hosts unimportant to the endemic virus-transmission cycles, but can be important for sustaining epidemics.

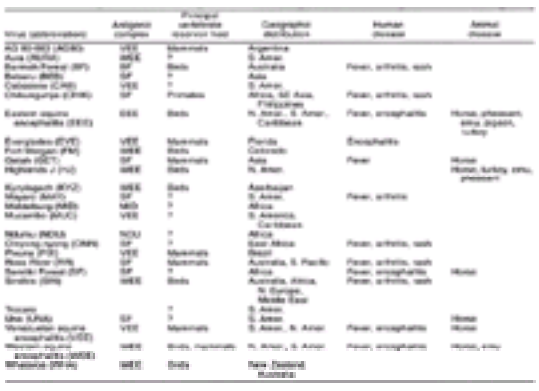

TABLE 1. *Alphaviruses, abbreviations, biologic features, and association with disease*

HISTORY

Records of diseases almost certainly due to alphaviruses date to the 18th and 19th centuries when epidemics of fatal encephalitis in horses in the northeastern United States and outbreaks of arthritis in Southeast Asia were recognized and recorded (71,208,557). The first clear report of epidemic encephalitis comes from the summer of 1831 when 75 horses died in Massachusetts (208). Over the next 100 years several local outbreaks of encephalitis in horses were noted along the Atlantic seaboard of the United States and in the pampas regions of South America (481). However, the first alphavirus to be cultured was western equine encephalitis virus (WEEV). This virus was isolated in 1930 from the central nervous system (CNS) tissues of two horses involved in an epidemic of equine encephalitis that occurred in the San Joaquin Valley of California (376). The virus of eastern equine encephalitis (EEEV) was isolated from the brains of affected horses in New Jersey and Virginia in 1933 (556). Both diseases occurred in summertime epidemics, suggesting an arthropod vector, and in 1933, Kelser showed that WEEV could be transmitted by mosquitoes (275). In 1936, an epizootic of equine encephalitis occurred in the Guajira region of Venezuela, and the virus isolated was not neutralized by antisera against EEEV or WEEV and was designated Venezuelan equine encephalitis (VEE) virus (184,300).

Summertime epidemics of polyarthritis were recognized in Australia and New Guinea in 1928 (119,407), and subsequent outbreaks of polyarthritis were reported in Northern Europe, Africa, and Southeast Asia (516). It is likely, of course, that the alphavirus-induced arthritic diseases are much older than these dates but were not clearly described or differentiated from more prevalent infections in these regions, such as dengue. This is considered to be particularly true of outbreaks of chikungunya (CHIK) that have occurred in India and Southeast Asia over the last 200 years (71,557). Viruses associated with epidemic polyarthritis were eventually isolated, both from mosquitoes collected in the areas of human disease, and later from humans. The first of these viruses was isolated in 1952 from a pool of *Culex* spp. mosquitoes collected near Sindbis, Egypt (551,552). However, it was many years before Sindbis virus (SINV) was linked to human disease (352).

The first clear association of an alphavirus with arthritic disease came in 1953 when CHIKV was isolated from the blood of individuals in Tanzania with severe arthritis (477). During the next several years, a number of viruses causing arthritis, often accompanied by a rash, were isolated in Africa, Australia, and South America (79,388,624). These viruses were added to the growing list of arthropod-borne (arbo) viruses, defined by the World Health Organization in 1967 as

> viruses which are maintained in nature principally, or to an important extent, through biological transmission between susceptible vertebrate hosts by hematophagous arthropods; they multiply and produce viremia in the vertebrates, multiply in the tissues of arthropods, and are passed on to new vertebrates by the bites of arthropods after a period of extrinsic incubation (440).

In 1954 arboviruses were divided by Casals and Brown (440) into three serologic groups, A, B, and C, based on cross-reactivity in hemagglutination inhibition (HI) tests. EEE, WEE, and VEE viruses constituted the group A arboviruses. A second cross-reacting set, including dengue, St. Louis encephalitis, and yellow fever viruses, constituted the group B arboviruses, and the nonreactive viruses were designated group C. As viruses became classified on the fundamental properties of the virion and the genome, the group A viruses became the Alphavirus genus within the *Togaviridae* family of enveloped RNA viruses.

INFECTIOUS AGENTS

Alphaviruses are enveloped plus-strand RNA viruses with icosahedral symmetry. The virions are 60 to 70 nm in diameter and sensitive to ether and detergent. The RNA is contained within a capsid formed by a single protein arranged as an icosahedron with T=4 symmetry. The nucleocapsid is enclosed in a lipid envelope derived from the host-cell plasma membrane that contains the viral-encoded glycoproteins, E1 and E2. These proteins form heterodimers that are grouped as trimers to form 80 knobs on the virion surface. Glycoproteins are arranged such that 240 copies of each interact with 240 copies of capsid protein.

The 49S genome is composed of a single-strand, nonsegmented, capped, and polyadenylated message-sense RNA that is infectious. Complete sequence information is available for representative members of most alphavirus complexes (87,101,140,285,303,306,316,372,538). The genomes are 11 to 12 kb in size and are organized with the nonstructural proteins (nsPs) at the 5'-end and the structural proteins at the 3'-end. The nsPs are translated from genomic RNA, and the structural proteins, from a subgenomic RNA (540).

Five potential structural proteins (C, E3, E2, 6K, and E1) are encoded as a polyprotein. The N-terminal portion of C is conserved, basic, and is presumed to bind the viral genomic RNA, whereas the C-terminal portion interacts with the cytoplasmic tail of E2 and with other copies of the C protein to form the nucleocapsid (540). The E3 protein serves as a signal sequence for E2, is cleaved from E2 in the trans-Golgi, and is often shed from the surface of the infected cell (617). The E2 glycoprotein is a transmembrane protein that has two or three N-linked glycosylation sites and contains the most important epitopes for neutralizing antibody. The intracytoplasmic portion has a second stretch of hydrophobic amino acids that probably tethers it to the inner surface of the membrane. The 6K protein serves as a signal peptide for E1, is important for budding, and small amounts are incorporated into the virion (51,167,324). The E1 protein has one or two N-linked glycosylation sites, a short (one or two residue) intracytoplasmic tail, and a positionally conserved internal hydrophobic stretch of amino acids in the N-terminal portion that serves as the fusion peptide for virion entry into the cell. Lipid content and glycosylation patterns are determined by the host cell (274,460). The 5' portion of the genome encodes four nsPs that function in replication of the viral RNA and production of the subgenomic RNA (540) (covered in Chapter 29).

Propagation and Assay in Tissue Culture

Initial isolations of alphaviruses have classically been by intracerebral inoculation into suckling mice, a host very susceptible to infection with most alphaviruses (237,477,485,551,552,613,624). Many alphaviruses also can be isolated

and propagated efficiently in primary chick embryo fibroblasts (CEFs) and in a wide variety of continuous mammalian cell lines such as human epithelial (HeLa, MRC5) cells, baby hamster kidney (BHK) cells, monkey kidney (Vero) cells, and mouse fibroblast and neuroblastoma cells (Fig. 1) (59,303,413).

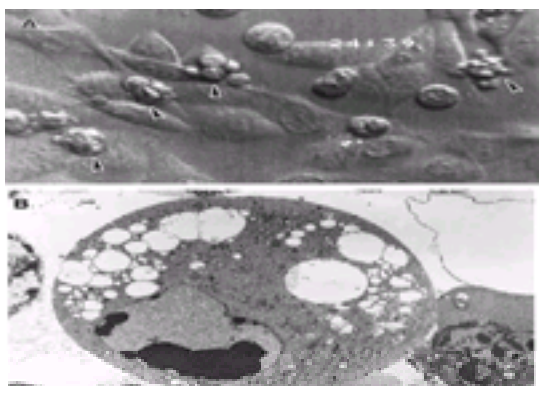

FIG. 1. Effects of Sindbis virus infection on vertebrate and invertebrate cells. **A:** Cytopathic effects (CPEs) in baby hamster kidney (BHK) cells infected at a low multiplicity. Infected cells show rounding, shrinkage, and cytoplasmic blebbing. **B:** Electron micrograph of an infected BHK cell, showing chromosomal condensation and cytopathic vacuoles.

Most alphaviruses will form plaques on susceptible mammalian or avian cells under an agar overlay. Mosquito cell lines also support replication, but often without cytopathic effect (CPE) (447,535,537,565). The first plaque assay of an animal virus was performed by using WEEV on CEF cells (131), and plaque assay remains a convenient and sensitive way to quantitate infectious virus. Plaque size has been used to differentiate strains and is determined by the type of overlay used, by relative virus binding to negatively charged sulfated polysaccharides present in the overlay, and by replication efficiency (52,56,494,549).

Biologic Characteristics

Hemagglutination

Alphaviruses can hemagglutinate avian (e.g., goose, chicken) erythrocytes (439,482), and this has been used as a method for quantitating virus and for measuring antiviral antibody by HI (93). Hemagglutination requires prior exposure of the virus to acidic pH, is dependent primarily on the E1 glycoprotein, and probably reflects binding of the fusion domain of the E1 glycoprotein to lipids in the erythrocyte membrane (88,93,102,585,619). E2 also participates in hemagglutination because some monoclonal antibodies (MAbs) specific for E2 also have HI activity (38,451). The HI test has been useful for determining antigenic relationships among alphaviruses (69).

Cellular Receptors

The nature of alphavirus receptors and the role of receptors in tissue and cellular tropism is an area of active investigation. Binding of virus to the cell surface and entry into the cell is a multistep process that is dependent on virus glycoproteins E1 and E2, cell-surface molecules, low pH in the endosome, and fusion of membrane lipids. Variations in any of these components will affect the efficiency of infection and the likelihood that any particular cell will become infected *in vivo.* Virus-specific attachment to cells *in vivo* occurs at neutral pH and is primarily a function of the E2 glycoprotein. The important role for E2 in initiating virus–cell interaction is evidenced by the ability of anti-E2 MAbs to inhibit binding to cells (56,335), of antiidiotypic antibodies to E2-specific MAbs to recognize putative virus receptors on cells (580,601), and of amino acid changes in E2 to alter virus binding to cells of different types (130,567).

Identification of specific alphavirus receptors has been difficult and may be complicated by experimental use of virus strains that are adapted to replicate in tissue culture (293). Because each alphavirus infects a wide range of hosts, often including birds, mammals, and mosquitoes, they must use either an evolutionarily well-conserved cell-surface molecule or multiple molecules as receptors for initiation of infection. None of the alphavirus receptors identified to date has been shown to be used exclusively, suggesting the possibility of several receptors. Alternatively, alphaviruses may use receptor–coreceptor combinations to achieve wide host range and the specific tropisms observed *in vivo.* The first specific alphavirus receptor to be identified was the major histocompatibility complex (MHC) class I molecule receptor for Semliki Forest virus (SFV) on mouse and human cells (223). This molecule is not absolutely required because cells lacking MHC molecules can still be infected with SFV (415). The high-affinity laminin receptor has been identified as a receptor for SINV on BHK cells (599) and as a likely receptor for SINV and VEEV on C6/36 mosquito cells (335,599). Again, this molecule appears to account for only a portion of the total virus interaction with the cells studied and does not, for instance, contribute to SINV binding to avian cells (599).

Heparan sulfate, a ubiquitously expressed glycosaminoglycan, has recently been identified as an important initial binding molecule for SINV, but not for RRV (56,293). Addition of heparin, treatment of cells with heparinase, or use of cells deficient in heparan sulfate decreases SINV binding to cells and virus plaque formation. Interaction with heparan sulfate, a highly sulfated, negatively charged molecule, probably explains the effects of ionic strength and charge on the attachment of virus to cells (356,358,435). The E2 glycoprotein of SINV contains a heparin-binding domain that overlaps the E2c neutralizing epitope (Fig. 2), and amino acid changes in this region toward more positively charged residues increase the efficiency of attachment to cells in tissue culture (57,293). However, these changes generally decrease virulence when tested in mice, suggesting that the changes represent adaptations of the virus to replication *in vitro* (57,293).

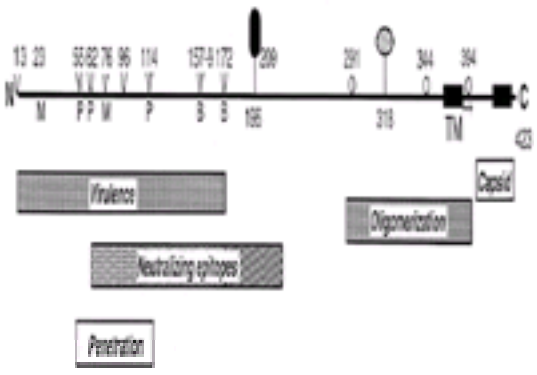

FIG. 2. Linear map of the E2 glycoprotein of Sindbis virus showing glycosylation sites, hydrophobic domains, and amino acid residues involved in induction of neutralizing antibody, oligomerization with E1 (*0*), virion binding (*B*), and penetration (*P*), capsid interaction, virion maturation (*M*), and virulence (*V*).

Entry into the cell after initial binding requires endocytosis followed by a conformational change in the trimer of E1–E2 heterodimers that is induced by exposure to low pH in the endosome (221,622). E1 proteins dissociate from E2 and form E1 trimers. During this change, the internal fusion peptide in E1 is exposed (48,166,220). Amino acid changes in E1 affect the requirement for cholesterol in the target cell membrane and the optimal pH for fusion (39,282,334,433). Fusion with the cell membrane to initiate infection is dependent on presence of a membrane potential (222).

Alphaviruses can interact and fuse with liposomal membranes that do not contain a receptor protein, and this *in vitro* system has been studied extensively to define the fusion process. Binding to these artificial membranes requires exposure of the virion to low pH (387,521,622), the E1 glycoprotein (422), and cholesterol in the target cell membrane (282,334), and probably involves a mechanism similar to hemagglutination of avian erythrocytes (387). Subsequent fusion with liposomes is dependent on the low pH-induced trimerization of E1 and on the presence of sphingomyelin in the target membrane (99,282,334,404,521,628).

Effects on Vertebrate Cells

Alphaviruses replicate rapidly in most vertebrate cell lines with the release of progeny virus typically within 4 to 6 hours after infection. At the time of virus entry, there is a transient increase in permeability (397). Insertion of newly synthesized glycoproteins into the plasma membrane renders infected cells capable of adenosine triphosphate (ATP)-dependent polykaryocyte formation on exposure to acid pH (276). Infection causes extensive CPE, characterized by cell rounding, shrinkage, and cytoplasmic blebbing (see Fig. 1A), with the death of infected cells within 24 to 48 hours (315,447). Many alphaviruses kill cells by inducing apoptosis, a process initiated by infection and carried out by the targeted cell (11,183,315). This process is associated with blebbing of the plasma membrane, condensation of nuclear chromatin, and formation of apoptotic bodies (see Fig. 1B) (315). Viral proteins are concentrated in the surface blebs from which budding continues to occur (474). This process does not hamper, and may enhance, virus replication because inhibition of apoptosis usually decreases virus yield (311,323,490).

The mechanism(s) by which alphaviruses induce apoptosis is not completely understood. Apoptosis of cultured cells can be initiated at the membrane during SINV fusion (259). Membrane-bound sphingomyelinases are activated, perhaps by the glycoprotein transmembrane domains, and sphingomyelin, a lipid necessary for alphavirus fusion, is degraded, releasing ceramide, an efficient inducer of cellular apoptosis (258,261). Once the apoptotic process is initiated, cellular caspases are activated with cleavage of caspase-3 substrates such as poly(ADP ribose) polymerase and fragmentation of chromosomal DNA (582). Alphavirus-induced apoptosis can be slowed or prevented, often in virus strain- and cell type–dependent ways, by expression of ceramidase (258), expression of a dominant inhibitory form of Ras (260), inhibition of constitutive expression of NFkB (325,326), overexpression of Bcl-2 family member and interacting proteins (183,315,318,323,490,583), and inhibition of caspase activity (403).

Alphavirus-induced vertebrate cell death also can occur by nonapoptotic mechanisms. Alphaviruses efficiently shut down protein synthesis in infected cells (402), deplete nicotinamide adenine dinucleotide (NAD) and energy stores (582), and induce dysfunction of Na^+K^+ATPase, causing loss of membrane potential and change in intracellular cation concentrations (27,172,584).

Persistent infection can occasionally be established in mammalian cell cultures *in vitro.* Mouse fibroblasts producing interferon (IFN), or BHK cells with high concentrations of defective interfering particles, can be persistently infected with SINV (243,616). Infection with SINV mutated at position 726 of the nsP2 protein (Pro ® Ser) leads to reduced RNA synthesis and persistent infection (128). Persistent infection also can be established if the cell infected is resistant to virus-induced apoptosis. This occurs in primary cultures of mature neurons (315,581) and in AT3 rat prostatic carcinoma cells overexpressing the cellular antiapoptotic protein Bcl-2 (315).

Effects on Invertebrate Cells

Studies of alphavirus infection of cell lines derived from *Aedes albopictus* and *Ae. aegypti* larvae demonstrate differences in alphavirus replication between vertebrate and invertebrate cells. Kinetics of virus replication are similar, but frequently virus matures within vesicular structures in the cell, and virions are released by exocytosis rather than at the plasma membrane (178,377,537). In mosquito cell lines, alphaviruses are much more likely to cause persistent noncytopathic infection (105,178,242,429,430,447,535,537) or death by a nonapoptotic process (271) than in vertebrate cells. The uncloned lines derived from *Ae. albopictus* larvae contain many types of cells with properties representative of different

mosquito tissues. Several cloned cell lines have been derived that vary in their responses to alphavirus infection. Lytic infection occurs in clones that support high levels of virus replication, as is seen with SINV infection of the C7-10 clone and SFV infection of HVP clones (377,565). Persistent infection is associated with a short period of relatively high virus replication followed by a decrease in virus production and in the numbers of cells in the culture that are producing virus, as is seen with SINV infection of the C6/36 clone (105).

Superinfection Exclusion

Vertebrate and invertebrate cells infected with one alphavirus cannot be productively infected with the same, or a closely related, alphavirus at a later time. Exclusion is established after translation of the nsP genes of the first virus to enter. The superinfecting genome can be translated, but not replicated (536). Recent studies suggest that this is due to the presence of the trans-acting protease nsP2, which prematurely cleaves the replicase polyprotein required for minus-strand synthesis, thus blocking replication of the superinfecting virus (272).

Antigenic Composition

All alphaviruses are related and share common antigenic sites, as revealed by HI and complement-fixation (CF) tests with polyclonal immune sera (69) and by cytotoxic T-lymphocyte lysis of infected cells (330,395). Antigenic cross-reactivities probably reflect sequence conservation in the C protein and E1 glycoprotein (185,330) and may confer some cross-protection and also interfere with sequential alphavirus immunization (116,363,539). These cross-reactivities formed the basis for the original classification into the group A arbovirus serogroup (440) and continue to be a valuable means for initial identification and classification of alphaviruses (69). Closely related viruses within a serogroup form a complex. Seven broad antigenic complexes have been identified within the alphavirus serogroup: Barmah Forest (BF), EEE, Middelburg (MID), Ndumu (NDU), SF, VEE, and WEE (see Table 1), and an eighth, Trocara, has recently been described (566). The BF, EEE, MID, and NDU complexes each contain only a single virus, whereas the SF, VEE, and WEE complexes include several viruses. Viruses within each complex can be subtyped by using reactivity with MAbs, kinetic HI, or neutralization assays (60).

Antibodies to E1 are more likely to cross-react with other alphaviruses than are antibodies to E2 (38,241,629,634). This is consistent with the documented sequence conservation in the E1 protein. Competitive binding assays using MAbs have identified approximately seven epitopes on the E1 glycoproteins of SINV, SFV, WEEV, and VEEV (38,241,373,470,495). Most E1 epitopes are not exposed on the virion surface, but are present on the surface of infected cells or on acid-exposed virions (9,193,373,495,531,532,629). he *in vitro* biologic activities of antibodies to E1 include HI, neutralization of virus infectivity, and inhibition of fusion. Neutralization of virus infectivity and HI activity often map to separate epitopes on E1, indicating that these are functionally distinct domains (38,86,241,495,531). Mapping of MAb binding sites to specific E1 sequences has been limited. One acid-exposed epitope involves E1-157 of SFV (9). A neutralizing MAb distinguishes strains of SINV differing only at residues 72 and 313 of E1, and an MAb escape mutant for a different epitope has a change at E1-132, suggesting the involvement of these regions in neutralization (193,531,539).

Antibodies to E2 are usually virus specific. Competitive binding assays using MAbs have identified four to five epitopes on the E2 glycoproteins of SINV, SFV, RRV, and VEEV (38,279,373,419,470,472,592). *In vitro* biologic activities of antibodies to E2 include HI, neutralization of virus infectivity, and blocking of virus binding to the cell surface (102,427,470). Many anti-E2 MAbs have both neutralizing and HI activity, suggesting that these functions overlap and that the conformational change in E2 that occurs after exposure to acidic pH is less drastic than that of E1 (193). Neutralization escape mutants, naturally occurring variants, lgt11 expression libraries, site-directed mutagenesis, and recombinant viruses have been used to map the various epitopes on E2 and have identified two major neutralizing sites (107,431,497,533,539,600). Overlapping epitopes in the middle of the E2 linear sequence encompass residues 181 to 216 in SINV, 180 to 216 in VEEV, and 216 to 251 in RRV, and identify one neutralizing site (7,107,193,262,539,592) (see Fig. 2). This is a hydrophilic region that for many alphaviruses includes an N-linked carbohydrate, suggesting that this portion of the protein forms a loop exposed on the virion surface. There are probably linear determinants in this region because these MAbs frequently react in Western blots and recognize l fusion proteins, and antibodies to peptides from this region are protective against challenge (531,600).

The second neutralizing epitope on E2 appears to be more complicated and is primarily conformational. Amino acid changes over a large linear range (e.g., residues 62–159 of SINV and 4–234 of RRV) affect MAb binding, and MAbs to this epitope do not react with denatured proteins in Western blots (see Fig. 2). The region defined by this epitope is responsible for SINV binding to heparan sulfate and is obscured if pE2 is not cleaved (56,480). Visualization by cryoelectron microscopy of the binding of MAbs to this epitope on SINV and RRV identifies one of the two knobs on the glycoprotein spikes as this region of E2 (522).

Evolution and Phylogeny

Alphaviruses, which replicate in arthropods, birds, and mammals, derive from a single unknown protoalphavirus and are part of the alphavirus superfamily of viruses. Viruses in this superfamily, including many RNA plant viruses, have similar genetic organization and replicase proteins, but diverse coat proteins (297,541). Among alphaviruses, amino acids important in secondary structure (e.g., cysteines) have been conserved for the glycoproteins E1 and E2, suggesting that the three-dimensional structure of the virion is similar for all. The capsid protein and E1 are the most conserved of the structural proteins, whereas E2 is more divergent. Sequence analysis, which includes information from the entire genome, generally groups the viruses similarly to that derived by antigenic analysis and has detected at least one recombination event (Fig. 3). Current criteria for species demarcation of alphaviruses combine genetic, ecologic, and antigenic information. Species generally have distinct transmission cycles and differ by more than 23% at the nucleotide level and 10% in amino acid sequence when E1 protein genes are compared. Based on E1 sequence, alphaviruses are currently grouped into six clades that generally correspond to recognized antigenic complexes: BFV, NDUV, SFV,

WEEV, EEEV, and VEEV (see Fig. 3).

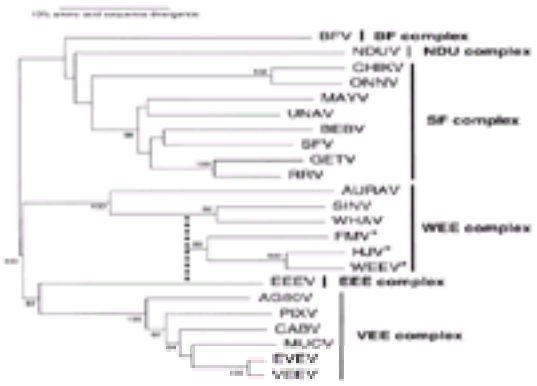

FIG. 3. Unrooted phylogenetic tree of representative alphaviruses generated from E1 envelope glycoprotein amino acid sequences using neighbor-joining analysis. Numbers adjacent to nodes indicate bootstrap support values exceeding 80 for groups to the right. *, Recombinant viruses. *Dashed line,* the presumed recombination event that generated an ancestral recombinant virus from eastern equine encephalitis (EEEV)- and SINV-like ancestors. Courtesy of Scott Weaver.

Like other RNA viruses, alphaviruses undergo genetic change primarily by accumulation of point mutations in the genomic RNA. However, this occurs at a rate that is much slower ($1–7 \times 10^{-4}$ substitutions/nucleotide/year) than is estimated for other RNA viruses (5×10^{-3} substitutions/nucleotide/year) (53,95,444). Recombination between alphaviruses can be demonstrated *in vitro* but is infrequent and usually puts the chimeric virus at a replicative disadvantage (301,541). However, successful recombination has occurred at least occasionally in nature because WEEV resulted from recombination between EEEV and a Sindbis-like virus, an event that is estimated to have occurred thousands of years ago (205,605) (see Fig. 3). Because there are New World WEE complex viruses that do [WEE, Fort Morgan (FM), Highlands J (HJ)] and do not (Aura) show evidence of this recombination and Old World members of the WEE complex (SINV, Whataroa) do not have recombinant genomes (606), alphaviruses most likely originated in the Americas and later spread to the rest of the world (316,606). Other data that support this view of alphavirus evolution are phylogenetic reconstructions, the greater sequence divergence within the New World viruses than the Old World viruses, and the antigenic relationship between Mayaro virus in South America and SFV in Africa (69).

Alphaviruses replicate in and are transmitted horizontally by a wide range of mosquito species. However, each virus usually has a principal or preferred mosquito vector for the enzootic cycle. Most alphaviruses can infect a variety of vertebrates, but use either birds or mammals as their primary amplifying host (see Table 1). The specific mosquito and amplifying host used by an alphavirus will contribute significantly to determining the geographic distribution of that virus. Experiments modeling evolution *in vitro* by passaging virus in vertebrate (BHK) cells, invertebrate (C6/36) cells, or alternating vertebrate and invertebrate cells show that fitness increases with passage in all instances, but fewer mutations accumulate if replication alternates, as it does in nature, between vertebrate and invertebrate cells (603). It is hypothesized that a short transmission season and host mobility influence alphavirus genetic diversity and evolution in a geographic region (95,604). Viruses using avian enzootic hosts (e.g., EEEV, WEEV, SINV) extend over wide geographic regions and evolve as a few highly conserved genotypes, whereas viruses using mammalian enzootic hosts with a more limited range of dispersal (e.g., RRV, VEEV) evolve within multiple geographically restricted genotypes (348,484,630).

Some strains of alphaviruses associated with epidemics or epizootics are antigenically and biologically distinguishable from enzootic strains. Recent phylogenetic evidence indicates that, at least for VEEV, the virulent epizootic strains evolve by mutation from avirulent viruses being maintained in the enzootic cycle (444,461).

PATHOGENESIS AND PATHOLOGY IN VERTEBRATES

Excellent and well-studied model systems exist for the study of several alphaviruses, and much of our detailed knowledge about alphavirus pathogenesis comes from studying mice infected by various routes of inoculation to induce infection. Information from these models is combined where appropriate with information from studies of humans with alphavirus-induced disease to deduce the pathogenesis of infection. Specifics are covered in sections on the individual viruses.

Entry

The primary mode of alphavirus transmission to vertebrates is through the bite of an infected mosquito. Mosquitoes salivate during feeding and deposit virus-infected saliva extravascularly (574). Saliva virus titers are highest early after the mosquito is infected and decline, along with transmission rates, after 1 to 2 weeks, but mosquitoes remain infected for life (379).

Sites of Primary Replication

The initial sites of virus replication probably vary with the virus and host. Mice have received most extensive study. After subcutaneous inoculation, viruses may infect skeletal muscle at the local site (e.g., EEEV, WEEV, SFV, RRV, SINV, and Getah virus) or be taken up by and infect Langerhans cells in the skin (e.g., VEEV) (Fig. 4) (197,230,265,331,398). Langerhans cells transport virus to lymph nodes draining the site of inoculation, which also may become infected (346).

Infection of Langerhans cells may be the most common mode of initiating natural infection.

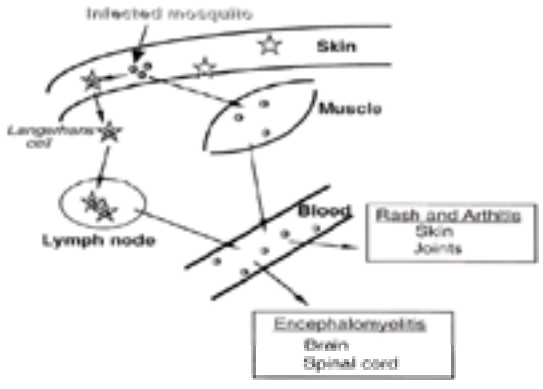

FIG. 4. Basic steps in alphavirus infection of vertebrates. Virus is delivered extravascularly by an infected mosquito and infects local muscle cells or Langerhans cells in the skin. Langerhans cells can carry virus to local lymph nodes. Virus is delivered to the blood and spreads to target tissues such as skin, joints, and the central nervous system, in addition to distant muscle and lymphatic tissue.

Spread

Alphaviruses induce a substantial plasma viremia in their amplifying hosts and in hosts susceptible to disease (see Fig. 4 and Fig. 5). The ability to mount and sustain a viremia is dependent on the continued efficient production of virus at a primary site of replication, delivery of virus into the vascular system, and slow clearance from the blood. Animal studies have shown that small plaque viruses are generally less virulent because they are cleared more rapidly from the circulation than are large plaque viruses (249,256,441). This phenomenon is related to the ability of small plaque viruses to bind heparan sulfate, and thus to be rapidly removed from the circulation by the highly sulfated glycosaminoglycans in the liver (57). Ability to invade target organs is dependent in part on the duration and height of the viremia, but also on other invasive characteristics of the virus (343).

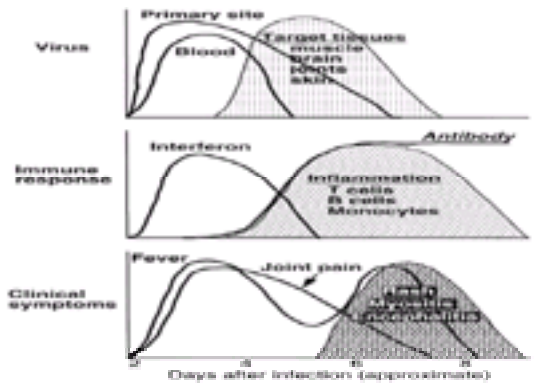

FIG. 5. Schematic diagram of the pathogenesis of alphavirus-induced disease. Viremia may be accompanied by production of interferon, other proinflammatory cytokines, and fever. Virus then spreads through the blood to other target tissues. As the immune response is induced, the viremia is terminated, but fever is renewed with appearance of a mononuclear inflammatory response in the infected tissue. In infections that lead to rash and arthritis, joint pain usually appears early after infection and before the appearance of the rash.

Cell and Tissue Tropism

Viruses that replicate initially in skeletal muscle and lymph nodes near the site of inoculation often spread through the bloodstream to more distant skeletal muscles and other lymphatic tissues. In mice, cardiac myocytes, brain and spinal cord neurons, and brown fat cells are frequent secondary sites of replication for many alphaviruses (see Fig. 5) (8,265,331,386,399). RRV and Getah virus cause polymyositis (230,399,503). EEEV, WEEV, SFV, and SINV cause encephalitis (23,125,247,331,400), and VEEV causes lymphoid depletion and encephalitis (177,180,255,587,597).

In humans, the skin is a target for alphaviruses that cause a rash (160,352); the joints, for those alphaviruses that cause arthritis (157); and the nervous system, for alphaviruses that cause encephalitis (171). RRV and SINV have been recovered from skin biopsies (234,352). The target cells for RRV replication in skin are basal epidermal and eccrine duct epithelial cells (160). The specific target cells within joints for infections leading to arthritis are not clear. In mice, RRV and WEEV infect chondrocytes and periosteal cells (8,399), and human synovial cells support RRV infection *in vitro* (100,268). Joint fluid taken from humans with acute arthritis has not yielded infectious virus, but viral antigen can be detected in macrophages, and macrophages support RRV replication *in vitro* (157,329).

The mechanism by which encephalitic alphaviruses enter the CNS is not entirely clear. Murine studies have shown infection or transport by cerebrovascular endothelial cells (265,281,426,525), infection of choroid plexus epithelial cells (331), and infection of olfactory neurons (90,590). Tissue culture–adapted strains of RRV and SFV can productively infect mouse brain endothelial cells *in vitro* (126), and SINV, SFV, and EEEV have been detected in mouse brain endothelium *in vivo* (265,281,426,525). EEEV also may initiate CNS infection in experimental animals by infecting choroid plexus

epithelial cells (331). For VEEV, initial infection is of olfactory epithelium with spread to olfactory neurons and subsequently along neural tracts to the CNS (90,590). Neuroinvasiveness is a component of virulence that varies between viruses and virus strains (129,343). Once within the CNS, virus can be spread cell to cell or through the cerebrospinal fluid (CSF) (246,417). For most encephalitic alphaviruses, the targeted cell within the CNS is the neuron (135,247,331,417), and damage to this cell can be severe and irreversible. SFV, RRV, and VEEV also can cause persistent CNS infection associated with infection of microglial and oligodendroglial cells, leading to demyelination (54,505).

Immune Responses

Innate Responses

Type I (a/b) IFN is induced after alphavirus infection of experimental animals (44,174,231,254,510,588) and presumably of humans (see Fig. 5). Study of *ts* mutants suggests that formation of dsRNA is the necessary step in replication for IFN induction because viruses with mutations in the protease domain of nsP2, which cannot process the nonstructural polyprotein and thus cannot initiate plus-strand RNA synthesis, do not induce IFN (206,354,595). Alphaviruses and strains of alphaviruses vary in their ability to induce IFN (441,494,510), and the amount of IFN produced is usually linked to the amount of virus produced (203,254,588). IFN appears rapidly, may not require virus replication, and is diminished by splenectomy (25,254,296). The primary source of IFN after peripheral inoculation may be macrophages or dendritic cells in lymphatic tissue (35,518). *In vitro* production of IFN follows the initial release of virus from infected cells by 2 to 3 hours (232).

IFN is an important part of the host response to alphavirus infection. Animals can be protected from lethal infection if treated with IFN or IFN-inducers before or soon after infection (150,254,504,554,633). Animals unable to respond to IFN because of deletions of the IFN receptor or of crucial IFN signaling molecules develop fatal infections even when infected with normally avirulent strains of virus (55,188,530). IFN appears to act primarily to limit virus replication early, during the time the specific immune response is being induced (Fig. 6). Treatment of cells with IFN inhibits alphavirus replication (113,254,391,396), but the mechanism by which this occurs, and therefore the IFN-induced host responses important for control of replication, are not known. Attachment and entry are not affected, and input mRNA is translated (113,452). However, later replication steps, including formation of replication complexes, structural protein synthesis, and morphogenesis, are inhibited (163,396,452).

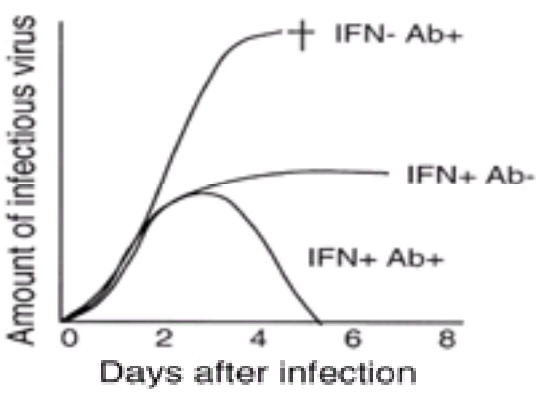

FIG. 6. Independent effects of type 1 interferon (*IFN*) and antiviral antibody (*Ab*) on alphavirus replication in tissue. Early control of replication is dependent on IFN, and in the absence of IFN, infection is often fatal. Clearance of virus is dependent on virus-specific immune responses, and antibody plays a prominent role.

The only IFN-induced protein shown to have an effect on alphavirus replication is human MxA, a large cytoplasmic guanosine triphosphatase (GTPase) that prevents accumulation of genomic and subgenomic RNA by an unknown mechanism (304). Transgenic expression of the human MxA protein in IFN-ab receptor knock-out mice decreases SFV replication and provides some protection against the otherwise fatal disease that occurs in these mice (218). The roles of other IFN-induced host proteins have not been reported. Virus strains vary in their sensitivity to the antiviral activities of IFN, and this generally correlates with virulence (49,530). Mutations associated with altered sensitivity to IFN have been mapped to nsP1 (476).

IFN also may contribute to alphavirus-induced disease. Fever during the viremic phase of infection, as is seen with CHIKV and RRV, is probably a response to the IFN induced early after infection (see Fig. 5). It has been postulated that the rapidly fatal disease induced by alphaviruses in newborn mice may be due to the production of large amounts of IFN and proinflammatory cytokines (292). Acute-phase responses induced by alphaviruses before the virus-specific immune response include increases in tumor necrosis factor (TNF)-a, interleukin (IL)-1, and IL-6, and levels generally correlate with the extent of virus replication (186,292,620). Adult mice deficient in IL-1b have reduced mortality after CNS infection with a neurovirulent strain of SINV, again suggesting the possibility that cytokine effects may contribute to mortality (322).

Virus-Specific Adaptive Responses

Both cellular and humoral immune responses are induced by infection (see Fig. 5). In experimentally infected adult mice, antiviral antibody is usually detected in serum within 3 to 4 days after infection (190,503). The cellular immune response, manifested by the presence of virus-reactive lymphocytes in draining lymph nodes and blood and the infiltration of mononuclear cells into infected tissues, also appears within 3 to 4 days after infection (118,194,364). These responses appear later (7–10 days after infection) in neonatal mice (510). The relative roles of each in recovery from infection and

protection against reinfection is an area of ongoing investigation.

Humoral Immunity

Virus-specific IgM antibody is detectable very early in human disease (61,72) and often provides a means for rapid diagnosis of infection (61,65,74). Virus-specific immunoglobulin A (IgA) also appears early in infection, but declines rapidly (73). IgG antibody appears in serum after 7 to 14 days and is maintained at relatively high levels for years (63,119,281). Rapidity of host antibody synthesis is predictive of outcome from encephalitis, because patients without evidence of antibody at the time of illness are most likely to die (61). Many lines of evidence support the hypothesis that recovery from alphavirus infection is dependent primarily on the antibody response (195,416,637,638). Antibody can neutralize virus infectivity and promotes virus clearance by the reticuloendothelial system in conjunction with complement (252). Appearance of antibody correlates with cessation of viremia (see Fig. 5).

The most extensive experimental studies to define the antibody specificity and the mechanisms of antibody-mediated recovery and protection have been done using VEEV, SFV, and SINV for infection of mice. Protection can be demonstrated by passive transfer of antibody before or after infection. Multiple epitopes on the E1 and E2 glycoproteins induce protective antibody. Both neutralizing MAbs, mostly anti-E2, and nonneutralizing MAbs, both anti-E1 and anti-E2, can protect against alphavirus challenge and promote recovery (36,37 and 38,198,241,359,373,472,496,532,634), suggesting that virus neutralization *per se* is not the only mechanism of protection. There is a correlation of protection with the ability of the MAb to bind to the surface of infected cells, but this is not absolute (532). Protection requires intact bivalent antibody, but complement is not required, suggesting that complement-mediated lysis of infected cells is not the mechanism of protection (227,360). However, complement may play an auxiliary role because virus clearance from blood is delayed in complement-deficient mice (228,229).

Antiviral antibody also can alter intracellular alphavirus replication and therefore promote clearance and recovery. Treatment of immunodeficient mice persistently infected with SINV or SFV with antiviral antibody clears infectious virus from the CNS without causing death of infected neurons or neurologic damage (12,314). SINV clearance from tissue is dependent on antibodies to the E2 glycoprotein (314), and MAbs specific for either of the neutralizing epitopes on SINV E2 can down-regulate intracellular virus replication *in vitro* by a nonlytic mechanism (314). Antibody against an N-terminal peptide of VEEV E2 that is not neutralizing can limit virus replication *in vivo* (240), and a nonneutralizing MAb to SFV E2 can limit virus replication *in vitro* (37). Anti E1 MAbs also may be able to alter intracellular virus replication, but this has been less extensively studied (85).

The process by which antibody alters intracellular virus replication requires bivalent antibody, but does not require the Fc portion of the MAb, complement, or other cells (314,581). Soon after antibody binding, virion budding from the plasma membrane is inhibited, perhaps by restoring cellular Na^+K^+ATPase function and K^+ flux or host protein synthesis (112). The effects of antibody on control of virus production *in vitro* can be amplified by treatment of infected cells with IFN-a (113). *In vivo* studies also suggest that IFN and antibody act synergistically to promote recovery from alphavirus infection (see Fig. 6), but the mechanisms by which these systems interact have not been identified (97,520).

Mechanisms of virus clearance that depend on antibody may be particularly important in the nervous system, where limited expression of MHC antigens may restrict the role of T lymphocytes (283,314). The disappearance of infectious virus is rapid, whereas the decline in viral RNA occurs more slowly (314). After recovery from encephalitis, viral RNA remains detectable in the CNS for life. Therefore one consequence of a nonlytic mechanism for clearance of virus from tissue is that the virus genome is not completely eliminated if the originally infected cells survive (312,313). This leads to a need for long-term control of virus replication that is accomplished in part by infiltration of antibody-producing B cells into the CNS that remain present for the life of the animal (189,191,192,576,577).

Antibody also is important for protection from infection (390). Inactivated vaccines protect against EEE, VEE, and WEE (448,449). Passive transfer of antibody before infection can protect from fatal disease (195,502). Mammals retain seropositivity for long periods after infection (72) and thus are protected from reinfection, but antiviral antibody may be more transient in birds (351).

Cellular Immunity

Alphavirus infection induces virus-specific lymphoproliferative, cytokine, and cytotoxic T-lymphocyte responses (3,68,194,330,355,383). The importance of these cellular immune responses for recovery or their potential contribution to fatal disease has not been established. After epidermal virus inoculation, Langerhans cells increase expression of MHC class II antigens, as well as accessory and costimulatory molecules that enhance activation of naive T cells (267). The mononuclear inflammatory process in alphavirus encephalitis is immunologically specific (364) and includes infiltration of natural killer (NK) cells, CD4 and CD8 T lymphocytes, B cells, and macrophages (118,244,382,393,478). Relative proportions of these mononuclear cells vary with the time after infection (244,382). T cells probably play some role in virus clearance *in vivo* because viral RNA decreases more rapidly when CD8 T cells are present (77). VEEV-specific T lymphocytes can inhibit virus replication *in vitro,* and RRV-specific CD8 T cells can clear virus from persistently infected macrophages (281,330).

Pathologic Changes

Encephalomyelitis

Pathologic changes in the CNS of humans with fatal neurologic disease and mice with experimentally induced encephalomyelitis begin with infiltration of mononuclear and occasional polymorphonuclear inflammatory cells into perivascular regions (196,364,382,409). This phase often includes perivascular extravasation of red blood cells and endothelial cell swelling and hyperplasia (409). Lymphocytes and monocytes then move from the perivascular regions to infiltrate areas of the parenchyma that contain virus-infected neurons. This inflammatory process is accompanied by

gliosis and evidence of inflammatory and glial cell apoptosis (171). Neonatal mice and human infants may die with widespread virus-induced neuronal cell death before the inflammatory process, a manifestation of the cellular immune response, can be initiated (319,400).

Neuronal cell death may be apoptotic, particularly in young animals (319), or may be characterized by cytoplasmic swelling, vacuolation, membrane breakdown, and cellular degeneration, suggesting necrosis (171,212,400). Demyelination has been described as a consequence of EEEV and WEEV infection in humans (28,409,410) and of WEEV, RRV, and SFV infection of mice, probably as a result of infection of oligodendrocytes (54,505).

Reticuloendothelial Infection

The pathology of VEE in horses includes cellular depletion of bone marrow, spleen, and lymph node tissue, and pancreatic necrosis (289). Small mammals also develop widespread necrosis of reticuloendothelial system tissues and may develop ileal necrosis (20,181,587,597). Leukopenia is commonly observed during infection (385).

Arthritis

Synovial fluid from patients with chronic RRV-induced arthritis contains increased protein, CD4 T lymphocytes, and abundant activated macrophages (94,157). Complement levels are normal, and immune complexes are not present (158). Little information is available on the pathologic changes in affected joints because the disease is not fatal in humans, and animal models for alphavirus-induced arthritis have not been developed.

Rash

Skin biopsies taken from patients with RRV-induced rash show perivascular infiltration of lymphocytes (primarily CD8 T cells) and monocytes. There is no evidence of immune complex deposition (160).

Release and Transmission

A common feature of alphaviruses is their transmission by mosquitoes and maintenance in a natural cycle of replication in vertebrate and invertebrate hosts. Mosquitoes become infected by feeding on a viremic host, are able to transmit the virus 4 to 10 days later (external incubation), and remain persistently infected. Maintenance of this cycle requires an amplifying host that develops a viremia of sufficient magnitude to infect feeding mosquitoes. For many alphaviruses, humans are dead-end hosts, unable to infect mosquitoes efficiently (289). However, there is evidence that human–mosquito–human transmission has been important in epidemics of RRV, ONNV, and CHIKV polyarthritis (337,485,560), and that horse–mosquito–horse transmission is important in epizootics of VEE (466,547).

Other modes of transmission occasionally are important. Horses infected with VEEV may shed virus in nasal, eye, and mouth secretions as well as in urine and milk (76,288). In this situation, VEEV also can be transmitted by the respiratory route. Aerosol transmission of VEEV and CHIKV has occurred in laboratory settings (76,307,557,564). EEEV persists in the feather follicles of infected pheasants, and transmission among penned pheasants has been documented to occur through feather picking and cannibalism (488). Person-to-person transmission has not been documented (307,466).

Veterinary Correlates and Animal Models

The first alphaviruses to be cultured, WEEV, EEEV, and VEEV, came to the attention of virologists because they caused fatal disease in horses; these viruses remain important equine pathogens (117,289,376,442,556). EEEV and WEEV cause encephalitis in horses, whereas VEEV causes severe respiratory disease associated with leukopenia; encephalitis may or may not be present. Getah virus causes an urticarial rash and hind-leg edema in horses (508). WEEV, EEEV, and HJV cause disease in domesticated birds such as chickens, pigeons, pheasants, turkeys, and emus (a species exotic to the Americas) (21,110,146,152,200,336,578,594,614). The alphaviruses associated with arthritis in humans have not been recognized as important causes of disease in domestic animals, although isolated cases are occasionally reported (170).

Good small-animal models exist for the encephalitogenic alphaviruses but are less satisfactory for study of the arthritogenic alphaviruses. In mice, alphaviruses generally infect lymphatic tissue, muscle, brown fat, brain, and spinal cord, but the extent and relative importance of infection at these sites differs among these viruses. For instance, RRV and Getah cause primarily myositis, VEEV causes reticuloendothelial infection, and WEEV and EEEV cause encephalitis (8,380,399). In mice infected with relatively avirulent strains of SFV, RRV, and VEEV, the acute encephalitic phase is accompanied by infection of oligodendroglial cells and demyelination (54,505). For all alphaviruses, fatal infection in mice is usually associated with CNS infection, even if encephalitis is not a manifestation of the human infection. For instance, SINV infection of mice is studied as a model for acute viral encephalitis, although SINV causes arthritis and rash, not encephalitis in humans (246,347,575). Specifics of these animal model systems are discussed with the individual viruses.

Virulence

Virulence is a measure of the ability of the virus to cause fatal disease, and for alphaviruses, this usually reflects the severity of neurologic disease (370). Outcome is influenced by the host, with most showing an age-dependent susceptibility to disease (Fig. 7) (8,45,203,389,399,417,503). Resistance increases with maturation and is associated with decreased virus replication in tissues at the site of virus inoculation and in target tissues (e.g., brain) and not with changes in the ability of infected mice to mount a virus-specific immune response (12,24,190,197,389,399). Avirulent alphavirus strains may replicate poorly even in newborn animals, whereas virulent strains can usually cause disease in adult as well as newborn animals. The ability of a virus strain to cause fatal disease or a particular complication of

infection also is often dependent on the genetic background of the host (123,534,562,568).

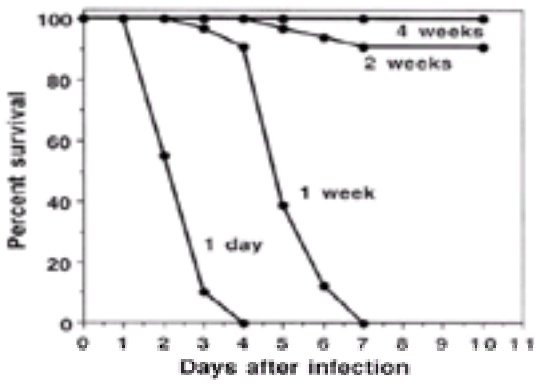

FIG. 7. Age-dependent susceptibility of mice to fatal disease after infection with the AR339 strain of Sindbis virus (SINV). Reprinted from ref. 196, with permission.

For encephalitic alphaviruses, another component of virulence is their ability to enter the CNS efficiently (neuroinvasiveness). Many alphavirus strains can cause fatal disease after intracerebral or intranasal inoculation, but not after subcutaneous or intraperitoneal inoculation. The time course of virus clearance from the blood often correlates with virulence, virulent strains being cleared more slowly than avirulent strains (250,251,253,256). The determinants of peripheral replication, viremia, neuroinvasiveness, and neurotropism (ability to replicate in CNS cells) all contribute to virulence and are likely to be influenced by different molecular characteristics of the virus.

The viral determinants of virulence have been most extensively studied in murine models for SINV, SFV, RRV, and VEEV infections. Viruses with altered virulence have been selected after chemical mutagenesis (26,50,423), by passage in tissue culture (32,108,263,280,553), by passage in mice (196,370,553), by isolation of MAb escape mutants (593) or plaque variants (249), and by manipulation of cDNA virus clones (108,344,550,567,570). Nucleotide and amino acid changes affecting virulence have been mapped to the 5' nontranslated region (NTR), nsP2, nsP3, E1, and E2. Specifics are covered in the sections dealing with each of these viruses.

Persistence

There is substantial evidence that alphaviruses can persist after appearance of an immune response, clearance of virus from the circulation, and apparent clearance of virus from tissue (313). Several progressive cases of WEEV in humans have been reported, and pathologic examination of CNS tissue months to years after resolution of acute encephalitis has shown an active inflammatory process (408,409). Viral RNA and proteins can be detected in the nervous system long after recovery of mice from SINV- or SFV-induced encephalitis (123,281,312,313,577). It is postulated that this persistence of RNA is due to failure of the virus or the immune system to eliminate the infected cells. Interestingly, passive antibody protection against fatal encephalitis predisposes to persistent infection and the late onset of progressive disease (502).

Congenital Infection

Alphaviruses can be transmitted transplacentally. This has been documented in mice for RRV, SFV, VEEV, and Getah virus (2,16,18,302,378,529) and in humans for RRV, WEEV, and VEEV (5,98,369,512). In mice the virus infects the placenta, where it is able to persist and spread to the fetus despite the development of maternal antibody. The outcome of fetal infection is dependent on the timing of infection relative to transfer of maternal antiviral IgG to the fetus. Fetuses are protected if transfer occurs before infection, but transfer of antibody after infection does not mediate recovery (378). In monkeys, congenital infection with VEEV induces malformations of the brain and eye (332). In humans, no abnormalities were observed in infants infected with RRV at 11 to 19 weeks of gestation; however, earlier infection may lead to fetal death (5). Epidemics of VEE are associated with increases in spontaneous abortion (466,609).

PATHOGENESIS AND PATHOLOGY IN MOSQUITOES

The ability of alphaviruses to infect mosquitoes efficiently with spread to and replication in the salivary glands is essential for maintaining the natural cycle of transmission. Not all mosquitoes taking a blood meal from a viremic host will become infected, and not all infected mosquitoes develop salivary gland infection and the ability to transmit the virus. Many alphaviruses preferentially infect a narrow range of mosquito species, and this host specificity plays an important role in determining the geographic distribution of the virus. Even within a species, strains of mosquitoes may vary in susceptibility to alphavirus infection. For instance, strains of *Ae. albopictus* from different geographic regions differ in susceptibility to infection with CHIKV and in the amount of virus produced after infection (559), and field and laboratory populations of *Culex tarsalis* differ in susceptibility to WEEV (235). Strains of virus also differ in their abilities to infect mosquitoes, and laboratory-adapted strains may establish infection relatively inefficiently (500,501). The extrinsic incubation period, or time between taking an infected blood meal and ability to transmit infection, is dependent on the rapidity of virus replication and dissemination to the mosquito salivary glands. This period is relatively short (2–7 days) for alphaviruses compared with other arboviruses (500). Studies of the pathogenesis of alphavirus infection of invertebrates are few compared with studies in vertebrates. The most extensive studies are of EEEV infection of its enzootic vector *Culiseta melanura* and of WEEV infection of its vector *Cx. tarsalis.*

Entry and Sites of Primary Replication

Posterior midgut epithelial cells are the initial site of infection (498,610), and infection is facilitated when virus in the serum is concentrated next to these cells as the blood meal clots (Fig. 8) (612). Susceptibility of mosquitoes to alphavirus infection is probably determined in large part by the ability of the virus to bind and infect these epithelial cells (235,500). Changes in both the virus and the vector can affect this interaction (632). Infection is often established more efficiently when mosquitoes are reared at low temperature (372,456). WEEV rapidly fuses with microvillar membrane preparations from *Cx. tarsalis* mosquitoes, and both WEEV and CHIKV bind better to membranes from susceptible mosquitoes than to membranes from refractory mosquitoes (235,394). A receptor for VEEV and SINV on the surface of the C6/36 line of larval *Ae. albopictus* cells is the high-affinity laminin receptor (335,599), and proteins of 60 and 38 kd have been identified as putative receptors for CHIKV on brush-border membranes from *Ae. aegypti* (394).

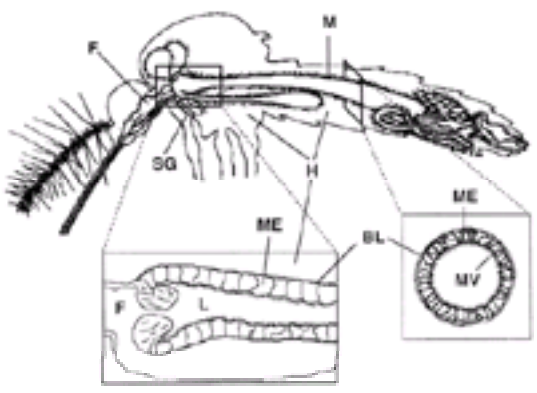

FIG. 8. Diagram of mosquito internal anatomy showing the essential sites for alphavirus infection. *BL*, basal lamina; *L*, lumen; *F*, foregut; *M*, midgut; *ME*, midgut epithelium; *MV*, microvilli or brush border; *SG*, salivary gland. Adapted from ref. 611, with permission.

The efficiency of alphavirus entry is affected by the levels of cell-membrane cholesterol (334,357). Mosquitoes, like other insects, obtain sterol needed for reproduction and development from dietary blood. Cholesterol-independent mutants of SFV replicate better than do parental SFVs in cholesterol-depleted C6/36 cells and in adult *Ae. albopictus* mosquitoes (10).

Spread

For the mosquito to become capable of transmission, virus must reach and replicate in the salivary glands (see Fig. 8). For most alphaviruses, spread beyond the midgut to other tissues is through the hemolymph (500). Virus buds primarily from the basolateral surface of the infected midgut epithelial cells and accumulates next to the basal lamina (500), a layered structure composed of mucopolysaccharide, which acts as a barrier to hemocoel entry. Infected midgut epithelial cells often degenerate and slough 36 to 48 hours after infection, and this process may facilitate penetration of the virus into the hemocoel (500,611).

Infection of salivary gland acinar cells from the hemolymph requires that the virus again traverse a basal lamina, a process that may depend primarily on hemolymph titer. The fat body is an important site for virus amplification (602,610). EEEV infects the midgut, fat body, muscle, and salivary glands without involving the nervous system or the ovarioles (498,610), whereas VEEV infects the nervous system (602), and SINV infects respiratory tissue (42).

Once salivary gland infection is established, virus matures by budding into apical cavities or randomly into vesicles, basolaterally and apically. This process may be associated with cytopathic changes in the salivary glands (379). The rapidity of virus growth and dissemination to the salivary glands is dependent on the ambient temperature. Higher temperatures accelerate the transmission cycle in warm months (458,571,572). This can be as short as 2 to 3 days (500). In general, virus content of an individual mosquito reaches peak values within 4 to 7 days after infection (379,500).

For transovarial transmission to occur, virus must be able to infect oocytes early in development. Failure to infect ovarioles regularly precludes efficient transovarial transmission of most alphaviruses (42,114,245,498,602). Eggs also can be infected after they have been fertilized. Low levels of vertical transmission have been documented in the laboratory for RRV in *Ae. vigilax* and for SINV in *Ae. australis* (424). Vertical transmission in nature has been reported for RRV, SINV, and WEEV (114,165,327,455).

Pathology, Persistence, and Host Response

Although generally considered to be benign for the invertebrate vector, infection may reduce survival and reproductive capacity (499,500). Mosquitoes remain infected and infectious for life (379,500). In the fat body and salivary glands, infection is persistent, although titers decline after the acute phase of infection, decreasing efficiency of transmission (498). Cultures of cells that become persistently infected also produce large amounts of virus initially, and then 1,000-fold lower amounts coincident with the production of an antiviral protein (105,463). The antiviral protein is a small (3 kd) hydrophobic peptide that inhibits cell proliferation and induces an antiviral state (96,341,463). Cultures can be cured by frequent media changes or by addition of antiviral antibody (242,462). Clones of mosquito cells differ with respect to virus replication and production of and response to the antiviral protein. It has been suggested that these biologically different clones are representative of cells from different tissues in the mosquito. Some tissues (e.g., fat bodies) produce large amounts of virus, whereas others (e.g., head ganglia) produce small amounts, and others (e.g., ovarioles and malpighian tubules) remain virus negative (377).

ALPHAVIRUSES ASSOCIATED PRIMARILY WITH ENCEPHALITIS

Eastern Equine Encephalitis

EEE was first recognized as a disease of horses in the northeastern U.S. In the summer of 1831, more than 75 horses died in three coastal counties of Massachusetts (208). Between 1845 and 1912, epizootics were recorded on Long Island and in North Carolina, New Jersey, Florida, Maryland, New Jersey, and Virginia (208,500). The virus responsible for EEE was first isolated in 1933 from the brains of affected horses in New Jersey and Virginia during a widespread outbreak that also involved coastal areas of Delaware and Maryland (556). Although human cases were suspected earlier, it was not until 1938 that an outbreak in the northeastern U.S. resulted in 30 cases of fatal encephalitis in children living in the same areas as equine cases. At that time EEEV was isolated from the CNS of humans (153,613), as well as from pigeons (152) and pheasants (578a).

Based on seasonality, location of cases near salt marsh areas, lack of evidence of transmission from horse to horse through contact, short period of equine viremia, and geographic distribution of cases, Ten Broeck et al. (555) postulated that insects transmitted infection and that birds were likely to be the reservoir host. The first arthropod isolates were actually from chicken mites and lice, which can transmit infection only inefficiently (132,500). Transmission of EEEV by *Ae. sollicitans* in the laboratory was accomplished in 1934 (374), and subsequently multiple *Aedes* species were shown to be competent vectors (109), but recovery of EEEV from naturally infected mosquitoes did not occur until 1949, with isolates from *Mansonia perturbans* in Georgia (239) and *Culiseta melanura* in Louisiana (83). Subsequent work showing the competence of *Cs. melanura* and a consistent association between infected birds and the isolation of virus from this vector has led to the current understanding that *Cs. melanura* is the primary enzootic vector for EEEV in North America (103,236,305,489,500).

Epidemiology

EEEV causes localized outbreaks of equine, pheasant, and human encephalitis in the summer. EEEV is enzootic in North America from New Hampshire southward along the Atlantic seaboard and Gulf Coast to Texas, in the Caribbean, and in Central America. Inland foci exist in the Great Lakes region and South Dakota (392). EEEV also is enzootic along the north and east coasts of South America and in the Amazon Basin, but human infections in these regions cause mild or subclinical disease (Fig. 9) (77). In North America, the primary enzootic cycle is maintained in shaded swamps, where the vector is the ornithophilic mosquito *Cs. melanura* (Fig. 10) (489,500). The enzootic vector in the Caribbean is probably *Cx. taeniopus* (147,596). In South and Central America, the enzootic cycle is maintained in moist forests where *Culex* (*Melanoconion*) spp. appear to be the primary vectors (500).

FIG. 9. Geographic distribution of eastern equine encephalitis (EEEV). The map shows the locations of the isolation of viruses from the four recognized EEEV lineages. Reprinted from ref. 608, with permission.

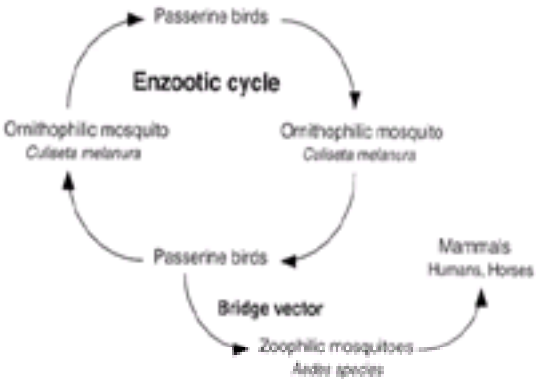

FIG. 10. Enzootic and epidemic/epizootic cycles of eastern equine encephalitis (EEEV) as an example of an alphavirus that uses a species of mosquito with different host feeding preferences to bridge from the enzootic avian–ornithophilic mosquito cycle to infect mammals such as humans and horses. Similar mechanisms are operative in transmission of Sindbis virus to humans.

Birds are the primary reservoir host, and many species are susceptible to infection, but often remain asymptomatic despite prolonged viremia (289). The amplifying species for EEEV in North America are wading birds, migratory

passerine songbirds, and starlings (103,295,368). Young birds in general are probably important for virus amplification because they are more susceptible to infection, have a prolonged viremia, and are less defensive toward mosquitoes (103). In Central and South America, forest-dwelling rodents, bats, and marsupials are frequently infected and may provide an additional reservoir, but these transmission cycles are not well characterized (500,579). Infection also has been reported in reptiles and amphibians (392).

The mechanism of virus overwintering in temperate areas is not known. The virus may be maintained by resident birds or reintroduced annually by migratory viremic birds or wind-borne infected mosquitoes coming from subtropical areas of year-round transmission (507,608). There is no convincing evidence for overwintering in mosquitoes, although laboratory evidence of transovarial transmission by *Cq. perturbans* has been obtained (392). Ovarioles are not involved during experimental infection of *Cs. melanura* (498).

Morbidity and Mortality

EEEV is the most virulent of the encephalitic alphaviruses, causing a high mortality due to encephalitis. Most cases are associated with exposure to wooded areas adjacent to swamps and marshes (60,392), and approximately equal numbers occur in female and male subjects (144). Children younger than 10 years are most susceptible (144), with one in eight infections in children resulting in encephalitis compared to one encephalitis case in 23 infections in adults (179). The case fatality rate was 60% to 70% in earlier studies and 30% to 40% in more recent studies, with the highest rates in children and the elderly (60,111,141,144,445).

Origin and Spread of Epidemics

In the northern part of the North American range, human and equine cases of EEE occur between July and October, whereas in the southern region, cases can occur throughout the year (445). In the Caribbean, outbreaks appear to be linked to virus introduction by southbound migratory songbirds (500). In North America, human and equine cases usually occur within 5 miles of swamps maintaining enzootic transmission. Outbreaks are initiated when the virus spreads from the enzootic cycle involving ornithophilic mosquitoes into mosquito populations that feed on a variety of hosts (see Fig. 10). Multiple species of mosquitoes with catholic feeding habits such as *Cq. perturbans, Ae. sollicitans, Cx. salinarius, Ae. canadensis, Ae. vexans, Anopheles quadrimaculatus,* and potentially *Ae. albopictus* can act as bridge vectors in different regions (381,500,586).

Cases of equine encephalitis are usually the first indication of an outbreak. Epizootics appear approximately every 5 to 10 years and are associated with heavy rainfall and warmer water temperatures that increase the populations of enzootic and epizootic mosquito vectors (182,310,350,392). Most of the epidemics have occurred in Massachusetts and surrounding states (144), but the largest outbreak on record occurred in 1947 in Louisiana and Texas, with 14,344 cases of equine encephalitis and 11,722 horse deaths (87). Since 1955, an average of seven cases of EEE have been diagnosed in humans in the U.S. each year (Fig. 11) (60). There is no evidence that horses or humans are important in the transmission cycle during epizootics (290).

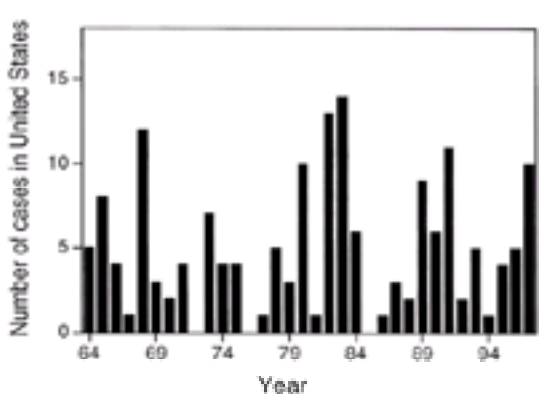

FIG. 11. Numbers of human cases of eastern equine encephalitis reported annually in the United States since 1964. Data from the Centers for Disease Control and Prevention, with permission.

Molecular Epidemiology

Antigenic differences between North and South American strains of EEEV have long been recognized (58,75), and the strains can be distinguished by reactivity with MAbs to the E1 glycoprotein (471). Sequence comparisons indicate that EEEV has evolved independently in North and South America over the last 1,000-year period. Currently one variety of EEEV is recognized in North America and the Caribbean, and three varieties are recognized in South America: one in the Amazon basin, one on the coasts of South and Central America, and a third in Brazil (46,608) (see Fig. 9). North American isolates are highly conserved, differing over a large geographic range by less than 2% in nucleotide sequence over a 63-year period, providing a calculated yearly nucleotide substitution rate of 1.6×10^{-4} (46,608). South American viruses comprise several genotypes, which differ by up to 25% in nucleotide sequences and are evolving at a faster rate (4.3×10^{-4} substitutions/nucleotide/year) (604). The South American groups are estimated to have diverged about 450 years ago and may be evolving locally within different vector–host relationships (604,608). Restriction digestion patterns of PCR products from the E1 gene and 3' NTR can distinguish these EEEV strains and provide a rapid tool for screening specimens (543).

Clinical Disease and Pathology

Illness may consist only of 1 to 2 weeks of fever, chills, malaise, and myalgias, followed by recovery (392). In cases of encephalitis, prodromal symptoms of fever, headache, and myalgias are common. The onset of encephalitis tends to be fulminant and is associated with continued fever, increased headache, vomiting, restlessness, irritability, seizures, obtundation, and coma (111,141,144,211,392). Meningismus is frequent, and focal signs including cranial nerve palsies and hemipareses are not uncommon (111,445). Hyponatremia due to inappropriate secretion of antidiuretic hormone is a common complication, and edema of the face and extremities a few days after onset has been noted (111,141). Death typically occurs within 2 to 10 days after onset of encephalitis (392).

CSF examination is almost always abnormal. Pressure is increased, and white cell counts range from 10 to 2,000/µL. Polymorphonuclear leukocytes are often abundant early in disease, with a shift to mononuclear cells over the first few days of illness (111,392). The presence of red blood cells or xanthochromia is not uncommon (445). CSF protein levels are increased, whereas glucose is low to normal (141,445). Electroencephalographic (EEG) findings are relatively nonspecific, usually showing slowing (111,445). Computed tomography (CT) scans may be normal or show only edema (111,445). Magnetic resonance imaging scans are more often abnormal, with focal lesions most commonly observed in the thalamus, basal ganglia, and brainstem (111).

Poor outcome is predicted by high CSF white cell count or severe hyponatremia, but not by the size of the radiographic lesions (111). Recovery is more likely in those individuals with a long (5- to 7-day) prodrome and without coma (445). Sequelae, including paralysis, seizures, and mental retardation, are common, with 35% to 80% of survivors, particularly children, having significant long-term neurologic impairment (111,141,144).

Histopathology on fatal cases demonstrates a diffuse meningoencephalitis, with widespread neuronal destruction, perivascular cuffing with polymorphonuclear as well as mononuclear leukocytes, and vasculitis with vessel occlusion in the cortex, basal ganglia, and brainstem. The spinal cord is frequently spared (141,153). Virus antigen is localized to neurons, and neuronal death is marked by cytoplasmic swelling and nuclear pyknosis (171). Apoptotic glial and inflammatory cells are frequently found in the regions of affected neurons (141,171,392).

Veterinary Correlates, Host Range, and Animal Models

EEEV is an important cause of disease in horses, pheasants, emus, and turkeys in North America and has been reported to cause encephalitis in dogs and pigs as well (110,141,152,201,336). Horses develop encephalitis with signs of depression, progressive incoordination, seizures, and prostration (392). The case fatality rate is 80% to 90%. Most survivors are left with neurologic sequelae (500).

Birds vary in their susceptibility, with some birds developing disease, while many others show no morbidity or mortality despite a prolonged viremia (289,336). In general, birds, even with fatal disease, do not develop encephalitis (289). Chickens, turkeys, emus, and whooping cranes have viscerotropic involvement with multifocal necrosis in the heart, kidney, and pancreas and lymphoid depletion in thymus, spleen, and bursae (110,201,392,578). Pheasants are an exception and develop encephalitis with a 50% to 70% mortality (336).

Laboratory studies of monkeys, mice, guinea pigs, and hamsters confirm the neurovirulence of EEEV for mammals (125,153,331,389,556,635). Newborn mice show extensive neuronal damage and rapid death (400). At age 3 to 4 weeks, mice become relatively resistant to peripheral, but not intracerebral, inoculation of virus (331,389). Hamsters develop encephalitis, hepatitis, and lymphatic organ infection (125).

Virulence

EEEV strains vary in their pathogenicity, with the South American strains being less virulent than the North American strains in experimental animals (500). Human encephalitis has not been recognized in South America (77), but occurs regularly in North America. Viruses with a temperature-sensitive, small-plaque phenotype and decreased virulence for mice and hamsters have been selected after chemical mutagenesis (49,50,125). The molecular bases of these differences in virulence between strains of EEEV have not yet been defined.

Diagnosis and Prevention

Diagnosis is based on virus isolation or detection of antibody. Virus can be isolated from CSF, blood, or CNS tissue by inoculation into newborn mice or onto a variety of tissue-culture cells, most commonly CEF or Vero cells (528). Antibody is usually measured by enzyme immunoassay (EIA) (500), with detection of IgM in serum and CSF particularly useful (61,62).

Infection in mosquito populations can be monitored by virus isolation, by reverse transcription–polymerase chain reaction (RT-PCR), or by seroconversion of sentinel pheasants or chickens. This information can be used to guide insecticide spraying to reduce adult and larval mosquito populations and prevent human cases (15,182). A formalin-inactivated vaccine derived from a North American strain of EEEV (PE-6) is available for horses and emus and for investigational use in humans to protect laboratory workers. This vaccine does not induce significant neutralizing or anti-E2 antibody to South American strains of EEEV (542).

Western Equine Encephalitis

Epizootics of viral encephalitis in horses were described in 1908 in Argentina, and in 1912, 25,000 horses were estimated to have died in the central plains of the U.S. (481). In the summer of 1930, a similar epizootic occurred in the San Joaquin Valley of California, causing an estimated 6,000 cases of equine encephalitis. During this outbreak, WEEV was isolated from the brains of two affected horses by intraocular inoculation of another horse, and this virus was subsequently used to infect a variety of experimental animals (376). WEEV was suspected at that time to be a cause of

human as well as equine encephalitis (375), and in 1938, WEEV was recovered from the brain of a child with fatal encephalitis (237).

Mosquitoes were implicated in disease transmission when it was demonstrated that horses developed a viremia (238) and that experimentally infected *Ae. aegypti* mosquitoes were capable of transmitting the virus to horses (275). However, it was not until the summer of 1941 during a widespread epidemic in the northern plains of the U.S. and Canada that the virus was isolated from naturally infected *Cx. tarsalis* mosquitoes (207). Subsequently, WEEV was isolated from *Cx. tarsalis* in other epizootic sites (104) and recognized to be the principal vector.

Other New World WEEV Complex Viruses

The WEE complex in the New World includes three viruses in addition to WEEV: Highlands J (HJ), Fort Morgan (FM), and Aura viruses (64). These viruses have different ecologic niches and vary in virulence. Only WEEV is recognized to cause human disease (60). Viruses in the WEE complex found in the Old World (e.g., Sindbis, Whataroa, and Kyzylagach viruses) are discussed in the section on Sindbis virus. WEEV, HJV, and FMV are all of the lineage that diverged since recombination between a Sindbis-like virus and EEEV (205). Aura virus is a “prerecombinant” virus (see Fig. 3).

Highlands J Virus

WEEV-like viruses were first isolated in the eastern part of the U.S. in 1952, and the prototype HJV was isolated in 1960 from a blue jay in Florida (225). HJV is enzootic on the East Coast of the U.S. and is maintained in a cycle similar to that of EEEV, with *Cs. melanura* the primary vector (489) and migrating birds the primary reservoir (103). HJV was initially thought to be a variant of WEEV, and it is now recognized that all alphaviruses in the WEEV complex isolated in the eastern U.S. are strains of HJV (216). Rates of divergence of WEEV and HJV of 0.1% to 0.2% per year have been estimated (95). HJV can occasionally cause encephalitis in horses (270), but is a recognized pathogen for turkeys, pheasants, partridges, ducks, emus, and whooping cranes (146,200,201,594,608).

Fort Morgan Virus

FMV and its close relative, Buggy Creek virus, were isolated from swallows, sparrows, and swallow nest bugs in eastern Colorado (67) and Oklahoma (233). FMV is not recognized as a pathogen.

Aura Virus

Aura virus was isolated in 1959 in Brazil from *Culex* (*Melanoconion*) spp. collected near the Aura River and later from *Ae. serratus* in Brazil and Argentina (78). This virus is likely to be related to the “Sindbis-like” virus that recombined with EEEV to produce WEEV (479). It has not been linked to human disease and is relatively nonpathogenic for mice (78,479).

Epidemiology

WEEV is widely distributed in the western plains and valleys of the U.S. and Canada and in South America. In North America, WEEV is maintained in an endemic cycle involving domestic and passerine birds (particularly finches and sparrows) and *Cx. tarsalis,* a mosquito well adapted to irrigated agricultural areas (60). Occasional isolations have been made from *Ae. melanimon* and *Ae. dorsalis,* also competent vectors. There is substantial evidence for a transmission cycle involving *Ae. melanimon* and the blacktail jackrabbit (60,209) in addition to the *Cx. tarsalis* avian cycle. Serosurveys and virus isolations provide evidence of natural infection in chickens and other domestic birds, pheasants, rodents, rabbits, ungulates, tortoises, and snakes (60,209). In some areas of South America, most mosquitoes from which WEEV has been isolated feed primarily on mammals, and antibodies are common in small mammals including rats and rabbits, whereas in other areas, antibodies are found primarily in birds (514,608). The mechanism of overwintering of WEEV in endemic areas is unclear. Interseasonal persistence can occur in salt-water marshes, where vertical transmission of WEEV in *Cx. tarsalis* has been demonstrated. These mechanisms would allow intermittent virus dissemination into regions without evidence of WEEV activity for substantial periods (455,457).

Morbidity and Mortality

WEEV in the western U.S. has caused epidemics of encephalitis in humans, horses, and emus, but the case fatality rate of 10% for humans, 20% to 40% for horses, and 10% for emus is lower than that for EEE (21). Increased risk is associated with residence in a rural environment (308,333). In North America, cases are seasonal, with the largest numbers of cases in July and August (333). In older children and adults, male subjects are 2 to 3 times more likely to develop disease than are female subjects (333). The estimated case-to-infection ratio is 1:58 in children younger than 5 years and 1:1,150 in adults (60). Clinically apparent disease is most common in the very young and those older than 50 years (333). Severe disease, seizures, fatal encephalitis, and significant sequelae are more likely to occur in infants and in young children (133,149,294). The overall case fatality rate is 3%, but increases to 8% in those older than 50 years (333).

Seroprevalence in humans was 34% in rural areas of California endemic for WEEV in 1960 (164) and 1.3% to 2.6% in similar areas in 1993 through 1995 (453,454). An average of 34 human cases of WEE occurred per year in the U.S. from 1955 to 1984, but have steadily declined in frequency since that time (Fig. 12). No human cases of WEE have been reported in the U.S. since 1994.

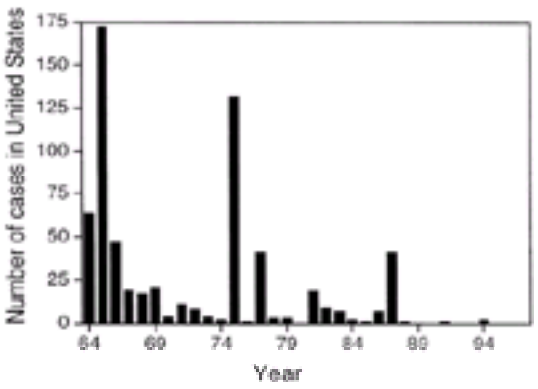

FIG. 12. Numbers of human cases of western equine encephalitis reported annually in the United States since 1964. Data from the Centers for Disease Control and Prevention, with permission.

The lack of significant human disease during equine outbreaks of WEE in South America may be related to the feeding habits of the vector or to a difference in virulence for humans and horses of South American strains of WEEV (481).

Origin and Spread of Epidemics

Periodically, large, often widespread, epidemics of equine encephalitis have occurred from mid-June to late-September in North America, with significant spillover into the human population. Typically, in an epidemic season, equine cases appear before cases in humans (442). Major epizootics occurred in the U.S. in 1931, 1933 through 1935, 1937, 1938, 1941, 1944, 1947, 1950, and 1952. In 1941, more than 3,400 human WEE cases were reported in the plains of the western U.S. and Canada, with attack rates up to 167 cases/100,000 population (60). During the 1952 epidemic in California's Central Valley, attack rates were 36 cases/100,000 humans and 1,120/100,000 equids (60).

These outbreaks correlated with increases in the population densities of *Cx. tarsalis* in the region (420). Large equine WEEV epizootics are separated by silent periods without apparent WEEV activity. Studies of differential virulence of epizootic and enzootic strains first suggested that epizootic strains arise from nonpathogenic enzootic strains (33). Sequence analysis of the viruses found at the initial focus of the 1982 WEE epizootic in Argentina indicated that the enzootic virus was the source of a virulent variant, which emerged by mutation or selection to cause the epizootic. The epizootic vector in South America is *Ae. albifasciatus,* and rabbits may serve as an amplifying host (608).

Molecular Epidemiology

WEEV has four major lineages, two in South America and two widely distributed in North and South America and the Caribbean (606,608). One was isolated during the 1982 to 1983 epizootic in Argentina; a second is related to the McMillan strain found in North and South America and Cuba from 1930 to 1972; a third was found in the same regions from 1964 to 1993; and a fourth was found in Brazil and Argentina (608). Within California, separately evolving lineages have been identified in the Central Valley and the southern part of the state (299).

Clinical Disease and Pathology

WEEV causes encephalitis with signs and symptoms similar to those of EEE. There is a 3- to 5-day prodrome of fever and headache that may progress to restlessness, tremor, irritability, nuchal rigidity, photophobia, and altered mental status (149,294,308). Paralysis is not uncommon (294,369). Infants often present with rigidity, seizures, and a bulging fontanel (149,308,369). Transplacental transmission results in perinatal infection manifesting within the first week of life as fever, failure to feed, and seizures (98,369,512). CSF pleocytosis is typical, with 100 to 1,500 cells/µL. Neutrophils are present early in disease, and mononuclear cells later (308,369).

In infants younger than 1 year, approximately 60% of survivors have brain damage, and in some, the disease is progressive (369,410). Common problems are mental retardation associated with quadriplegia, spasticity, recurring seizures, cortical atrophy, ventricular dilatation, and intracranial calcification (133,149,410,527). In older individuals, recovery is typically rapid, with remission of signs and symptoms within 5 to 10 days, and sequelae are less common (~5%) (149).

Pathology of acute cases of WEE shows leptomeningitis and perivascular cuffing with polymorphonuclear leukocytes in the earliest cases, and lymphocytes, plasma cells, and macrophages at later times. This inflammatory process is accompanied by endothelial hyperplasia, petechial hemorrhages, and glial nodules in the areas of neuronal degeneration. Lesions are found primarily in the basal ganglia, brainstem, cerebellum, cerebral cortex, and spinal cord (149,409). In addition, there are areas of focal necrosis and demyelination, particularly in the subcortical white matter and basal ganglia (409,410).

Occasionally in infants and children, there is pathologic evidence of progressive disease consistent with persistent infection (226,369,409,410). Individuals surviving months to years after onset of encephalitis (often with progressive disease) may have cystic lesions, gliosis, and demyelination, with areas of active mononuclear inflammation (226,409,410).

Veterinary Correlates, Host Range, and Animal Models

WEE was first recognized as a neurologic disease of horses, mules, and ponies characterized by fever, incoordination,

drowsiness, and anorexia, leading to prostration, coma, and death in approximately 40% of the affected animals (117,375). Emus also develop symptomatic, often fatal, disease characterized by ataxia, paralysis, and tremors (21). As a part of its enzootic cycle, WEEV infects sparrows, finches, blackbirds, mourning doves, pheasants, cowbirds, swallows, and chickens. The virus can cause fatal disease in sparrows, whereas chickens, which are often used as sentinels, develop asymptomatic infection (459). Mammals are less frequently involved, but bats, blacktail jackrabbits, gray squirrels, and ground squirrels become infected (579).

Experimentally infected newborn mice die within 48 hours after infection, with involvement of skeletal muscle, cartilage, and bone marrow. In weanling mice, brain, heart, lung, and brown fat appear to be the primary target tissues (8). After intracerebral inoculation, there is infection of the choroid plexus and ependyma, with subsequent spread to neurons and glial cells in the brain, cerebellum, and brainstem and to motor neurons in the spinal cord (331). After peripheral inoculation, WEEV replicates in skeletal muscles, causes a necrotizing myocarditis, and occasionally spreads to the CNS (331,386). Infection of hamsters with relatively avirulent WEEV strains leads to progressive neuropathologic changes consisting of perivascular inflammation, microcavitation, and astrocytic hypertrophy (641).

Virulence

Variants of WEEV with decreased pathogenicity for mice and hamsters (e.g., B628 clone 15) have been selected by passage on CEF cells (263,641). Large-plaque strains tend to be more virulent than do small-plaque strains (249). Epizootic strains appear to be optimized for viremia and neuroinvasiveness and are generally more virulent for mice and guinea pigs than are enzootic strains, and North American strains are more virulent than are South American strains (33,34,210). The molecular bases for any of these differences in virulence have not been defined.

Diagnosis and Prevention

Diagnosis can be made by detecting WEEV-specific IgM in serum (61), by isolating virus in mice or cultured cells, or potentially by RT-PCR with patient serum or CSF (432). An inactivated vaccine is available for horses and as an experimental preparation for laboratory workers (449).

Venezuelan Equine Encephalitis

In 1934 during an outbreak of equine encephalitis in the Guajira region of Venezuela, a virus (VEEV) was isolated from the brains of encephalitic horses. This virus was antigenically distinct from the viruses causing equine encephalitis in the eastern and western portions of North America (EEEV and WEEV) and became the third encephalitic alphavirus identified in the Americas (30,300). Between 1943 and 1963, VEE-related viruses were isolated and identified in many locations in South America, Central America, the Caribbean islands, and the southern regions of the U.S. (84,493). The first reported human cases of VEE were in laboratory employees working with these isolates (76,307).

Studies in Central America during this period indicated an enzootic cycle involving *Culex* (*Melanoconion*) spp. mosquitos and rodents (168,184,493). In 1969 an epizootic/epidemic of VEE appeared and spread over the next few years from Peru through Central America, Mexico, and into Texas, causing human disease and a high mortality among horses (287). Virus isolations during the epizootic were primarily from *Psorophora confinnis* and *Ae. sollicitans* mosquitoes and from horses, suggesting that the epizootic and enzootic transmission cycles differed (547).

The VEEV Complex Viruses

Using a short-incubation HI test, isolates of viruses related to VEEV were originally classified into subtypes I through IV (636). When Cabassou (CAB) and AG80-663 viruses were isolated and shown to be within the VEEV antigenic complex, they became subtypes V and VI, respectively (66,116). Currently the VEE complex includes six subtype viruses: VEE (subtype I), Everglades (EVE, subtype II), Mucambo (MUC, subtype III), Pixuna (PIX, subtype IV), CAB (subtype V), and AG80-663 (subtype VI). The VEE subtype I viruses have been further subdivided serologically into IAB, IC, ID, IE, and IF (66,636), and the MUC subtype III viruses, into IIIA, IIIB (Tonate), and IIIC (286). However, analysis of the phylogenetic relationships of the VEEV complex viruses gained from sequencing has led to a suggested reclassification of EVE (II) with IAB, IC, ID, and IE, and of IF with AG80-663 (VI) (Fig. 13) (285,372,444).

FIG. 13. Evolutionary relationships of all the antigenic subtypes and varieties of Venezuela equine encephalitis virus (VEEV) complex viruses based on E3-E2 nucleotide sequences. The dose relationships of subtypes IAB and IC epizootic prototype strains to the prototype enzootic subtype ID strain are apparent. Virus strains are listed by subtype and virus name or strain. Numbers indicate bootstrap values for groups to the right. Reprinted from ref. 444, with permission.

Epidemiology

Enzootic VEE complex viruses are involved in perennially active transmission cycles in subtropical and tropical areas of the Americas (e.g., EVE in Florida; VEE ID and IE in Central America; VEE IF, MUC, PIX, CAB, and AG 80-663 in South America). In endemic areas, mosquito isolates are made primarily from *Culex* (*Melanoconion*) spp. mosquitoes that live in tropical and subtropical swamps throughout the Americas and breed near aquatic plants (168,184,493). These mosquitoes feed at dawn and dusk on a wide variety of rodents, birds, and other vertebrates. Wild birds are susceptible to infection (82), but mammals, such as cotton rats and opossums, have been implicated as the most likely reservoir hosts by virus isolation and serology (184,493,596). Only VEEV causes significant disease in horses or humans, although there have been isolated case reports of clinically evident human infection with other VEE complex viruses (136,137).

Morbidity and Mortality

Humans living in areas of enzootic transmission have a high prevalence of antibody, but there has been little recognized disease in these populations (184,492). During epidemics, attack rates vary widely between regions [for instance, from 13% to 93% in different communities during the 1995 outbreak in La Guajira, Colombia (466)]. All ages and both sexes are equally susceptible to infection; however, disease manifestations vary with age (466). Individuals younger than 15 years are more likely to develop fulminant disease with reticuloendothelial infection, lymphoid depletion, and encephalitis. In older children and young adults, a relatively benign influenzal illness is most common (137). Individuals older than 50 years also are prone to develop encephalitis, but most recover (137). The incidence of encephalitis in clinically ill humans is generally less than 5%, and the mortality, less than 1% (466). Essentially all deaths occur in children.

Origin and Spread of Epidemics

VEE epizootics/epidemics have occurred at approximately 10- to 20-year intervals in cattle-ranching areas of Venezuela, Colombia, Peru, and Ecuador, when heavy rainfall leads to increased populations of the epizootic vectors *Ae. taeniorhynchus* and *Ps. confinnis* (466). Formalinized vaccines containing residual live virus were probably responsible for initiating the IAB outbreaks in South America that spread to Central America and Texas between 1969 and 1972 (287) and in Peru in 1973 (444,607). Until recently, viruses causing epizootics were always subtype IAB or IC, whereas enzootic viruses were ID, IE, or IF, and the epizootic and enzootic strains were thought to be maintained in separate transmission cycles. During 1995, a major VEE outbreak occurred in coastal areas of Venezuela and Colombia, causing disease in 75,000 to 100,000 people. This region had experienced a similar outbreak in 1962 through 1964. Viruses isolated on both occasions and during a smaller 1992/1993 outbreak in Venezuela were serotype IC. A similar virus had been obtained from a mosquito pool collected in Venezuela in 1983, when there was no epidemic activity. Analysis of these viruses indicated that the epizootic IC virus was not maintained in a separate cycle, but rather evolved from an enzootic ID virus in northern South America (Fig. 14) (444,461,609). Further evidence for enzootic viruses as a source of epizootic strains is the association of subtype IE viruses with two recent equine epizootics in Mexico (411).

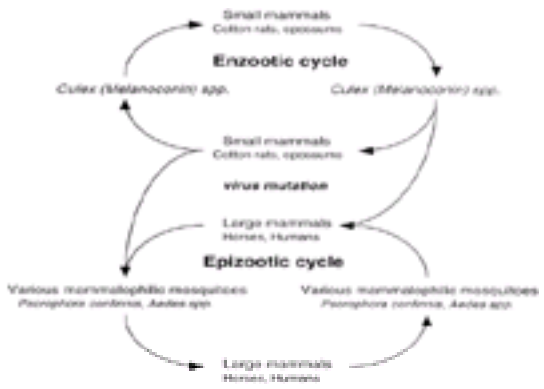

FIG. 14. Enzootic and epidemic/epizootic cycles of Venezuela equine encephalitis virus (VEEV) as an example of an alphavirus for which the epizootic strain arises by mutation from the enzootic virus. Similar mechanisms may be operative in transmission of epidemic western EEV (WEEV).

During outbreaks, virus has been isolated from several species of mosquitoes including *Ae. taeniorhynchus, Ae. aegypti, Mansonia dubitans,* and *Ps. confinnis* (547). During epizootics, horses are an important amplifying species, and availability of susceptible equines provides a means for virus spread (547).

Molecular Epidemiology

The classification and analysis of distribution of the VEEV complex viruses is an area of active investigation. Sequence analysis shows the greatest divergence for the E2 glycoprotein and the C-terminal region of nsP3 (372,444). Four enzootic subtype IAB/IC/ID/II lineages have been identified: ID isolates from Colombia and coastal Ecuador; the Everglades (EVE, II) viruses from Florida; ID strains from Panama; and ID strains from Colombia, Venezuela, and Peru. All epidemic/epizootic strains are related to the latter lineage (444). Three distinct geographically separate IE lineages also have been recognized: northwestern Panama, Pacific coast (Mexico and Guatemala), and Gulf/Caribbean coast (Mexico and Belize) (412).

Clinical Disease and Pathology

Enzootic strains produce mild disease in humans. Infection with epizootic strains of VEEV can cause significant disease, and transmission can occur by the respiratory route, as well as by mosquitoes (264,307,609). Accidental laboratory aerosol infections of young adults with epizootic strains of VEEV cause a febrile illness with the abrupt onset of chills, headache, myalgia, somnolence, vomiting, diarrhea, and pharyngitis 2 to 5 days after exposure, without evidence of encephalitis (76,137,307). Natural epidemic human infection was first described in 1952 in Colombia (137) and subsequently in Venezuela and Panama during the 1962 through 1964 outbreak that resulted in 32,000 human cases and 190 deaths (137,264). The 1995 outbreak in Colombia caused an estimated 75,000 human cases, 3,000 with neurologic complications, and 300 deaths (466,609). Neurologic symptoms tend to appear 4 to 10 days after onset of illness, with headache and vomiting the most common initial symptoms. Specific neurologic abnormalities include focal or generalized seizures, paresis, behavioral changes, and stupor or coma (466,609). Children recovering from encephalitis may be left with neurologic deficits, particularly seizure disorders (309).

Laboratory studies often show lymphopenia (264). Pathology on fatal cases has shown myocarditis, focal centrilobular hepatic necrosis and inflammation, and generalized lymphoid depletion (264). Fetal abnormalities, spontaneous abortions, and stillbirths may occur with infection during pregnancy (466,609). Congenitally infected infants show severe neurologic damage, with widespread necrosis, hemorrhage, and hypoplasia resulting, in the most severe cases, in hydranencephaly (618).

Veterinary Correlates, Host Range, and Animal Models

Enzootic strains of the VEE complex can infect horses, but these infections are asymptomatic or cause short-term fever, low-level viremia, and little clinical illness, and may immunize horses against infection with epizootic strains (148,224). Disease induced by epizootic strains is characterized by fever, depression, and diarrhea leading to death 6 to 8 days after infection. Viremia persists until death, with titers up to 10^8 infectious units/mL blood. Virus also can be recovered from eye washings, nasal washings, and urine. Leukopenia coincides with the viremia and is progressive in fatal cases. In animals that recover, antibody appears approximately 7 days after infection (288). Pathology on fatal cases shows pancreatic necrosis and cellular depletion in bone marrow, lymph nodes, and spleen. The brains of horses with signs of neurologic disease show swollen cerebrovascular endothelial cells, edema, extravasation of blood, and leukocytic infiltration into the perivenular spaces (177,288).

Infection of rhesus macaques with epizootic strains of virus elicits a biphasic febrile response: the first phase is coincident with the viremia, and the second phase with termination of viremia [i.e., the appearance of the immune response (see Fig. 5) (177,385)]. Symptoms are usually mild, consisting of anorexia, loose stools, irritability, and occasionally tremor or myoclonus at the time of fever (385). Examination of tissues shows lymphocyte depletion early, mild hepatitis, myocarditis, and encephalitis. Lesions in the brain are found primarily in the olfactory cortex and basal ganglia and consist of lymphocytic perivascular cuffing and glial nodules (177,587). Leukopenia is common. Abnormalities in glucose metabolism can be detected in young monkeys for several months after infection (41). Infection with enzootic strains causes little disease (385).

Experimental infection of small laboratory animals with VEEV produces a variety of disease patterns. After subcutaneous inoculation of guinea pigs, rabbits, or hamsters with virulent strains of VEEV, there is a viremia, and virus replicates in bone marrow, lymph nodes, spleen, and brain. There is rapid destruction of myeloid and lymphoid cells in lymph nodes, spleen, thymus, intestinal and conjunctival lymphoid tissue, liver, and bone marrow, and damage to the intestinal wall and pancreas. Hamsters also develop cerebral hemorrhage and neuronal cell death (177,180,255,587,597). Death occurs 2 to 4 days after infection and may be associated with ileal necrosis, bacteremia, and endotoxemia (181). EVEV, MUCV, and PIXV are progressively less virulent (255).

Mice are increasingly used for studies of VEEV pathogenesis. In addition to myeloid and lymphoid necrosis, mice develop encephalomyelitis, leading to death in 6 to 7 days (177,587). After subcutaneous inoculation, virus replicates first in Langerhans cells, which migrate to the draining lymph node (see Fig. 4) (346). Virus enters the CNS by the olfactory route after respiratory or peripheral inoculation and then spreads caudally to all regions of the brain, causing encephalitis and neuronal apoptosis (90,248,534). There is transplacental transmission of infection (529).

Virulence

Comparative studies of the virulent TRD and avirulent TC-83 strains of the IAB serotype and construction of recombinant viruses have led to identification of the 5' NTR (nt 3) and the E2 glycoprotein (particularly residues 76, 120, and 209) as important determinants of VEEV virulence for mice (108,284). Attenuated viruses infect dendritic cells less efficiently and replicate less well in lymphoid tissue and in the CNS than do virulent viruses (187,346,534). Analysis of the E2 sequences of endemic and epidemic VEE viruses suggests that determinants of equine virulence are different from determinants of murine virulence (444). Changes most frequently associated with acquisition of equine virulence are a Thr to Met change at position 360 of nsP3 and replacement of uncharged residues with Arg at positions 193 and 213 of the E2 glycoprotein (598).

Diagnosis and Prevention

Diagnosis can be made by virus isolation from blood or pharynx (76,307,609) or by documenting the presence of anti-VEEV IgM or an increase in IgG antibody. HI, CF, or neutralization or EIA tests can be used for serologic diagnosis (473), and RT-PCR, for detection of viral RNA (47).

The earliest vaccines to be developed for horses and laboratory workers were formalin-inactivated preparations (448,449). These vaccines had repeated problems with residual live virus producing disease and with poor

immunogenicity and are no longer in use (287,444,548,607). A live attenuated vaccine (TC-83), developed by serial passage of the Trinidad donkey (TRD) strain in guinea-pig heart tissue culture cells (32), is protective for horses and laboratory workers, but 15% to 30% of recipients develop fever and pharyngeal viral shedding (134,436). Therefore a formalin-inactivated TC-83 vaccine (C-84) was produced (134). Both the live and inactivated vaccines are immunogenic, but live TC-83 provides better protection against aerosol challenge in hamsters than does C-84 and is therefore preferred despite the reactogenicity (257). To produce an optimal vaccine, several experimental VEEV vaccines are currently under development (31,89).

A number of measures have been shown to be effective in controlling an outbreak. These include immunizing equines, limiting equine movements from regions of infection, applying larvicides to mosquito-breeding sites, and spraying insecticides to control adult mosquitoes (466,547).

ALPHAVIRUSES ASSOCIATED PRIMARILY WITH POLYARTHRITIS AND RASH

Chikungunya

An outbreak of a crippling arthritic disease of sudden onset was first recorded in the Newala District of Tanzania in 1952 and initially thought to be dengue (468). Because of the severe arthritic symptoms, the disease was given the Swahili name, *chikungunya*, meaning “that which bends up” (468). The virus, isolated in 1953 from serum and from *Aedes* spp. and *Culex* spp. mosquitoes, was distinct from dengue virus and related to the group A arboviruses (477). Subsequent large epidemics were recognized in the Transvaal of South Africa (173), Zambia (469), India (72), Southeast Asia (278), and the Philippines (80). CHIKV is a member of the SFV complex.

Epidemiology

Chikungunya is endemic in India, Southeast Asia, the Philippines, and most of sub-Saharan Africa (Fig. 15) (80,278,557,558). In Africa the virus is maintained in cycles similar to that of yellow fever virus. There is a rural cycle involving *Ae. africanus, Ae. furcifer,* and wild primates, and an urban cycle involving *Ae. aegypti* and humans (115). In rural areas, the disease is endemic, with small numbers of cases occurring most years (115). In urban areas, outbreaks are sporadic and explosive, with infection of a large proportion of the susceptible population within a few weeks (468). Outbreaks typically occur during the rainy season and are associated with increased population densities of *Ae. aegypti* (72,278,337). All ages are susceptible. After an epidemic, the disease typically vanishes from an affected region for years, possibly because large portions of the population have become immune. In Asia, where there is no evidence for a rural cycle, the virus may be maintained in an urban cycle with *Ae. aegypti* or require reintroduction before the onset of epidemics (443). Laboratory-acquired infections also have been reported (564).

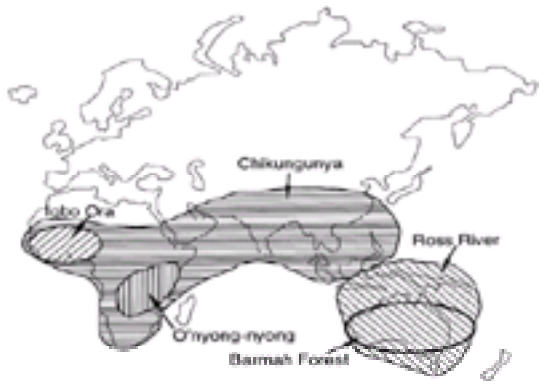

FIG. 15. Geographic distribution of several alphaviruses that cause epidemic polyarthritis and rash: chikungunya, o'nyong-nyong, Igbo Ora, Barmah Forest, and Ross River viruses.

CHIKV is thought to have originated in Africa and then spread to other parts of the world. Two distinct lineages exist, one in western Africa, and another in southern and eastern Africa and Asia (443). In the latter lineage, the Asian strains group as a genotype distinct from the African strains.

Clinical Features

The disease is of sudden onset, with an incubation period estimated at 3 to 12 days (468). No prodrome is recognized (72). Fever increases rapidly to 103°F to 104°F and may be accompanied by a rigor. The onset of fever corresponds to the period of viremia and may be related to the ability of this virus to induce large amounts of IFN (see Fig. 5) (174). Virus titers in blood reach greater than 10^6 pfu/mL (72). Joint pain appears suddenly and is often incapacitating in its severity. Patients typically lie on their sides with all joints flexed. Essentially any joint can be involved, and pain is rarely accompanied by redness or swelling (277). Headache is typically present, and in 80%, a maculopapular rash appears 4 to 8 days after the initial illness. The rash may be associated with a second increase in fever (see Fig. 5), lasts approximately 2 days, and is described as “irritating” or “itchy” (468,563). Leukopenia is typical.

In the majority of patients, joint pains continue to recur in a milder form without fever for many months after the original illness (477). Joint radiographs are normal or show soft-tissue swelling without evidence of bone or joint damage (277). Fatalities are rare, and when they occur, are associated either with young age or with a thrombocytopenic, hemorrhagic version of the illness that can lead to shock (72,487,563). In India, but not Africa, inguinal lymphadenopathy and red

swollen ears also are observed as part of the clinical picture (72,563).

Diagnosis and Prevention

The primary differential for CHIK is between dengue and o'nyong-nyong (ONN) fevers. Dengue overlaps the CHIK geographic distribution extensively, but is characterized more by myalgia than by arthralgia (277). ONN is clinically similar, but has geographic overlap only in east Africa (see Fig. 15) (72,173). CHIKV can be isolated from serum during the initial fever (173,477). Detection of IgM antibody provides a specific and reliable means of early diagnosis (62).

An experimental live attenuated vaccine has been developed by passage of an isolate from Thailand in MRC-5 cells (317). This vaccine induces long-term production of neutralizing antibody and can be used to protect laboratory workers from infection (363).

O'nyong-nyong and Igbo Ora

In 1959 an outbreak of a new disease, originally mistaken for dengue, was reported from northwestern Uganda (516). It is likely that an epidemic of ONN occurred in the same region in 1904 through 1906 (516). The name *o'nyong-nyong* originated from one of the first tribes to be affected, the Acholi, and refers to the painful joints characteristic of the disease (204). Virus was first isolated from the serum of a patient with acute arthritis (624) and subsequently from anopheline mosquitoes (626). ONNV is a member of the SFV complex and antigenically most closely related to CHIKV, from which it is estimated to have diverged thousands of years ago (443,624). The virus reemerged in southern Uganda in 1996 to 1997 to cause the most recent epidemic (303), suggesting a 30- to 50-year epidemic cycle.

In 1967 a related virus, Igbo Ora, was isolated from humans in western Nigeria (388). It has subsequently been recovered from humans and anopheline mosquitoes in the Central African Republic, Nigeria, and the Ivory Coast (320).

Epidemiology

ONNV is a virus of East Africa (see Fig. 15) that causes sporadic, widespread outbreaks of fever, rash, and arthritis with high attack rates. The first epidemic recognized to be ONN originated in northwestern Uganda in 1959 and spread south and east to Kenya, Tanzania, Zaire, Malawi, Mozambique, and Zambia to affect more than 2 million people (625). Serologic studies suggesting that the virus also occurs in the West African countries of Nigeria, Ghana, and Sierra Leone (631) may reflect infection with the closely related Igbo Ora virus (320).

The enzootic vector and vertebrate reservoir host for ONNV are unknown. Interepidemic seroconversions and mosquito isolations indicate continuous sporadic transmission in East Africa, and it is possible that humans or nonhuman primates are the primary reservoir (303). ONNV is transmitted principally by *Anopheles funastus* and *An. gambiae* (345,626). Human–mosquito–human transmission occurs during epidemics, and spread from one region to another occurs through the movement of viremic humans (485). The most recent outbreak began near swamps and lakes in the rural Rakai district of south-central Uganda. Serosurveys showed infection rates of 45% to 96% in areas of epidemic transmission, with the ratio of apparent to inapparent infection ranging from 1:4 to 1:24 (485,627). All ages and both sexes are equally susceptible (291). The seroprevalence for Igbo Ora in Nigeria is approximately 25%. Among domestic animals in the same region, cattle have the highest seroprevalence (40%) (414), but the enzootic reservoir for this virus also is not known.

Clinical Features

The onset of fever is sudden and often accompanied by a rigor. The characteristic syndrome includes joint pains, rash, lymphadenitis, and conjunctivitis. Fever is typically moderate (100°F to 101°F) and lasts approximately 5 days. Joint pain most often occurs in the knees, but ankles, elbows, wrists, and fingers also can be affected. The pain usually lasts 6 to 7 days and is severe enough to be immobilizing in 80% to 90% of patients. Pain can persist for up to 3 months, but this is uncommon. The generalized morbilliform maculopapular rash erupts 4 to 7 days after the onset of symptoms and is similar to that of CHIK. It begins on the face and extends to the trunk and extremities, occasionally affecting the palms. Cervical lymphadenopathy distinguishes the disease from CHIK, occurs in approximately half of the patients, and most frequently involves posterior cervical lymph nodes. Leukopenia is common. Fatalities have not been described, but morbidity is substantial (291,516). The disease caused by Igbo Ora virus infection is similar, but lymphadenitis is uncommon (320,388).

Diagnosis

The disease is often clinically confused with malaria, measles, denque, and rubella (516), but also resembles CHIK. Virus can be isolated from serum early in the illness (625). Diagnostic serology includes a positive IgM EIA or neutralizing antibody to ONNV that is more than two-fold greater than that to CHIKV (485). IgM persists for about 60 days after infection (291).

Ross River

Epidemics of polyarthritis in Australia were first described in towns on the Murrumbidgee River in New South Wales in 1928 and then in troops stationed in the Northern Territory and Queensland during World War II (124,347,407,517). Serologic studies subsequently suggested an alphavirus as the causative agent (515), and RRV (strain T48) was first isolated from *Aedes vigilax* mosquitoes trapped near the Ross River in Queensland in 1959 (347). The first human isolate was made in 1971 from the blood of a child with fever (121). In 1979 RRV spread from Australia to Fiji, Samoa, and the Cook Islands, causing an explosive outbreak of tens of thousands of cases of polyarthritis on these Pacific islands. Virus

was first isolated from the serum of patients with polyarthritis during this epidemic (4,475,560).

Epidemiology

RRV is endemic throughout the coastal regions of much of northern and central Australia and epidemic in the rest of Australia, in Papua New Guinea, and in the Solomon Islands (6,475,560). In general, the Wallace and Weber hypothetical lines in the Indo-Australian archipelago that separate the fauna of the Asian and Australian regions appear also to separate the geographic distributions of CHIKV and RRV (see Fig. 15) (347,558). RRV is the most common cause of human arboviral disease in Australia, and cases occur primarily in late summer and early autumn (215,347). Two salt marsh–breeding mosquitoes, *Ae. camptorhynchus* and *Ae. vigilax,* are probably the major vectors in coastal regions of Australia (22,70,169). In suburban areas, fresh water–breeding mosquitoes, *Cx. annulinostris* and *Ae. notoscriptus,* are important vectors (465). A wide variety of mammals, primarily macropods, appear to serve as vertebrate hosts for the enzootic cycle (122,170,475).

Morbidity and Mortality

Infection rates can be as high as 1:30 during outbreaks (347). Estimates of ratios of apparent-to-inapparent infection vary from 1:3 to 1:50 (6). Seroprevalence is similar in both sexes and, in populations living in epidemic areas, ranges between 6% and 15%, whereas in endemic areas, it reaches 5% to 72%, with estimated infection rates of 0.4% to 2.4% per year (156,215). Clinically apparent infections are rare in children, and the highest incidence of disease is in the 30- to 40-year age group (4,214). Clinical disease rates in coastal regions of Queensland have been estimated at 0.37/1,000 adults/year (6). Polyarthritis may be more common in female subjects, but not all studies show this trend (4,6,119,214). The MHC class II antigen HLA-DR7 may predispose to clinical disease (161), but no association with MHC class I molecules HLA-A or HLA-B has been identified (6).

Origin and Spread of Epidemics

In Australia, outbreaks are seasonal and have been associated with prolonged inundation of salt marshes due to increased tidal heights or heavy rains with localized flooding during the summer (347). In arid regions, outbreaks often occur within 2 or 3 weeks of heavy rains, suggesting that RRV survives in desiccation-resistant mosquito eggs with vertical transmission (327). This is further suggested by isolation of RRV from field-caught immatures and male *Ae. vigilax* and *Ae. tremulus* mosquitoes (114,327). Epidemic polyarthritis, initiated by a viremic traveler from Australia to Fiji, occurred on several South Pacific Islands between 1979 and 1980 in explosive outbreaks similar to those of urban CHIK with a human–mosquito–human transmission cycle and *Ae. polynesiensis* as the vector (475,560). Human viremias of more than 10^6 mosquito ID_{50}/mL have been documented (560). RRV has not been found in the region since, suggesting that an endemic cycle was not established.

Molecular Epidemiology

Strains of RRV from the northeastern (Queensland) and southeastern (New South Wales) regions of Australia are antigenically distinguishable. Genotyping reveals a third distinct group in western Australia (483,630). Pacific Island isolates all belong to the southeastern genotype. The data suggest genetic divergence and independent evolution of RRV within geographically isolated enzootic foci, consistent with mammals as a vertebrate reservoir (483).

Clinical Features

RRV infection most often induces fever, arthralgia, and rash (see Fig. 5), but not all patients develop all three symptoms (214,557). The incubation period for onset of disease can be as short as 2 days or as long as 21 days, with an average of 7 to 9 days (162,475). Usually the illness has a sudden onset. Fever is the initial symptom, is low grade, and is typically followed by the onset of pain, swelling, and tenderness in multiple joints. Joint involvement is usually symmetric, and both small and large joints can be affected. Characteristically, the rash appears on the third or fourth day of illness, is maculopapular, nonpruritic, and present on the face, trunk, and extremities, with occasional involvement of the palms and soles. The rash generally lasts 3 to 4 days, but can be prolonged (155). Frequent accompanying signs and symptoms include lymphadenopathy, lethargy, headache, myalgias, and photophobia. Glomerulonephritis also has been reported (159). Duration of illness varies considerably. The average period of incapacity is 6 weeks (214). Joint symptoms may be protracted, with almost half of affected individuals still having chronic generalized malaise and/or joint stiffness a year after infection (506). Essentially all experience gradual improvement without destructive joint changes or long-term problems.

Examination of synovial fluid shows increased protein and the presence of lymphocytes, monocytes, and activated macrophages (94,157). Cell counts are moderate, ranging from 1,500 to 15,000 cells/mm^3 (157). RRV replicates in and causes persistent infection of synovial cells and macrophages *in vitro,* but this has not been documented to occur *in vivo* (100,268,329). There is no evidence of a role for immune complex formation in the pathogenesis of prolonged and recurrent arthritis (94,158).

The skin lesions show mononuclear perivascular inflammation without evidence of immune complex deposition. Most of the infiltrating cells are $CD8^+$ T lymphocytes. RRV antigen is present in the basal epidermal and eccrine duct epithelial cells (160).

Animal Models and Host Range

Despite its extensive host range, RRV is known to induce clinically evident disease only in humans, mice, and possibly horses (169,553). The most commonly studied animal model of RRV infection is the mouse. The prototype T48 strain has been extensively passaged in mice and is virulent (380,399). In newborn mice, T48 infects cardiac muscle, causing

myocardial necrosis and death 3 to 4 days after infection (399). The mechanism of virus entry into muscle is not clear because there is no evidence of infection of vascular endothelial cells (399,505). By 1 week of age, infection is no longer fatal, and infection of the CNS leads to demyelination and destruction of the internal granule cell layer of the cerebellum (505). The ability of the virus to replicate in muscle and CNS continues to decline with increasing age. Sites of myocardial and skeletal muscle infection become calcified (399,503). Necrosis and calcification are results of virus-induced cellular damage, not of immune-mediated damage (503). Replication also occurs in perichondrium, periosteum, and skin (399). In pregnant mice, virus can replicate in the placenta and spread to the fetus 1 to 2 days later (378).

The less virulent NB5092 strain induces severe myositis and muscle cell death in newborn mice after subcutaneous inoculation (399). Mice become stiff and unable to move, and then gradually regenerate muscle and recover function after virus is cleared (399). CNS disease is minimal, with patchy infection of ependymal cells and ependymitis, leading to hydrocephalus. Neurons are only occasionally infected (380). Brown fat is another important site of virus replication (399). By age 1 week, mice no longer develop signs of disease (399).

Virulence

Two prototype strains of RRV isolated from *Ae. vigilax* are recognized. T48, isolated in Queensland, is virulent for newborn mice, whereas NB5092, isolated in New South Wales, is not (170). These viruses have amino acid differences at 36 residues in the nsPs and at 12 residues in the structural proteins (140). Virulence has been associated primarily with amino acid changes in E2. Viruses with changes in epitope E2-b2 show more rapid penetration kinetics for BHK cells and decreased virulence for mice (593). A small-plaque mutant of T48 with a deletion of 21 nucleotides encoding E2 residues 55 to 61 grows normally in BHK cells, but replicates less well in muscle and brain of newborn mice, causing less paralysis than does the parental T48 strain (591).

Passage of the avirulent NB5092 strain in newborn mice selected for a more virulent virus with amino acid changes in E2 (370,553). Passage of NB5092 on CEF cells led to the isolation of less virulent variants with antigenic and amino acid changes in E2. Viruses with an Asn to Lys change at E2-218 produce lower viremia and more rapid clearance than does the parental virus (280). Of unproven but possible significance is the fact that the epidemic strain of RRV in the Pacific differed from the parent Australian strain by a change from Thr to Ala at E2-219 (53).

Diagnosis and Prevention

Diagnosis is aided by geographic location and travel history. The differential diagnosis includes rubella, other alphavirus-induced arthritides, Henoch–Schönlein syndrome, and, in the chronic form, rheumatoid arthritis and other chronic rheumatic diseases (155). Virus can be recovered from blood early in disease (4,475,560), but most diagnoses are made by using serology. The most sensitive and commonly used serologic test is an IgM capture EIA, which can remain positive for 1 to 2 years after the onset of disease (74).

Vector control remains the primary means of prevention. A candidate inactivated vaccine has been developed and tested in animals (1).

Sindbis

The prototype strain of Sindbis virus, AR339, was initially isolated from *Cx. univittatus* collected near Sindbis, Egypt, in 1952 (552). Because the virus caused fatal disease in mice, it was originally thought to be a coxsackievirus (551). Humans living in the Nile Delta at that time had a seroprevalence of 27%, but no disease was recognized to be associated with infection (552). Over the next 25-year period, SINV was isolated in Europe, the Middle East, Africa, India, Asia, Australia, and the Philippines from a variety of mosquito and vertebrate species (120,339,352,405,615). SINV was first isolated from the blood of febrile humans in Uganda in 1961 and recognized in South Africa as a cause of rash and arthritis in 1963 (352).

Epidemiology

SINV is the most widely distributed of the alphaviruses causing arthritis in humans (Fig 16). The primary sites of recognized SINV-mediated human disease are in Northern Europe (Ockelbo in Sweden, Pogosta Fever in Finland, and Karelian Fever in Russia) (139) and South Africa (see Fig. 16) (269). In the many other regions where the virus exists, human infection occurs, but results only in subclinical disease fever or mild arthralgias. The basic maintenance cycle of SINV is between *Culex* spp. and *Culiseta* spp. mosquitoes and wild birds (347). In Sweden the enzootic cycle involves *Cx. torrentium, Cs. morsitans,* and passerine birds (154,338). In Australia isolates are primarily from *Cx. annulirostris* (603). Vertical transmission in mosquitoes can occur (114).

FIG. 16. Geographic distribution of Sindbis virus. Northern Europe and South Africa, regions with significant outbreaks of

arthritis and rash disease in humans, are designated in bold. Mild disease also has been recognized in Australia.

Morbidity and Mortality

The age-adjusted prevalence for SINV is 2% to 8% in endemic regions of northern Europe and 0.1% to 0.2% in neighboring nonendemic areas. Risk is highest between parallels 60 and 64 (139,339).

Origin and Spread of Epidemics

Spread of SINV from its enzootic cycle between birds and ornithophilic mosquitoes to humans involves introduction of the virus into *Aedes* spp. mosquitoes with less specialized feeding habits, as bridge vectors (see Fig. 10) (573). In Northern Europe the primary bridge vector is *Ae. cinereus,* and availability of this species may determine the frequency of human infection. Cases begin to appear in late July and continue into the fall. Large outbreaks occur approximately every 7 years (339).

Molecular Epidemiology

Antigenic and genetic analyses of strains from different locations indicate that viruses from Africa and Europe form one major lineage, and those from Asia and Australia, another lineage, suggesting that the ancestral SINV has diverged into two distinct groups (340,421,484). A third lineage has recently been identified in southwestern Australia (484). Strains isolated in Northern Europe and South Africa, where SINV-induced disease occurs, are more closely related to each other than to strains isolated in south and central Europe and the Middle East, where disease is rare (339,513). Within a region, strain divergence is temporal rather than geographic, consistent with migratory birds serving as the major vertebrate host (484).

Clinical Features

When clinical disease is apparent, the primary manifestations of infection are rash, joint pain, and mild fever, often occurring concurrently (139,575). SINV can be recovered from skin lesions, which have a macular base with central vesicle formation and are occasionally hemorrhagic (139,199,352). The rash is distributed diffusely over the trunk and limbs and affects the palms and soles. Joint pain preferentially affects large joints and may be severe enough to be immobilizing. Most patients recover within 14 days, but joint pain and stiffness may persist for months to years (139,366,575). In Australia, SINV-induced arthritis and rash is milder and less frequent than RRV-induced disease or SINV-induced disease in northern Europe and Africa (347).

Animal Models and Host Range

SINV can infect a wide variety of vertebrates and has been extensively studied in mice as a model for acute encephalitis. The virus has been most frequently isolated from domestic and wild birds, its major host, but on occasion from small mammals and amphibians. Seroprevalence is 11% in central Sweden in passerine birds without recognized disease.

In mice there is an age-dependent susceptibility to fatal encephalitis (see Fig. 7) (266). In young mice, virus replicates to high titer and spreads rapidly, causing death in 3 to 5 days. In older mice, virus replication is more restricted, and mice often recover. After peripheral inoculation, virus replicates in muscle, produces a viremia, and then spreads to the brain and spinal cord, where the primary target cells are neurons (246). Ability of SINV to spread to the CNS and cause fatal disease is dependent on the strain of virus and the genetic background, as well as the age of the mouse (247,298,342,343,357,510,568). Within 3 to 4 days, neutralizing antibody and a SINV-specific perivascular mononuclear inflammatory response appears, consisting of T cells and monocytes (382). Spread of infection is limited initially by IFN, and infectious virus is cleared within 7 to 8 days after infection, primarily through the effects of antiviral antibody (see Fig. 6) (55,189,314,450). Even after clearance of infectious virus, viral RNA persists in the CNS, and reactivation of infection appears to be prevented by continued production of antiviral antibody by B cells resident within the CNS (312,313,577).

Virulence

Strains of SINV differing in virulence have been derived from independent isolates from Egypt (AR339), South Africa (SR86), and Israel (SV-Peleg). Variants of AR339 and SV-Peleg differing in virulence have been derived by passage in mice (194,342) and in tissue culture (373). Virulence is determined primarily by the 5' NTR and the E2 glycoprotein, but can be influenced by changes in E1 and nsP2 (106,344,367,497). Changes in nucleotide 5 or 8 from A to G increase neurovirulence by unknown mechanisms (129,367). A number of amino acid changes in the E2 glycoprotein affect virulence by altering efficiency of virus entry into the CNS and of neuronal infection (see Fig. 2) (106,219,438,497,567,570). Neuroinvasion is affected by changes at residues 55 and 190 of E2 (129). A Gln-to-His change at E2-55 increases efficiency of infection of neurons and is a major determinant of increased virulence in older mice (127,569,570).

Diagnosis

Diagnosis is most often made by serology, with the major differential being with other causes of acute rash and arthritis such as parvovirus B19 and rubella. SINV-specific IgM increases during the acute phase of the disease and then tends to decrease slowly for 3 to 4 years, independent of persistent symptoms (406).

Barmah Forest

Barmah Forest virus (BFV) is an Australian alphavirus first isolated in 1974 from *Cx. annulirostris* mosquitoes collected in the Barmah Forest in the Murray River Valley region of southeastern Australia and soon thereafter in southwest Queensland (14). It is the only recognized member of the BFV complex and has a unique E2 protein without N-linked glycosylation (306). Human disease was first reported in 1986 with an epidemic of polyarthritis in New South Wales (40), and BFV was first isolated from the blood of a patient in 1988 (434). In 1989 BFV, previously restricted to eastern portions of Australia, was isolated in Western Australia. Human cases of BFV-induced arthritis in this region were documented in 1992, and an outbreak occurred during the summer of 1993 to 1994, suggesting recent introduction of the virus into this region (328).

The vertebrate reservoir host is unknown, but serosurveys suggest that marsupials may play a role (328). Conversely, sequence analysis shows a high degree of homology over the geographic distribution, consistent with an avian vertebrate host (437). The main mosquito vectors appear to be *Ae. vigilax* and *Ae. camptorhynchus,* salt marsh–breeding mosquitoes that also are the primary vectors of RRV in the same regions (43,328).

Serosurveys show higher rates of infection in men than in women (1.5:1) The highest seroprevalence is in the north coastal areas of New South Wales, where 13% of the population tested was positive (14,213). Infection rates of 0.23% per year occur in the population of Queensland (434).

Clinically evident disease is most common in the 30- to 50-year age group, with both sexes equally affected (29). The most common clinical features are fever, lethargy, polyarthritis, and myalgia, which are often accompanied by a vesicular rash (14,29,434). Diagnosis may not be made because the illness is frequently mild and overlaps the clinical spectrum and geographic distribution of RRV and SINV infections (see Fig. 15 and Fig. 16). A single case of glomerulonephritis has been reported (273). In more than half of infected individuals, recovery takes several weeks, with lethargy the most prominent persisting symptom (29). Rash is more prominent in BFV, whereas arthritis is more prominent in RRV (151). The serology is distinct (434).

Mayaro

Mayaro virus was first isolated in 1954 from the blood of febrile forest workers in Trinidad and then from several individuals with a febrile illness associated with frontal headache in the Guama River area of Brazil (13,79). Subsequently the virus has been documented to be widely distributed in northern South America and the Amazon Basin. Human cases are sporadic and occur primarily in persons with recent contact with humid tropical forests. The principal mosquito vectors are in the forest-dwelling genus *Haemagogus,* but the virus also can infect and be transmitted by *Ae. aegypti,* and the possibility of urban outbreaks has been raised. The diagnosis can be made by isolation of virus from blood in Vero or C6/36 cells or by serology with an IgM capture EIA (62,561).

OTHER ALPHAVIRUSES

Semliki Forest

SFV was first isolated in 1942 from *Ae. abnormalis* collected in the Semliki Forest of western Uganda (523). It is widely distributed in Africa with mosquito (e.g., *Ae. africanus, Ae. argenteopunctatus*) isolates documented from Mozambique, Nigeria, and the Central African Republic (349,361,365). Although SFV is one of the most extensively studied of the alphaviruses, and serosurveys indicate that human infection is relatively common (339,361,523), SFV has been linked to human disease on only two occasions (361,623). In the first case, reported in 1979, a 26-year-old laboratory worker in Germany with a 1-year history of “purulent bronchitis,” working with the Osterrieth strain of SFV, developed fever and headache followed by seizures, coma, and died of encephalitis. SFV was isolated from CSF and from brain. No antiviral antibody was detectable at the time the CNS symptoms began, but was detected at the time of death 1 week later (623). The history of chronic pulmonary infections and failure to produce antiviral antibody rapidly suggest that this individual had an immunodeficiency disorder involving antibody production. In 1987 SFV was isolated from serum samples of individuals in the Central African Republic with fever, persistent headache, myalgias, and arthralgias (361).

Animal Models

SFV can cause encephalitis in horses, mice, rats, hamsters, rabbits, and guinea-pigs (19,45,467,523,640). Severity and type of disease are dependent on the age of the animal at the time of infection, on the route of inoculation, and on the virulence of the strain of SFV used for infection (45,197). Mice have been most extensively studied, and the strain of inbred mouse infected also can influence outcome (545).

In newborn and suckling mice inoculated peripherally, virulent and avirulent strains of SFV replicate rapidly and extensively in muscle, elicit a high-titered viremia, spread to the CNS, and cause death within 2 to 4 days (197,398). SFV replicates in cerebrovascular endothelial cells *in vitro* (126), and viral antigen also can be detected in endothelial cells *in vivo* (281,525), but it has been suggested that endothelial cells transport virus from blood to brain without replicating virus (426). Once within the CNS, the virus replicates primarily in neurons and spreads rapidly along neural pathways, producing neuronal cell death (417).

In weanling (3- to 5-week-old) mice, SFV replicates rapidly, but reaches lower peak titers in muscle, blood, and brain than in younger animals. There is a continued age-dependent decrease in virus replication to age 12 to 15 months (197). Virus enters perivascular regions of the brain and initiates foci of infection within the CNS. After intranasal inoculation, virus infects olfactory neurons first and then spreads within the CNS (417). The primary target cells in the brain are neurons, but glial cells also are infected (19,143,281). A mononuclear inflammatory response consisting of T lymphocytes, B lymphocytes, and monocytes is apparent 3 to 4 days after infection, peaks at 2 to 3 weeks, and is mostly

resolved by 6 weeks (393). Inflammation is accompanied by microglial and astrocyte activation (91,118,393,546).

Mice that survive infection develop demyelination, accompanied by mild paralysis, 2 to 4 weeks after infection (92,425,546). Clearance of infectious virus is complete 7 to 10 days after infection, and this clearance is mediated by antibody (12). Viral RNA and protein persist for months (123,281), and hydrocephalus can be a late consequence of infection (639). Mice infected with virulent strains can be passively protected from fatal encephalitis with immune serum, but then develop a delayed disease associated with persistent infection, inflammation, and neuronal degeneration (502). Focal areas of demyelination are found in the optic nerve and cerebellum 14 to 21 days after SFV infection and are characterized initially by swelling and vacuolation of oligodendrocytes and loss of myelin sheaths, followed by apparent oligodendrocyte dedifferentiation and then remyelination (54). Demyelination is macrophage mediated and appears to be the result of oligodendrocyte infection, the cellular immune response to infection, and induction of an autoimmune response to myelin basic protein (142,509,544). SJL mice have prolonged inflammatory responses and demyelination after infection compared with other strains of mice (123,524).

SFV infection of the CNS also can increase the susceptibility of mice to induction of experimental autoimmune encephalomyelitis (384), apparently by damaging the blood–brain barrier, increasing adhesion molecule expression on endothelial cells, and facilitating entry of autoimmune T lymphocytes into the CNS (138,525,526).

Virulence

Isolates from mosquitoes collected in 1942 in Bwamba, Uganda (523), in 1948 in Kumba, Nigeria (349), and in 1959 in Namancurra, Mozambique (365), have given rise to a variety of strains of SFV with differing levels of virulence. The most commonly studied are virulent strains V12, V13, and L10 [Uganda strain independently passaged in mice in Bethesda (V) and London (L)], and avirulent strain A7 (Mozambique strain AR2066 passaged in mice) and its less virulent derivative A7-74 (45). In addition, avirulent strains of L10 have been derived by chemical mutagenesis (e.g., m9) (26). Virulent and avirulent strains differ in their ability to invade and replicate in the CNS of weanling mice and rats after peripheral inoculation (19,44,446), but all strains cause fatal disease in newborn or suckling mice (197,398). Resistance to fatal disease develops between ages 1 and 3 weeks (45,418). In 3- to 4-week-old mice, avirulent SFV is restricted in replication and spread in the CNS compared with virulent strains of virus and compared with avirulent strains in younger mice (143,418). This difference in replication is associated with decreased budding of infectious virus and is independent of host immune response (12,143). Mature neurons and pancreatic and myocardial cells can be made more susceptible to replication of avirulent virus by treatment with aurothiolate compounds, which induce intracellular membrane proliferation (371,491). In general, reduced virulence correlates best with reduced ability to replicate in neurons (23).

In vitro studies of the differences between virulent and avirulent strains of SFV have shown differential replication in mouse neuroblastoma cells and primary cultures of rat neurons (17). Efforts to identify specific nucleotide and amino acid changes important for virulence have used comparative sequence analysis and an infectious SFV cDNA clone pSP6-SFV4 derived from the prototype virulent L10 strain (324). However, SFV4, the virus derived from this cDNA, is less virulent than L10 (176). Construction of SFV4/A7 chimeric viruses has shown that determinants of virulence reside in both the structural and nonstructural regions of the genome (550). NsP2, nsP3, and E2 are important determinants of virulence (175,464,486). The 3' NTRs differ significantly in length, but this is not important for virulence (486).

Other SFV Complex Viruses

The SFV complex includes nine viruses and has representatives in both the Old World (BEB, CHIK, GET, ONN, RR, and SF) and the New World (MAY and Una). Human disease, when present, is generally characterized by fever that may be accompanied by arthritis and rash. CHIKV, ONNV, RRV, MAYV, and SFV were discussed previously.

Una Virus

Una virus was first isolated from *Psorophora ferox* mosquitoes collected in the Amazonian region of Brazil in 1959 (78). This virus is pathogenic for mice, relatively unstudied, and is not recognized to cause human disease. Una virus also has been isolated in Trinidad (78).

Getah Virus

Getah virus was first isolated from *Culex* spp. mosquitoes collected in Malaysia in 1955 and causes myositis when inoculated into mice (230). It is maintained in a cycle similar to that of Japanese encephalitis virus with transmission by *Cx. tritaeniorhynchus* and amplification in domestic pigs (519). Getah virus is widespread in Asia, with documented presence in India, Sri Lanka, China, Southeast Asia, Malaysia, and Japan (353,428,558). Disease in humans is limited to fever (321), but it causes abortion in pigs and is an important pathogen of horses (508,511). The equine disease is characterized by fever, an urticarial rash, and hind-leg edema (508).

Me Tri Virus

Me Tri virus was isolated from *Cx. tritaeniorhynchus* mosquitoes collected in the Hanoi province of Vietnam. Serologic surveys suggest that infection of humans and domestic animals is common. It may be a significant human pathogen because a retrospective study identified nine cases of encephalitis in children associated with seroconversion to this virus (202).

Alphaviruses of Fish

Atypical alphaviruses, sleeping disease virus and salmon pancreas disease virus, have recently been isolated from rainbow trout and Atlantic salmon. These viruses cause significant disease on fish farms. Both have unusually large E1

and E2 structural glycoproteins and relatively low (30–34%) homology to other alphaviruses (589,621).

DIAGNOSIS

The differential diagnosis of alphavirus-induced diseases often includes more than one alphavirus in addition to other mosquito-borne viral diseases such as dengue and West Nile fevers, other rash diseases such as rubella and parvovirus B19, and other causes of encephalitis. IgM capture EIAs can be used for diagnosis early in disease (65). The IgM response is relatively specific for each antigenic complex and is useful even at later times, because IgM persists for at least 2 to 3 weeks after onset of disease (62). RT-PCR primers can amplify the conserved region of all alphaviruses (432) and should be useful for rapid diagnosis.

PREVENTION AND CONTROL

Treatment

There is currently no available specific antiviral treatment for any alphavirus-induced disease. Supportive treatment for those with encephalitis can be lifesaving, because individuals can make remarkable recoveries from coma. Symptomatic treatment for arthritis is beneficial.

Vaccines

Formalin-inactivated vaccines against EEE, WEE, and VEE are available for horses and against EEE for birds. Experimental inactivated human vaccines against EEE, WEE, and VEE also are available for laboratory workers exposed to these agents, with yearly booster doses required for EEE and WEE. PE-6, the investigational inactivated EEE vaccine for humans, induces good immunoreactivity against the North American, but not the South American, varieties of EEEV (542). Live attenuated vaccines have been developed for VEEV (TC-83) and CHIKV. Side effects are common after immunization with TC-83 (134,317,436). In both horses and humans, prior immunization against one alphavirus interferes with development of neutralizing antibody to subsequent alphavirus vaccines (116,363).

Other

Prevention of infection with most alphaviruses relies primarily on efforts to control mosquito populations by spraying and reducing breeding places. A variety of means can be used for assessing the need for mosquito abatement. These include monitoring mosquito population densities, seroconversion of sentinel animals, and presence of virus in populations of mosquitoes capable of transmitting virus to humans or domestic animals. Use by individuals of protective measures such as mosquito repellents and protective clothing is important.

PERSPECTIVE

The ability to construct full-length cDNA alphavirus clones that can be transcribed into infectious RNA provides tremendous potential for understanding the functions of various genes and their importance for replication and virulence in the multiple hosts necessary for maintenance of these viruses in their natural cycles. An understanding of the folding and three-dimensional structures of the structural glycoproteins is needed for interpretation of much of the sequence and virulence data that have been acquired. Further sequence information on virulent and avirulent strains and functional analysis of the nonstructural proteins is likely to provide the next level of understanding of virus–host relationships.

In addition, there is a need for improved approaches to prevention and treatment. There is a particular need for a vaccine for RRV and an improved VEEV vaccine. In addition, there is a need for effective antialphaviral drugs. Continued advances in understanding of the structure of viral proteins is likely to offer new approaches to therapeutics. Both of these areas have implications for defense against biologic warfare and bioterrorism, because VEEV, EEEV, and WEEV are all on the Centers for Disease Control (CDC) category B list of critical biologic agents (81).

CHAPTER 31 Rubella Virus

Janet Chantler, Jerry S. Wolinsky, and Aubrey Tingle

Rubella virus (RV) is the etiologic agent of a mild exanthematous disease associated with low-grade fever, lymphadenopathy, and a short-lived morbilliform rash. Originally described as a distinct disease in the early 1800s (195), it was named Rõtheln by the German physician de Bergen (cited in reference 103), leading to the common name of *German measles,* a milder form of the much more serious exanthem caused by the paramyxovirus, measles virus. The physician H. Veale proposed the name *rubella* in 1866 (345) as a term more “euphonious” to English ears.

Rubella is predominantly a childhood disease, endemic throughout the world, although a comprehensive vaccination program in most industrialized regions, including North America, Europe, Japan, and Australia, has reduced the incidence of disease to low levels in these areas. Vaccination is not carried out in many of the developing countries, however, and therefore most of the world's population is still infected naturally and is susceptible to epidemics of rubella that occur in irregular cycles at about 6- to 10-year intervals.

Rubella was considered a relatively benign infection, associated with considerably less morbidity than measles, until an observation by an astute ophthalmologist, Dr. Norman Gregg, uncovered a sting in the tail of this underestimated virus. In 1941, Gregg encountered a large number of children with cataracts, many of whom had additional serious congenital defects. He noted that this apparent epidemic of congenital cataracts was directly preceded by a large rubella outbreak. He proposed that the cataracts and the often associated congenital cardiac abnormalities were the consequence of maternal infection during pregnancy (128). Although initially met with considerable skepticism, further studies by other investigators made it clear that RV could have devastating effects on a developing fetus when acquired by the mother in early pregnancy (358). This important finding introduced the concept of viruses as teratogenic agents and spurred the efforts to develop an attenuated vaccine.

Isolation and growth of the virus in cell culture was achieved in 1962 (254,357), and this opened the way for vaccine development. Finally in 1969, rubella vaccination was introduced in the United States, 5 years after the last major epidemic in this country and shortly before the next significant outbreak was predicted. It never occurred, and the vaccine strategy adopted in the United States has been remarkably successful in controlling natural rubella and its devastating teratogenic effects (306). Recently, recommendations for a drive to eradicate rubella have been issued by the World Health Organization by addition of rubella vaccine to the measles vaccine already being administered worldwide.

INFECTIOUS AGENT

RV is the only member of the genus *Rubivirus* in the family Togaviridae. This family of viruses is characterized as small enveloped particles that contain a positive-stranded RNA genome of 10 to 12 kb. The other genus in this family comprises the alphaviruses, a large group of arthropod-transmitted viruses that share a similar genetic organization and replication strategy. There is, however, no serologic cross-reactivity between the alphaviruses and RV, and only limited regions of genetic homology in the non-structural proteins representing the functional domains for enzymes such as the replicase and protease (see Structure and Organization of the Genome).

An unusual feature of RV is that there are no related animal viruses (c.f., measles and canine distemper viruses), and only one serotype exists, although some strain variation in virulence, teratogenicity, and antigenicity has been reported, particularly between wild-type and attenuated vaccine strains (see Phenotypic Variation). Although the virus shares many aspects of its genomic structure and replication strategy with the alphaviruses, it does not have an arthropod vector, and humans are believed to be the only natural host and reservoir for the virus.

Morphology and Physicochemical Properties of the Virion

Electron microscopy of purified preparations of RV or thin sections of infected cultured cells, stained with

phosphotungstic acid, have shown the virion to be a spherical particle measuring 60 to 70 nm in diameter (222) (Fig. 1). Each virion consists of a 30-to 35-nm electron-dense core surrounded by a lipid envelope derived from the host cell. Embedded in this are two glycoproteins (E1 and E2), which form a “fringe” 5 to 8 nm in diameter that can occasionally be resolved as surface spikes with knobbed ends, containing both envelope proteins. Between the core and the envelope is an electron-lucent zone that is wider and more distinctive than that of the other togaviruses (222). The core has been suggested to have a T=3 icosahedral symmetry and contain 32 capsomers (196), further distinguishing RV from the alphaviruses, which are reported to have a T=4 symmetry. The core consists of a single strand of 40S RNA comprising slightly less than 10 kb complexed with multiple copies of a single capsid protein, C, in the form of disulfide-linked homodimers (16). The RNA in the core structure is susceptible to degradation with ribonuclease, a treatment that causes disintegration of the core, indicating that the RNA is an integral component of the core structure (157).

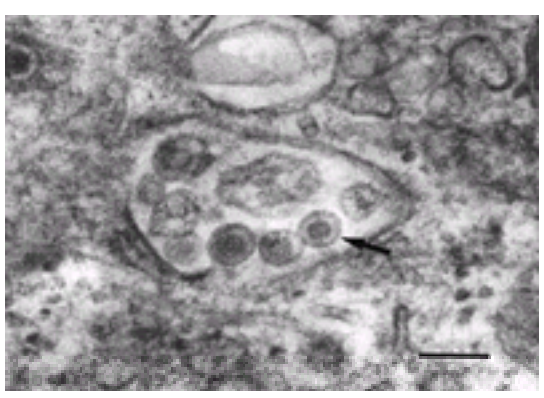

FIG. 1. Mature rubella virus (RV) virions in a cytoplasmic vacuole. A typical RV virion (*arrow*) consisting of a spherical core surrounded by a host-derived lipid bilayer. The bar represents 100 nm. (Electron micrograph courtesy of Dr. Jia-Yee Lee.)

The buoyant density of rubella virions in sucrose gradients has been reported to be between 1.17 and 1.19 g/mL (reviewed in 155). Sucrose-gradient purified virus observed by electron microscopy is contaminated with membranous material, derived from the cellular membranes from which the virus buds during assembly. This may explain the wide range of sedimentation coefficients that have been reported for this virus, ranging between 240S and 350S (13,297).

Rubella virions are heat labile and rapidly inactivated at 56°C (half-life, 5 to 20 minutes) and also at 37°C with a slower decay curve (half-life, 48 hours) associated with some infectivity remaining even after 7 days (210). The virus is stable for prolonged periods if stored in the presence of protein stabilizers at –60°C or below, but infectivity is rapidly lost at –20°C. The virus is also sensitive to hydrogen ion concentrations outside the pH range of 6.8 to 8.0. It can be lyophilized and is then stable at 4°C for years and at room temperature for months, a property that has been exploited for vaccine distribution (199).

RV can be inactivated by lipid solvents, such as ether, chloroform, and detergents like sodium dodecyl sulfate (SDS), sodium deoxycholate, and saponin (255). Protein denaturing agents like formaldehyde, ethylene oxide, and b-propriolactone, as well as ultraviolet light or photodynamic dyes that can cause RNA breaks, also abrogate infectivity.

Biologic Characteristics

RV has a restricted host range (only humans) *in vivo* but replicates in a wide variety of mammalian cell types *in vitro,* including primary AGMK cells and BHK21, RK13, and Vero cell lines. All strains of the virus (including wild-type strains) are slightly temperature sensitive, giving higher yields of virus at 35°C than at 37°C, and the vaccine strains RA27/3 and Cendehill are completely growth restricted at 39°C, whereas some wild-type isolates replicate to some degree at 41°C (54). In comparison to the rapid lytic infection of mammalian cells by the alphaviruses, RV replicates more slowly with an eclipse phase of 10 to 12 hours (4 hours for Sindbis or Semliki Forest viruses) and with maximal titers of virus released between 30 and 48 hours (about 8 hours for alphaviruses). In addition, viral yields are low, typically in the range of 0.1 to 10 infectious progeny per cell (about 10^4 plaque-forming units per cell [pfu/cell] for Sindbis virus). The reasons for the poor replicative ability are not well understood but may relate to low uptake of virus, to inefficiency of the replicase-transcriptase, or to the assembly process. One factor that may play a role is the high guanosine + cytosine (G+C) content of the virus (69.5%), which is associated with a high degree of secondary and tertiary structures in the genomic RNA that may impede replication, transcription or translation. Also related to the G+C content, codon use by RV is significantly different from that of normal eukaryotic cells (reviewed in 110), requiring use of transfer RNA that may be of low abundance in the cell, a factor that may limit the rate of protein synthesis (327).

Effects on Host Cell

At high multiplicities of infection (MOIs), RV causes rounding and detachment of cells commencing 24 hours after infection and increasing over the next 48 to 72 hours. At low (less than 1 pfu/cell) or moderate MOIs (1 to 3 pfu/cell), however, there is little visible cytopathic effect in many cell lines (174), and chronic infections can readily be established (see Persistence). Cellular macromolecular synthetic pathways appear not to be inhibited to a substantial degree even after high MOIs (5 to 10 pfu/cell). For example, cell RNA synthesis occurs for 72 hours after infection (135), and protein synthesis continues at normal or only mildly reduced levels for 48 to 72 hours in most cell lines (48,135). In mitogen-stimulated peripheral blood mononuclear cells, however, cell protein synthesis is inhibited by more than 90% by 48 hours after infection (55). In a number of specialized cell types, RV infection has been reported to affect “luxury functions” while allowing cell survival (360,373), although the growth rate of such chronically infected cells is reduced (373). Growth inhibition is particularly notable in primary diploid cells derived from human fetal organs (284), providing an

explanation for underdevelopment of organs in congenitally infected children that results in microcephaly and in autocrine and bone abnormalities (see Congenital Rubella Syndrome).

Although RV is not considered a highly cytopathic virus, infection of cultured cells disturbs the organization of the cytoskeletal elements, in particular actin filaments (32). Recently, apoptosis or programmed cell death has been shown to play a role in the cytopathic response of several cells (98,280). Most detached cells showed evidence of chromatin fragmentation and cell death that could be prevented by the caspase inhibitor z-VAD-fmk but not by bcl-2 or bcl-XL, at least in RK13 cells (98). However, cell survival rather than induction of apoptosis is clearly the dominant response to RV infection at MOIs of 1 pfu/cell or less, with many cells surviving in a chronically infected state.

Stimulation of membrane biosynthesis may also occur in RV-infected cells. Both proliferation and distention of endoplasmic reticulum (ER) and Golgi membranes, often associated with budding virus, have been identified by electron microscopy (223). The proliferation of membranes and formation of vesicular structures is believed to be associated with viral replication complexes and identifies sites of both viral RNA synthesis and assembly (181) (see Life Cycle). Other effects on host cells include the presence of chromosomal breakages in both human diploid cells infected *in vitro* (156) and cell lines derived from congenitally infected fetuses (7,46).

Phenotypic Differences Among Rubella Virus Strains

Although there is only one serotype of RV, strains of the virus exist that differ in properties such as hemagglutination (184), plaque morphology (174), temperature sensitivity, virus yield, and cell tropisms (54). Phenotypic variation also occurs *in vivo,* particularly in the reduced virulence of the vaccine strains, which are associated with milder acute symptoms and a lower incidence of complications than natural infection (21,331). This includes joint and neurologic symptoms (105,331) as well as teratogenic effects (17) (see Adverse Reactions).

All RV strains cross-react serologically, and the major neutralization epitopes appear to be conserved, although differences have been noted in the kinetics of neutralization (125) and in reactivity to certain monoclonal antibodies (54). Both infection and immunization, however, are believed to give protection against all other strains for the duration of the immune response elicited, except in cases in which incomplete immunity is induced (332). The vaccine strains RA27/3 and Cendehill display different tissue tropisms from wild-type–positive strains, including growth restriction in both peripheral blood mononuclear cells (PBMC) and the B-cell lines, Raji and Cess cells (54). These two strains also show limited growth in cells derived from human joint tissue (210), with the Cendehill strain completely inhibited in synovial organ cultures. In comparison, wild-type strains grow to high titer (54) in all of these cells. The determinants of tropism for joint tissue have recently been mapped to the 5' end of the genome, not to the structural proteins, and therefore are thought to involve intracellular replication and not binding and entry (187).

Structure and Organization of the Genome

The genome of RV is a single molecule of positive-stranded RNA that is about 10 kb in length. The 5' end of the RNA has a 7-methyl-guanosine cap (239), and at the 3' end, there is a poly(A) tract with a mean length of 53 nucleotides (348). The genome has a G+C content of 69%, the highest of any RNA virus identified to date. Early studies on RV in the 1970s identified two species of virus-induced RNA in infected cells of 38S to 40S and 24S to 26S (158,308). The larger species represents the full-length genome and is infectious when transfected into cells (158). The 24S species was initially shown in the alphaviruses to represent a subgenomic messenger RNA (mRNA) that encodes the structural viral proteins; a similar strategy for expression of RV structural proteins was confirmed in 1984 (239).

The genome comprises two long polycistronic open reading frames (ORFs) separated by a nontranslated region of 123 nucleotides (278,372) (Fig. 2). The 5' ORF encodes the two nonstructural proteins p150 and p90, whereas the 3' ORF, which is also represented in the 24S subgenomic RNA species, encodes the three proteins, E1, E2, and C, that form the virion structure.

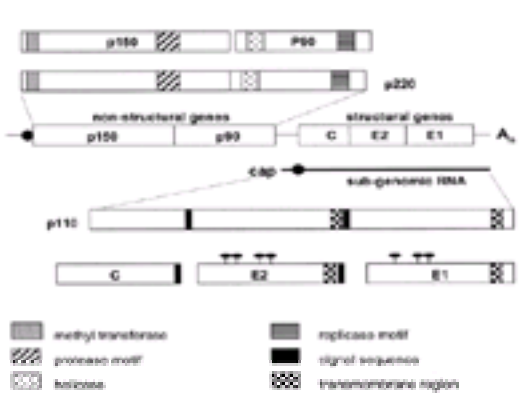

FIG. 2. Schematic diagram showing the organization of the rubella virus (RV) genome and the synthesis and processing of the nonstructural and structural proteins. Transmembrane regions and signal sequences of E1 and E2 are indicated. Regions of the nonstructural proteins believed to encode enzymatic functions, including the putative replicase and protease, are marked.

Cis-Acting Elements

Preceding each ORF is a short nontranslated region that is predicted to form a stem-loop structure believed to be important in viral RNA translation or initiation of RNA synthesis (229,272). The predicted 5' stem-loop encompasses

nucleotides 15 to 65 and has a terminal loop as well as a bulge in the stem and a hinge region (Fig. 3). It is thought to form a pseudoknot (279), a structure that has been shown in a number of plant and animal viruses to enhance protein binding and have a role in RNA replication (80,94). Within the single-stranded leader sequence (nucleotides 1 to 14) and the stem-loop, there are three AUG start codons at nucleotides 3, 41, and 57. Translation of the long ORF encoding the nonstructural genes is initiated at AUG_{41}, whereas the first and third AUGs are in a different reading frame and are terminated at nucleotides 54 and 90, respectively. Site-specific mutagenesis studies have indicated that AUG_3 is not essential for viral replication (278), and it is not known whether a short peptide synthesized from either AUG_3 or AUG_{57} plays any role in replication, but it is notable that the three AUGs are conserved in all strains sequenced to date (187,279). Analysis of the 5' end sequences of a number of RV strains has shown that the stem-loop is largely conserved, with mutations restricted to the terminal loop or the hinge region (161,279). Mutations in the 5' stem-loop are associated with differences in viral yield and plaque morphology (279) as well as tropism for joint tissue (187). Several proteins are known to bind to the 5' stem-loop, including the autoantigen La (lupus antigen) (272), a known RNA-binding protein that complexes with several viral RNAs, including the poliovirus 5' non-translated region (NTR) (203) and the human immunodeficiency virus TAR element (47). La affects translation efficiency of HIV (326), whereas in Sindbis virus, La binds the 3' positive-strand stem-loop and has been suggested to have a role in initiation of negative-stranded synthesis (253). In RV, calreticulin, not La, binds to the 3'positive-strand stem-loop with a potential role in negative-strand synthesis (229).

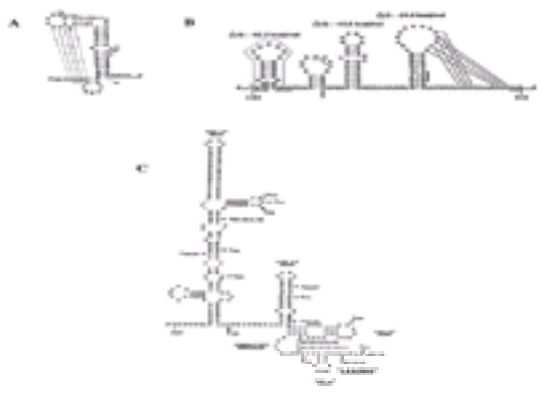

FIG. 3. Predicted stem-loop structures in the 5'end sequence (**A**), the 5' subgenomic end sequence (**B**), and the 3' end sequence (**C**). Potential pairing of bases to form pseudoknots in structures A and B are shown with *dotted lines.* (**A** and **B** from ref. 110, with permission; **C** from ref. 61 with permission.)

The 123-nucleotide region between the nonstructural and structural genes also contains a region that is predicted to form a series of stem-loops (see Fig. 3). This region has 58% homology with the equivalent sequence in Sindbis RNA and is thought to be involved in regulating synthesis of the subgenomic RNA. These stem-loops are also present in the 78-nucleotide 5' NTR of the subgenomic RNA, where they may play a role in translation of the structural genes. At the 3' end, there is a short NTR of 59 nucleotides following the stop signal at nucleotide 9701. A complex secondary structure involving three major stem-loop structures has been predicted for the 3'-terminal 240 nucleotides (61) (see Fig. 3). This is the region that binds the phosphorylated form of calreticulin (229), a calcium-binding protein that has been identified in both the nucleus and cytosol, in the lumen of the ER in plasma membrane fractions, and in the extracellular space (315). In addition to calreticulin's originally identified function in regulating calcium metabolism in muscle, it interacts with integrins and modulates expression of hormonally regulated genes (88). Possible roles for calreticulin in RV replication have been suggested to include promotion of viral RNA replication or translation, targeting of RV RNA to certain cell membranes where RNA synthesis occurs, and sequestering viral RNA during persistence (10).

Encapsidation Signal

The region on the RNA involved in binding to the capsid protein is a 29-nucleotide sequence located in the 5' nonstructural gene region between nucleotides 347 and 375 (183).

Nonstructural Gene Open Reading Frame (ORF)

The nonstructural genes are clustered at the 5' end of the genome within a long open reading frame commencing at AUG_{41}. This is translated into a single polyprotein, greater than 200 kd, that is cleaved into two products, p150 and p90 (192) (c.f., the four nonstructural genes found in the alphaviruses).

P150. The 5' proximal protein is a 150-kd protein comprising 1300 amino acids (106). It encodes a cysteine protease with catalytic activity shown by site-specific mutagenesis to be associated with the catalytic dyad, cys1151 and His1272 (62). This cleaves the polyprotein between Gly1300 and Gly1301 in a process that can occur both in cis and trans (372). A predicted methyl transferase (MT), with sequence homology to an MT domain in the a-like supergroup of positive-strand RNA viruses (295), is found at the 5' end of p150. It comprises a glycine-rich loop preceded by a hydrophobic segment implicated in binding S-adenosyl methionine. MT is believed to have a role in capping the viral RNA (173). In addition, p150 contains a region, X, with sequence homology to the alphavirus protein NSP3. The function of this protein is not known, but it appears to be essential for alphavirus replication (130).

P90. The second nonstructural protein, p90, comprises 905 amino acids and encodes the replicase and helicase motifs. The GDD tripeptide at amino acids 1965 to 1967 is identified as the core component of the replicase by comparison with global RNA-dependent RNA polymerase consensus sequences (162). An RNA-stimulated nucleoside triphosphalase (NTPase), involved in promoting unwinding of the template during RNA replication has been found associated with the

helicase motif (124).

The Structural Gene ORF

The structural genes are clustered within the 3' ORF and are translated only from the subgenomic 24S RNA. There are two in frame AUG initiation codons in the subgenomic RNA separated by 21 nucleotides. The downstream AUG is in the more favorable context for translation initiation (175), but the results of *in vitro* mutagenesis experiments suggest that both codons can be used indiscriminately (66). The gene order was determined by synchronized translation to be *NH2-C-E2-E1-COOH* (236), several years before the subgenomic RNA had been sequenced (65,114,347). As with the nonstructural genes, the subgenomic ORF is translated into a precursor polyprotein of 110 kd that is subsequently cleaved to give the individual structural proteins.

C. The 32-kd capsid protein exists as a disulfide-linked dimer (16,350) that interacts with the genomic RNA to form the electron-dense core of the virus particle. The amino-terminus is rich in arginine and proline residues, and the net basic charge helps to neutralize the negative charge on the phosphate backbone of the RNA, allowing its condensation into the nucleocapsid structure. The peptide sequence involved in interaction with the RNA lies within this region, encompassing 29 residues between amino acids 28 and 56 (183). Unlike the capsid protein of the alphaviruses, C protein of RV does not possess autoprotease activity, and its release from the polyprotein requires cellular signal peptidase (65). The hydrophobic recognition signal required by this enzyme is located in the carboxylterminus of C, and cleavage occurs at the same time as translocation of E2 into the lumen of the ER (149,237). The retention of the signal sequence by C is believed to promote association of this protein with membrane fractions, which in turn affects capsid morphogenesis, a process that occurs in association with membranes (15,325) (see Life Cycle).

E1. The 58-kd envelope glycoprotein E1 normally exists as a heterodimer with E2 to form the viral spike that protrudes from the surface of the virion. E1 consists of 481 amino acids and has three potential N-linked glycosylation sites (asn-X-Ser/Thr), all of which are used (148). The molecular weight of the unglycosylated E1 computed from the amino acid composition (predicted from sequence data) is 53 kd (65,114), and a molecule of this size has been identified in tunicamycin-treated cells (238,299). E1 is a class 1 membrane protein, and its single transmembrane sequence comprises 22 amino acids near the carboxylterminus (65). A region between amino acids 81 and 109 is thought to be involved in interaction with E2 and also in the membrane fusion induced by E1 at low pH (371). Palmitylation of residues within the transmembrane region, on the cytoplasmic side of the lipid bilayer, is also thought to occur (350).

E2. The second component of the spike, E2, is a heavily glycosylated polypeptide that exists in infected cells as a heterogeneous population of species varying in molecular weight from 42 to 54 kd (238; reviewed in 110). E2 consists of 282 amino acids, and its unglycosylated precursor is 30 kd (238,299). Thus, 15 to 25 kd of its molecular mass is carbohydrate, comprising both N- and O-linked glycans (188). There are four potential N-linked glycosylation sites (Asn-X-Ser/Thre) in most RV strains (the M33 strain has only three), and all appear to be used (282). On analysis by SDS-PAGE, E2 migrates as a broad smear that can sometimes be resolved into two to four discrete bands (54,238) and by isoelectric focusing (pH, 5.0 to 8.6) into more than 15 species (350). E1/E2 dimers are frequently seen in extracts of infected cells and are the dominant species in mature virions (16). E2 is believed to be largely buried beneath E1 in the virus particle because it is protected from the activity of glycosidase (141), neuraminidase, and trypsin (259) as well from monoclonal antibodies specific for the aminoterminal portion (351). Like E1, E2 is a class 1 membrane protein with a 39 residue transmembrane region located in the carboxylterminus between amino acid 517 and 555 (113). This region is in juxtaposition to a stretch rich in arginine residues that is located on the inside of the envelope and is thought to form a hydrophilic anchor. It is followed by a further 20 hydrophobic residues that serve as the signal sequence of E1 (15). The arginine-rich sequence is a potential cleavage site for trypsin-like proteases but appears not to be cleaved, so that the E1 signal sequence is retained on E2 (15,191,237). Electrostatic binding between these positively charged arginines and clusters of aspartic acid and glutamic acid residues in the capsid protein are thought to mediate interaction between the nucleocapsid and E2, and thereby play a role in viral assembly (118).

Life Cycle

The replicative cycle of RV is similar in many respects to that of other Togaviridae (see Chapter 29 and Chapter 30) and will only be summarized here with emphasis on differences that have been found; it has been reviewed in detail in (110). The virus growth cycle is much longer than that described for alphaviruses, with an eclipse phase of 10 to 12 hours and maximal viral titers released between 36 and 48 hours after infection of permissive cell lines such as BHK/21 cells and Vero cells (135). Infection of cultured cells is an asynchronous process even when high MOIs are used (5 to 10 pfu/cell); foci of infection are first seen at 24 hours, and the infection then spreads to other cells over the next 24 hours (308). The reason for this may relate to poor uptake of the virus or to host factors affected by the cell cycle, although partially synchronized RK13 cells infected 24 hours after subculture of a stationary monolayer exhibit the same effect (48).

The cellular receptor for RV has not yet been identified. There is some evidence that it may be a lipid because treatment of Vero cells with phospholipases A2 and C abrogated RV infection, whereas proteases and glycosidases had only a limited effect (194). Entry of the virus is believed to be through receptor-mediated endocytosis, and in agreement with this, exposure of the envelope glycoproteins to low pH (less than 6.0) makes them fusogenic (166). In addition, there is evidence that capsid protein C undergoes a conformational change at low pH that renders it hydrophobic (197). This may allow the nucleocapsid to adhere to the endosomal membrane and facilitate uptake of the viral RNA into the cytoplasm.

The genomic RNA provides the mRNA template for translation of the nonstructural genes as a greater than 200-kd precursor that is proteolytically cleaved to yield the two nonstructural genes *p150* and *p90* (see Fig. 2). The replicase encoded by *p90* then uses the input RNA as a template for negative-strand complementary RNA in a process that has not been well characterized for RV but that is thought to resemble that described for the alphaviruses (outlined in Chapter 29). Only full-length negative-strand RNA has been detected in infected cells; therefore, this must act as template for both the full-length progeny positive-strand RNA and the subgenomic mRNA that encodes the structural proteins (135). Stem-loop structures at the 3' ends of both the positive- and negative-strand RNAs bind several host

proteins that may have a role in RNA replication, including the phosphorylated form of calreticulin (227). The negative-strand RNAs are found solely in double-stranded complexes with positive-strand RNA (19S to 20S replicative intermediates) and have been localized to vesicles intimately associated with rough ER by 8 hours after infection. These replication complexes (Fig. 4) form a striking feature of RV morphogenesis and are characterized as virus-modified lysosomes lined internally with vesicles containing irregular internal structures (180,189). The localization of double-stranded replicative intermediates and RV nonstructural proteins within the replication complexes indicates that they represent sites of viral RNA synthesis (178,181). In addition, the detection of RV core particles at the cytoplasmic side of the vesicles lining the lysosomal vacuole suggests that the complexes are also the sites of nucleocapsid assembly (182).

FIG. 4. A typical rubella virus (RV) replication complex. The replication complex is characterized as a virus-modified lysosome containing vesicles (*closed arrows*) that line the inner membrane of a vacuole (*v*). Each vesicle has a double membrane and contains an irregular internal structure. These vesicles have a distinct morphology and should not be mistaken for RV virions. The rough endoplasmic reticulum (*open arrows*) surrounds the replication complex. The bar represents 200 nm. (Electron micrograph courtesy of Dr. Jia-Yee Lee.)

Both full-length and subgenomic positive-strand RNAs are synthesized from the full-length negative-strand templates in a molar ratio of 1.6:1 (135). Stem-loop structures at the 3' end of the negative-strand RNA and in the region surrounding the subgenomic promoter, which are believed to act as cis-regulatory sequences, are described under Structure and Organization of the Genome (see Fig. 3). The progeny full-length positive-strand RNA has three possible fates. It may be sequestered in the replication complexes as template for negative-strand synthesis, undergo translation to yield the nonstructural protein precursor, or at later stages of infection, be encapsidated as part of the assembly process. The mechanism whereby these events are regulated is not yet understood.

The subgenomic RNA has only one purpose: to act as template for the structural viral protein 110-kd precursor (65,239). Its translation occurs in hypertonic salt conditions that greatly reduce cellular mRNA translation, indicating that it has a higher affinity for ribosomes or translation factors than cell mRNAs, a factor that may be important in view of the inability of RV to inhibit host translation (48). The processing of the 110-kd precursor into the three virion polypeptides requires cellular signal peptidase and occurs during translocation of E1 and E2 into the lumen of the ER (149). This is a marked difference from the alphaviruses, for which C is cotranslationally cleaved from the structural protein precursor by an autoprotease located within the capsid protein (205). Moreover, in RV, the E2 signal sequence is retained by C, giving it a hydrophobic “tail” that allows it to remain membrane-associated, a factor thought to have important implications in virus assembly (15).

Posttranslational processing of the envelope glycoproteins has been studied in considerable detail (15). The translocation of the E1/E2 precursor into the lumen of the ER occurs at the same time as its cleavage by signalase into polypeptides of about 30 and 53 kd. Within the ER, E1 and E2 form disulfide-linked heterodimers that are subsequently transported to the Golgi stack. Transport to the Golgi occurs much more slowly (60 to 90 minutes) than for the alphaviruses, a finding thought to be due to slow maturation and folding of E1 in the ER. When expressed separately in COS cells from plasmid expression vectors, E2 is transported alone to the Golgi complex, although less efficiently than in the presence of E1 (15). E1 is not transported alone, however, because of an ER location signal located in a region encompassing the transmembrane domain and the cytoplasmic tail (146). Instead, it aggregates and accumulates in cytoplasmic vesicles derived from an intermediate compartment between the ER and Golgi apparatus (150).

The E1/E2 heterodimers are targeted to the medial and *trans*-Golgi apparatus, where glycosylation occurs. N-linked glycosylation of proteins is thought to be important in the initiation and maintenance of folding into the correct biologically active conformation as well as in protecting proteins from proteolytic attack (261). It also affects the immunogenicity and antigenicity of proteins (120). Mutants in which the glycosylation sites in either E1 or E2 have been eliminated by site-directed mutagenesis were found to be processed more slowly and transported less efficiently to the cell surface (282). They were also found to be less stable and undergo aberrant disulfide bonding. Both E1 and E2 are N-glycosylated, a process that is heterogeneous and involves the addition of high-mannose, complex-type, and hybrid-type glycans (188,299). In addition, E2 is O-glycosylated (188,299) at sites that are less well defined but have been suggested to include a region rich in hydroxy amino acids and proline (amino acids 97 to 123) (110). O-glycosylation involves the initial addition of *N*-acetyl galactosamine, which can occur in the ER or the Golgi apparatus, followed by the addition of galactose and sialic acid in the *trans*-Golgi complex.

Some of the processed glycoproteins are transported to the plasma membrane, but most are retained in the Golgi stack or are found in the ER or in membranes surrounding intracellular vesicles (15,145). Virus budding occurs at all of these membranes (14,243), with the majority of virion assembly occurring at intracellular membranes. Nucleocapsid formation also occurs in association with membranes, in part due to the hydrophobic region at the carboxylterminus of C that acts

as the signal sequence for E2 in the polyprotein (325). Thus, unlike the alphaviruses, RV RNA encapsidation does not occur in the cytoplasm forming crystalline arrays of capsids visible under EM; instead, capsids are first apparent in association with partially budded membrane (see Fig. 4). Interaction of C with the cytoplasmic tail of membrane-bound E1 is believed to play a role in virion assembly (147). The ability of RV to mature within cytoplasmic vesicles, rather than at the cell surface, may help the virus to avoid elimination by the immune system and to produce persistent infections.

RV Persistence

Although cell death by apoptosis occurs in various highly susceptible cell lines infected at high MOI, infection of a wide variety of cells *in vitro* with low MOIs of RV results in viral persistence (361). Cell lines derived from congenitally infected infants have also been shown to be chronically infected (284,285). Both temperature-sensitive mutants (28,361) and defective interfering (DI) particles are generated during RV persistence and are thought to play a role in controlling the degree of viral replication (2), but neither is required to establish persistent infection. During long-term persistence of Vero cells, DI RNA becomes the dominant species of viral RNA, with genomic RNA decreasing to low levels (2,112). In summary, RV persistence generally occurs as a chronic infection, with most cells expressing viral antigen and RNA, much of which is DI RNA. These cultures release low levels of temperature-sensitive progeny virus and DI particles.

The interferons may play a role in viral persistence and are induced in a number of chronically infected cell lines (322) as well as in human PBMC, both *in vitro* (37) and *in vivo* (258). Both interferon-a and interferon-g restrict RV replication, reducing the levels of viral RNA in the cell as well as inhibiting viral translation (228). This could promote both establishment and maintenance of the carrier state. Interferon, however, is clearly not essential as persistent infections can be established in Vero and BHK/21 cells, which are unable to produce interferon, and exogenous interferon was not found to have an effect on RV persistence in these cells (322). Antiviral antibody also inhibits RV replication while allowing persistence of the viral genome (51). Incubation of human lymphoid cells with a polyclonal anti-RV rabbit antibody after viral adsorption prevents expression of viral proteins within the cells while allowing maintenance of the viral genome for at least 14 days. Subsequent removal of the antibody is associated with enhanced synthesis of viral proteins and release of progeny virus. A similar phenomenon described with measles virus has also been proposed to play a role in viral persistence (116). PBMCs are a known site of RV persistence *in vivo* both in congenitally infected infants (284) and in adults who develop rubella-associated arthritis after natural infection or immunization (53). Viral persistence *in vivo* occurs in the presence of high levels of neutralizing antibody, which may limit viral spread but actually promote viral persistence. *In vitro,* persistent infection of many cell lines occurs in the absence of exogenous antibody (361), and addition of antibody to these persistently infected cultures reduces the level of virus produced but does not cure the cells of the infection (2,361).

Another site of RV persistence *in vivo* is joint tissue (57,108) (see Complication). Both wild-type and vaccine strains of the virus have been found to infect and persist in a chondrocyte cell line (54) as well as in primary cultures of human joint tissue (210). Only the Cendehill vaccine strain showed no growth in cell and organ cultures derived from human joints; all other strains tested replicated readily in joint tissue and persisted for more than 3 months. Virus derived from these chronically infected cultures was temperature sensitive, but DI particles were not detected.

Animal Models

There are no reliable animal models for the study of clinically symptomatic rubella infection. However, a variety of laboratory animals (including subhuman primates) can be asymptomatically infected with RV. Rhesus and African green monkeys, as well as baboons and chimpanzees, develop viremia, shed virus in respiratory secretions, and produce humoral immune responses in a manner that parallels events in humans (152). Marmosets are also susceptible to infection but do not show clinical disease and do not transmit virus to their offspring (256). Conflicting results have been reported from experiments in rats demonstrating subclinical infections in which the virus either does (11) or does not (301) invade the fetus to cause growth retardation and ocular abnormalities. Rabbits also provide a model for the growth retardation and ocular malformations of congenital rubella infection (171). In this system, a concentration of virus occurs in chondrocytes, indicating a proclivity of RV for joint tissue (185). Ferrets develop viremia after intranasal inoculation of RV (83), and ferret pups reportedly develop central nervous system (CNS) vascular lesions similar to those reported in the congenital rubella syndrome (293). Finally, mice do not develop overt disease, but both humoral and cell-mediated responses to infection can be detected after intravenous or intrasplenic injection. Even highly immunodeficient SCID mice do not develop significant symptoms after injection of 10^7 pfu of Therien strain (J.K. Chantler, unpublished observation, 2000). Unfortunately, none of the animal systems has proved sufficiently reliable to study details of the pathogenesis of either acquired or congenital rubella.

Antigenic Composition and Determinants

Complement-Fixing and Hemagglutination Antigens

Early serologic investigations of rubella used crude complement fixation (CF) antigens extracted from virus-infected cells. These particulate CF antigens could be separated into two fractions on density gradients composed of mixtures of mature and relatively immature forms of the two virion glycopolypeptides (307). The relative proportions of E1 and E2 differed in the two fractions, and only the rapidly sedimenting fraction contained detectable amounts of C (143). This fraction lacked hemagglutination activity but had some residual infectivity, probably because of the small amount of nucleocapsid found in it. Both fractions were contaminated by host cellular components (143).

Antigen for hemagglutination inhibition (HAI) assays has generally been prepared from free virus or the slowly sedimenting CF antigen. Tween 80 and ether extraction of the crude preparation provides a potent and noninfectious hemagglutinin (HA). The minimal structure that retains HA activity of RV remains uncertain, however. The classic HA antigen is composed of nearly equal proportions of the E1 and E2 glycoproteins embedded in a slowly sedimenting particle with a density of 1.08 to 1.10 in sucrose (342). This compares with a density of 1.18 to 1.20 for the intact virion or nucleocapsid core. The extracted HA is a 26S particle that retains biologic activity. By electron microscopy, it appears as

a 15-nm rosette with a hollow core (341). Whether molecular interactions between the E1 and E2 molecules must be preserved to retain the biologic functions associated with specific regions of either glycoprotein has not been determined.

B-Cell Epitopes

The mature E1 molecule contains monoclonal antibody-defined domains that are involved in virus attachment to the surface of red blood cells (hemagglutination) and the initiation of infection (368). Less is known about the epitopes of E2 because few monoclonal antibodies have been produced that react with this protein. Polyclonal human serum reacts well with E2, however, indicating that this molecule is antigenic; in addition, several strain-specific antigens are thought to reside on this molecule (95). Current evidence indicates that E1 is the dominant surface molecule of the virus particle and is probably the main target for the detection and subsequent elimination of RV by the host's humoral immune system. During the last 10 years, the fine antigenic structure of E1 has been characterized, using expressed proteins, proteolytic peptide fragments, and synthetic peptides to deduce functional sites on E1 (59,215). HAI and neutralization sites have been localized to $E1_{245}$–$E1_{285}$, with three critical regions for antibody binding ($E1_{245}$–$E1_{251}$, $E1_{260}$–$E1_{266}$, and $E1_{275}$–$E1_{284}$) (142). A peptide-($E1_{213}$–$E1_{239}$)–based enzyme-linked immunoassay (ELISA) has shown good correlation between conventional ELISA, HAI, and neutralizing titers (218).

T-Cell Epitopes

Lymphocyte proliferation, cytotoxicity, and lymphokine secretion have been measured using T cells from individuals with diverse major histocompatibility complex (MHC) backgrounds who have either been infected naturally or have been vaccinated. At least 17 immunodominant T-cell epitopes stimulated with peptide antigens have been identified by lymphoproliferation. These include four major regions on E1 (amino acids 38 to 74, 190 to 280, 324 to 377, and 389 to 422) (215,246), two on E2 (amino acids 150 to 170 and 244 to 263) (215), and four on C (amino acids 1 to 29, 119 to 152, 205 to 233, and 255 to 280) (200,246). A further set of T-cell epitopes capable of inducing cytotoxic class I or II MHC-restricted T-cell clones are identified in Table 1. However, the functional significance of immunologic recognition of lymphoproliferative or cytotoxic T-cell epitopes in protective immunity remains poorly defined.

TABLE 1. *Defined T-cell epitopes of rubella virus*

Recent studies have identified potential antigenic mimicry epitopes of RV using techniques of monoclonal antibody cross-reactivity, *in vivo* immunization, and identification of sequence homology (Table 2). The significance of these epitopes in the induction of autoimmune disorders associated with rubella infection *in utero* (see Late-Onset Sequelae) remains unclear.

Rubella protein	a.a. Sequence	Tissue specificity	Methodology employed	Reference
C	64-87	Pancreatic islet cell la-2 protein	Monoclonal antibody cross-reactivity	162

EPIDEMIOLOGY

Incidence

Rubella is endemic worldwide, with regular seasonal peaks occurring in the spring months in temperate climates. Before the introduction of vaccines, epidemics of rubella occurred at intervals of 6 to 9 years in the United States and England; somewhat more frequent epidemics have been reported in other European countries (8). In tropical countries, epidemics

probably also occur, but the lack of significant clinical symptoms in affected children allows them to pass unrecognized (67).

Age

The age at which rubella is naturally acquired in the industrialized world has shifted since the introduction of universal vaccination at 12 to 18 months of age. Before this, peak infection occurred in the 5- to 9-year-old group, with the disease being uncommon among preschool-aged children (153,172). The burden of disease in the United States, however, has in large part shifted from children to young adults (43). In developing countries, however, where rubella vaccine is not consistently given (more than 70% of countries of low economic status do not have a national policy of rubella vaccination, including much of Africa and India) (290), infection at an early age is still the norm, with high seroconversion rates found in both preschool populations and in the 5- to 9-year-old group (123). Despite this, a substantial number of women of childbearing age (10% to 25%) were found to be rubella susceptible in a survey in India (24), and the incidence of congenital rubella syndrome (CRS) during rubella outbreaks in many developing countries is high: 1 to 2 per 1000 live births (84).

Mortality

Death attributed to acquired rubella is exceedingly uncommon. Less than 0.1% of all cases of rubella reported to the Centers for Disease Control and Prevention between 1966 and 1994 were fatal (42,45).

Origin and Spread of Epidemics

Because humans are the only known natural host of RV, continued cycling of the virus within the human population is required for perpetuation of the disease between seasons of maximal endemic occurrence. Congenitally infected infants who shed high levels of virus for many months of postnatal life represent a potential source of maintenance of the virus in nature for relatively short intervals. The development of pools of susceptible individuals generally explains the appearance of epidemics at intervals of 3 to 9 years in different geographic locations, with major epidemics of worldwide scope every 10 to 30 years. Much of the regional variation in the age of onset of rubella, the incidence of the disease, and the appearance and spread of epidemics can be explained on the basis of population densities, socioeconomic factors, and levels of medical sophistication in a given community. Infection rates during the course of an epidemic are highest among closely housed susceptible individuals, including adolescents and young adults (e.g., student populations or military establishments) (275).

Molecular Epidemiology

Studies of the genetic variation in RV strains isolated from different locations worldwide have recently been carried out by sequence comparison of the E1 gene (111,165). Two genotypes were identified: genotype 1 comprised 60 viral isolates from North America, Europe, and Japan, whereas genotype 2 represented 3 isolates from China and India. The two genotypes were found to differ by 8% to 10% at the nucleotide level, as opposed to about 2% within each genotype. This translated into only 1% to 3% amino acid substitutions in the E1 protein, attesting to a high degree of genetic conservation between rubella strains. Moreover, only one strain from genotype 2 contained a mutation in one of the known epitopes defined by monoclonal antibodies, confirming the antigenic similarity between strains previously noted (see Phenotypic Variation).

CLINICAL FEATURES

Acute Rubella

The infection caused by RV in early childhood or adult life is usually mild, with most cases passing as subclinical or unrecognized events (127,309). Clinically apparent rubella is characterized by any combination of symptoms that include maculopapular rash, lymphadenopathy, low-grade fever, conjunctivitis, sore throat, and arthralgia (377). The rash is the initial manifestation of the disease in about 50% of all cases (Fig. 5). It is first seen on the face and spreads to the trunk and limbs (153). Lesions appear as distinct pink maculopapules that later coalesce and then fade rapidly over several days. An associated posterior cervical and suboccipital adenopathy is characteristic. The entire clinical syndrome clears rapidly in days and is seldom attended by more significant symptoms, but arthropathy, thrombocytopenia, and encephalopathy can occur. The course of the acquired infection and the accompanying immune response is shown in Figure 6.

FIG. 5. Child with rubella showing rash with delicate pink macules. Occasional maculopapules and hemorrhagic elements may be seen. Individual macules often coalesce to form a pinkish flush. The rash is often absent in mild cases.

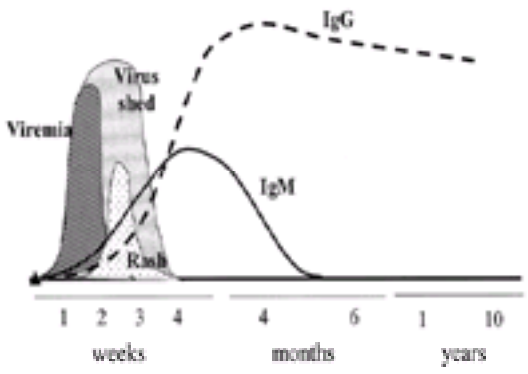

FIG. 6. Schematic diagram representing the course of acute rubella infection from the time of initiation of the infection by droplet spray. Note that the rash, which is often the first overt sign of infection, appears after 2 weeks and lasts 2 to 10 days. The patient is infectious and shedding virus from the time of infection until 1 to 2 weeks after the appearance of rash.

RV appears to be spread principally by aerosols. The mucosa of the upper respiratory tract and the nasopharyngeal lymphoid tissue serve as portals of virus entry and are the initial sites of virus replication. Spread of virus through lymphatics or a transient viremia then seeds regional lymph nodes. Local replication of virus in these nodes accounts for the posterior cervical and occipital nodal enlargement that may begin 5 to 10 days before the onset of the rash (127). The incubation period of 7 to 9 days is followed by the appearance of virus in serum, and the onset of viral shedding into the nasopharynx and stool, providing a source of spread to susceptible individuals. This viremic phase may be marked by mild prodromal symptoms and malaise. The maculopapular rash begins 14 to 21 days after natural exposure, but somewhat earlier after experimental infection or vaccination. The presence of virus in serum ceases shortly after the rash appears (305), with the onset of detectable circulating antibodies. Mononuclear cell-borne viremia (34,56) and virus in nasopharyngeal secretions, however, can be detected for a week or more after the rash subsides. Other sites of virus isolation include the conjunctival sac (134), urine (357), synovial fluid (139), lung (303), and cerebrospinal fluid (CSF) (321). Most of these isolations have been made at the time of the rash.

Immune Response

A serologic response is measurable at the onset of the rash and continues to evolve over the next few weeks. Immunoglobulin M (IgM) antibodies are present at the onset of clinical symptoms (300) and, depending on the sensitivity of the assay used, may be detectable for more than a year after acute infection (5). IgG antibodies can also be detected early in some patients, and by 2 weeks, anti-RV antibodies are present belonging to all immunoglobulin classes, including IgA, IgD, and IgE (300). Low levels of IgF antibody persist indefinitely after natural infection. IgG detected at early stages after primary infection is of low avidity (31), maturing gradually during the next 3 months. Detection of this low-avidity IgG together with antiviral IgA has been promoted as an alternative to the measurement of rubella-specific IgM, to distinguish reinfection or viral persistence from primary exposure (70,129). This is of particular importance when infection is suspected in the first 3 months of pregnancy when therapeutic abortion may be under consideration.

When measured by immunoprecipitation or immunoblot techniques, most of the immunoglobulin response appears to be directed at the E1 glycoprotein, with proportionally lesser amounts of the response directed at E2 or C (60,230). Male patients may have a more rapid and robust antibody response than female patients, but the latter have a stronger anti-E2 response (219). A peptide-based IgG ELISA ($E1_{213}$–$E1_{239}$) that uses a molecule that simulates the putative disulfide-bonded neutralization epitope of E1 shows good concordance with both conventional whole RV-based ELISA and neutralization titers (218).

Immune complexes containing RV-specific antigen are frequently found up to 3 months after either natural or vaccine-induced rubella infection (76). Notably, they are detected for longer periods in patients with chronic joint symptoms, indicating that virus persists in these patients (77). Deposition of such viral immune complexes on articular surfaces may form part of the pathogenic mechanism of rubella-associated arthritis. In addition, complexes of rubella antigen with antibody have been shown to cause release of superoxide anion from human polymorphonuclear cells *in vitro,* a reaction that would promote an inflammatory reaction *in vivo* (170). High levels of rubella-specific immune complexes have also been detected in children with CRS and may play a role in the pathogenesis of late-onset manifestations in this syndrome (77).

Transient depression of lymphocyte responsiveness to mitogenic stimulation follows natural or vaccine infections in children and adults (36,190). Similarly, delayed-type hypersensitivity to irrelevant antigens, such as purified protein derivative, is suppressed for several weeks after natural rubella (220). During this period of generalized immune suppression, RV-specific cell-mediated immune responses develop and can be measured *in vitro* within 1 or 2 weeks of onset of the clinical illness (35). The cellular responses wane over the next few years but persist at low levels indefinitely after natural rubella. Recent studies have defined the epitope specificity of defined CD4+ and CD8 + T-cell clones (186,246) (see Table 1).

Complications

Joint Symptoms

Natural rubella can be complicated by acute arthralgia or arthritis, especially when it occurs in adolescent and adult women (105,317). Incidence rates for arthralgia and arthritis exceed 60% in some outbreaks and may be considered a manifestation of rubella rather than a complication of the infection (133). For example, in one documented outbreak of rubella, 52% of adult women and 9% of adult men developed objective evidence of arthritis, with symptoms being more severe among the women (331). Manifestations of rubella arthropathies vary from joint pain alone to joint swelling, effusions, and loss of joint motion with local heat and erythema. Joint symptoms usually begin within 1 week of the appearance of the rash and may involve any joint, with the fingers and knees being most commonly affected (53,331). Paresthesia may accompany the arthropathy, especially if there is an associated synovitis and compression of the median nerve below inflamed carpal ligaments (75,302). Symptoms usually resolve within several weeks but may persist for years, are sometimes episodic, and, rarely, can be disabling (53,217,331). A similar set of symptoms occurs 9 to 27 days after vaccination but is encountered at a reduced frequency compared with that after natural rubella (105,331) (see Vaccine Adverse Reactions). Factors that affect the incidence of joint symptoms include age (355), gender (331), and MHC gerotype (216) of the infected patient, with adult women forming the most susceptible population. Hormonal influences also affect the incidence of joint symptoms. This includes an increased incidence after puberty in girls and women (105), a higher incidence in women immunized postpartum (333), and variation in incidence relating to the time of infection relative to the menstrual cycle (226). Reinfection with RV, although usually asymptomatic, can also result in arthropathy (177).

The pathogenesis of rubella arthritis is unknown, but the mechanism may involve local viral replication. Several groups have reported the isolation of RV from synovial fluids of symptomatic joints for up to 1 month after acute infection (108,139,235). Virus has also been isolated from PBMC of patients with symptoms (52,53) and has been detected by amplification of RNA extracted from PBMC of several women with chronic arthropathy after vaccination (217). Replication and persistence of virus in an extraarticular site and deposition of immune complexes on articular surfaces may therefore play a role in pathogenesis.

A current controversy is whether RV can be causally implicated in some forms of chronic degenerative arthritis, particularly juvenile and adult forms of rheumatoid arthritis (260,262,318). It is known that different strains of RV can infect and persist in joint tissue for prolonged periods both *in vitro* (210) and *in vivo* (235,320), and joints may be a preferred site of persistence because of their lower temperature (81). Evidence in favor of a role for RV in juvenile or adult rheumatoid arthritis includes the established arthrotropism of RV, with a number of case studies showing a temporal association of rubella infection with onset of arthropathy, the progression of joint symptoms in patients with documented rubella arthritis to a disease indistinguishable from adult or juvenile rheumatoid arthritis (193,201), and several studies that have detected rubella antigen in rheumatoid synovial tissue (juvenile or adult) (126,234) or have isolated the virus from this site (57). Indirect evidence implicating RV includes the detection of higher levels of antirubella antibody in synovial fluid relative to serum of some patients with arthritis (213), a finding of spontaneous secretion of RV-specific immunoglobulin by synovial cells cultured *in vitro* (58), the presence of proliferative responses to RV antigen by synovial lymphocytes (50,104), and unusual *in vitro* responsiveness of peripheral blood mononuclear cells from a patient with rubella-associated arthritis to synthetic peptides (214). However, more recent studies using the reverse transcription–polymerase chain reaction (RT-PCR) technique have failed to confirm the previous results showing the presence of RV in joint tissue of patients with adult or juvenile rheumatoid arthritis (30,109). Whether this is an issue of sensitivity of the RT-PCR technique remains to be determined. Moreover, an inability to detect RV in synovial fluid does not discount the possibility that the virus triggers an immune reaction that may damage joint tissue. Overall, the body of evidence indicates that RV is still a plausible candidate as one of several viral triggers for chronic degenerative forms of arthritis.

Thrombocytopenia

Transient asymptomatic depression of thrombocyte counts is common with rubella (73), but symptomatic thrombocytopenic purpura follows rubella in only 1 of 1,500 cases (344). The latter condition is usually self-limiting and may occur in the absence of rash as a plausible cause of some cases of idiopathic thrombocytopenic purpura (251). Very rarely, epidemic rubella has been associated with hemolytic anemia (344). There are sporadic reports of cardiac arrhythmia with acute childhood rubella (117) and of thyroiditis (225) and hepatic dysfunction (240) with rubella in adults.

Encephalopathy

The most serious complication of postnatal rubella is postinfectious encephalopathy or encephalomyelitis (18). Estimated to occur in 1 of 6,000 cases of natural rubella, the symptoms of postinfectious rubella encephalopathy appear abruptly 1 to 6 days after the onset of rash in an otherwise typical case of rubella. The most frequently encountered symptoms include headache, vomiting, stiff neck, lethargy, and generalized convulsions. An isolated myelitis or polyradiculitis may also occur (25). Physical examination often reveals nystagmus, diminished superficial skin reflexes, and variable deep tendon reflexes. The CSF is clear, with cell counts averaging 50/mm^3, comprising largely lymphocytes (349). Whereas the electroencephalogram is characteristically normal in uncomplicated rubella, it is pathologically altered in rubella encephalitis (252). Evidence for the direct involvement of RV in the pathogenesis of rubella postinfectious encephalopathy is not consistently found. However, RV antigens have been detected *in situ* within brain tissue (71), and virus has been isolated from one CSF sample (321) indicating that RV has the capacity to invade the mature CNS.

Rubella postinfectious encephalopathy usually requires only supportive treatment, and the course of the disease is generally concluded within a few days. Treatment of rubella encephalopathy with corticosteroids has been reported (231). The necessity for routine intervention is questionable, however, because 80% of all patients recover spontaneously (168). In the 20% of patients who die, the disease course typically includes coma, respiratory distress, apnea, and then death, usually within a few days of onset of symptoms.

Congenital Rubella Syndrome

Although postnatal rubella is rarely associated with severe complications, infection of a developing fetus after transplacental transmission of virus from the mother has dire consequences for fetal development (73,285,354). Maternal infection shortly before conception does not appear to lead to intrauterine infection (101). After conception, however, infection occurs in 90% of cases during the first 8 weeks of gestation, falling to a low of 25% to 35% during the second trimester and rising again near term (78,212,354) (Fig. 7).

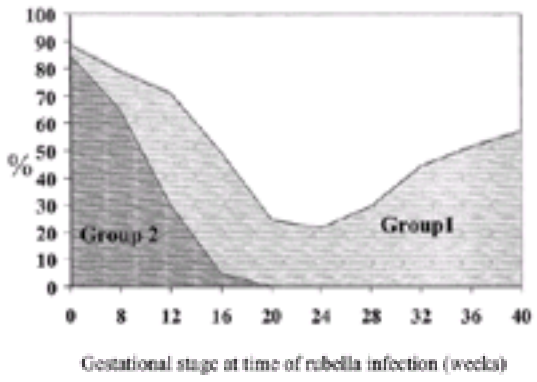

FIG. 7. Relationship between the time of maternal rubella infection and the consequences to the fetus. In group 1, the fetus is infected but shows no clinical manifestations at birth. Those in group 2 are born with congenital rubella syndrome (CRS).

Effects on Placenta

RV infection of the placenta in early gestation produces scattered foci of necrotic syncytiotrophoblast and cytotrophoblast cells and damages the vascular endothelium (338). Infection at later stages induces chronic multifocal mononuclear cell infiltrates in the placental membranes, cord, and decidua, along with vasculitis. These culminate in placental hypoplasia and macroscopic placentitis (119). After placental infection is established, there can be subsequent dissemination of virus to the fetus. This is not invariant, however, and virus is more often recovered from placental products than from fetal products of conception (4). After entry, virus is capable of spreading widely throughout the developing fetus, and almost any organ may be infected (19). A chronic and generally nonlytic infection is then established in the fetus.

Clinical Consequences

The effects of RV invasion of fetal tissue are varied. Very early infection may result in resorption of the embryo. Whether placental infection alone can lead to spontaneous abortion or abnormalities of fetal development is conjectural. Premature delivery and stillbirths are other potential outcomes of the fetal infection (212), but in most cases, the infected fetus survives, and the pregnancy continues to term (97). Increasingly, in many countries, clinically recognized maternal rubella now terminates in therapeutic abortion, particularly when infection occurs during the first 8 weeks of gestation when the occurrence of birth defects is extremely high (67% to 85% in different studies) (Fig. 7) (212,221). Fetal damage, therefore, is not universal even when there is serologic (221) or virologic evidence of fetal infection (263). The current rubella vaccine RA27/3 has extremely low teratogenicity, and inadvertent vaccination in early pregnancy is no longer considered an indication for therapeutic abortion (276). Viral transmission to the fetus resulting in persistent infection has, however, been described (150a).

The most common clinical manifestations of congenital rubella (present in at least 10% of patients) include hearing loss, congenital heart disease usually manifested as patent ductus arteriosus or pulmonary artery or valvular stenosis, psychomotor retardation, cataract or glaucoma, retinopathy, neonatal thrombocytopenia purpura, hepatomegaly and splenomegaly, and intrauterine growth retardation (75). Less common features (present in 5% to 10% of patients) include bony radiolucencies, hepatitis (usually with jaundice), and hemolytic anemia (3,72,97) (Table 3). Many of the clinical manifestations of congenital rubella are evident at birth or shortly thereafter (Fig. 8). Some, including hepatosplenomegaly and hepatitis, are transient and resolve within weeks in surviving infants (74). Intrauterine growth retardation resolves more slowly, if at all (277,337). Other defects remain as permanent and generally nonprogressive sequelae of the *in utero* effects of RV. Still other defects may not be recognized at birth. Delayed appearance can be explained by either the late onset of postnatal active multisystem disease, the dependence of these conditions on the normal development of function in the child before they are manifest, or the very delayed development of organ-specific progressive dysfunction.

	5. Meningoencephalitis
	6. Radiolucent bone disease
	7. Progressive or late-onset manifestations
	a. Mental retardation
	b. Diabetes mellitus
	c. Progressive Panencephalitis

TABLE 3. *Manifestations of congenital rubella syndrome*

FIG. 8. Child with congenital rubella syndrome.

Most children with CRS (80%) show some type of neural involvement (92). Clinical manifestations expressed in infancy include bulging anterior fontanel, lethargy, irritability, and motor tone abnormalities. Residual signs in survivors include mental retardation, motor disabilities, abnormal posture and movements, and neurosensory hearing loss. Laboratory findings may include increased CSF protein and abnormal electroencephalogram. Virus has been isolated from about 30% of CSF samples (93). Neuropathologic findings at autopsy of symptomatic newborns and infants differ from those found in early products of gestation (reviewed in detail in reference 364). Inflammatory changes in the brain are variably observed (93,292).

RV can be isolated from almost any organ at birth and from selected tissues for 1 year or more in surviving infants (206). More than 80% of congenitally infected newborns excrete substantial amounts of RV into their nasopharyngeal secretions and urine at birth, and 3% continue to shed virus for as long as 20 months (72). This chronic shedding of RV by neonates is an indicator of early gestational infection (78).

Mechanisms of Teratogenesis

The pathogenic mechanisms underlying RV teratogenesis remain unknown but are likely to be multifactorial (97,266). Direct effects of virus replication on focal clones of cells and their progeny during critical stages of the ontogeny of specific fetal organs are thought to give rise to the wide range of abnormalities that together comprise CRS (275). Chronic infection of fetal cells from many different tissues results in slowed growth rates and reduced survival. Infection of epithelial cells *in vitro* is associated with a marked depolymerization of actin filaments, and disruption of these cytoskeletal structures could disturb mitosis (32). Human embryonic cells persistently infected *in vitro* with RV display an altered responsiveness to the growth-promoting properties of epidermal growth factor as well as a decreased capacity for collagen synthesis (373). Thus, it is probable that noncytopathic RV infection of selected embryonic cell types *in utero* upsets the normal delicate balance of cellular growth and differentiation and has profound effects on organogenesis. Any of these effects, alone or in concert, could explain the observation that the small, but otherwise grossly normal, organs of congenital rubella infants contain reduced numbers of cells (224).

Direct cytolytic effects of RV also contribute to the observed damage. For example, the cataracts of congenital rubella contain highly characteristic pyknotic cells in the lens nucleus, and noninflammatory necrosis of the pigmented cells of the retinal epithelium produces focal areas of decreased and increased pigmentation of the retina (176). Focal cellular necrosis has also been noted in the myocardium, skeletal muscle, and inner ear (338). Necrosis of vascular endothelium is also prominent early in the *in utero* infection (338), and the evolution of these vascular lesions could readily explain many of the vascular abnormalities observed at term (208). In the CNS, focal areas of noninflammatory parenchymal and perivascular necrosis are common, and damage of large vessels is sometimes accompanied by ischemic necrosis of adjacent neural tissue (292).

In addition to these direct effects of RV replication in host tissue, there is considerable evidence that perinatal and also postnatal damage is, at least in part, immune mediated. Pathologic signs in infants who die at some interval after birth usually include mononuclear inflammatory infiltrates in one or more organs, particularly the lungs and brain (314,328). Circulating immune complexes containing RV antigens may involved in the immunopathogens of late-onset disease (328). They are found in the serum of nearly half of all infants with the congenital rubella syndrome, and there is an increased likelihood of finding rubella-specific immune complexes in the serum of CRS children with active clinical problems (77).

The persistence of RV in fetal tissue throughout gestation, and in infants with CRS for prolonged periods after birth, raises the question of how the virus avoids immune elimination. Clearly, neither transferred maternal IgG nor fetal IgM can eliminate virus *in utero,* although both have neutralizing capacity *in vitro* (75). Antibody may in fact promote persistence, as it has been shown to do *in vitro* (2,51). Moreover, fetal IgM is not synthesized until about 20 weeks of gestation, and cell-mediated immune responses are not detectable until 27 weeks, leaving the infant highly vulnerable before this time (211).

Immunologic Responses

Maturation of the immune response is abnormally slow in CRS with regard to both isotype switching and the development of high-avidity IgG (136,330). In addition, the humoral immune response of CRS infants differs qualitatively from that of naturally infected or immunized children. Whereas the latter groups possess some IgG class antibodies against each of the three structural proteins of the virus, CRS infants often lack antibodies to the C protein and demonstrate weak reactivity to the E2 protein (91,281). Perhaps more telling, these children show selective tolerance to the E1 protein (198) and, more specifically, little or no antibody to the putative E1 neutralization domain (218,281).

Infants with CRS also demonstrate prolonged impairment of RV-specific cell-mediated immune responses (35), including cytotoxicity (115) and lymphokine secretion *in vitro* (35). RV-responsive T-cell lines derived from several congenital rubella children and adults failed to respond to RV peptides that commonly stimulate lymphocyte proliferative responses in normal immune adult donor cells (246). These data suggest that early fetal infection results in selective immune tolerance to a limited but critical number of RV epitopes that must be recognized to clear the virus successfully.

Late-Onset Sequelae

Although many of the effects of fetal rubella are manifest at birth and may be transient, some defects, such as retinopathy, mental retardation, hearing loss, and endocrine abnormalities, may not become clinically apparent for several years (202,310). One study reported that 37% of preschool CRS children were mentally retarded, 7.4% were autistic, and 3.3% had behavioral disorders consistent with neural damage (64). Hearing loss is also a frequent manifestation in about 60% of CRS children reaching school age (221,359). In addition, asymptomatic congenital rubella (with positive IgM serology at birth) accounted for a substantial proportion of all cases of sensorineural hearing loss in early childhood before the widespread use of rubella vaccines (257). Eyesight may also be affected in up to 80% of young adults born with CRS (122). In these patients, bilateral pigmentary retinopathy (57%), bilateral or monocular cataracts (27%), and microphthalmia (23%) were the most common manifestations of ocular disease. Psychomotor retardation (62%), cardiac abnormalities (58%), and mental retardation (42%) are also frequently associated with CRS, and multiorgan disease is found in 88% of patients (122).

Delayed Endocrine Disease

Congenital rubella infection is also associated with a variety of endocrine abnormalities, including polyglandular autoimmunity (283,310). Type 1 diabetes mellitus occurs as overt or latent disease in as many as 20% of young adults with the congenital rubella syndrome (121,311). One follow-up study over 36 years of a series of 50 individuals with congenital rubella determined that 9 had developed clinical diabetes mellitus at a mean age of 28 years (207). In a younger cohort composed primarily of congenital rubella cases from the 1964 to 1966 epidemic, 20% had islet-cell surface antibodies, and 12% had developed diabetes by 17 years of age (121). An increased frequency of the class 2 antigens DR3 and, to a lesser extent, DR4 has been found in CRS patients who develop diabetes (121,296). This is the same MHC antigen pattern found in type I diabetes mellitus and in autoimmune polyglandular syndrome type II (283). Overall, children with congenital rubella appear to have a 50-fold increased risk for developing type I diabetes as compared with age-matched controls (232). In contrast, no clear association has been found between acute postnatal rubella and type I diabetes, although infection occasionally results in the transient induction of insulin autoantibodies or in the appearance of islet cell antibodies (26). A study of two children with acute-onset, fatal type I diabetes failed to show the presence of the RV genome in pancreatic tissues by RT-PCR amplification or *in situ* hybridization (33).

Several mechanisms to explain the induction of type I diabetes by viruses have been proposed, with virus-induced autoimmune events being central (376). It is of interest that the pancreas is probably a frequent target for RV replication *in utero* (72) and that human fetal islet cells support rubella replication *in vitro* (233). The lack of a suitable animal model has limited studies on pathogenesis. In one study, however, rubella RA27/3 vaccine virus adapted to growth in neonatal hamster pancreatic b-cells was found to induce both hypoinsulinemia and hyperglycemia in infected hamster pups (287). In these animals, cell-free RV was recoverable from pancreas, viral antigens were present in islet cells, and increasing mononuclear infiltration of the islets occurred over the first 3 weeks of the infection. Islet cell antibodies developed in 40% of infected pups (287).

The target antigens of the islet cell autoantibodies found in type I diabetes sera include antibodies to insulin, islet cell antigen (ICA) 69, glutamic acid decarboxylase (GAD) 65 and 69, and heat-shock protein (hsp) 65 (12,250,346). It has been suggested that cross-reactivity of antiviral antibodies or T-cell–mediated immune responses with islet antigens may trigger an autoimmune reaction against islet tissue (374). Evidence in favor of this includes the identification of a monoclonal antibody to RV capsid protein that reacts with pancreatic islet cell Ia2 protein (163), and CD4 and CD8 T-cell clones isolated from CRS patients have been shown to recognize GAD 65 peptides in an HLA-restricted manner (247).

Antibodies reactive with microsomal or thyroglobulin fractions of thyroid tissue have also been frequently found in congenital rubella sera (in 20% to 40% of cases in selected series [68,121,311]). In a study of children with congenital rubella enrolled in residential schools for the deaf (11 to 12 years of age), thyroid function studies were abnormal in 5% and present in 20% of those with thyroid autoantibodies (311). The relation of congenital rubella infection to the thyroid dysfunction is unclear, although in one case, RV antigen was detected in thyroid tissue obtained at surgery from a 5-year-old boy with CRS and Hashimoto's thyroiditis (378). Pituitary involvement may also occur as some children with CRS are growth hormone deficient (277). Hamsters infected with the M33 strain of RV or immunized with recombinant RV E1 or E2, develop pituitary autoantibodies and lymphocytic hypophysitis (375). These observations suggest that virus-induced autoimmune mechanisms may partially account for the late appearance of polyendocrine diseases that frequently complicate congenital rubella.

Delayed Neurologic Disease

An unusual late-onset rubella encephalitis has been described, referred to as *progressive rubella panencephalitis* (PRP) (339,356). Like other slow virus diseases of the CNS, PRP is characterized by a prolonged asymptomatic period,

followed by the onset of symptoms of neural deterioration during the second decade of life. These include behavioral changes, intellectual decline, ataxia, spasticity, and sometimes seizures (365). Ingravescent neurologic dysfunction follows, ultimately leading to death within 8 years. Although PRP has most often been associated with congenital rubella in children and young adults, it may also be a very rare, late complication of natural childhood rubella (1,87,366). Several lines of evidence link RV to the etiology of PRP. Sera and CSF from affected children contain antibodies that react with the structural proteins of RV (369). Rubella-specific immune complexes have been demonstrated in sera (76), and RV antigen has been visualized *in situ* within CSF cells (1). RV has been isolated from PBMC (367) and from brain by co-cultivation techniques (79).

Neuropathologic changes are found throughout the brain parenchyma and include microscopic evidence of subacute to chronic inflammatory change in the leptomeninges and in perivascular cuffs composed of mononuclear lymphocytes and plasma cells (339,340,356). There is extensive destruction of white matter, accompanied by loss of myelin, relative preservation of axons, and severe gliosis. No intranuclear or intracytoplasmic inclusions are seen, and viral particles have not been identified (365).

The pathogenesis of PRP is unclear. However, the continued or renewed generation of RV proteins, if not the complete virus, is likely during symptomatic persistent infection to provide the viral components of the circulating immune complexes found in PRP (76). The organ-specific vascular lesions of PRP strongly suggest that immunoglobulins are deposited in response to antigens produced locally. The nearly complete destruction of Purkinje cells indicates either some degree of selective tropism for RV within the CNS or a more profound and lethal effect of infection on the metabolism of these cells. This could also account for the selective loss of myelin and oligodendroglia, although immunopathologic mechanisms could also be active.

DIAGNOSIS

Differential

The most common symptoms of rubella (lymphadenopathy, erythematous rash, and low-grade fever) can readily be confused with similar illnesses associated with maculopapular rash caused by other common viral and nonviral pathogens or drug-induced eruptions (27). The basic differential diagnosis includes measles, scarlet fever, roseola, erythema infectiosum, and rash-associated enterovirus or adenovirus infections (74). In one series of patients with rubelliform rash and arthritis or arthralgia, rubella was confirmed in only 36% of the cases. Of the remainder, 7% were attributable to human parvovirus infections, and 54% were of unknown etiology (312). Parvovirus B19 infections typically cause a rubelliform rash and arthralgias in young female patients (343), and dengue can be confused with rubella in endemic areas (38). Therefore, a definitive diagnosis of rubella can be made only by specific laboratory studies.

Similarly, confirmation of a diagnosis of congenital rubella cannot be established solely on the basis of clinical findings. It requires either the direct isolation of RV or serologic evidence of acute infection in the infant. In the absence of confirmatory laboratory data, a clinical diagnosis compatible with CRS requires the presence of any two of the following: cataracts or congenital glaucoma, congenital heart disease, hearing loss, or pigmentary retinopathy. In the presence of only one of the preceding manifestations, the additional finding of purpura, hepatosplenomegaly, jaundice, microcephaly, mental retardation, meningoencephalitis, or radiolucent bone disease can suffice (41) (see Table 3).

Laboratory

Diagnosis of postnatal rubella and congenital infection (following birth) is normally carried out serologically by detection of rubella-specific IgM by ELISA (63). After postnatal rubella, IgM is usually detectable from the time of presentation until 5 to 6 weeks after the symptoms subside (209). Infants infected *in utero* produce rubella-specific IgM for many months after birth (330). Although tests for rubella-specific IgM are highly sensitive, they may be compromised by cross-reactivity with other viruses (especially parvovirus B19 and Epstein-Barr virus) (352) or by the presence of rheumatoid factor, which can give rise to false-positive results in assays that measure IgM indirectly (298). Confirmation of rubella infection has normally been carried out by a standard fourfold rise in antibody titer between an acute and convalescent serum sample (63). More recently, measurement of low-avidity rubella-specific IgG has been proposed as an alternative test for recent infection (31,129). This test is based on the finding that the avidity of antibodies for their antigenic target increases with time, reflecting maturation of the immune response. By inclusion of a mild detergent, such as 35 mM diethylamine, or a chaotropic agent, such as 8 M urea, in the wash buffer of a standard IgG ELISA test, the avidity of the IgG can be measured (31).

Other diagnostic serologic tests include measurement of HAI (167,323) or neutralization antibodies (291), but these are difficult to perform and are now used infrequently. ELISA tests, however, do not distinguish antibodies that are of functional significance, and patients may possess detectable ELISA antibodies in the absence of neutralizing or HAI antibodies (332). In addition, analysis of the antigen specificity of ELISA-positive sera on immunoblots has shown that some patients have a skewed response to the major viral antigens E1 and E2. This is particularly notable in CRS patients but has also been shown in patients undergoing reimmunization (91,198,204).

Viral isolation may occasionally be warranted, particularly to confirm infection during pregnancy or in a neonate. In acute infection, the virus is readily isolated from nasopharyngeal secretions for about 6 days before and after the appearance of rash (86). Although virus can be isolated from circulating lymphocytes and affected skin, these sites do not yield virus frequently enough for clinical diagnostic purposes. Cord blood or placental tissue may be used to confirm congenital infection at time of birth. In addition, virus can readily be isolated from nasopharyngeal secretions, feces, and urine of the neonate. Later, the throat and CSF become the best sources of viral isolation because the infants with CRS shed less virus (264).

Nucleic acid amplification techniques have also been developed for detection of RV RNA in clinical samples (29,49,99,164,289). This involves reverse transcription of RNA isolated from a tissue source, followed by amplification of

the complimentary DNA produced by polymerase PCR using primers specific for a selected region of the RV genome (usually the E1 gene). The technique appears to be as sensitive as viral isolation although not much more sensitive, owing to limitations of the RT step (29,49). Sequencing of the amplified product provides confirmation that it is rubella specific and not due to mispriming. A restriction endonuclease digestion step has been successfully used to eliminate false-positive results caused by carryover from a previous reaction (96). In the case of suspected congenital infection, *in utero* diagnosis using RT-PCR has been applied to samples obtained by amniocentesis, cordocentesis, or chorionic villus sampling (29,144,289). The technique is sensitive and specific in this setting and provides results much earlier than viral isolation (288).

PREVENTION AND CONTROL

Treatment

Most cases of acquired rubella are subclinical or mild and require no specific treatment. The complications of rubella, when they occur, are treated symptomatically. Under highly controlled experimental conditions, the administration of pooled human gammaglobulin containing high-titer, neutralizing, antirubella antibody abrogated clinical symptoms and prevented detectable viremia (304). However, nasally infected volunteers receiving gammaglobulin containing low-titer, RV-neutralizing antibody were variably protected from developing either rash or viremia (304). When the gammaglobulin was protective, it was administered within 24 hours of mucosal virus challenge. Because patients with rubella shed virus before the onset of the rash, and many never develop either a rash or symptoms, the use of gammaglobulin to modify the course of rubella or to attempt to prevent congenital infection in pregnant contacts of rubella cases has little merit. The successful use of antiviral chemotherapy to limit virus replication in congenitally infected infants has not been reported.

Vaccines

Development

After isolation of RV in cell culture in 1962 (254,357), attenuation of the virus was carried out by serial passage in a variety of cell lines, giving rise to several vaccine strains (reviewed in 20). These included the original vaccine used widely in North America, HPV77/DE5 (39); the Cendehill strain, used more extensively in Europe (265); and several Japanese strains, Takahashi, To336, and Matsuba (313). An early variant of the HPV77 strain passaged in dog kidney cells, HPV77/DK12, was found to be highly reactogenic, even in children, and was soon removed from distribution (319,320). The Cendehill and To336 strains have been found to be the best tolerated by adult women, who are particularly susceptible to side effects (21). The HPV77/DE5 strain was the predominant strain used in North America until 1979, when it was replaced by the RA27/3 vaccine because of concerns about waning immunity in HPV77/DE5 vaccine recipients (154). The RA27/3 strain was derived from an isolate from the kidney of a rubella-infected fetus and was attenuated by passaging 4 times in human embryonic kidney followed by 17 to 25 times in WI-38 fibroblasts (269). This strain was reported to induce a more vigorous immune response than HPV77/DE5 and had the added advantage that it had been attenuated in human cells and was therefore not subject to possible side effects associated with vaccines grown in nonhuman cells (267,268). RA27/3 was licensed in 1979 and is now the only rubella vaccine available in North America. After subcutaneous administration, it induces an antibody response in about 95% of recipients older than 12 months of age (154). The vaccinated individuals show only mild symptoms, and transmission to susceptible bystanders is thought not to occur (131). In addition, although the antibody titers are lower than those following natural infection, protection is believed to endure for more than 12 years in most of those immunized (137,241).

Adverse Reactions

Unfortunately, the current RA27/3 vaccine is not problem free (159,160). The incidence of acute adverse reactions is lower than that after natural rubella (331) but higher than that reported for the Cendehill and To336 strains (21,105). This includes fever, lymphadenopathy, arthralgia and arthritis, paresthesia, and carpal tunnel syndrome (105). Between 10% and 40% of adult rubella seronegative women vaccinated with the RA27/3 vaccine develop acute, usually transient, arthritis or arthralgia (273,331,334). In a few subjects, the joint reactions can be recurrent or persistent, similar to symptoms seen when they follow natural rubella (333,334). In patients immunized with HPV77/DE5 vaccine, the virus was shown to persist in PBMC for up to 6 years after immunization (52,53). In addition, rubella-specific immune complexes persist for extended intervals after vaccination and are found more frequently in patients who experience complications (77). In a recent randomized double-blinded study of adverse effects of rubella vaccine in 546 rubella seronegative women immunized postpartum with vaccine or placebo, acute arthritis or arthralgia was recorded in 30% of women receiving vaccine, and persistent or recurrent joint manifestations lasting up to 12 months in 58 patients (22%) (334). Acute joint symptoms, however, were also found in 20% of women receiving placebo, and 15% of these women experienced persistent joint reactions (41 patients), raising the question of the role of the vaccine in inducing chronic joint symptoms. Two other studies have not found a significant increase in the incidence of joint symptoms in women receiving rubella vaccine over controls (286,316). It seems clear that the incidence of arthritis due to rubella vaccination is lower than previously thought (331,335). Natural rubella, however, is well-known to be frequently complicated by arthritis (151,244,331), and the various vaccines have different levels of association with joint symptoms that parallel their ability to infect joint tissue *in vitro* (210). Therefore, it would seem likely that a proportion of the joint symptoms seen after rubella immunization are vaccine induced. The finding of an association of HLA-DR1 and HLA-DR4 with an eightfold higher incidence of joint symptoms after RA27/3 rubella vaccination (216) suggests that RV causes joint symptoms selectively in genetically predisposed individuals. This factor should be taken into account in any future studies based on statistical analysis of populations.

Vaccination Policy

Rubella vaccine is probably the only vaccine that is administered to protect a population other than the one that is immunized. More specifically, young children are vaccinated to provide herd immunity and to protect the developing fetuses of susceptible pregnant women. In view of this, divergent vaccination policies have been developed in different

countries, with vaccine delivery targeted at different age groups and sexes (89). Consequently, there have been markedly varied initial results in achievement of the vaccine's key goal (90). The United States and Finland chose to disrupt the natural spread of infection by mandatory vaccination of all preschool-aged children, supplemented by vaccine administration to susceptible postpubertal women (6). In the United Kingdom and other European countries, however, a decision was made to immunize adolescent girls and allow natural rubella to continue to circulate, owing to concerns that vaccination would not provide long-lasting protection (140,336). After a rubella epidemic in 1986 (23), however, the vaccination program in the United Kingdom was expanded to include preschool-aged children, with booster doses provided to adolescent girls. Several European countries (138) and Australia have also switched to universal vaccination of infants, together with selective vaccination of seronegative adult women (324).

Risk in Pregnancy

A serious concern of rubella vaccination programs has been the potential risk to the developing fetus in mothers who are immunized during early pregnancy. In such instances, the placenta and fetal tissue may become infected (132). None of the 712 children born of mothers inadvertently immunized within 3 months of conception, however, were found to have malformations compatible with CRS (17,40). This included vaccination with the earlier Cendehill and HPV-77/DES vaccines as well as with the current RA27/3 vaccine. Thus, vaccine strains of RV appear to lack the teratogenic capacity of natural (wild-type) RV. Because a potential risk to the fetus still exists, pregnancy remains a contraindication to rubella vaccination. Inadvertent vaccination of a seronegative pregnant woman, however, is not generally considered to be sufficient reason for routine termination of pregnancy (276).

Reinfection

Reinfection occurs rarely after natural infection but has been reported in a small number of individuals after rubella vaccination (82,267). Subclinical reinfection, defined by a fourfold or greater rise in preexisting antibody titer, was found in about 10% of girls immunized 5 years previously with the RA27/3 vaccine after reexposure to the virus during an epidemic (82). Lack of an early vaccine-induced anti-E1 response was correlated with reinfection and resulted in an anamnestic antibody response, with RV-specific, high-avidity IgG produced (100,329). Failure to detect specific IgG in sequential sera collected after rubella exposure also suggests reinfection (329). Whereas limited replication of RV in the nasopharynx is seen during reinfection, viremia and systemic manifestations appear to be uncommon (242). As a consequence, reinfection during gestation rarely results in viral spread to the fetus and CRS (102,107). Unfortunately, there are several dozen rare but well-documented exceptions (22,85,353).

New Vaccine Strategies

Despite the efficacy of the current rubella vaccine program in the United States, problems still exist. These include potential dangers associated with vaccination of pregnant women or immunocompromised patients and also lack of immunity of some women of childbearing age due either to “missed opportunity” for vaccination (179), vaccine failure, or durability of the immune response elicited (169). A further problem is the refusal of some women to be vaccinated either because of concerns about side effects or for religious reasons.

New rubella vaccine strategies under assessment include the development of subunit vaccines and the use of recombinant DNA technology to engineer a vaccine strain that combines desirable properties of strains currently available. A subunit vaccine comprising the E1 protein, which contains the major neutralizing epitopes, has been proposed (370). In addition, DNA vaccines incorporating all three structural proteins, or just E1 and E2, have been constructed and have shown some promise in mice (274). Although the immune response induced may not be long lasting, such nonreplicating vaccines can be given safely to pregnant women to boost immunity during the critical stage of fetal development. Similarly, in immunocompromised individuals, a subunit vaccine would not be associated with the risk for dissemination and disease that accompanies immunization with a live vaccine. With regard to the general population, use of a live attenuated vaccine that will promote the strongest and most enduring immune response is still advisable. With current knowledge on the genetic determinants of virulence and joint tropism, the potential exists for development of a recombinant vaccine designed to be highly immunogenic but not associated with unwanted side effects (187).

PERSPECTIVES

In North America and much of Europe, where universal rubella vaccination has been carried out for some time, rubella and CRS have been largely controlled (69). Notably, there were 20,000 infants born with CRS after the 1964 epidemic in the United States, whereas the total number of cases reported in the 30 years since introduction of the vaccine has been less than 1,000 (306). Regrettably, RV is still endemic in many developing countries, although accurate information on the incidence of rubella and, more importantly, of congenital rubella, is difficult to obtain (84). Recently, the World Health Organization and the Pan American Health Organization have issued recommendations for a drive to eradicate rubella by addition of rubella vaccine to the measles vaccine already being administered worldwide. Implementation of a policy to distribute a combined measles–rubella vaccine to the less advantaged populations of the world has the potential to reduce greatly the burden (both economic and social) of CRS at little extra cost than that of the univalent measles vaccine. Because RV infects only humans, the potential to eradicate rubella and, more importantly, the devastating consequences of congenital infection is clear (44,270).

Eradication of rubella is a laudable goal but will not happen quickly. In the interim, improvements in the vaccine and the policy for its administration need to be addressed. Recent recommendations by the Advisory Committee on Immunization Practices in the United States have included the introduction of a second dose of MMR (measles–mumps–rubella) vaccine to be administered 1 month after the first (294). In some other countries, a second dose of vaccine given before school entry or in early adolescence has been introduced, whereas in others, a single dose in infancy followed by selective vaccination of seronegative women is recommended. Careful monitoring of the success of each of these strategies will need to be done to determine which is the most effective. With regard to the vaccine itself, the RA27/3

vaccine has a good safety record and provides long-lasting immunity (271). It is not, however, problem free (160,334), and production of recombinant or subunit vaccines for selected populations, including pregnant women and the immunocompromised, should be considered. In addition, the recent finding of an association of HLA genotype with incidence of joint reactions (216) may allow the prediction of which individuals have the genetic susceptibility to develop complications and opens the way to selective immunization of this target group with a more attenuated vaccine.

In conclusion, it is clear that RV is still a significant human pathogen that takes an enormous toll on the health of the world's population through the widespread manifestations of CRS, most notably in relation to blindness and hearing defects. Although the virus has now been cloned and sequenced, there is still remarkably little known about its pathogenesis, particularly regarding its teratogenicity, its relationship to autoimmune diseases like diabetes and arthritis, and its mode of persistence at the molecular level.

CHAPTER 32 *Flaviviridae*: The Viruses and Their Replication

Brett D. Lindenbach and Charles M. Rice

At the dawn of human virus research, nearly one century ago, Walter Reed demonstrated that the disease known as yellow fever could be experimentally transferred via the filtered serum of an infected individual (565) and that this infectious agent was transmitted to man by mosquitoes (566). The discovery of this viral pathogen eventually led to the derivation of a live-attenuated strain that has been effectively used for human vaccination for over 60 years (452,664,701). It is now appreciated that yellow fever virus (YF) is but one representative of a large family of related positive-strand RNA viruses, the *Flaviviridae* (from the Latin *flavus*, yellow). This family currently consists of three genera: the flaviviruses, the pestiviruses (from the Latin *pestis*, plague), and the hepaciviruses (from the Greek *hepar*, *hepatos*, liver) (177,761). In addition to these genera, a group of unassigned viruses, the GB agents, are awaiting formal classification within the family. As detailed later, members of this family exhibit diverse biologic properties and a lack of serologic cross-reactivity, although they share similarities in virion morphology, genome organization, and presumed RNA replication strategy. The increasing significance of *Flaviviridae* as human and animal pathogens (Chapter 33 and Chapter 34) emphasizes that their study remains no less pertinent than in Reed's time.

The flaviviruses and pestiviruses were formerly considered to be members of the family *Togaviridae*, based on traditional methods of virus classification. However, through the study of viral genes, virus structure, and the viral replication cycle, it became apparent that these viruses represented an evolutionarily distinct group, and they have been subsequently reclassified as a separate virus family, the *Flaviviridae* (761). The diversity of viruses within the *Flaviviridae* is partially illustrated in Figure 1 and Table 1. Comparative sequence analysis has permitted classification of positive-stranded RNA viruses based on inferred evolutionary relationships. The *Flaviviridae* are members of the positive-strand virus supergroup 2, bearing distant similarity in their RNA-dependent RNA polymerases (RdRps) to coliphages and the plant-infecting carmo-, tombus-, diantho-, and subgroup I luteoviruses (345). The *Flaviviridae* are the only member of polymerase supergroup 2 to also encode RNA helicases, although members of polymerase supergroup 1 contain similar helicases. Thus this family of viruses is likely to exhibit a unique mode of genome replication.

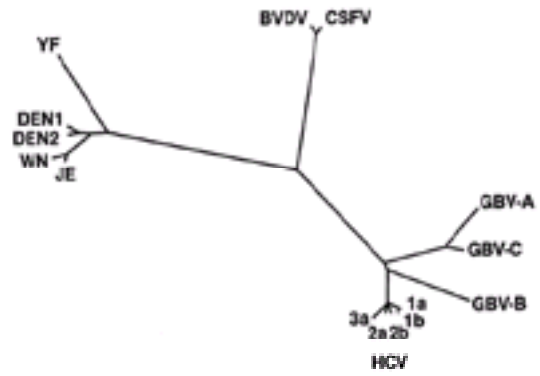

FIG. 1. The *Flaviviridae*. Phylogenetic tree based on parsimony analysis of NS3 helicase regions. Shown are members of the *Flavivirus* genus: yellow fever virus (*YF*), dengue-1 (*DEN-1*), dengue-2 (*DEN-2*), West Nile virus (*WN*), and Japanese encephalitis (*JE*); the *Pestivirus* genus: bovine viral diarrhea virus (*BVDV*) and classical swine fever (*CSFV*); several hepacivirus (*HCV*) isolates; and the unclassified viruses GBV-A, GBV-B, and GBV-C. (Figure adapted from ref. 640, with permission.)

TABLE 1. *Members of the Flaviviridae*

FAMILY CHARACTERISTICS AND REPLICATION CYCLE

Common features believed to be shared by the three genera and highlights of the replication cycle are diagrammed in Figure 2. Our understanding of these steps is far from complete and the current view is based largely on studies with flaviviruses. Modifications are likely as more information becomes available, particularly for hepatitis C virus (HCV) and the pestiviruses. Enveloped virions are composed of a lipid bilayer with two or more species of envelope (E) proteins surrounding a nucleocapsid that consists of a single-stranded positive-sense genome RNA complexed with multiple copies of a small, basic capsid (C) protein.

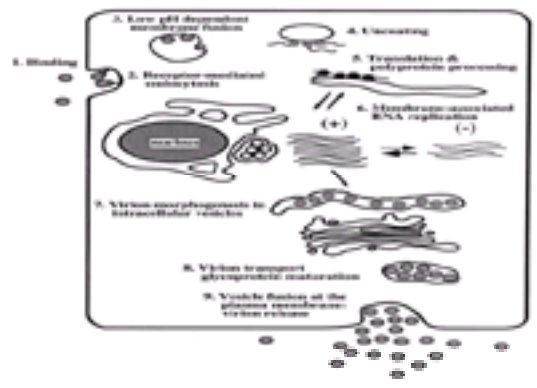

FIG. 2. Life cycle of the *Flaviviridae*. See the text for further details.

Binding and uptake are believed to involve receptor-mediated endocytosis via cellular receptors specific for viral envelope proteins. Fusion of the virion envelope with cellular membranes delivers the nucleocapsid to the cytoplasm, where translation of the genome RNA occurs. The organization of the genome RNA is similar for all genera. All known viral proteins are produced as part of a single long polyprotein of more than 3,000 amino acids that is cleaved by a combination of host and viral proteases. The structural proteins are encoded in the N-terminal portion of the polyprotein, with the nonstructural proteins in the remainder. Sequence motifs characteristic of a serine protease, RNA helicase, and an RdRp are found in similar locations in the polyproteins of all three genera (444). The cleavage products containing these regions are believed to form the enzymatic components of the RNA replicase. RNA replication occurs in cytoplasmic replication complexes that are associated with perinuclear membranes, and it occurs via synthesis of a genome-length minus-strand RNA intermediate. RNA synthesis is resistant to actinomycin D, an inhibitor of DNA-dependent RNA polymerases. Progeny virions are thought to assemble by budding through intracellular membranes into cytoplasmic vesicles. These vesicles follow the host secretory pathway, fuse with the plasma membrane,

and release mature virions into the extracellular compartment.

THE FLAVIVIRUSES

Background and Classification

The flavivirus genus consists of nearly 80 viruses, many of which are arthropod-borne human pathogens. Flaviviruses cause a variety of diseases including fevers, encephalitis, and hemorrhagic fevers (Chapter 33). Entities of major global concern include dengue fever with its associated dengue hemorrhagic fever (DHF) and shock syndrome (DSS) (reviewed in refs. 219,234, and 584), Japanese encephalitis (451), and yellow fever (reviewed in ref. 709). Other flaviviruses of regional or endemic concern include Kyasanur Forest disease, Murray Valley encephalitis (MVE), St. Louis encephalitis, tick-borne encephalitis (TBE), and West Nile (WN) viruses. Decreases in mosquito control efforts during the latter part of the 20th century, coupled with societal factors such as increased transportation and dense urbanization, have contributed to the reemergence of flaviviruses such as dengue (DEN) in South and Central America (453, 480). In 1999, WN virus was isolated for the first time in the western hemisphere during an outbreak in New York City that was responsible for several human cases of encephalitis, including four deaths (17,22,358).

Vaccination is available for YF, using the live-attenuated 17D strain, and for TBE and Japanese encephalitis (JE) using inactivated virus (253). Efforts to derive live-attenuated strains of other flaviviruses have met with only limited success. Development of effective DEN vaccines that exhibit cross-protection, thought to be important for preventing subsequent dengue-associated immunopathogenesis (see later), are proving to be particularly challenging. The ability to genetically manipulate flaviviruses, described later, is being used to develop novel approaches to vaccine design (65,95,223,224,408,526). One promising candidate live-attenuated vaccine is a chimeric flavivirus created by replacing the structural glycoproteins of YF-17D with those of JE (95,224,454,455). A similar approach to create a vaccine against DEN-2 is under investigation (223).

Viruses within the genus are categorized into antigenic complexes and subcomplexes based on classical serologic criteria (85,86) or into clusters, clades, and species, according to molecular phylogenetics (349,807). These latter methods have permitted the classification of viruses such as YF, which lacks close relatives. Mosquito-borne and tick-borne flaviviruses, although quite distinct, appear to have evolved via a common ancestral line that diverged from non-vector-borne viruses (i.e., those for which no arthropod vectors are known) (349,807). The salient features of flavivirus taxonomy are illustrated in Figure 3, with emphasis given to viruses that are mentioned in this chapter. Two additional points should be clarified with regard to this genus organization. First, the trivial name tick-borne encephalitis virus is commonly applied to both Central European encephalitis virus and Far Eastern encephalitis virus, although they clearly represent distinct viruses with differences in vector species, geographical distribution, and sequence relatedness (153). In addition, because of the high mutation rate of RNA viruses, it is expected that each flavivirus exists as a complex, interrelated population of quasi-species (Chapter 13). Recent evidence for intertypic recombination among DEN viruses hints at the unrealized diversity potentially lurking within flavivirus populations (774).

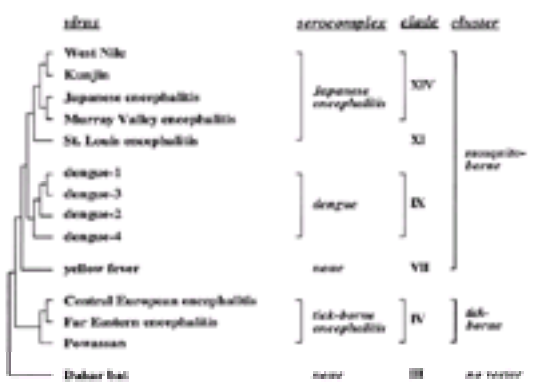

FIG. 3. Organization of the *Flavivirus* genus. The dendrogram on the *left* shows the relationships of selected flaviviruses based on a recent phylogenetic analysis (349). Evolutionary distance is not represented in this figure. The serologic and phylogenetic classifications of these viruses are indicated to the *right*.

Experimental Systems

Flaviviruses can be cultured in whole animals such as chick embryos, suckling mouse brain, and mosquitoes, as well as in primary or established cell lines of mammalian, avian, or insect origin. In vertebrate cells, dramatic cytopathic and ultrastructural effects can occur, including vacuolation and proliferation of intracellular membranes (472); infection is commonly cytocidal, although some vertebrate cell types do not show these effects and become chronically infected. Even during the peak of virus production, a major inhibition of host macromolecular synthesis is not observed (68,713,759,760). Arthropod cells in culture may demonstrate cytopathic effects, most frequently manifested as cell fusion and syncytia formation (reviewed in refs. 68,663, and 712). However, infection of mosquito cells is often noncytopathic, and persistent infections can be established (476). Mosquitoes remain chronically infected for life and produce extremely high levels of infectious virus particles in the salivary glands.

The life cycle of flaviviruses is increasingly understood at the molecular genetic level, and complete genome sequences exist for at least one member of each taxonomic group (see, for example, refs. 232,248,322,412, and 573). Furthermore, flaviviruses can be recovered from cells containing RNA transcripts of viral cDNAs, allowing flavivirus biology to be probed with reverse genetics (213,218,281,310,322,331,354,366,410,527,572,665). Such reverse genetic systems are also being exploited to express foreign genes (323,726), to provide stable genetic stocks for live-attenuated flavivirus

vaccines (331,572), and to assist in the design of novel vaccine strategies (65,95,223,224,408,526).

Structure and Physical Properties of the Virion

Flavivirus particles appear to be spherical, 40 to 60 nm in diameter, containing an electron dense core (about 30 nm diameter) surrounded by a lipid bilayer (Fig. 4A) (472). Mature virions sediment between 170 and 210S, have a buoyant density of 1.19 to 1.23 g/mL, and are composed of 6% RNA, 66% protein, 9% carbohydrate, and 17% lipid (592,712). Because of the lipid envelope, flaviviruses are readily inactivated by organic solvents and detergents (592). Three viral proteins are associated with virions: the E (envelope), M (membrane), and C (capsid) proteins. The E protein is the major surface protein of the viral particle, probably interacts with viral receptors, and mediates virus–cell membrane fusion. Antibodies that neutralize virus infectivity usually recognize this protein (reviewed in ref. 253), and mutations in E can affect virulence (reviewed in Chapter 33). M protein is a small proteolytic fragment of prM protein, which is important for maturation of the virus into an infectious form, as described later. Discrete nucleocapsids, composed of C protein and genomic RNA (120 to 140S, buoyant density 1.30 to 1.31 g/mL), can be isolated after solubilization of the envelope with nonionic detergents (592).

Binding and Entry

It is thought that flaviviruses attach to the surface of host cells through an interaction of E protein with one or more receptors, and many E-reactive antibodies have been shown to neutralize virus infectivity by interfering with virus binding (251,280). The patterning of receptor expression in animal tissues is likely to contribute to flavivirus tropism *in vivo*, although such receptors have not been specifically identified. Several cell surface proteins have been described as candidate flavivirus receptors (47,329,346,416,470,548,596). In addition, recombinant E protein from DEN-2 virus has been shown to interact with highly sulfated glycosaminoglycans, and cell surface expression of heparan sulfate was required for efficient infection of mammalian cells by a laboratory-passaged strain of DEN-2 virus (107). Consistent with a role for glycosaminoglycans in flavivirus entry, the infectivity of DEN viruses can be partially neutralized by incubation with heparin or highly sulfated heparan (107,280). An additional mechanism of flavivirus binding, typically referred to as antibody-dependent enhancement (ADE), has been demonstrated for a number of flaviviruses cultured *in vitro* (236,237 and 238,388,509,510 and 511,520,616). ADE involves the increased binding of virus opsinized with subneutralizing concentrations of flavivirus-reactive antibodies to cells expressing immunoglobulin Fc receptors (509,616). It has been hypothesized that this mechanism might occur *in vivo* and, by altering tissue tropism, could contribute to the enhanced pathogenesis frequently observed in secondary infections by other DEN types (reviewed in refs. 234,235, and 584).

After binding, it is generally believed that virions are taken up by receptor-mediated endocytosis (192,292,481,487), although direct fusion at the plasma membrane has also been observed (244,245). Ultrastructural studies have localized single virions and virion aggregates to clathrin-coated pits on the cell surface, and uptake of virus particles into coated vesicles rapidly follows attachment (192,194). Virions are later found in uncoated pre-lysosomal vesicles, where an acid-catalyzed membrane fusion is thought to release the nucleocapsid into the cytoplasm (192,194,254,481). Consistent with this, a conformational change in the viral E protein, which probably exposes a fusogenic domain (567; and see later), occurs at low pH (11,221,254,330,583,611,659). Acid pH can promote fusion of virions with liposomal membranes *in vitro* or at the plasma membrane of cultured cells (193,194,222,330,550,667), although in the latter case this mode of entry does not lead to productive infection (194,330). Following entry and fusion, nucleocapsids are presumably disassembled, genomic RNA is translated, and RNA is initiated.

Genome Structure

The genome of flaviviruses consists of a single-stranded RNA about 11 kilobases (kb) in length. This RNA contains a 5' cap (m^7G5'ppp5'A) at the 5' end and lacks a polyadenylate tail (756). Genomic RNA is the messenger RNA for translation

of a single long open reading frame (ORF) as a large polyprotein, as described later. Surrounding the ORF are 5' and 3' noncoding regions (NCRs) of around 100 nucleotides (nt) and 400 to 700 nt, respectively. These regions contain conserved sequences and predicted RNA structures that are likely to serve as cis-acting elements directing the processes of genome amplification, translation, or packaging. Although it is not yet feasible to directly study the structures of flavivirus RNAs *in vivo*, the ability of RNA to adapt alternative foldings could regulate these competing processes (231,538).

The 5' NCR sequence is poorly conserved between flaviviruses, but it appears to contain common secondary structural elements that influence the translation of flavivirus genomes (69,84,231). However, the most significant function of the 5' NCR probably resides in its reverse complement, the 3' NCR of viral minus strands, which forms the site for initiation of plus-strand synthesis. Deletions engineered into the 5' NCR of DEN-4 were shown to have dramatic effects on the ability to recover live viruses, but they do not correlate with the translational efficiency of the mutant genomes (84). Interestingly, one of the resultant mutants exhibited a limited host-range growth phenotype, suggesting potential interactions of this region (or its reverse complement) with host-specific factors. In keeping with this, cellular proteins were shown to bind specifically to a terminal stem-loop in the 3' NCR of WN virus minus strand (627).

The 3' NCR of the flavivirus genome, which presumably functions as a promoter for minus-strand synthesis, exhibits a great deal of sequence divergence and size heterogeneity. Nevertheless, computational analyses have revealed features that are common to all flaviviruses or that are conserved within specific taxonomic groups, and that tend to cluster in a region proximal to the 3' end (538,552,735,739). RNA folding predictions based on thermodynamic considerations, covariation analyses, and biochemical probing support the existence of a 90- to 120-nt stem-loop structure at the 3' terminus of all flavivirus genomes, with the potential to form a pseudoknot involving an adjacent stem-loop (70,206,231,411,412,538,552,573,627,666,677,751,811). Several lines of evidence suggest a functional role for this structure in viral RNA replication. Mutations engineered within the 3' terminal stem-loop of the genome of DEN-2 virus greatly affected the ability to recover live viruses, and one of the recovered viruses exhibited a host restricted-growth phenotype (808). Several cellular proteins bind to this region of WN virus RNA, including the phosphorylated form of translation elongation factor 1a (49,50). Furthermore, viral replicase proteins NS3 and NS5 have been shown to bind to the terminal stem-loop RNA *in vitro* (103,133). The conserved portion of the 3' NCR also contains consensus sequences (CS1 and CS2) that are retained among all mosquito-borne flaviviruses, one of which has the potential to base-pair with a conserved region in the 5' region of the ORF, suggesting that cyclization of flavivirus genomes is possible (231). A DEN-4 genome engineered to contain a deletion in CS1 indicates that this element is required for virus viability (429). Complementarity in the proposed cyclization sequences was recently shown to be required for efficient RdRP activity *in vitro*, although the upstream element could be supplied in trans (803). Similarly, stretches of conserved RNA sequence and potential cyclization sequences are also found in the genome RNAs of tick-borne flaviviruses (412,413,415). Other regions in the 3' NCR, which may be dispensable for virus replication in culture, nevertheless appear to be important determinants for growth in mammalian hosts, and further analysis of such regions is likely to contribute greater insight into flavivirus pathogenesis and vaccine development (414,429,537).

Translation and Proteolytic Processing

The flavivirus genome is translated as a large polyprotein that is processed co- and posttranslationally by cellular proteases and a virally encoded serine protease (described later) into at least 10 discrete products. As depicted in Figure 5, the N-terminal one quarter of the polyprotein encodes the structural proteins, and the remainder contains the nonstructural (NS) proteins, in the following order: C-prM-E-NS1-NS2A-NS3-NS4A-NS4B-NS5 (573). Based on the deduced hydrophobicity of the viral proteins, their predicted membrane topology is illustrated in Figure 6. This model is supported by experimental data (89,757), although the transmembrane regions have not been well defined.

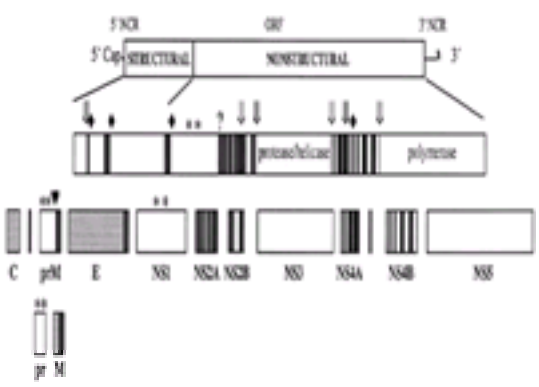

FIG. 5. Translation and processing of the flavivirus polyprotein. At the top is depicted the viral genome with the structural and nonstructural protein coding regions, the 5&cap, and the 5' and 3' NCRs indicated. Boxes below the genome indicate precursors and mature proteins generated by the proteolytic processing cascade. Mature structural proteins are indicated by *shaded boxes* and the nonstructural proteins and structural protein precursors by *open boxes.* Contiguous stretches of uncharged amino acids are shown by *black bars. Asterisks* denote proteins with N-linked glycans but do not necessarily indicate the position or number of sites utilized. Cleavage sites for host signalase (w), the viral serine protease (‾), furin or other Golgi-localized protease (©), or unknown proteases (**?**) are indicated.

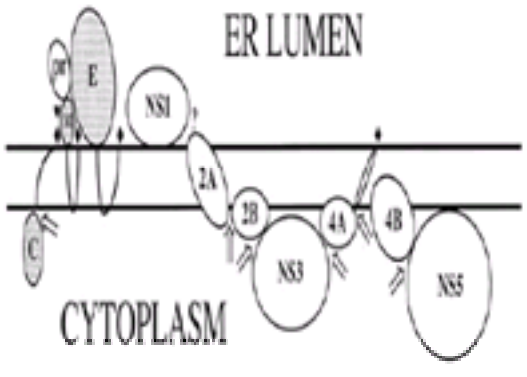

FIG. 6. Membrane topology of flavivirus proteins. The proposed orientation of the flavivirus polyprotein cleavage products with respect to the ER membrane is shown. The proteins are drawn to scale (areas are proportional to the number of amino acids) and arranged in order (left to right) of their appearance in the polyprotein. Mature structural proteins are *shaded* and C-terminal membrane-spanning segments of M and E are indicated. Cleavage sites for host signalase (w), the viral serine protease (‿), furin or other Golgi-localized protease (©), or unknown proteases (**?**) are indicated.

Features of the Structural Proteins

The C Protein

C protein (about 11 kd) is highly basic (55,573,711), consistent with its proposed role in forming a ribonucleoprotein complex with packaged genomic RNA. Basic residues are concentrated at the N- and C-termini of C, and they probably act cooperatively to specifically bind genomic RNA (323). The central portion of C contains a hydrophobic domain that interacts with cellular membranes and may play a role in virion assembly (418). The nascent C protein (anchC) contains a C-terminal hydrophobic domain (491) that acts as a signal sequence for translocation of prM into the lumen of the endoplasmic reticulum (ER). Mature C protein is generated by viral serine protease cleavage at a site upstream of this hydrophobic domain (16,395,785).

The prM Protein

The N-terminus of prM (about 26 kd) is generated in the ER by host signal peptidase. This processing event appears to require prior processing of anchC by the cytoplasmic viral serine protease (16,395,788), although the temporal order of these cleavages has been questioned (787,788). However, in support of this model, signalase cleavage at this site can be made viral protease-independent by cleaving anchC with another protease (660) or by improving the context of the signalase cleavage site (366,661). Interestingly, improvement of the prM signalase cleavage context was shown to be lethal for YF virion production (366). Thus, the availability of viral protease activity may regulate structural protein processing, and therefore virion assembly, over the course of an infection. During the egress of virions through the secretory pathway, prM is cleaved by the trans-Golgi resident enzyme furin (653), to form the structural protein M (about 8 kd) and the N-terminal “pr” segment, which is secreted into the extracellular medium (474). The N-terminal “pr” segment is predominantly hydrophilic and contains one to three N-linked glycosylation sites (93) and six conserved cysteine residues, all of which participate in intramolecular disulfide bridges (492). The structural protein M, located in the C-terminal portion of prM, is present in mature virions and contains a shortened ectodomain (about 41 amino acids) followed by two potential membrane-spanning domains. Antibodies to prM can mediate protective immunity (316), perhaps by neutralization of released virions that contain some uncleaved prM (see later).

The E Protein

E protein (about 50 kd) is a type I membrane protein, containing adjacent transmembrane domains in the C-terminus that serve to anchor this protein to the membrane and as the signal sequence for NS1 translocation (573). E protein contains 12 highly conserved Cys residues that form intramolecular disulfide bonds (492), and it is often glycosylated (93,768).

The three-dimensional structure of TBE E protein was determined by x-ray crystallography of a soluble tryptic fragment obtained from purified virions (Fig. 7) (567). These data indicate that E protein is divided into three structural domains and forms head-to-tail homodimeric rods that are thought to lie parallel to the virion surface in a meshlike network. This structural model provides a framework for understanding the molecular basis of E protein interactions. Structural regions of the ectodomain contain putative receptor binding sites (107, 567), a potential fusogenic domain (567), contact sites for E homodimer formation (567), a region involved in prM–E interaction (12), and the trigger for low-pH-induced rearrangement (659). E protein homodimers disassociate at low pH, and each monomer reassociates with two adjacent E proteins, perhaps around a three-fold axis of symmetry at the stalk, to form trimeric complexes (11,254,659). E trimers are thought to extend outward from the virion surface, presumably exposing the hydrophobic fusogenic domains. The stem-anchor region of E, for which structure was not determined, contains determinants for E trimer formation and for stabilization of prM-E heterodimers (12,741). Mutations in the putative receptor binding site in the TBE E protein gave rise to viruses with attenuated growth in culture and reduced virulence in mice (409). For some mosquito-borne flaviviruses, a similar region of E protein contains a putative integrin-binding motif Arg-Gly-Asp. Mutation of this sequence in E of MVE virus produced viruses with decreased entry kinetics, increased reliance on glycosaminoglycans for entry, and attenuated virulence (366).

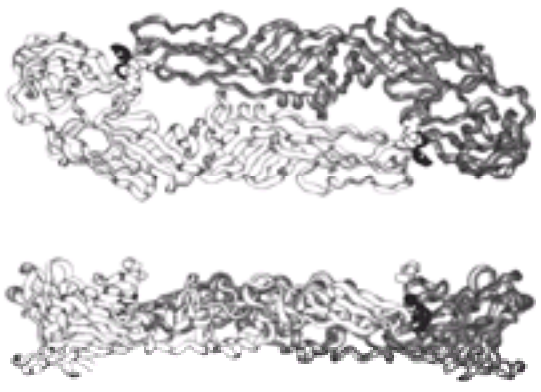

FIG. 7. Envelope protein structure. The structure of a tick-borne encephalitis (TBE) E glycoprotein dimer is represented in this ribbon diagram, as viewed perpendicularly (*top*) or laterally (*bottom*) with respect to the lipid bilayer. Individual E monomers are colored *gray* or *white*, and the proposed fusogenic domains are in *black.* (Kindly provided by Steve Allison and F. X. Heinz. Adapted from ref. 567, with permission.)

Features of the Nonstructural Proteins

The NS1 Protein

The NS1 glycoprotein (M_r of about 46 kd) exists in cell-associated, cell-surface, or extracellular nonvirion forms. NS1 is translocated into the ER lumen and released from the C-terminus of E by signal peptidase (161,571,757). It contains 12 highly conserved cysteines that form intramolecular disulfide bonds, and it is rapidly glycosylated on two or three Asn residues (367,419,646). NS1 is cleaved from its downstream neighbor, NS2A, around 10 minutes after synthesis by an unknown, membrane-bound, ER-resident host protease (93,160,161). The eight C-terminal hydrophobic residues of NS1, and more than 140 amino acids of NS2A, are necessary determinants of this cleavage (93,160,272,517). Truncated and elongated forms of NS1, which presumably contain alternate C-terminal cleavage sites, have also been described for some viruses (53,419). In addition, murine cells persistently infected with JE virus have been found to produce truncated forms of NS1, although this appears to be caused by an uncharacterized adaptation of the host cells rather than by alterations within the viral genome (104). Twenty to 40 minutes after synthesis, NS1 forms homodimers that are resistant to denaturation with 6M urea or 5M guanidinium-HCl, but that are unstable at high temperatures or low pH (769). Dimers of NS1 exhibit a partially hydrophobic nature, pelleting with membranes and fractionating equally into the aqueous and detergent phases upon extraction with Triton X-114 (769). A point mutation has been identified in Kunjin NS1 that destabilizes NS1 dimers and confers a replication defect on the virus (233), indicating a functional role for NS1 dimerization. NS1 appears to be peripherally associated with membranes, as it does not contain any putative transmembrane domains or known lipid modifications, and it can be released from membranes by sodium carbonate (pH 11.5), 8M urea, or 5M guandinium-HCl (161,757).

NS1 is slowly secreted from mammalian cells and is not secreted from mosquito cells (419,530,770). During secretion, one of the N-linked glycans is modified to contain complex sugars (367,419,477,540), and three NS1 dimers come together into a soluble hexameric form (132,170).

NS1 was first characterized as the soluble (non-virion-associated) complement-fixing (SCF) antigen present in the sera and tissues of experimentally infected animals (63). It is now understood that the extracellular forms of NS1 strongly elicit humoral immune responses, and immunization with purified or recombinant NS1 can be protective (159,297,383,546,617,706). Furthermore, protective immunity can be passively transferred with antibodies against NS1, apparently by their ability to direct complement-mediated lysis of infected cells via interaction with the cell-surface-associated form of NS1 (255,618,619). The secretion of a viral NS protein that elicits protective immune responses is one of the more curious aspects of flavivirus biology that await further inquiry.

Several lines of evidence implicate NS1 in the process of RNA replication. NS1 has been found to co-localize with markers of RNA replication in association with membrane structures that are presumed sites of replication (404,764). Mutations at the first or both N-linked glycosylation sites of NS1 dramatically impair virus replication (477,539) and demonstrate a decrease in viral RNA accumulation (477). Furthermore, a YF mutant containing a temperature-sensitive lesion in NS1 showed a profound decrease in RNA accumulation under nonpermissive conditions (478). NS1 can be supplied in trans to a YF genome lacking a functional NS1 gene, and RNA replication is blocked at a very early stage in the absence of complementing NS1 (384). Further genetic analysis has revealed that DEN NS1 does not productively interact with the YF replicase in trans (385). This block in replication can be suppressed by a mutation in NS4A, indicating that an interaction between NS1 and NS4A is critical for replicase function and suggesting a potential mechanism whereby NS1 participates in the cytoplasmic process of RNA replication (385).

The NS2A and NS2B Proteins

NS2A is a relatively small (about 22 kd), hydrophobic protein of unknown function. Cleavage of NS1-2A occurs in the ER, as previously mentioned, whereas the C-terminus is generated via cleavage at the NS2A/2B junction by the cytoplasmic serine protease, indicating that this protein must be membrane spanning. An alternative cleavage within YF NS2A can also be utilized by the viral protease, leading to a C-terminally truncated form of this protein that is about 2 kd smaller in mass (92,483). Mutations that block cleavage at either site are lethal for some aspect of YF replication (483). NS2A has been localized to presumed sites of RNA replication, and *in vitro* studies with a recombinant glutathione-S-transferase-KUN NS2A fusion protein suggest that this protein binds to NS3 and NS5, as well as to RNA transcripts of the 3' NCR (405). Thus, this protein might function in recruitment of RNA templates to the membrane-bound

replicase.

NS2B is a small (about 14 kd) membrane-associated protein containing two hydrophobic domains surrounding a conserved hydrophilic region (573,757). It forms a complex with NS3 and is a required cofactor for the serine protease function of NS3 (20,90,94,162,299). Deletion analysis indicates that a 40-amino-acid region in the central conserved domain of NS2B is required for NS2B-3 protease activity, and mutations in the central conserved domain that destabilize interaction with NS3 abolish protease activity (94,121,146,162,299).

The NS3 Protein

NS3 is a large (about 70 kd) cytoplasmic protein that associates with membranes via its interaction with NS2B (20,94,121). NS3 contains several enzymatic activities that implicate this protein in polyprotein processing and RNA replication.

The N-terminal one third of NS3 contains homology to trypsin-like serine proteases (34,35,198), an enzymatic activity that has been confirmed by deletion analysis (97,163,534,752) and by site-directed mutagenesis of the residues comprising the proposed catalytic triad (YF NS3 residues His-53, Asp-77, and Ser-138) (97,541,722,752,810) or the substrate-binding pocket (533,722). Mutations in NS3 that abolish protease activity also prevent the recovery of viable mutant viruses, substantiating a crucial role for this enzyme in the virus life cycle (94). Expression of the N-terminal 167 to 181 residues of NS3, together with NS2B, is sufficient to form the active protease (90,373). The NS2B-3 protease cleaves in both cis and trans configurations, and it mediates cleavages at the NS2A/NS2B, NS2B/NS3, NS3/NS4A, and NS4B/NS5 junctions, as well as cleavages that generate the C-termini of mature C (16,786) and NS4A (377), and minor cleavages within NS2A (483) and NS3 (20,700). Alignment of known cleavage sites and mutation of these residues have been used to characterize the substrate specificity of this enzyme. These data indicate that the NS2B-3 protease preferentially cleaves after pairs of basic residues and before an amino acid with a small side chain (94,96,378,483). However, some nonconservative mutations at these sites are tolerated, and several canonical dibasic cleavage motifs within the polyprotein are apparently not utilized, suggesting that contextual information contributes to cleavage site selection. The structure of a recombinant DEN-2 NS3 protease domain, in the absence of cofactor NS2B, has recently been resolved to 2.1 Å by using x-ray crystallography (475). This model exhibits structural similarities to other serine proteases including the NS3-4A protease of HCV (described later), provides a framework for the interpretation of NS3 mutagenesis studies, and suggests that NS2B could contribute to substrate binding specificity (475).

The C-terminal three quarters of NS3, which slightly overlaps the serine protease domain (373), has been implicated in RNA replication. This region has significant homology to RNA helicases containing the motif Asp-Glu-Ala-(Asp/His) (199). These enzymes utilize the energy of nucleoside triphosphate (NTP) hydrolysis to power RNA unwinding (302). RNA-stimulated NTPase activity has been demonstrated for full-length and N-terminally truncated NS3 (373,744,754). Recently, DEN-2 NS3 has been shown to contain an NTP-dependent RNA unwinding activity, consistent with the function of NS3 as an RNA helicase (373). The precise role of an RNA helicase is not known for flaviviruses (302), but it may help to dissociate nascent RNA strands from their template during RNA replication, or perhaps unwind secondary structures involved in template recognition or initiation of RNA synthesis. In this regard, NS3 was shown to bind to a region of the 3' NCR containing the terminal stem-loop, in association with NS5 (103,133). A minor truncated form of NS3 has been described that apparently results from recognition of a cryptic NS2B-3 protease cleavage site within the helicase domain of NS3 (20,541,700). The biologic consequences of this alternative processing event are not well understood, although it may serve to disrupt the helicase function of NS3. In addition to the NTPase/RNA helicase activity of NS3, the C-terminal region of this protein also contains an RNA triphosphatase activity, which is distinct from the NTPase activity (755). This enzyme is likely to be involved in modifying the 5' end of the genome in preparation for 5' cap addition by a guanylyltransferase activity.

NS4A and NS4B

NS4A and NS4B are relatively small (about 16 kd and 27 kd, respectively) hydrophobic proteins that are membrane associated (377,405,762). Based on its subcellular distribution (405) and interaction with NS1 (385), NS4A appears to function in RNA replication, perhaps by anchoring replicase components to cellular membranes. NS4B also localizes to presumed sites of RNA replication, but it also appears to be dispersed throughout cytoplasmic membranes, and possibly the nucleus (762).

The N-terminus of NS4A is generated by the NS2B-3 protease (394), whereas the C-terminus of NS4A contains a transmembrane domain that serves to translocate NS4B into the ER. The NS2B-3 protease cleaves at a site within NS4A, just upstream of this signal sequence, and mutations that block this cleavage also block subsequent signal peptidase cleavage in the ER lumen to generate the N-terminus of NS4B (377,533). This unusual coordinated processing scheme, which is strikingly similar to processing at the C–prM junction, might serve to regulate replicase function. Furthermore, unprocessed NS3-4A and NS4A-4B have been detected in flavivirus-infected cells (93,394,533), suggesting that polyprotein cleavage in this region may be inefficient or controlled in additional ways. NS4B is posttranslationally modified to a form that appears to be about 2 kd smaller than the nascent protein, although the nature of this modification is unknown (93,533).

NS5

NS5, the largest (about 103 kd) and most conserved flavivirus protein, contains sequence homology to RdRPs of other positive-strand RNA viruses, including the invariant Gly-Asp-Asp (GDD) motif common to these enzymes (573). Purified recombinant NS5 exhibits RdRP activity in primer extension reactions (681), and NS5 protein has been found to fractionate with RdRP activity in infected cell extracts (116). NS5 also shares homology with methyltransferase enzymes involved in RNA cap formation and is thus probably involved in methylation of the 5' RNA cap structure (344). Site-directed mutagenesis has confirmed that motifs implicated in polymerase and methyltransferase activities are essential for virus replication, and that the functions of NS5 can be supplied in trans (318,319,320 and 321). NS5 can be

phosphorylated by an unknown cellular Ser/Thr kinase (311,466,561), a feature that is also conserved in the NS5A proteins of the pestiviruses and HCVs (see later). The role of NS5 phosphorylation remains obscure, but it may regulate the interaction of NS5 and NS3 (311), or a subcellular redistribution of NS5 into the cell nucleus (176,311).

RNA Replication

Following translation and processing of the viral proteins, a viral replicase is assembled from NS proteins, the viral RNA, and presumably some host factors. The replicase associates with membranes, probably through interactions involving the small hydrophobic NS proteins. Replication begins with the synthesis of a genome-length minus-strand RNA, which then serves as a template for the synthesis of additional plus-strand RNAs. The first round of minus-strand accumulation has been detected just over 3 hours after infection (384). Viral RNA synthesis appears to be asymmetric *in vivo*, with a plus-strand accumulation more than 10 times greater than that of minus strands (120,477). Viral minus strands appear to accumulate even late after infection and have been isolated exclusively in double-stranded forms (120,756). Flavivirus replication can be followed *in vivo* by metabolic labeling of virus-specific RNAs in the presence of actinomycin D, an inhibitor of DNA-dependent RNA polymerases. Three major species of labeled flavivirus RNAs have been described, one type sedimenting at 40S, another at 20S, and a heterogeneous population at 20S to 28S (120,756). 40S RNA is sensitive to RNase treatment and is identical to virion-associated RNA, consistent with its being genomic RNA (756). 20S RNA, frequently termed the replicative form (RF), is likely to be a transiently stable duplex of viral plus- and minus-strand RNAs based on RNase resistance and conversion to an RNase sensitive form that comigrates with 40S RNA by heat denaturation (756). The 20S to 28S RNAs are partially sensitive to RNase treatment and are described as replicative intermediate (RI) RNAs that most likely contain duplex regions and recently synthesized plus-strand RNAs displaced by nascent strands undergoing elongation (117,120). Pulse-chase analyses indicate that RF and RI RNAs are precursors to the 40S (genomic) RNA (117,120). This mode of replication, with minus strands serving as templates for the production of multiple plus strands, can be described as semiconservative and asymmetric (117).

RdRP activity has been studied *in vitro* by using crude cytoplasmic preparations of infected cells, and similar RNA forms have been demonstrated in these reactions (31,115,117,214,215 and 216,803). However, these *in vitro* systems appear to involve chain elongation rather than *de novo* initiation, and the complete process of flavivirus RNA replication has not yet been fully reconstructed in an *in vitro* model. Physical characterization of these preparations indicates that flavivirus RdRP activity co-sediments with dense membrane fractions enriched for several NS proteins and membrane structures morphologically similar to those found in virus-infected cells (116). RdRP activity has also been retained after solubilization in various detergents (116,214), although an intact flavivirus replicase has not yet been purified.

Membrane Reorganization and the Compartmentalization of Flavivirus Replication

Several studies have described ultrastructural changes in membranes of flavivirus-infected cells, predominately in the perinuclear region. In general, the earliest event is the proliferation of ER membranes (473,486), followed by the appearance of smooth membrane structures around the time of early logarithmic virus production. Smooth membrane structures are small clusters of vesicles containing electron-dense material within the lumen of smooth ER (87,363,473,486,488). These structures continue to accumulate during later times of infection, when they become adjacent to newly formed convoluted membranes. Convoluted membranes appear to be contiguous with the ER as randomly folded membranes or highly ordered structures that are sometimes described as paracrystalline arrays (363,473). All of these membrane alterations are concentrated in densely sedimenting membrane fractions from Kunjin-infected cells that are enriched for RdRP activity along with viral proteins NS2A, NS2B, NS3, NS4A, NS4B, and possibly NS1 (116). With the improved preservation of cellular membranes afforded by cryosectioning, Mackenzie et al. (404) demonstrated the appearance of vesicle packets, clusters of vesicles (each 100 to 200 nm in diameter) bound by a smooth membrane, during late times of infection. It seems likely that vesicle packets are related to or identical with smooth membrane structures, and they are often associated with smooth ER or Golgi-like membranes undergoing a morphologic process of wrapping. Such structures are also enriched for markers of the trans-Golgi (403).

The subcellular sites of RNA replication have been probed by metabolic labeling of nascent RNAs (64,662,763), by immunolabeling with sera reactive to double-stranded RNA, which presumably recognizes RF and RI RNAs (404,405,763,764), and by *in situ* hybridization (212). Apart from one report of nuclear replication (64), all investigations concur that viral RNAs accumulate in association with cytoplasmic membranes in the perinuclear region of mammalian cells and, in particular, with vesicle packets (404). NS1, NS2A, NS3, and NS4A have all been shown to localize to vesicle packets (404,405,764). Thus, it appears that along with double-stranded RNA, proteins implicated in RNA replication associate with vesicle packets. In contrast, the components of the viral serine protease, NS2B and NS3, co-localize with convoluted membranes (764). The membrane reorganization that occurs in infected cells might therefore give rise to adjacent, but distinct subcellular structures where viral polyprotein processing or RNA replication take place. It should however be emphasized that vesicle packets have been described only at late times after infection compared to the onset of RNA replication, and the sites of early RNA synthesis have not been defined. Furthermore, much remains to be learned about how interactions among NS proteins (103,133,311,385,405), between NS proteins and viral RNA (103,133,405), and between viral RNA and host factors (49,50,627) combine to form an active replicase.

Assembly and Release of Virus Particles

Ultrastructural studies indicate that virion morphogenesis occurs in association with intracellular membranes (reviewed in ref. 472). Electron microscopic studies of flavivirus-infected cells have consistently demonstrated morphologically mature virions within the lumen of a compartment believed to be the ER (142,246,247,292,333,363,404,424,473,485,497,650,651,740). In many studies, virions appear to accumulate within disorderly arrays of membrane-bound vesicles (see Fig. 4B). Budding intermediates and clearly distinguishable cytoplasmic nucleocapsids have not been frequently observed, suggesting that the process of assembly is rapid. Nascent virions are believed to be transported by bulk flow through the secretory pathway to the cell surface, where exocytosis occurs. Budding of virions at the plasma membrane has been occasionally observed (246,424,497,650), and it does not appear to be a major mechanism for virion formation. These ultrastructural observations, together with studies on structural protein biosynthesis, oligomer formation, and the properties of intracellular and released virions, suggest the

following model for virion assembly and maturation: The highly basic C protein interacts with viral genomic RNA in the cytoplasm to form a nucleocapsid precursor. The orientation of C, prM, and E with respect to the ER membrane would suggest that nucleocapsids acquire an envelope by budding into the ER lumen. Cosynthesis of E and prM is necessary for proper folding of E (341). These proteins have been shown to be associated as detergent-stable heterodimers (11,12,254,741,753) that can form higher-order structures, which may represent virion-associated lattices (741).

Later stages in virion maturation include glycan modification of E (for some viruses) and prM by trimming and terminal addition (93,419,491), implying that virions move through an exocytosis pathway similar to that used for synthesis of host plasma membrane glycoproteins. Although differences in the efficiency of prM cleavage have been noted (474,741), this cleavage generally distinguishes released virus from intracellular virus particles (626). Intracellular M-containing virions have not been detected, suggesting that prM cleavage occurs just prior to release of mature virions. This cleavage can be inhibited by elevating the pH in intracellular compartments (254,550,626), consistent with catalysis by furin (254,550). Although inhibition of prM cleavage does not impair virus release, studies on prM-containing particles suggest that this cleavage is required to generate highly infectious virus (11,220,254,551,626,653,753). As seen for the alphavirus structural proteins (729,730 and 731, and see Chapter 29), experimental data suggest that flaviviruses use oligomerization and prM cleavage to regulate the activation of E-protein-mediated fusion activity. The current hypothesis is that the function of prM in the prM–E heterodimer is to prevent E from undergoing an acid-catalyzed conformational change during transit of immature virions through an acidic intracellular compartment (220,222,254,550,753). Upon cleavage of prM and release of mature virus, the E–M interaction is destabilized (753). The differences in intracellular and extracellular virions are illustrated in Figure 8. The hemagglutination activity exhibited by flaviviruses, which depends on low pH, probably results from activation of the fusogenic activity of E protein.

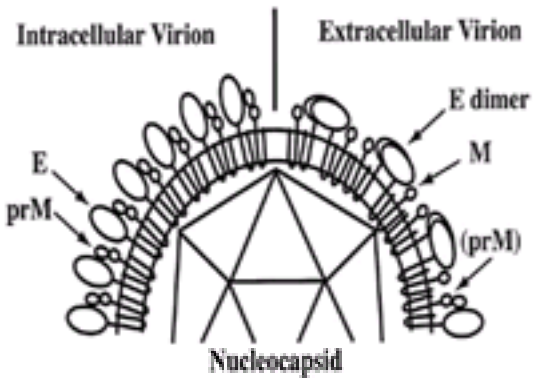

FIG. 8. Envelope proteins of intracellular and extracellular flavivirus virions. (Adapted from ref. 91, with permission.)

In addition to mature virions, slowly sedimenting (70S) noninfectious particles, which are also capable of agglutinating red blood cells at acid pH (called SHA, for slowly sedimenting hemagglutinin; for review, see ref. 592), are released from flavivirus-infected cells. SHA particles appear as 14-nm doughnut-like structures and are composed of E and M, with variable amounts of prM (592). Recent studies have shown that expression of prM and E is sufficient for release of SHA-like particles (11,341,420). These particles, which are fusogenic, provide an excellent model system for examining the functions of E and prM (12,611), and they show promise as immunogens that elicit protective immunity (128,342,343,420,524).

Generation of Defective Flaviviruses and the Involvement of Host Resistance Genes

Defective-interfering (DI) particles have been valuable tools for the study of RNA virus replication, and DIs can contribute to viral pathogenesis *in vivo*. For some virus families, strongly interfering DI particles, containing truncated and rearranged genomic RNAs, are easily generated by high-multiplicity passage. These RNAs contain cis-acting sequences necessary for replication and packaging but do not encode a complete or functional set of viral proteins, and therefore they need a helper virus to supply these functions in trans. In the case of flaviviruses, although DI particles have been observed in persistently infected vertebrate cell cultures, strongly interfering DIs are not readily obtained under these conditions or during serial high-multiplicity passaging (68). Several potential explanations exist for this observation, including the possibility that, under the conditions tested, most of the virus-specified components of the replication machinery are required in cis. In this regard, some viral replicase components can be supplied in trans (151,266,318,319,320 and 321,384), whereas several Kunjin virus nonstructural genes or their gene products are apparently required in cis (321). It is unclear whether this latter observation is the result of defects at the protein or RNA level. One group has recently described DI genomes in Vero cells persistently infected with MVE virus (357). Characterization of these RNA species indicated that they contain in-frame deletions of 2.3 to 2.6 kb in the prM, E, and NS1 genes. It is unlikely that the truncated NS1 is functional, and it is most likely complemented in trans, although it may contribute to interference. Of the few flavivirus DIs that have been characterized, all contain in-frame deletions, suggesting that selective pressure maintains the downstream ORF for the translation of one or more NS proteins in cis.

A system in which DIs appear to be readily generated has been studied in some detail (reviewed in ref. 68). Investigations into the heritable susceptibility of mice to YF infection (608) led to the discovery that multiple dominant alleles at a single locus on chromosome 5 can confer resistance to flaviviruses (67,598,599,600 and 601,719,720). Flaviviruses can replicate in resistant mice, but the spread of infection is slower, with significantly lower peak viremias (10^3- to 10^4-fold) than in susceptible mice. In primary fibroblasts from resistant mice, viral RNA synthesis was reduced, lower titers of infectious virions were released, and a high proportion of DIs were found even after a single growth cycle (67). Analyses of viral RNAs in the brains of infected mice suggest a block in RNA replication but do not necessarily support the existence of DI particles in this system (721). Nevertheless, these results indicate that a specific, but as yet unidentified, host gene can have dramatic effects on flavivirus RNA synthesis. Interestingly, RNA–protein complexes

involving the 3' NCR of the viral minus strand were found to be less stable in cell extracts prepared from a flavivirus-resistant mouse strain (627).

THE HEPATITIS C VIRUSES

Background and Classification

Following the development of diagnostic tests for hepatitis A and B viruses, an additional agent, which could be experimentally transmitted to chimpanzees (14,265,671), became recognized as the major cause of transfusion-acquired hepatitis. The causative agent, previously designated non-A, non-B hepatitis, and now referred to as hepatitis C virus, was identified in 1989 through expression cloning of cDNAs derived from the serum of an experimentally infected animal (113). Recognition of this pathogen led to the development of diagnostic tests for screening blood supplies, which dramatically decreased the incidence of posttransfusion hepatitis. Nevertheless, about 170 million people, roughly 3% of the human population, are infected with HCV (19), and virus transmission remains a significant public health concern. The most notable feature of HCV infections is that they typically persist, often lasting for decades, with more than 70% of cases progressing to chronic hepatitis, a condition that predisposes patients to developing chronic active hepatitis, cirrhosis of the liver, and hepatocellular carcinoma (Chapter 34). In addition to the sequelae resulting from chronic liver infection, HCV has been associated with other human diseases. Of nearly 30 such associations, which include a number of autoimmune diseases, the linkage between HCV infection and mixed type II cryoglobulinemia is the most striking. This disease is characterized by symptoms ranging from palpable purpura and fatigue, to life-threatening vasculitis of vital organs, such as the kidneys (2). Treatment for HCV typically involves the use of interferon-a, with or without ribavirin, although poor response to these treatments is not uncommon. The considerable diversity among HCV isolates, the emergence of genetic variants in chronically infected individuals, and the low level of protective immunity elicited after HCV infection present major challenges to the development of more effective therapies and vaccines. HCV is extremely refractile to growth in culture and there are currently no good animal models of this disease outside the chimpanzee. Despite these obstacles, intense scientific scrutiny over the past decade has yielded an astonishing wealth of information about this virus and its components. Much has been learned about the enzymology of viral replication proteins, and high-resolution crystallographic analyses have provided structural information for approximately 40% of the HCV genome and more than half of the nonstructural region. Understanding the biologic roles of these proteins is likely to come from recent progress in efficient initiation of HCV RNA replication in culture.

HCV is the sole member of the *Hepacivirus* genus (582). Hepaciviruses share some common features with the pestiviruses including genome organization, limited sequence relatedness, and a similar mechanism of translational control. HCV exhibits even greater similarity to the recently described GB agents, but there are also some important differences such as the potential to encode an obvious capsid protein. Within the *Hepacivirus* genus, numerous isolates of HCV are currently grouped into six major genotypes and several subtypes based on phylogenetic analysis of complete genome sequences or subgenomic fragments (81,636), although this taxonomic scheme appears to be inadequate for fully describing the diversity of recent HCV isolates, particularly those from Southeast Asia (582). It remains unclear whether there is a correlation between HCV genotype and disease severity or clinical outcome, although patients with genotype 1 viruses are clearly less responsive to treatment with antivirals (see ref. 457 and references therein).

Experimental Systems

Progress toward an understanding of HCV molecular biology has been hampered by its limited replication in cell culture and the lack of small animal models. Most of the early work, aimed at defining the physical properties of the virus and pathogenesis induced during acute and chronic infection, involved clinical samples from patients with posttransfusion hepatitis and chronic liver disease, or from experimental infection of chimpanzees (734). In chimpanzees, HCV RNA is detected in the serum as early as 3 days after inoculation and typically increases to 10^5 to 10^7 HCV RNA molecules per milliliter during the acute phase. Little evidence of hepatocellular damage is seen despite these high levels of viremia. Two to 3 months after infection, inflammatory infiltrates are seen in the liver, with areas of focal necrosis and release of enzymes such as alanine amino transferase (ALT) into circulation. This acute hepatitis coincides with the emergence of HCV-specific cellular immune responses and the appearance of HCV-specific antibodies in many (but not all) cases. In humans, acute hepatitis with overt clinical disease is seen in only about 25% of those infected. Circulating virus becomes undetectable and is apparently spontaneously cleared in 20% to 30% of cases (15). In chimpanzees, the rate of acute resolved infection may be somewhat higher (32). Chronic infections predominate, with only rare instances of clearance without treatment with interferon alone or in combination with ribavirin. Although HCV was originally thought to replicate poorly *in vivo*, recent models based on measuring viral loads after interferon therapy (356,484) or plasmapheresis (549) suggest a production rate of about 10^{12} virions per day and a virion half-life of 2 to 3 hours.

Since 1997, the availability of functional cDNA clones and infectious transcribed RNAs have allowed studies in the chimpanzee model to define the importance of viral replication determinants and to follow the evolution of the virus and host immune responses in acute-resolving versus chronic infections. For example, it has been shown that the HCV-encoded enzymes and conserved RNA elements in the 3' NCR are essential (340,792) and that extensive variation in the glycoproteins or elsewhere are not required to establish chronic infection (406). Subunit vaccination studies (112) have provided evidence for protective immunity and encourage efforts to develop HCV vaccines for health care workers and other high-risk groups.

In contrast to the chimpanzee model, efforts to develop small-animal models for HCV infection have met with only limited success (202). One model, an irradiated beige/nude/X-linked immunodeficient (BNX) mouse reconstituted with bone marrow from mice with severe combined immunodeficiency disease (SCID), and engrafted with human liver tissue, supported limited HBV and HCV replication (189). Similarly, immunodeficient mice engrafted with human hepatocytes under the kidney capsule and maintained long term by stimulation of the hepatocyte growth factor receptor allow HBV and HDV replication but have not been shown to be permissive for HCV (496). Other murine models for HBV (73) or woodchuck hepatitis virus (516) may ultimately succeed for HCV, but further work is needed. A single report indicates that a Chinese subspecies of the tupaia or tree shrew, *Tupaia belangeri chinensis*, is susceptible to HCV infection (778).

These animals have not achieved widespread use, as they are outbred, caught in the wild, and difficult to maintain and breed in captivity, and HCV infection in them is sporadic even in immunocompromised animals.

Because of their remarkable contribution to the study of HBV pathogenesis (109), transgenic mice with liver-directed expression of HCV proteins have also been created. Thus far, the establishment of a transgenic mouse line that can launch replication-competent HCV RNAs or produce infectious virus particles has not been reported. Mice expressing the HCV capsid protein (also referred to as core or C protein), the structural region or even the entire HCV polyprotein have been derived. Interestingly, at least one line expressing the HCV C protein develops lipid droplets in hepatocytes (i.e., steatosis) and progresses to hepatocellular carcinoma (464,465). This could be related to HCV-associated disease in humans and C-protein-induced lipid droplet formation (25) and transformation (98,300,554,714) in cell cultures. However, studies with other transgenic mice have not confirmed these C-protein-associated effects (317,503,733). Transgenic mice expressing the HCV structural region have been reported to develop spontaneous focal infiltration of lymphocytes and hepatocyte necrosis, and they were more sensitive to liver cell damage induced by injection of anti-Fas antibody (267). In other cases, no pathology was noted (317,336). The Cre/loxP system can be used for activation of HCV transgenes in hepatocytes; it provides an elegant approach for studying the effects of HCV proteins on hepatocyte function and the role of HCV-specific immune responses in pathogenesis (732,733).

Most cell culture studies of HCV have utilized transient transfection protocols or infection with recombinant viruses designed to express HCV proteins. Although such experiments have provided useful information, they may not mimic the situation in HCV-infected hepatocytes. For more than two decades, attempts have been made to propagate the non-A, non-B agent, and later HCV, in various cell cultures. In the postgenomic era of HCV research, when viral RNA can be measured qualitatively and quantitatively, much more has been published on this subject. Continuous hepatoma, B-cell and T-cell lines, primary hepatocytes from humans and chimpanzees, and peripheral blood mononuclear cells (PBMC) have all been reported to support HCV replication (see ref. 29 for review). HCV replication is usually defined by strand-specific reverse transcriptase polymerase chain reaction (RT-PCR) detection of minus-strand RNA. Unfortunately, this technique has been generally unreliable because of false priming during the RT step (225,359,597). Furthermore, accumulation of minus-strand RNA does not necessarily reflect complete replication as opposed to arrest after a single round of minus-strand synthesis. Immunofluorescent detection of HCV antigens, *in situ* hybridization, selection of variant sequences during culture, infection of naive cells or a chimpanzee with cell culture supernate, electron microscopy, inhibition by interferon-a, antisense oligonucleotides, and HCV-specific ribozymes have all been used as indicators of HCV replication in cell culture. Unfortunately, none of the culture systems reported to date have been robust enough to permit classical virologic, biochemical, or genetic dissection of the HCV replication cycle.

One problem that has plagued (and perhaps confused) cell culture infection studies is the limited availability of standardized inocula. As described later, the physical properties of circulating HCV RNA and the specific infectivity of different isolates (RNA molecules per chimpanzee infectious dose, or CID) are highly variable. The best sources of infectious material are acute-phase human or chimpanzee sera that have been titrated for infectivity in chimpanzees. Recently, several laboratories have been making such inocula (often derived from infectious cDNA clones) for each of the major HCV genotypes and subtypes (see ref. 79, and later).

Human hepatitis viruses have been notoriously difficult to grow in cell culture. This presumably results from defects at one or multiple steps of the replication cycle. For positive-strand RNA viruses such as HCV, transfection with infectious RNA can circumvent the entry steps, allowing translation and initiation of RNA replication in permissive cells. Full-length cDNA clones of HCV have been constructed for genotypes 1a, 1b, and 2a and the infectivity of transcribed RNAs validated by intrahepatic inoculation of chimpanzees (36,337,790,791,793). Despite this, attempts to initiate replication by transfection of the same RNAs into cell cultures have not met with success. Such experiments are complicated by a high background of transfected RNA that can persist for months, depending on cell type. Two reports have claimed productive replication after transfection with transcribed RNAs (134,799). These results remain unconfirmed, and it is worth noting that neither study used transcripts containing the correct 3' NCR. This sequence is the most highly conserved RNA element in the HCV genome, and it was later shown to be required for replication *in vivo* (see later).

A breakthrough for the field was reported in 1999 by Lohmann et al. (397). Based on results for the pestiviruses (43), these investigators engineered bicistronic subgenomic HCV replicons in which the neomycin resistance gene replaced the majority of the HCV structural region and the internal ribosome entry site (IRES) from the encephalomyocarditis virus (EMCV) was used to drive translation of the HCV replicase (beginning with either NS2 or NS3). At low frequency, G418-resistant colonies could be selected that harbored persistently replicating HCV RNAs at a copy number of 500 to 5,000 plus-strand RNAs per cell. More recently, adaptive mutations in the NS5A protein have been identified that allow efficient initiation of HCV RNA replication in as many as 10% of transfected hepatoma cells (51). Thus far, this system has been established for only a single genotype 1b HCV isolate and is restricted to Huh7 cells, a human hepatoma line. Despite this limited host range, we now have a powerful genetic system that should also enhance efforts to identify specific inhibitors of HCV RNA replication. A major gap in our experimental arsenal continues to be the lack of systems that support efficient replication of full-length genome RNAs, particle assembly, and release of infectious virus.

Structure and Physical Properties of the Virion

The size of the infectious virus, based on filtration experiments, is between 30 and 80 nm (62,250,806). HCV particles isolated from pooled human plasma (675), present in hepatocytes from infected chimpanzees, and produced in cell culture (303,535,625,631) have been tentatively visualized by electron microscopy (see Fig. 4F). Initial measurements of the buoyant density of infectious material in sucrose yielded a range of values, with the majority present in a low density pool of less than 1.1 g/mL (60). Subsequent studies have used RT-PCR to detect HCV-specific RNA as an indirect measure of potentially infectious virus present in sera from chronically infected humans or experimentally infected chimpanzees. From these studies, it has become clear that considerable heterogeneity exists between different clinical samples, and that many factors can affect the behavior of particles containing HCV RNA (261,704,745). Such factors include association with immunoglobulins (261,745) or low-density lipoprotein (704,705,745) that may be influenced by genotype (479). In highly infectious acute-phase chimpanzee serum, HCV-specific RNA is usually detected in fractions of low buoyant density (1.03 to 1.1 g/mL) (88,261). In other samples, the presence of HCV antibodies and formation of

immune complexes correlate with particles of higher density and lower infectivity (261). Treatment of particles with chloroform, which inactivates infectivity (61,166), or with nonionic detergents, produces RNA-containing particles of higher density (1.17 to 1.25 g/mL) believed to represent HCV nucleocapsids (261,307,446) of about 33 nm (675). The virion protein composition has not been determined, but putative HCV structural proteins include a basic C protein and two membrane glycoproteins, E1 and E2 (see later).

Binding and Entry

For the reasons just stated (lack of standardized infectious stocks, heterogeneous physical properties of virions, and poor infection in cell culture), these steps in the HCV replication cycle have been difficult to study. Even in the infection systems reported, there has been no systematic determination of basic parameters such as optimal adsorption conditions, or requirement for internalization or acidification. Interestingly, it has been shown that bovine and human lactoferrin can block infectivity of HCV in cell culture (288), presumably by binding to virus particles via the E2 glycoprotein (798).

Candidate receptors include the tetraspanin CD81 and the low-density lipoprotein receptor (LDLR). CD81 binds the ectodomain of the E2 glycoprotein and, to a lesser extent, HCV RNA-containing material from infectious plasma (523). The determinants in CD81 responsible for E2 binding reside in the large extracellular loop (LEL), a domain that exhibits species-specific heterogeneity. Specific amino acids in the LEL, important for binding to human and chimpanzee CD81 but not to that of African green monkey, have been mapped (256). However, this initial match between E2–CD81 binding and HCV species tropism is not absolute, as HCV E2 binds even more avidly to tamarin CD81 even though these animals are probably not permissive hosts (10,431). CD81 is expressed on most cell types, including B and T cells, making it unlikely that it is the sole determinant of HCV hepatotropism. Interaction between HCV E2 and CD81-containing signalling complexes on B cells has been postulated to play a role in modulating B-cell activation. This is of interest given the association of HCV with extrahepatic B-cell disorders such as mixed type II cryoglobulinemia and possibly non-Hodgkins B-cell lymphoma (for review, see ref. 570). LDLR has been attractive as a candidate HCV receptor since the discovery of the association between infectious HCV and low-density lipoprotein (LDL) or very low density lipoprotein (VLDL) (3,456,704,705). Coating of virions with serum lipoproteins during their secretion from hepatocytes or after release into circulation could shield the virus from neutralizing antibodies and provide a mechanism for binding and entry that is independent of the HCV glycoproteins. Recent studies indicate that HCV RNA-containing particles can be endocytosed via the LDLR in cell culture (3). What is not clear from the experiments thus far is whether either of these interactions (with CD81 or LDLR) actually leads to productive infection.

In lieu of an efficient infectivity assay, surrogate approaches have been employed. One report utilized vesicular stomatitis virus pseudotypes incorporating cell surface expressed chimeric forms of the HCV glycoproteins (353). Particles expressing either E1 or E2 demonstrated low levels of infectivity that could be neutralized by polyclonal antibodies produced in chimpanzees that had been immunized with candidate glycoprotein subunit vaccines. Because the two HCV glycoproteins are believed to assemble as heterodimers and mature in the ER (see later), it is unclear if the infectivity being measured in this assay reflects the function of these proteins in the native HCV particle. More recently, a cell–cell fusion assay has been described that requires cell surface expression of both HCV glycoproteins, exhibits low-pH enhanced fusion, and shows some selectivity for certain hepatoma lines (678). Experiments using this system suggest that expression of human CD81 is not sufficient for fusion and that other cell surface proteins and glycosaminoglycans are important.

Genome Structure

The HCV genome is about 9.6 kb in length, considerably shorter than that of flaviviruses. Based on characterization of the HCV translation strategy, and the absence of sequences corresponding to the presumed methyltransferase and RNA triphosphatase enzymes of flaviviruses, it is expected that the HCV genome does not include a 5' cap structure. The 5' NCR is a highly conserved RNA sequence element, about 341 nt in length, that biochemical probing and computer modeling indicate is folded into a complex structure consisting of four major domains and a pseudoknot (Fig. 9) (72,270,645,738). The 5' NCR probably contains the reverse complement of the information that is read by the replication machinery (i.e., from the 3' end of viral minus strands) to direct plus-strand RNA initiation. As described later, the 5' NCR also functions as an IRES to direct cap-independent translation of a single large ORF of about 3,011 codons. The 3' NCR was initially thought to terminate in polyadenosine (239) or polyuridine (101,106,249,312,498,499 and 500,676,685,742,782). However, the previously mentioned studies could not exclude false-priming as a source of these findings. Improved methods for cloning 3' ends of RNAs later revealed that the HCV 3' NCR actually consists of a short (about 40-nt) variable domain and a polyuridine/polypyrimidine tract, followed by a highly conserved 98-nt sequence (339,683,684,783). The latter two regions were shown to be essential for recovery of infectious HCV in chimpanzees (340,792). Biochemical probing has not fully resolved the secondary structure of the conserved 98-nt element, although the 3'-most 45-nt sequence has been shown to form a stable stem-loop (52). The HCV 3' NCR has been shown to interact with several cellular proteins including polypyrimidine tract binding (PTB) protein (197,295,715), which may contribute to the enhanced translational efficiency observed for RNAs containing a 5' IRES element and the HCV 3' NCR (296), as well as glyceraldehyde-3-phosphate dehydrogenase (519), and ubiquitous cellular proteins of 87 and 130 kd (289).

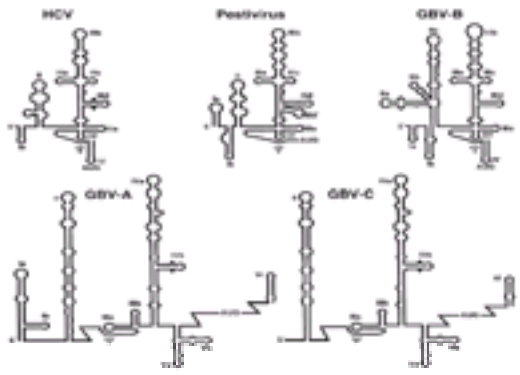

FIG. 9. Predicted secondary structures of pestivirus, hepatitis C virus (HCV), and GB virus internal ribosome entry site (IRES) elements. Model for the secondary and tertiary structures within the 5' NCRs of HCV, pestiviruses, GB virus A (*GBV-A*), B (*GBV-B*), and C (*GBV-C*). The polyprotein initiation site is indicated by AUG. Major structural domains are labeled *I to VI*. Predicted hairpin loops are indicated by *letters*, and pseudoknots are emphasized with a Y symbol. The models are based on computer-assisted folding and mutational analysis. (Courtesy of R. Rijnbrand and S. Lemon. For reviews see ref. 581.)

Translation and Proteolytic Processing

As mentioned before, the 5' NCR of HCV has been shown to have IRES activity, directing cap-independent initiation in a number of translation systems (182,270,287,401,569,578,716,737). The secondary structure of the HCV 5' NCR (see Fig. 9) provides a framework for understanding the function of the HCV IRES. Although it is unclear whether the approximately 109 5'-proximal nucleotides are necessary for IRES function (568,716), deletion of stem-loop I seems to have a positive effect on translation (270,578,800). The AUG codon used for initiation is precisely defined at a position within stem-loop IV (568,580), the stability of which affects IRES activity (268). The 3' boundary of the IRES is unclear, with conflicting reports concluding that sequences downstream of the initiation AUG are necessary (270,401,569) or that sequences lacking a complete stem-loop IV are sufficient (716,737). A pseudoknot formed by base-pairing of stem-loop IIIf to a region just upstream of stem-loop IV has been shown to be critical for IRES function (736, and see ref. 581 for further discussion). Interestingly, biochemical reconstitution of internal ribosomal entry for both hepacivirus and pestivirus IRES elements indicated that ribosomal 40S subunits and translational initiation factor eIF3 directly bind to discrete IRES regions, thereby bypassing the need for canonical translation initiation factors eIF4A, eIF4B, and eIF4F (514,515,642). Additional cellular factors that have been shown to bind the HCV IRES, typically enhancing translation, include PTB (8,304), La antigen (9), heterogeneous nuclear ribonucleoprotein L (230), and proteins of 25, 87, and 120 kd (184,797). Furthermore, IRES activity may also involve interaction with one or more cell cycle–specific factors (269).

The organization and processing of the HCV polyprotein is shown in Figure 10. Ten major polypeptides are produced by co- or posttranslational cleavage of the polyprotein and are arranged in the order NH_2-C-E1-E2-p7-NS2-NS3-NS4A-NS4B-NS5A-NS5B-COOH (203,204 and 205,379). Cleavages within the structural region (C/E1, E1/E2, and E2/p7) and at the p7/NS2 junction are thought to be mediated by the ER resident cellular signal peptidase, based on the hydrophobicity of regions just upstream of these cleavage sites (258,379,448,449,623), the dependence of cleavage on the presence of membranes (258,282,379,448,449,602,603) and signal-recognition particles (602,603), and mutagenesis of cleavage sites into suboptimal substrates for signal peptidase (448,449). An additional cleavage event probably removes the E1 signal sequence to produce mature C protein (282,602), although the responsible enzyme has not been definitively identified. Processing at the E2/p7 junction is incomplete, leading to accumulation of E2–p7 (379,448,623). Cleavages in the nonstructural region of the polyprotein are mediated by two virus encoded proteases: the zinc-stimulated NS2-3 autoprotease, which cleaves at the NS2/3 junction (204,259), or the NS3 serine protease (26,152,203,259,407,707), which utilizes NS4A as a cofactor for efficient processing at the 3/4A, 4A/4B, 4B/5A, and 5A/5B sites (27,157,380,688).

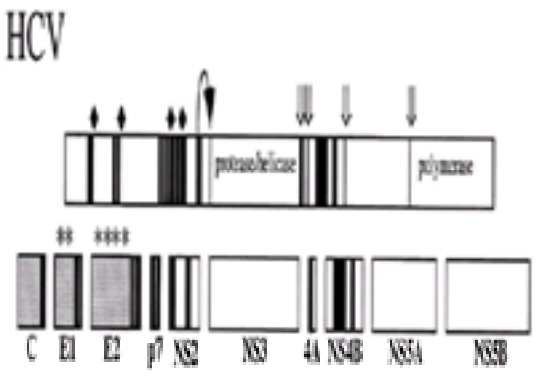

FIG. 10. Organization and processing of the HCV polyprotein. *Shading* and *symbols* identifying proteolytic cleavages are the same as described in Figure 3, except that the *curved arrow* indicates the autocatalytic cleavage at the NS2-3 site catalyzed by the NS2-3 autoprotease.

Features of the Structural Proteins

The C Protein

C is a highly conserved basic protein, appearing as 19- and 21-kd forms (82,205,241,282,390,391,461,553,602,670,796). The slower-migrating minor form is believed to result from signalase cleavage at only the C/E1 junction, whereas the faster-migrating “mature” form results from cleavage at a second site near residue 173, as discussed before. C protein associates with membranes, particularly the cytoplasmic surface of the ER (99,241,258,326,461,553,602,670). A minor 16-kd truncated form of C has also been reported by one group (391,392). In terms of HCV particle assembly, binding of C to the HCV 5' NCR (284,686) has been demonstrated, although nonspecific binding of RNA to C has also been reported (284,602). Multimerization of C, another likely step in the assembly process, has also been observed and requires the N-terminal 115 amino acids of C (423,490). Interaction of C with E1, but not with E2, has been suggested by coprecipitation experiments (393).

Nuclear localization of C, particularly truncated forms lacking C-terminal hydrophobic sequences, has also been reported (99,390,391,553,629,670,796). However, nuclear localization of the intact C protein remains controversial (25,82,461,462,602). Several functions have been proposed for nuclear forms of C protein, including the modulation of cellular gene transcription (555,558,559), repression of transcription from the human immunodeficiency virus 1 (HIV-1) long terminal repeat sequences (649), and the suppression of hepatitis B virus (HBV) transcription and replication in Huh-7 cells (629). This latter effect may be regulated by phosphorylation of C protein at Ser-99 and Ser-116 (628). However, expression of C protein in mice does not appear to inhibit transgene-initiated HBV replication (503). Several additional functions have been proposed for cytoplasmic forms of capsid protein. C protein has been shown to associate with 60S ribosomal subunits (602), which could be involved in the process of virion uncoating. C protein has also been found to associate with lipid droplets and to co-localize with apolipoprotein II (25), which may be related to the observation that the capsid protein has been shown to induce steatosis in transgenic mice (465) or to the reported association of HCV virions with lipids in the bloodstream (704,705). C protein also interacts with the lymphotoxin b receptor (102,422) and tumor necrosis factor receptor 1 (TNFR-1) (815), two members of the TNFR family of cytokine receptors. Interaction with these signalling pathways could be involved in modulating the effectiveness of host antiviral immune responses. In addition, these observations may be related to correlations between C protein expression and cellular sensitivity to apoptosis, although conflicting effects have been reported (102,556,557,585,815). The C protein has also been reported to transform primary rat embryo fibroblasts (REF) in cooperation with Ras (554) or an immortalized REF cell line called Rat-1 (98). In one study, capsid protein expression in transgenic mice induced hepatocellular carcinoma (464), although such tumors were not reported in other studies of transgenic mice expressing C protein (317,503,733). Thus, although the capsid protein has been the subject of much research, additional work is needed to determine the significance of these observations with respect to specific steps of the viral life cycle and HCV pathogenesis.

Envelope Glycoproteins

HCV E1 and E2, glycoproteins containing type I C-terminal transmembrane anchors, are heavily modified by N-linked glycosylation (205,258,275,283,290,335,336,360,372,425,426,443,489,547,593,623,648). Based on the extent and type of glycosylation (148,257,360,547,593,623,648), protection from protease digestion (258,393), and association with the ER-resident proteins calnexin (114,149), calreticulin (114), immunoglobulin heavy-chain binding protein (BiP) (114), and protein disulfide isomerase (138), E1 and E2 have been shown to be retained within the lumen of the ER. Signals for ER retention have been mapped to the transmembrane domains of both glycoproteins (122,123,150,172). E1 folds slowly and noncovalently interacts with the membrane-proximal domain of E2 to form what are believed to be native heterodimers (123,138,148,149,205,360,426,443,547). In addition, disulfide-linked aggregates of E1 and E2 have been described (148,205). A valuable tool for studying HCV glycoprotein maturation has been a conformation-sensitive monoclonal antibody, H2, with specificity for noncovalently associated E1E2 heterodimers, which are protease resistant and have been released from the ER chaperone calnexin (138). Kinetic studies with this reagent indicated that stable noncovalent E1E2 complexes form slowly, with a $T_{1/2}$ of about 2 hours, and that formation of native heterodimers is inefficient, accounting for about 5% of the E1E2 complexes (138). The limiting events in complex assembly appear to be formation of intramolecular disulfide bonds in E1 and glycosylation of E1, steps that require coexpression of E2 (147,149,443), as well as productive interaction of the glycoproteins with ER chaperones (114,149,443). Interestingly, calreticulin and BiP preferentially associate with aggregates of misfolded proteins, whereas calnexin is associated with newly synthesized glycoproteins, oxidized monomeric forms, and noncovalent heterodimers (114,149). Overexpression of these three chaperones (using vaccinia virus), either individually or in combination, does not increase the efficiency of productive E1E2 folding (114), suggesting that other unidentified chaperones and folding enzymes may be limiting for proper HCV glycoprotein folding.

As viral glycoproteins, E1 and E2 must have critical interactions with host molecules. It has been noted that E1 residues 264 to 290 bear similarity to suspected or known fusion peptides from flavivirus and paramyxovirus glycoproteins and may perform an analogous function during HCV entry (173). As mentioned, the ectodomain of E2 was shown to bind to the human tetraspanin-family cell surface membrane protein CD81 (523), an interaction that appears to involve a conformationally sensitive region of E2 (171,173) and an extracellular subdomain of CD81 (171,256). This interaction may play a key role in HCV binding and entry, but direct demonstration of this is lacking. In addition, interaction of CD81 with soluble forms of E2 was shown to have antiproliferative effects on lymphocytes (171). The N-terminal portion of E2 contains a hypervariable region (HVR1) (351,493) that is likely to reflect adaptation of the virus to the host immune response and selection of immune escape variants (164,165,315,622,633,750). Indeed, E2 HVR1 has been shown to be a target for neutralizing antibodies (257,314,749,750). Nonetheless, recent work has shown that HVR1 is not essential for replication or chronic infection in chimpanzees, although deletion of this sequence debilitates the virus (175). In addition, expression of E2 has been shown to inhibit the function of the interferon-inducible double-stranded-RNA-activated protein kinase PKR (699), although it is unclear how the proposed interaction involving the E2 ectodomain with cytoplasmic PKR actually occurs.

Features of the Nonstructural Proteins

p7 and NS2

No function is known for the small hydrophobic p7 protein, which is thought to be inefficiently released from the C terminus of E2 by signal peptidase (379,448,449,623). By analogy with pestivirus p7 (154), HCV p7 and E2–p7 are probably not associated with virions, although an efficient cell culture system is needed to test this.

NS2 (about 23 kd) contains a predicted cysteine protease domain (200), which interacts with the immediately downstream 180 amino acids of NS3 to form the NS2/3 autoprotease that cleaves at the NS2/3 junction (204,259). NS2/3 protease activity is necessary for the *in vivo* infectivity of full-length HCV genomes (340). However, NS2 is dispensable for RNA replication of subgenomic HCV replicons in culture (51,397), and no function is known for NS2 other than in NS2–3 cleavage. NS2/3 activity, which is distinct from the serine protease activity of NS3, is stimulated *in vitro* by addition of microsomal membranes (204,603), various detergents (522), and Zn^{2+} (259). The former two reagents probably allow for proper conformation of the moderately hydrophobic NS2. It is unclear whether Zn^{2+} plays a catalytic or structural role in 2–3 processing. Interestingly, crystallographic (328,400,789) and biochemical (135,658) analyses have identified a site for tetrahedral coordination of Zn^{2+} (HCV polyprotein residues Cys-1123, Cys-1125, Cys-1171, and His-1175) in the region of NS3 required for NS2–3 protease activity, and suggested that this Zn^{2+} ion plays an essential structural role in the NS3 serine protease domain. Consistent with a role for this Zn^{2+} ion in both types of processing, mutations at Cys-1123, Cys-1125, and Cys-1171 inhibit NS2–3 cleavage as well as downstream cleavages catalyzed by the serine protease (259). Mutation of His-1175 has a less dramatic effect (204,259,658), perhaps because this residue indirectly interacts with Zn^{2+} via an H_2O molecule. Although cleavage at the 2/3 site is thought to occur by an autocatalytic mechanism, bimolecular cleavage has been shown to occur, albeit inefficiently, with functional NS2 and/or NS3 protease subunits when coexpressed with substrates containing mutations in either NS2 or NS3 (but not both) that inactivate the NS2–3 protease (204,562). Requirement for a functional NS2 or NS3 region in cis suggests that the overall conformation of NS2/3 may play a role in orienting the NS2/3 cleavage site. In support of this model, mutagenesis of the P5 to P3' positions at the NS2/3 cleavage site indicated that conformation is a more important determinant for cleavage than primary sequence (263,562).

The NS3 Protein

Like the flavivirus NS3 protein, HCV NS3 (about 70 kd) encodes a serine protease domain in the N-terminal one third of the protein, and an NTPase/helicase domain in the C-terminal two thirds. The serine protease is responsible for cleavage at the NS3/4A, NS4A/4B, NS4B/5A, and NS5A/5B sites (26,152,203,205,259,407,707), and it is required for infectivity of HCV genomes *in vivo* (340). Cleavage at the NS3/4A site occurs in cis, whereas trans cleavage can occur at downstream sites (27,380,689,707). Analysis of cleavage products has revealed that these cleavage sites are highly conserved and conform to the sequence (Asp/Glu)XXXX(Cys/Thr)(Ser/Ala) (152,203,525). As shown by site-directed mutagenesis and molecular modeling, the P1 residue appears to be an important determinant for cleavage efficiency except at the NS3/4A autocleavage site (28,338,370,525). NS4A is a cofactor for serine protease activity, critical for all serine protease-dependent cleavages except NS5A/5B, although this cleavage can be stimulated by NS4A (27,157,380,690). Cofactor activity requires stable complex formation between NS3 and NS4A (30,158,381,607), an interaction that also serves to stabilize NS3 and anchor it to cellular membranes (260,690,773).

The structure of the NS3 serine protease domain alone (400), or in complex with an NS4A-derived cofactor (328,789) has been determined by x-ray crystallography. The HCV serine protease structure is similar to other members of the trypsin superfamily, with active site residues and a substrate binding pocket located in a cleft separating two b-barrel domains. Unique to the HCV enzyme, the NS4A cofactor forms an integral part of this structure, interacting with the extreme N-terminal residues of NS3 to form two antiparallel b strands not found in trypsin and altering the geometry of the catalytic site (328,789). These data also reveal an important structural role of the coordinated Zn^{2+} ion for proper folding of the serine protease domain (328,400), a result that is supported by biochemical studies (135,658). Within the predicted substrate-binding pocket, Phe-1180 probably interacts with the conserved Cys residues present in the P1 position of the 4A/4B, 4B/5A, and 5A/5B sites (328,400,525,789). Based on the interaction of NS3 and NS4A, protein engineering studies have created single-chain NS3–NS4A fusion proteins (scNS3–NS4A) with full serine protease activity (144,274,504,692). The structure of full-length NS3 with NS4A cofactor was determined by x-ray crystallography of one scNS3–NS4A (Fig. 11) (795). Folding of the protease and helicase domains of this molecule resembles that of each individual domain (the helicase domain is described later), separated by a single flexible loop (795). Interestingly, the C-terminus of NS3 interacts with the protease active site in a manner consistent with a protease:product (795). Since NS3/4A cleavage occurs autocatalytically, this model provides a unique glimpse at polyprotein cis processing and suggests structural rearrangements that are needed for subsequent trans processing events (795).

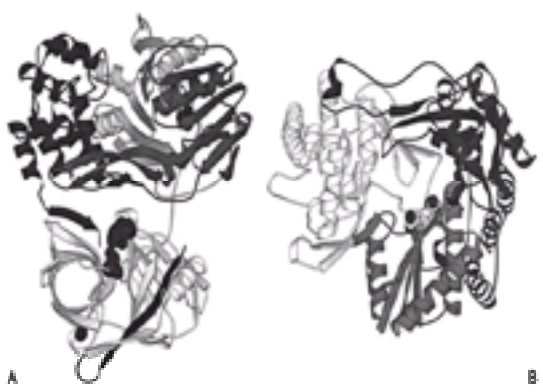

FIG. 11. Structures of enzymatic components of the HCV replicase. **A:** The b-barrels of the HCV protease and three subdomains of the helicase are colored from *white to black* along the polypeptide chain. The NS3 protease catalytic triad,

the solvent-exposed protease-associated zinc, and a phosphate ion in the helicase NTP binding site are indicated by *dark spheres*, and NS4A is represented by a *black strand.* **B:** The HCV NS5 RNA-dependent RNA (RdRP) polymerase exhibits a globular shape, unique among known polymerase structures. Nevertheless, this viral enzyme retains the typical polymerase subdomain organization consisting of fingers, palm, and thumb subdomains shown in *black*, *gray*, and *white*, respectively. Catalytic residues within the canonical RdRP GDD motif are shown as space-filling *spheres.* In both diagrams, ribbons follow the polypeptide fold and reveal locations of sheets and helices. [Courtesy of N. Yao, C. Lesburg, and P. Weber (see refs. 371 and 795).]

HCV NS3 is a member of the Asp-Glu-Cys-His (DECH) subfamily of DEAD-box helicases. The NTPase/ helicase activities of NS3 have been demonstrated for recombinant full-length NS3 (188,271,352,463) or the C-terminal two thirds of NS3 (252,301,325,531,669,674). Like the flavivirus enzyme, HCV NS3 ATPase activity is stimulated by single-stranded nucleic acids (227,228,271,301,305,463,531,669,674). NS3 unwinds RNA and DNA homo- and heteroduplexes in a 3' to 5' direction (674), and this requires Mg^{2+} or Mn^{2+} and ATP, suggesting that helicase activity is coupled to ATP hydrolysis (301,463, 531). However, other NTPs and dNTPs can substitute for ATP in this reaction (301,464), and ATP is not required for RNA binding (188). The crystal structure of the HCV NS3 helicase domain has been determined to a resolution of 2.1 to 2.3 Å in the presence (327) or absence (110,794) of a bound oligonucleotide. These data all reveal three well-defined structural domains surrounding a central axis and separated by distinct clefts (110,327,794). The first two domains, which contain all of the conserved NTPase/helicase motifs, each contain a parallel, six-stranded b sheet surrounded by a number of a helices. However, domain 1 contains a seventh, antiparallel b strand, and domain 2 contains an additional pair of antiparallel b strands that extend into the vicinity of domain 3, which is completely a helical. The catalytic site is located in domain 1 near the cleft that separates it from domain 2. RNA substrate binds in the cleft that separates domains 1 and 2 from domain 3, with the 5' end near domain 2 (327). Although the precise role of RNA helicases in replication is unknown, mutations in NS3 that disrupt helicase activity ablate HCV infectivity *in vivo* (340).

In addition to its roles in HCV polyprotein processing and RNA replication, several other functions have been proposed for NS3. Cyclic AMP–dependent protein kinase (PKA)-dependent phosphorylation was inhibited by synthetic peptides corresponding to a region of HCV NS3 that exhibits similarity to a PKA inhibitor protein and a PKA autophosphorylation site (56,57 and 58). Furthermore, a truncated NS3 protein containing this region was able to interact with the catalytic subunit of PKA and inhibited its forskolin-stimulated nuclear translocation and PKA-catalyzed phosphorylation (57). The serine protease domain of NS3 has been found to have weak transforming activity in NIH-3T3 cells (595) and can suppress actinomycin D–induced apoptosis (180). It is unclear whether these effects may be related to an observed subcellular co-localization of NS3 and the cellular tumor suppressor gene product p53 (294,471).

NS4A and NS4B

The 54-residue NS4A protein (about 8 kd) contains a hydrophobic N-terminal domain followed by a highly charged region. The serine protease cofactor activity of NS4A (see preceding) is contained within a 12-amino-acid region in the central portion of NS4A (30,381,630,690,708). NS4A also associates with membranes (690,773), probably through the hydrophobic N-terminal region, and interacts with other replicase components (293,382). NS4B (about 30 kd) is a hydrophobic protein of unknown function.

NS5A

NS5A is a hydrophilic but membrane-associated protein that exists in at least two forms with apparent molecular masses of 56 and 58 kd. Although these forms were originally thought to be the product of alternative proteolysis (260), it is now clear that they result from differential phosphorylation (306,691). NS5A phosphorylation occurs mostly on serine residues and, to a lesser extent, on threonine (306,564). The “basal” phosphorylation site (or sites) of HCV-J NS5A, which is thought to occur for both p56 and p58, has been mapped by serial deletion to the region downstream of polyprotein residue 2350 (690). p58 is “hyperphosphorylated” at additional sites that remain unmodified in the p56 form. Deletion analyses suggest that these hyperphosphorylation sites reside in a conserved, central region of the polyprotein that extends from residue 2200 to residue 2250 (690). Site-directed mutagenesis of the nine conserved serines in this region tentatively identified these sites of p58 phosphorylation as Ser-2197, Ser-2201, and Ser-2204 (690). For an HCV genotype 1a isolate, a major site of *in vitro* and *in vivo* phosphorylation has been mapped to NS5A residue Ser-2321. However, this serine residue is not conserved among the different HCV genotypes (563). For the HCV-J isolate, NS4A associates with NS5A (21) and enhances p58 production and, by inference, hyperphosphorylation at the upstream sites (306,691). However, this effect of NS4A seems to be isolate specific (262) and more recent studies suggest that multiple determinants, including all of the upstream NS proteins, influence NS5A phosphorylation when the protein is expressed in the context of an HCV NS polyprotein (334,389,482).

The kinase responsible for NS5A phosphorylation is thought to be of cellular origin, since (a) NS5A contains no recognizable kinase motifs, (b) phosphorylation of NS5A expressed transiently in cultured cells occurs in the absence of other viral proteins (564,691), and (c) phosphorylation of NS5A expressed in *E. coli* depends on the addition of eukaryotic cell extracts (285,563). Although the identity of the NS5A kinase is not known, biochemical properties of an NS5A-associated kinase activity with similarities to the kinase responsible for NS5A phosphorylation *in vivo* have already been characterized. This NS5A-associated kinase is active *in vitro* over a broad pH range, has an apparent preference for $MnCl_2$ over $MgCl_2$, and is inhibited strongly by $CaCl_2$ at concentrations over 0.5 mM (564). Furthermore, specific inhibitors of PKA and protein kinase C have little or no effect on NS5A phosphorylation *in vitro* or *in vivo*. However, both types of NS5A phosphorylation are inhibited by olomoucine, an inhibitor of certain proline-directed kinases. The resistance of NS5A phosphorylation to treatment with a specific PKA inhibitor casts some doubt on the suggestion that PKA is the major effector of NS5A phosphorylation (285). Although the preference of the NS5A-associated kinase for Mn^{2+} over Mg^{2+} is somewhat unusual among serine/threonine kinases, as is its inhibition by Ca^{2+}, the NS5A and NS5 proteins of bovine viral diarrhea virus (BVDV) and YF, respectively, associate with a kinase that has similar properties

(561). More work is needed to determine the role of NS5A and NS5A phosphorylation in viral replication.

Analysis of full-length genome sequences for three HCV genotype 1b isolates obtained from different Japanese patients before and after interferon therapy found mutations clustered primarily in E2 HVR1 and the C-terminal half of NS5A (155). Further analysis suggested that the amino acid sequence from polyprotein position 2209 to 2248 in NS5A correlated with the effectiveness of interferon treatment in these and other Japanese patients infected with genotype 1b. Consequently, this stretch of amino acids was designated the interferon sensitivity–determining region (ISDR) (155,156). Although confirmed by most other groups working with Japanese patients infected with genotype 1b, 2a, or 2b HCV strains, this correlation was substantially weaker or lacking in patients infected with genotype 1a strains or European patients infected with strains of genotype 1b, 2b, or 3a (see ref. 508 for review).

In any case, following up on this possible link between NS5A and response to interferon, NS5A was found to interact with and inhibit the interferon-stimulated, double-stranded-RNA-dependent kinase PKR (187). PKR is a major effector of the host antiviral defense pathway that represses translation by phosphorylating the a subunit of the translation initiation factor eIF2. Evidence suggests that HCV NS5A interacts with PKR and inhibits dimerization that is required for PKR activation (185). The region of NS5A implicated in this interaction with PKR includes the ISDR as well as downstream sequences. Several studies have shown that cells expressing NS5A can partially resist the antiviral effects of interferon (186,505,528,647). Somewhat surprisingly, such effects can be observed in the absence of the ISDR (528) and occur independently of the PKR-eIF2 pathway in the context of the complete HCV polyprotein (178). Interestingly, mutations that allow more efficient initiation of HCV subgenomic replicon replication in cell culture cluster in NS5A in the region just upstream of the ISDR and include a 47-amino-acid deletion that encompasses the ISDR (51). These data suggest that NS5A plays an active role in RNA replication and that the ISDR is not essential in cell culture. In addition, deletion of the ISDR does not appear to increase the sensitivity of HCV RNA replication to interferon a in this system (51), consistent with previous observations (528).

N-terminally truncated forms of NS5A fused to the DNA-binding domain of the *Saccharomyces cerevisiae* Gal4 protein activate transcription of reporter genes under the control of promoters containing Gal4 binding sites (119,313,687). This trans-activating ability has been linked to ISDR sequences that may be associated with increased interferon sensitivity (181). The physiologic relevance of these findings is questionable, because the full-length NS5A protein lacks this trans-activating ability and has a cytoplasmic localization. However, NS5A does contain a sequence in its C-terminal region that has the potential to function as a nuclear localization signal (286), raising the possibility that proteolytic removal of the N-terminal region of NS5A (417,463) could result in its transport to the nucleus and activation of the transcription of certain cellular genes. Indeed, recent work has provided evidence for caspase-mediated cleavages in NS5A that liberate a nuclear form whose ability to function as a transcriptional activator is regulated by PKA (606).

In addition to these features, NS5A interacts with several cellular proteins. These include growth-factor-receptor-bound protein-2 adaptor protein, an interaction that can perturb mitogenic signalling (682); a SNARE-like protein, hVAP-33, that is ER and Golgi associated and may participate in intracellular membrane trafficking (717); a novel cellular transcription factor SRCAP (190); and human karyopherin beta3, a protein that may participate in nuclear trafficking of RNAs and proteins (118). The role of these interactions in HCV replication or in virus-induced modulation of host cell function remains to be established.

NS5B

NS5B (about 68 kd) is a hydrophilic protein containing the GDD motif common to RdRPs. As expected, mutation of the polymerase active sites destroy the *in vivo* infectivity of HCV genomes (340) and replication of HCV subgenomes in culture (51,397). RdRP activity has been demonstrated *in vitro* for recombinant NS5B (7,44,396,784,805), although these reactions do not show specificity for HCV templates. DNA or RNA oligonucleotide primers can be extended by the NS5B RdRP on homopolymeric templates or cellular RNAs (6,7,44,396,784). RNAs terminating with the HCV 3' NCR, which contains a stable 3' hairpin (see preceding), can also be utilized as self-priming templates for RNA extension by NS5B (44,396). *De novo*, primer-independent initiation of RNA synthesis has recently been demonstrated in RdRP assays, usually by increasing concentrations of the initiating nucleotide (402,494,814). The more reliable of these studies (402,814) included templates that were chemically blocked at the 3' end and therefore unable to function as primers. Biochemical characterization of RdRP activity reveals a requirement for the divalent cations Mn^{2+} or Mg^{2+}, but not Zn^{2+} (6,44,167,396,402,784,805), near neutral pH (7,44,396,784), and low (i.e., 100-mM) concentrations of salt (399,784). The rate of elongation on a genome-length HCV RNA template was estimated to be 150 to 200 nucleotides per minute at 22°C (399,494), and it was independent of NS5B concentration (399), indicating that NS5B is highly processive. Terminal nucleotidyl transferase activity was reported in one preparation of NS5B purified from insect cells (44). However, several other purified NS5B preparations were apparently free of this activity (7,784,805), suggesting that it is more likely to be due to a copurifying cellular enzyme than an inherent property of NS5B (396).

The hydrophobic C-terminal 21 amino acids can be deleted from NS5B to produce soluble, fully active RdRP (167,396,402,784). This finding greatly enabled several high-resolution structural determinations of NS5B by x-ray crystallography (4,66,371). NS5B bears structural similarity to other polymerases, adopting a “right hand” conformation with a palm subdomain containing active site residues, and discernible fingers and thumb subdomains (see Fig. 11). However, extensive interactions between the fingers and thumb subdomains serve to fully encircle the NS5B active site. Despite the absence of substrate in these experiments, this resembles the closed conformation described for other polymerases (66), suggesting that NS5B may not undergo the typical conformational rotation upon template–primer binding (298,374). Residues thought to be involved in metal ion coordination, substrate binding, and nucleotide discrimination are spatially organized as for HIV-1 reverse transcriptase (4,66,371). Another notable feature of NS5B is a unique b-loop projecting from the thumb subdomain that probably interacts with the template–primer and could affect NS5B fidelity and/or processivity (4,66,371). The thumb subdomain also contains structural similarity to “armadillo” repeats, which could be involved in mediating protein–protein interactions within the replicase complex (66).

The C-terminal hydrophobic domain of NS5B mediates association with perinuclear membranes, the presumed site of

HCV RNA replication (784), and includes determinants for interaction with NS5A (784). Although NS5B binds RNAs nonspecifically, it does show some preference for RNAs containing the HCV 3' NCR (108,495). NS5B has also been shown to directly interact with NS3 and NS4A (293), which in turn have been shown to form complexes with NS4B and NS5A (21,382). It is likely, yet unproven, that these interactions are important for assembly of a functional HCV RNA replication complex.

RNA Replication

As in other *Flaviviridae*, RNA replication in HCV is likely to occur in association with perinuclear membranes and involve the combined actions of the viral polymerase, helicase, other viral nonstructural proteins, and presumably some host factors (260,293,334,382,482). Because of the lack of an efficient cell culture system, the events of HCV RNA replication are only poorly understood. Detection of viral plus- and minus-strand RNAs in infectious culture systems or clinical samples have been limited to RT-PCR amplification. The most reliable of these methods are designed to eliminate false priming and ensure strand specificity during reverse transcription (225,359). Characterization of HCV subgenomes efficiently replicating in culture by RT-PCR or Northern blot reveals that subgenomes accumulate to 50 to 5,000 copies per cell in these systems (51,397), and that minus strands are 5- to 10-fold less abundant than plus strands (397), which is in agreement with the plus-to-minus-strand ratio observed in infected hepatocytes (359). It has not yet been determined whether viral minus strands can be isolated as RIs or in duplex RFs.

Assembly and Release of Virus Particles

In the absence of an efficient system for culturing HCV, much of what we know about HCV virion assembly comes from heterologous expression studies. Although packaging signals of the HCV genome are not yet characterized, C protein has been shown to interact with stem-loop IIId of the 5' NCR (634,686). Furthermore, homotypic interactions of C protein (423,490) could be relevant to the formation of viral nucleocapsids. Based on the ER retention of viral glycoproteins E1 and E2, it seems likely that nucleocapsid precursors bud into the ER to acquire a lipid envelope and native heterodimers of the viral glycoproteins, then pass through the host secretory pathway and are released at the cell surface. Formation of virus-like particles (VLPs) by expression of the HCV structural proteins has met with limited success. Presumably nonenveloped (about 30 nm) and enveloped (about 45 nm) VLPs containing C protein were observed in HeLa G cells expressing the full-length HCV coding region via the vaccinia virus-T7 system (447). Enveloped VLPs containing HCV RNA were also observed in insect cells expressing the HCV 5' NCR and structural region via a recombinant baculovirus (33). These VLPs were observed in intracellular vesicles late in infection (at 72 to 96 hr) but were not secreted and could be released only after mild detergent treatment and sonication. One study indicated that extracellular HCV particles partially purified from human plasma do contain complex N-linked glycans, suggestive of transit through the secretory pathway, although these carbohydrate moieties were not shown to be specifically associated with E1 or E2 (604).

Association of Hepatitis C Virus with HCC

A significant fraction of chronically infected patients slowly progress from chronic active hepatitis to cirrhosis and then to hepato-cellular carcinoma (HCC) (see refs. 54 and 635 and references therein). The mean onset for development of primary HCC has been estimated to be 20 to 30 years (332,594). Studies have identified both positive- and negative-strand HCV RNA in tumorous tissue from some but not all patients. The slow onset and the apparent association with preexisting cirrhosis suggest that HCV may not directly cause HCC but rather predisposes the organ to carcinogenic events. However, these observations do not exclude the possibility that expression of particular HCV gene products in chronically infected cells might contribute to carcinogenesis. In this regard, expression of C (98,300,554,714), NS3 (595), NS4B (501), and NS5A (186,191) in certain cell cultures can lead to anchorage-independent growth, enhanced formation of colonies in soft agar, and induction of tumor formation in immunodeficient mice. As mentioned earlier, some transgenic mouse lines expressing the C protein develop hepatocellular carcinoma similar in appearance to the human cancer (464). However, the relevance of these observations to the association between HCV and HCC in humans remains to be established.

THE PESTIVIRUSES

Background and Classification

Pestiviruses are animal pathogens of major economic importance, particularly in the livestock industry. They include the type member, bovine viral diarrhea virus, as well as classical swine fever virus (CSFV), formerly known as hog cholera virus, and border disease virus (BDV) of sheep (536). Based on comparative studies, two distinct species of BVDV have recently been identified, BVDV-1 and BVDV-2 (39,42,513,576). Newly described pestiviruses further indicate that additional diversity exists within this genus (39,724). Within the *Flaviviridae*, pestiviruses show greater similarity in genome structure and translation to the hepaciviruses than do the flaviviruses. For this reason, pestivirus research has received increased attention in the search for surrogate model systems to understand the less tractable hepaciviruses.

Pestiviruses are responsible for a spectrum of diseases within their natural hosts (reviewed in ref. 702). CSFV, typically transmitted oronasally, leads to acute or chronic hemorrhagic syndromes with significant mortality. Ruminant pestiviruses, on the other hand, usually cause inapparent or mild symptoms in adult animals. A notable exception is BVDV-2, which is associated with a severe acute hemorrhagic condition in calves (130,513,560,576). In addition, congenital transmission of pestiviruses can cause fetal death and acute syndromes of the newborn, or it can lead to persistent infection of the offspring in a carrier state. Persistently infected ruminants can be susceptible to a rare but fatal mucosal disease (MD) later in life. Interestingly, development of MD correlates with viral genome alterations that affect the outcome of viral infection on host cells in culture. Recent efforts in pestivirus research have revealed interesting and novel features of these virus–host interactions. Although live attenuated strains and inactivated virus preparations are available for vaccination against CSFV and BVDV (450), there is a need for improved pestivirus vaccines. Insights into pestivirus biology are also being applied to the design of such tools (18,59,77,131,243,588,725,766).

Experimental Systems

In infected animal hosts, viral antigens and infectious virus can be detected in a variety of tissue types including epithelial cells at the site of entry, endothelial cells, lymphoreticular cells, and macrophages. In persistently infected animals, BVDV can be detected in most tissues including PBMC, the gastrointestinal tract, and neurons. Primary and continuous cell lines from natural host species are usually permissive for pestivirus replication in cell culture, although considerable differences in replication efficiencies have been noted (273,588). Highly permissive cell lines have been described for propagation of CSFV (458,588). Infection of permissive tissue culture cells is usually noncytopathic; however, variants of the ruminant pestiviruses capable of causing cytopathic effects can be isolated from animals with mucosal disease. Based on this cell culture phenotype, pestivirus isolates are referred to as either noncytopathogenic (ncp) or cytopathogenic (cp) biotypes.

Complete genome sequences have been determined for a number of pestiviruses (40,71,126,137,139,432,437,459,460,574,575,586). This has led to the construction of reverse genetic systems (347,430,437,442,459,586,727) that are being used to probe mechanisms of pestivirus replication and the molecular basis of cytopathogenesis and virulence.

Structure and Physical Properties of the Virion

Pestiviruses have been difficult to purify because of modest growth in cell culture, inefficient release from infected cells, and association with cellular debris (362). Identification of efficient culture systems has facilitated visualization of virus particles by electron microscopy (450,746) (see Fig. 4D,Fig. 4E) and the characterization of the structural components of the virion (703). The spherical particles are 40 to 60 nm in diameter and enveloped, and they contain an electron-dense inner core with a diameter of about 30 nm (273). Pestivirus virions band at a buoyant density of 1.134 g/mL in sucrose and are inactivated by heat, organic solvents, and detergents (588). Unlike flaviviruses, which are rapidly inactivated by low pH, pestiviruses can survive over a relatively broad pH range (376). The chemical composition of highly purified preparations of pestivirus particles has not been determined, but in addition to the genome RNA and lipid bilayer, four structural proteins are present. These proteins include capsid protein, C, and three envelope glycoproteins E^{rns} (for ribonuclease, soluble), E1, and E2 (591,703).

Binding and Entry

Based on examples from other viruses, the binding and entry of pestiviruses is likely to be a multistep process involving initial attachment of virions, interaction with specific receptor(s), internalization, and membrane fusion. Specific cell surface receptors for pestiviruses have not been fully characterized. One candidate receptor is a pair of proteins, with apparent relative masses of 60 kd and 93 kd, which are recognized by three monoclonal antibodies capable of blocking infection of several BVDV-1 strains (613). Another potential receptor is a 50-kd cell surface protein identified by using an antiidiotypic antiserum (directed against E2-specific antibodies) that can block binding of BVDV-1 to bovine cells (445,780,781). It has been shown that recombinant E2 and E^{rns} can bind independently to cell surfaces (277). E2 adsorption competitively inhibits infection with homotypic and heterotypic pestiviruses, whereas inhibition by E^{rns} demonstrates virus specificity and requires large amounts of E^{rns} (277). This latter point may be explained by a high receptor density, which correlates with the observed binding of E^{rns} to cell surface glycosaminoglycans (291). Additional information regarding the entry process may come from further characterization of a mutant bovine kidney cell line that is resistant to infection by several pestiviruses but is capable of supporting their replication following RNA transfection or chemically induced virus–cell fusion (174). This cell line was also found to be deficient in expression of the LDLR, a factor putatively involved in hepacivirus binding and entry, and antibodies against this receptor inhibited infection of bovine cells with BVDV-1 (3).

Genome Structure

The pestivirus genome consists of a single-stranded RNA of about 12.3 kb in length (71,126,137,139,432,460). As discussed later, larger and smaller genome RNAs containing duplications, deletions, and other rearrangements have been found for most cytopathic pestiviruses. The long ORF of about 4,000 codons is flanked by a 5' NCR of 372 to 385 nucleotides, and a 3' NCR of 229 to 273 nucleotides (71,126). The 5' terminus does not appear to contain a cap structure (71,140). Construction of chimeric BVDV genomes containing 5' NCRs of HCV or EMCV revealed that two 5'-terminal stem-loop structures in the BVDV genome (domains Ia and Ib in Fig. 9) are important for efficient RNA replication, and that the minimal 5' cis-acting replication element consists of only the terminal tetranucleotide, 5'-GUAU (179). Pestivirus genome RNAs do not contain 3' poly(A) (126,432,458) but appear to terminate with a short poly(C) tract. The 3' NCR consists of a variable region near the end of the ORF, followed by a conserved region (140,804). Structural probing revealed that the conserved region forms two hairpins separated by a single-stranded region, and mutational analysis indicated that the terminal hairpin and single-stranded region contain important primary and secondary structural elements that probably function in cis to direct minus-strand initiation (804).

Translation and Proteolytic Processing

Cap-independent translational initiation of the pestivirus genome is mediated by a 5' IRES element that bears structural and functional similarity to the HCV IRES (see Fig. 9) (72,140,529,579). Structure–function studies have demonstrated that domain I is dispensable for IRES activity, that domains II and III contain structures critical for function, that the 3' end of the IRES may extend into the ORF, and that a pseudoknot formed from base-pairing of loop IIIf to a region just upstream of the translational start site is necessary for IRES activity (111,529,579). As for hepaciviruses, the pestivirus IRES has been shown to bind ribosomal 40S subunits independent from translation initiation factors eIF4A, eIF4B, and eIF4F (514,515,642). Pestivirus proteins are translated from genomic RNA as a single large polyprotein, which is processed into individual viral proteins (458,543,587). The current model of pestivirus polyprotein processing comes mainly from analysis of virus-infected cells (5,125,127,591) and expression of pestivirus polyproteins using the vaccinia

or baculovirus systems (348,518,590,591,693,771,779). Cleavage products have been localized in the polyprotein using region-specific antisera (125,656) and proteolytic processing sites within the polyprotein have been determined by protein sequencing (154,348,591,655,693,779). The order of the cleavage products in the BVDV-NADL polyprotein is NH_2-N^{pro}-C-E^{rns}-E1-E2-p7-NS2-NS3-NS4A-NS4B-NS5A-NS5B-COOH (Fig. 12) (125,127,439).

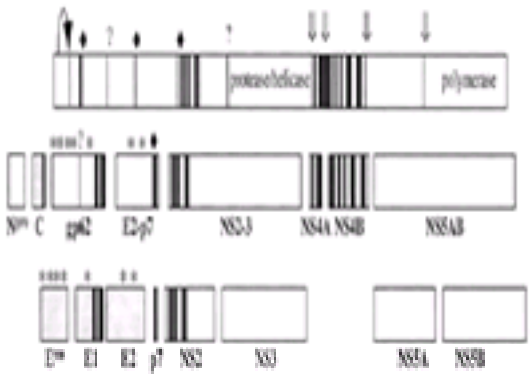

FIG. 12. Processing of the pestivirus polyprotein. *Shading* and *symbols* identifying proteolytic cleavages for the cpBVDV NADL strain are the same as those described in Figure 3, except that the proposed autocatalytic cleavage releasing the N-terminal nonstructural protein N^{pro} from the pestivirus polyprotein (see refs. 655 and 771) is indicated by a *curved arrow*.

Unlike other *Flaviviridae*, the first pestivirus protein encoded in the long ORF is a nonstructural protein, N^{pro}. This autoprotease is responsible for cleavage at the N^{pro}/C site (655,703,771). Processing in the pestivirus structural region appears to be mediated by at least two additional proteases. Although some of the cleavages are slightly delayed, host signal peptidase is believed to cleave at the C/E^{rns} and E1/E2 sites and the site generating the C terminus of E2 (591). The E^{rns}-E1 polyprotein (gp62) is converted slowly to the mature products by an unknown mechanism (591). E1 and E2 are believed to be anchored in the lipid bilayer via C-terminal membrane segments, and some E^{rns} remains associated with the virion via noncovalent interactions that have not been defined (591). A small hydrophobic protein, p7, is produced by signal peptidase, although incomplete processing at the E2/p7 site is observed leading to accumulation of uncleaved E2/p7 (154,242). The pestivirus NS3 protein contains the viral serine protease domain and is responsible for processing at four downstream nonstructural cleavage sites to generate NS4A, NS4B, NS5A, and NS5B (see Fig. 12) (693,771,779). Differences in NS2–3 processing are observed between pestivirus isolates (see ref. 42 and citations therein). Isolates of ncpBVDV do not process NS2-3, whereas those of BDV are able to cleave NS2–3 inefficiently, producing NS3. For CSFV and cpBVDV biotypes, NS2–3 cleavage is efficient but incomplete so that both NS2–3 and NS3 are observed. In the case of the cpBVDV biotypes, the cleavage generating the NS3 N-terminus is produced via several different mechanisms involving RNA recombinational events (detailed later). Enzymes responsible for cleavage at the NS2/3 site in the CSFV and BDV polyproteins have not been elucidated.

Features of Pestivirus Proteins

The N^{pro} Autoprotease

As mentioned earlier, the first protein in the pestivirus polyprotein, the N^{pro} autoprotease (655,771), is a nonstructural protein (703). This enzyme cleaves at its C-terminal sequence Cys¯Ser, which is conserved among pestiviruses (655). Site-directed mutagenesis has identified residues Glu-22, His-49, and Cys-69 as being important for catalysis, and it has been suggested that N^{pro} may be an unusual subtilisin-like cysteine protease (589). Autoproteolysis is the only known function of N^{pro}, and cellular ubiquitin, which directs appropriate C-terminal cleavage by ubiquitin C-terminal hydrolase, can functionally substitute for N^{pro} in replication-competent genomes (43,694,710). Furthermore, N^{pro} is dispensable for autonomous RNA replication in engineered and spontaneously derived subgenomes (43,467,694,710).

Pestivirus Structural Proteins

N^{pro} is followed by the virion nucleocapsid protein C, a conserved, highly basic, 14-kd polypeptide consisting of 21% Lys with a net charge of +12. The C terminus of the virion C protein has not been defined, and it is unknown if it retains the hydrophobic segment postulated to serve as the signal sequence initiating translocation of E^{rns} into the ER lumen.

The E^{rns} glycoprotein (gp44/48, formerly known as E0), is heavily glycosylated at seven to nine potential N-linked glycosylation sites, and it forms disulfide-linked homodimers (703). This protein does not contain a potential membrane-spanning domain and is found noncovalently associated with released virus particles or secreted into the culture medium (591,746,748). Recombinant E^{rns} binds strongly to the surface of cells, probably via interaction with glycosaminoglycans, and it can inhibit infection in a virus-specific manner (291,748). Interestingly, E^{rns} has been shown to possess an unusual ribonuclease activity with specificity for uridine residues (276,620,767). Glycosylation and dimer formation are not required for this activity (767). Although the function of E^{rns} ribonuclease activity is not yet clear, it appears to be important for some aspect of the virus life cycle. Antibodies that inhibit ribonuclease activity also tend to neutralize virus infectivity (767), and mutations in E^{rns} that destroy ribonuclease activity give rise to viruses that may be more cytopathic in culture but are attenuated *in vivo* (278,435). In addition, recombinant E^{rns} appears to be toxic to lymphocytes *in vitro* (76), perhaps contributing to the marked leukopenia seen in natural infections (668). Although cytotoxicity is a feature of other soluble ribonucleases (reviewed in ref. 612), it is unclear whether the ribonuclease

activity of E^{rns} is related to its toxicity.

Both E1 (gp33) and E2 (gp55) are predicted to be integral membrane proteins and contain two to three, and four to six N-linked glycosylation sites, respectively (see ref. 747). E1 and E2 are associated as disulfide-linked heterodimers that form slowly (591); E2 is also present in homodimers (703,747). As mentioned before, recombinant CSFV E2 can bind to cells and block infection of CSFV and BVDV, suggesting that a common E2 receptor is utilized by these pestiviruses for binding and entry (277). Although the precise roles of the viral glycoproteins in virus assembly and entry remain to be defined, monoclonal antibodies to E^{rns} (746) or E2 (145,506,723,747,758) can neutralize virus infectivity, and both antigens can elicit protective immunity (279,590,725).

Pestivirus Nonstructural Proteins

Following the virion structural proteins, the first nonstructural protein is p7, and it consists of a central charged region separating hydrophobic termini (154). The role of this small protein is unknown, but it appears to be required for production of infectious virus (242) but not RNA replication (43). Like the hepacivirus protein, pestivirus p7 is inefficiently cleaved from E2, probably via signal peptidase (154,379). Uncleaved E2–p7 is not required for replication in cell culture (242) and both E2–p7 and p7 appear to remain cell associated and do not copurify with virus particles (154).

The NS2 protein (about 54 kd) is present as the N-terminal portion of NS2–3 (about 125 kd) and is found as a mature cleavage product only for some cpBVDV strains (ref. 441 and citations therein). As detailed later, NS2/3 cleavage in cpBVDV can be regulated by several alterations in the NS2 coding region, including genome rearrangements and insertion of cellular sequences. The precise role of NS2 in NS2–3 processing is unclear, and the function of NS2 is largely unknown. Reconstruction of DI-like subgenomes that lack NS2 indicate that it is dispensable for autonomous RNA replication (43,467,694). However, a correlation between the efficiency of NS2–3 cleavage and the levels of RNA replication has been noted (347,430). NS2 also appears to contain a segment with homology to zinc-finger motifs present in some DNA binding proteins (136).

As for all members of the *Flaviviridae*, the pestivirus NS3 contains an N-terminal serine protease domain (34,91,198,772) followed by motifs characteristic of RNA helicases (199). Uncleaved NS2–3 must be capable of functioning in pestivirus replication, as this protein is not processed in cells infected with ncpBVDV strains. NS3 protease activity (and probably NS2–3 protease activity) requires NS4A as a protein cofactor (779). From cleavage site mapping and comparative analysis, the serine protease was shown to cleave between Leu and small uncharged amino acids L^{-}(S/A/N) (693,779). Most substitutions of the serine nucleophile eliminate processing at these sites (771,779) and destroy virus infectivity (779). Surprisingly, however, enzymatic activity was retained in mutants containing threonine at this position (695). Additional mutations that disable serine protease activity confirm its essential role in virus viability (207). The NS3 protein of BVDV has been purified and shown to possess RNA helicase (743) and RNA-stimulated NTPase (680) activities. Site-directed mutagenesis of the conserved helicase and NTPase motifs inhibited or destroyed these activities and viral replication coordinately (207,217).

The hydrophobic NS4A and NS4B proteins are similar in size, composition, and hydropathic properties to the NS4A and NS4B proteins of other family members. The only known function of these proteins is the serine protease cofactor activity of NS4A (771,779). As for HCV, cofactor activity involves interaction of a central domain of NS4A with the N-terminal region of NS3 (695).

The remaining two proteins, NS5A (about 58 kd) and NS5B (about 75 kd), are present as mature cleavage products as well as an uncleaved form, NS5AB (about 133 kd) (125,127). Neither protein contains the motifs postulated to be involved in methyltransferase or RNA triphosphatase activities, consistent with the lack of a 5' RNA cap structure on pestivirus genomes. Little is known about the function of NS5A. This protein was found to be phosphorylated by a cellular serine/threonine kinase with properties similar to enzymes that phosphorylate flavivirus NS5 and hepacivirus NS5A (561). NS5B contains motifs characteristic of RdRPs (124,126). The RNA polymerase activity of recombinant NS5B has been characterized *in vitro* and found to extend template-primed RNAs into double-stranded “copy-back” products (355,398,657,812) or to catalyze *de novo* initiation from short synthetic RNA or DNA templates (308,355). Polymerase activity is particularly responsive to GTP concentration, most likely because of a strong preference for initiation with guanylate (308,398).

RNA Replication

Analysis of pestivirus RNA replication is still at an early stage, although this process appears to be similar to that of flaviviruses. Minus- and plus-strand RNAs have been detected from 4 to 6 hours after infection, followed by the asymmetric accumulation of additional minus- and excess plus-strand RNAs (196). Accumulation of genome-length intracellular pestivirus RNAs, which co-migrate with virion RNA, generally follows the time course of infectious virus release, maximal virus titers being achieved about 12 to 24 hours after infection (196,458,542). Double-stranded RF RNAs and partial duplex RI RNAs, containing about six nascent strands, have been tentatively identified (195,196,542). The role of these RNA isoforms in replication remains to be elucidated.

As described later, there is good evidence that nonhomologous recombination can occur within pestivirus RNAs, and between pestivirus RNAs and host cellular RNAs (reviewed in ref. 441). Although the details of these recombination events are unknown, a likely mechanism is via copy-choice template recruitment during minus-strand synthesis, which is consistent with the coding orientation of cellular inserts. Given the frequency of pestivirus–cellular RNA recombinants compared to other positive-strand viruses, this is an interesting and potentially unusual characteristic of the pestivirus replicase.

Assembly and Release of Virus Particles

Other than the features of the virion structural proteins described before, little information is available on the assembly

and release of pestiviruses from infected cells. Pestivirus structural proteins are not found at the plasma membrane (209,748). Electron microscopic examination of virus-infected cells (46,208) suggests that pestiviruses mature in intracellular vesicles and are released by exocytosis. Formation of infectious BVDV-1 particles can be blocked by ER a-glucosidase inhibitors, presumably via misfolding of the viral envelope glycoproteins (816). A substantial fraction of infectious virus remains cell associated and some can be released from infected cells by successive freeze-thaw cycles (361,458). Interestingly, E^{rns} and E2 have been immunolocalized on isolated virus particles by electron microscopy, but E2 was not seen in particles undergoing secretion (or perhaps reattachment) at the cell surface (748). This suggests that E2 may be conformationally inaccessible to antibodies prior to a delayed maturation process.

Pathogenesis of MD and the Generation of Cytopathogenic Pestiviruses via RNA Recombination

Mucosal disease is the most severe outcome of BVDV infection and is usually fatal (reviewed in refs. 23,74,75,441, and 702). This disease can occur when a fetus is infected *in utero* with an ncpBVDV strain. If infection with ncpBVDV occurs between 80 and 100 days of gestation, animals may become tolerized to BVDV antigens and remain persistently infected for life. In the case of a persistently infected animal exhibiting MD, both cp and ncp biotypes of BVDV can be isolated (427). The close serologic relatedness of ncp–cp pairs isolated from an MD-affected animal led to the suggestion that cpBVDV might arise from ncpBVDV by a rare mutational event. Molecular characterization of a number of these ncp–cp pairs has verified this hypothesis and led to the remarkable discovery that some cpBVDV biotypes are generated via RNA recombination (211,434,438,439,698). In every case studied thus far, these rare events led to the production of NS3 (in addition to NS2–3), which is thought to be responsible for cpBVDV cytopathogenicity in cell culture and the pathogenesis of MD in the immunotolerant animal. Although less well characterized, a similar mucosal syndrome correlating with viral cytopathogenicity exists for BDV. Cytopathic CSFV strains have been described but do not seem to correlate with a particular disease state.

Sequence analysis of several independent cpBVDV isolates has revealed some common genome rearrangements resulting from RNA recombination (reviewed in ref. 441), and a few representative genome structures are illustrated in Figure 13. In the case of the Osloss and NADL strains, an in-frame insertion of cellular sequences is found in the NS2 gene (434,438). The Osloss insertion encodes a host ubiquitin monomer, which presumably directs cleavage at the ubiquitin/NS3 junction by the cellular enzyme ubiquitin C-terminal hydrolase. This role for the ubiquitin insertion has been confirmed for another cpBVDV with a similar genome rearrangement (697). The host sequence found in the NADL strain corresponds to a 270-nt portion of a bovine mRNA whose gene product has not been characterized (434). Deletion of this insertion from a cloned BVDV-NADL genome gave rise to a virus that did not produce NS3, was noncytopathic in culture, and exhibited reduced levels of RNA replication (430). Similar insertions of this same host gene have also been found to correlate with NS3 production and cytopathogenicity in two cpBDV isolates (37). Interestingly, a much smaller insertion is found in the NS2 gene of cpBVDV strain CP7, which contains a 27-nt duplication from an upstream region of the NS2 gene in an alternate reading frame (696). This insertion also leads to the production of NS3 (696) and a virus that is cytopathic in culture (437).

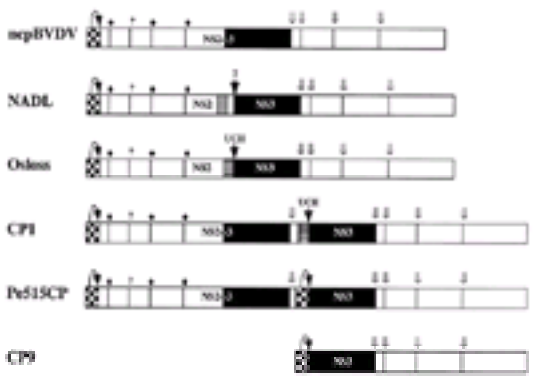

FIG. 13. Genome rearrangements associated with the generation of cytopathogenic bovine viral diarrhea virus (cpBVDV). The *top* diagram indicates the polyprotein of a typical ncpBVDV isolate. *Below*, the polyproteins encoded by five different cpBVDV isolates generated by RNA recombination are shown: NADL (432,433), Osloss (433), CP1 (438), Pe515CP (439), and CP9 (698). For all of the cpBVDV isolates, these polyprotein structures allow the production of both NS2-3 and NS3. In-frame insertions of host sequences are present in NADL (*shaded region*), Osloss (*striped region*), and CP1 (*striped region*). The enzyme responsible for NS3 production in the NADL strain is unknown, but the inserted ubiquitin sequences in Osloss and CP1 provide sites for processing by host ubiquitin C-terminal hydrolase (UCH) (697). For Pe515CP and the CP9 defective-interfering (DI) RNA, the N^{pro} autoprotease (*checkered box*) mediates the cleavage producing the NS3 N-terminus. The nomenclature and organization of the cleavage products and the symbols for the normal processing enzymes are defined in Figure 3 and Figure 10. The location of NS3 *(filled region*) is emphasized.

The CP1 and Pe515 cpBVDV strains contain large duplications encompassing the NS3 coding region and insertions of either ubiquitin sequences (438,439) or a duplicated copy of the N^{pro} autoprotease (439), respectively. Genome rearrangements with duplicated viral sequences flanking ubiquitin insertion sites have also been noted (545), which probably result from multiple independent recombination events (441). Additional cellular gene insertions have also been found in the context of genomic duplications, and they correlate with NS3 production and cytopathogenicity. These include the SMT3B ubiquitin homolog (544), a ribosomal S27a–ubiquitin gene fusion (41), and light chain 3 of microtubule-associated proteins 1A and 1B (436).

Several cpBVDV-1, cpBVDV-2, and cpCSFV strains consist of a paired DI particle and an ncp helper virus (38,350,440,698,710). An example of a cpBVDV-1 DI is represented by CP9, which contains a precise deletion of the C-E^{rns}-E1-E2-p7-NS2 genes resulting in an in-frame fusion of N^{pro} and NS3 (698). Such subgenomes are capable of

autonomous replication, express NS3, and induce cytopathic effects within cells (43,467,694). Pestivirus DIs interfere with the replication of helper viruses, which presumably provide packaging functions in trans.

Despite myriad ways that cp pestiviruses can be generated via RNA recombination, a few cpBVDV strains have been described that lack known genome alterations (136,210,512,545). For one such cp strain, BVDV-Oregon, NS2–3 cleavage was shown to be dependent on sequence information contained within NS2 and the first 66 amino acids of NS3 (348). Introduction of this NS2 gene into a heterologous ncpBVDV-1 genome led to NS2–3 processing and cytopathogenicity (347). Surprisingly, a relatively few amino acid changes in NS2 could account for this difference in cleavage efficiency. Nevertheless, due to the lack of an ncp counterpart, it can only be surmised that this strain had been derived by accumulated point mutations in the NS2 region.

Clearly, the unifying feature of cp pestiviruses is the production of NS3. As stated before, except for rearrangements that juxtapose ubiquitin or N^{pro} with NS3, the identity of the protease(s) responsible for NS2–3 cleavage in other cpBVDV strains, as well as in ncpCSFV and ncpBDV, is unknown. Involvement of the NS3 serine protease activity in NS2–3 cleavage has been excluded via mutagenesis or deletion in several cpBVDV polyproteins (348,436,696,779). One possibility is that foreign gene insertions in NS2 might signal a cellular protease to cleave at the NS2/3 junction, perhaps by inducing a conformation within NS2 similar to the NS2 proteins from ncpBDV, ncpCSFV, or BVDV-Oregon, which all cleave NS2–3 despite the absence of genome alterations. Alternatively, such changes might activate a latent or cryptic protease activity encoded by NS2. This could explain how the BVDV-Oregon NS2 gene is sufficient to direct NS2–3 cleavage, as well as explain NS2–3 cleavage in ncpCSFV and ncpBDV despite the absence of genome rearrangements. Further, in this regard, HCV and GBV-C (see the next section, The GB Viruses) NS2 proteins contain the catalytic residues of NS2–3 autoproteases, although there is scant homology to pestiviruses in this region. Thus if pestivirus NS2 does perform a catalytic role in NS2–3 cleavage, the mechanism is likely to be different from that of these other viruses. Regardless of the mechanistic details, it is interesting to note that pestiviruses differ among themselves and from other family members in NS2–3 cleavage efficiency. Perhaps inefficient cleavage may reflect a recent evolutionary adaptation, producing viruses that are less prone to cause disease but nevertheless successfully spread via congenital routes in domesticated animal herds.

Whereas there is a strong correlation between NS3 production and cytopathogenicity of cpBVDV, ncp strains of BDV and CSFV produce both NS3 and uncleaved NS2–3. This raises the issue of how NS2–3 cleavage leads to a cytopathic effect. One possibility is that NS3 may be directly cytopathic, perhaps involving the serine protease activity. Pestivirus cytopathology proceeds via apoptosis (264,621,809), a cell death pathway involving cellular protease effectors (reviewed in ref. 324). According to this model, the relative abundance of NS3 would determine its effect within a host cell. In this regard, cpBDV and cpCSFV seem to express increased amounts of NS3 (37,42,440). Alternatively, it has been noted that cpBVDV exhibits an increased efficiency of RNA replication compared with paired ncp viruses (347,430). Thus, NS2–3 cleavage might directly result in enhanced RNA replication, and a byproduct of this process could be responsible for cytopathogenicity. In this regard, enhanced levels of RI and RF RNA forms could activate the double-stranded RNA-activated kinase PKR, a known inducer of apoptosis (24,141,652). A larger question is how cytopathic effects on the cellular level lead to MD in infected animals. Increased cell death could directly contribute to tissue injury and induce inflammation. There is also evidence that animals with MD show increased numbers of infected cells (375), perhaps because of increased replication of cpBVDV. In addition, cpBVDV might exhibit differences in tropism that could contribute to disease (375).

THE GB VIRUSES

Discovery, Distribution, and Origin

In the early 1990s, a residual number of hepatitis cases were still not attributable to HAV, HBV, HCV, or the recently described hepatitis E virus (Chapter 89). Efforts aimed at identifying additional agents of hepatitis revealed three novel viruses that have been tentatively assigned to the *Flaviviridae*. Two of these viruses, GBV-A and GBV-B, were cloned via subtractive representational methods from the serum of a tamarin experimentally infected with a hepatitis agent originally derived from a human patient, GB (641). Although some human cases of non-A–E hepatitis showed serologic reactivity to GBV-A and GBV-B, RT-PCR analysis from these patients failed to detect either virus. Rather, a third related virus, GBV-C, was subsequently identified from one such patient (365,640). Cloning of novel viruses associated with non-A, non-B hepatitis by immunoscreening of a cDNA library identified an agent, initially termed hepatitis G virus (HGV), which turned out to be an independent isolate of GBV-C (386).

Based on sequence relatedness and overall genome structure, GBVs have been categorized within the *Flaviviridae*, although they remain unclassified at the genus level. GB viruses are most similar to HCV but phylogenetically distant enough to resist classification as hepaciviruses (see Fig. 1) (78,582). This is especially true for GBV-A and GBV-C, which share a number of unique features that distinguish them from other members of the family.

The inability to detect GBV-A or GBV-B in human samples led to investigations into their origins. Interestingly, GBV-A has been detected in several species of New World monkeys in the absence of experimental infection or overt disease (78,100,364,615). Viral sequences isolated from within a single primate species were highly related, whereas sequences isolated from separate species showed greater divergence, indicating that GBV-As are indigenous monkey viruses that have adapted to their hosts over extended periods of time (78,100,364,615). These results, and observations made during early cross-challenge experiments, provide support for the view that the original GBV-A isolate may have been acquired during passage of the GB agent in tamarins (78,502). The distribution of GBV-B in nature is unknown, as the only source of this virus is the original tamarin-passaged GB serum used to identify GBV-A and GBV-B.

Since its initial discovery, GBV-C has been found to be surprisingly common, with viral RNA detected in about 1% to 4% of healthy human volunteer blood donors (168,421,654,775). Phylogenetic analysis of GBV-C sequences has been complicated by an apparent bias against synonymous substitution in some parts of the genome, leading to differences in inferred relationships depending on the subgenomic regions under comparison (309,521,728). The molecular basis for

this bias is unclear; it may involve evolutionary constraints imposed by RNA secondary structures (637) or cryptic ORFs (507,643). Nevertheless, standardization of results has been achieved through the use of an appropriate molecular timepiece, such as the 5' NCR, the E2 gene, or complete genome sequences. These results indicate that variation among GBV-C isolates occurs in distinct genotypes that reflect their geographical distribution (183,387,469,643,644). GBV-C RNA has also been detected in the serum of wild chimpanzees (1) and chimpanzees infected with a putative hepatitis agent (48). Chimpanzee-infecting GBV-Cs were found to be more closely related to each other than to human-infecting GBV-Cs, suggesting coevolution of these viruses with their hosts (1,48,100).

Genome Structure and Expression

Complete or nearly complete genome sequences have been determined for a number of GBVs, and functional full-length infectious clones have been assembled for GBV-B (80) and GBV-C (777). Like the other family members, the GBV genomes encode a single long ORF containing structural protein genes [(C)-E1-E2] in the 5' one third, followed by nonstructural protein genes (NS2-NS3-NS4A-NS4B-NS5A-NS45B) in the remainder (365,468). The 5' NCR of GBV-B contains 445 nucleotides, which is about 30% larger than the HCV 5' NCR, but it has significant similarity in primary and presumed secondary structure to the HCV 5' NCR (see Fig. 11) (268,468). In contrast, GBV-A and GBV-C have 5' NCRs of 508 to 593 nucleotides that share about 50% identity to each other and can be folded into similar structures (see Fig. 11), but that do not resemble the 5' NCRs of HCV or GBV-B (639). The long 5' NCRs of all three GBVs contain multiple initiator AUG codons, and initiation of polyprotein translation is thought to be dependent on IRES activities, which have been demonstrated for all three GBV 5' NCRs (201,577,639). The GBV-B 3' NCR is 361 nucleotides in length, containing a short poly(U) stretch 30 nucleotides downstream of the stop codon, followed by 309 nucleotides of unique sequence (80,609). Although this region of the GBV-B genome does not contain sequence homology with HCV, the 3' 47 nucleotides of GBV-B is predicted to fold into a structure very similar to SL-I at the 3' end of the HCV genome (80,609). The 3' NCRs of GBV-A and GBV-C are highly conserved only within these virus groups, although a short 17-nucleotide stretch is also well conserved among all GBVs (609).

The relationships among GBVs and between HCV are also reflected in the organization of structural proteins. Like HCV, GBV-B encodes a basic capsid protein followed by two envelope glycoproteins. The genomes for GBV-A and GBV-C also contain E1 and E2 glycoproteins, but they lack any obvious capsid-like protein (386,468). *In vitro* translation of RNAs containing the GBV-A or GBV-C 5' NCR localized the translational start site to a conserved AUG immediately upstream of the E1 coding region (639). However, it has been observed that GBV-C-infected humans generate antibody responses against a small basic peptide that can be translated from an in-frame upstream AUG, suggesting that such a protein is expressed *in vivo* (777). Alternative explanations for the lack of a capsid-like protein include the possibilities that GBV-A and GBV-C might usurp a capsid-like protein of the host cell or a co-infecting virus, or that additional GBV proteins may be involved. In this regard, a region of the GBV-C NS5A gene exhibiting a bias against synonymous substitution has been noted to potentially encode a small basic protein (10 kd, pI 11.5) in an alternate reading frame (507). Furthermore, it remains possible that GBV-A and GBV-C virions might lack a distinct nucleocapsid. However, biophysical characterization of GBV-C particles indicate that GBV-C RNA can be found in low-density (1.07 g/mL) and intermediate-density (about 1.18 g/mL) fractions on a variety of density gradients (428,605,777). Pretreatment with detergents or organic solvents to remove membranes shifts the peak of viral RNA to a higher-density form that may represent nucleocapsids that have recently been visualized by electron microscopy (776).

The nonstructural proteins of GBVs show the greatest similarity to HCV, and the boundaries of cognate NS2, NS3, NS4A, NS4B, NS5A, and NS5B proteins have been proposed (365,468). Catalytic residues of the HCV NS2-3 autoprotease are conserved among GBV NS2 proteins (365,468), and this enzymatic activity has been described for GBV-C (45). Similarly, active sites of the HCV NS3 serine protease are retained in NS3 of GBVs. Biochemical characterization of the GBV-B serine protease activity indicates that it shares substrate specificity with the HCV enzyme and requires the virus-specific cofactor NS4A (83,610). The C-terminal region of GBV NS3 proteins retain the similarity to supergroup 2 RNA helicases that is common to the *Flaviviridae* (365,468), and NTP-dependent RNA unwinding activity has been demonstrated for NS3 proteins of GBV-B and GBV-C (229,813). NS5B contains similarity to the supergroup 2 RNA polymerases (365,468,641).

Association with Disease?

GBV-A has not been shown to cause disease in nonhuman primates, whereas GBV-B causes hepatitis in experimentally infected tamarins (80,614). As described before, although both of these viruses were thought to be derived from a source of human hepatitis, it appears that GBV-A had been acquired during primate passage and GBV-B has been isolated only from tamarin-passaged GB material. Attempts to identify a GBV in the original GB clinical sample have failed, most likely because of degradation during storage (614).

Human infection with GBV-C is well documented, although direct association of this virus with human disease has proven to be elusive (reviewed in ref. 638). Epidemiologic evidence suggests that it is primarily blood-borne, although other modes of transmission appear possible (105,169,240,624,654). These risk factors overlap with those of HBV and HCV, and the frequency of co-infections with GBV-C and other viruses have complicated etiologic determinations (13,386). It appears that a majority of GBV-C infections are subclinical, with only mild symptoms that typically resolve with the appearance of anti-E2 antibody (143,226,368,369,672,673). Viral persistence seems to occur in about 5% to 10% of GBV-C infections (226,421). A few studies have implicated GBV-C in acute and chronic non-A–E hepatitis (168), fulminant hepatitis (679,801,802), or other liver disease (129). However, recent work suggests that GBV-C is a lymphotropic virus (718). Clearly, more work needs to be done to establish the clinical significance of GBV-C and related viruses.

SUMMARY AND QUESTIONS

Although much has been learned about the general life cycle of the *Flaviviridae*, it is quite complex, and large gaps in our knowledge exist for every step. The ongoing development of improved genetic and biochemical tools to study these viruses will certainly enable a more complete picture of their biology. Recent progress has been made in identifying host

cell surface molecules that could be involved in binding and entry of viruses, although the details of such interactions, and how these control virus tropism and infection *in vivo*, is largely unknown. The general strategies of genome translation and polyprotein processing have been elucidated. Yet details such as the proteolytic processing mechanism of the flavivirus NS1-2A or pestivirus NS2-3 polypeptides need to be resolved. More effort is needed to understand the functional significance of polyprotein processing events for RNA replication, virus–host interaction, and virion formation. Furthermore, it is not understood how the competing processes of genome translation and genome replication are regulated for this virus family. New insights have emerged regarding the enzymology of some viral nonstructural proteins, as well as the identity of a few host proteins that most likely contribute to genome replication. However, the role of several nonstructural proteins in this process are unknown. More description is needed for how all these components, together with viral RNA, combine to produce a functional replicase. As for all positive-strand RNA viruses, the role of membranes in the process of RNA replication remains a mystery. It is interesting that phosphorylation of polypeptides upstream of the polymerase seems to be a conserved feature within the family. Identification of the relevant kinase(s) should allow the significance of this posttranslational modification to be addressed. Nearly all of what we know about virus–cell interaction for HCV has come from the study of heterologous systems, which have suggested important roles for HCV-specific gene products in interferon sensitivity and the development of HCC. The emergence of improved systems for studying HCV in culture will permit all of this work to be reevaluated, and moreover, it will undoubtedly reveal unexpected and novel aspects of HCV biology. Our understanding of virion formation is still at an early stage, and it is not yet clear how structural proteins combine to form nascent virions, where this process occurs, and whether packaging is temporally regulated within the replication cycle. The lack of obvious capsid proteins for GBV-A and GBV-C raises the questions of whether these virions actually contain nucleocapsids and, if so, what the identity of the capsid proteins is. It is fascinating that pestiviruses encode a ribonuclease within the extracellular domain of an envelope glycoprotein, although the biologic role of this activity remains to be clarified. Also, what is the role of the secreted flavivirus NS1 protein? Why does production of NS3 by cpBVDV correlate with cytopathogenicity and fatal MD? Are GBVs involved in human disease? What mechanisms are involved in the establishment and maintenance of chronic infections by pestiviruses and HCVs? Answers to these and other pressing questions should reveal the unique aspects to the replication of this evolutionarily distinct family of viruses. This will provide information useful for the development of effective immunization and therapeutic strategies to control diseases caused by these diverse and important pathogens. Clearly, the most exciting period of research into the *Flaviviridae* lies ahead.

CHAPTER 33 Flaviviruses

Donald S. Burke and Thomas P. Monath

The genus *Flavivirus* is composed of about 73 viruses (Table 1). Of these viruses, 34 are mosquito borne, 17 are tick borne, and 22 are zoonotic agents transmitted with no known vector, often transferred between rodents or bats (Fig. 1).

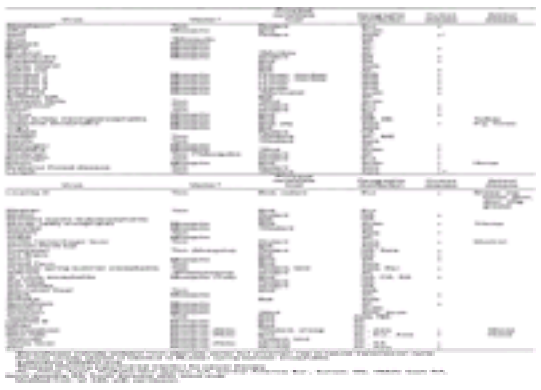

TABLE 1. *The Flaviviridae (arboviruses): vector–host relationships and disease associations*

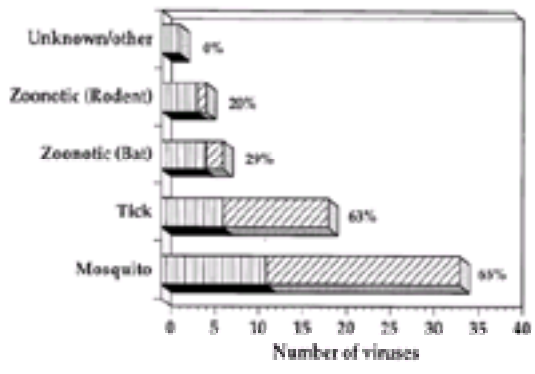

FIG. 1. Number of recognized flaviviruses, by mode of transmission. The number of viruses (*cross-hatched column*) and proportion (%) causing human disease in each transmission category are shown. Most viruses are mosquito or tick borne, and more than 60% of these agents cause human illness.

Forty species of the flavivirus family have been associated with human disease. Twenty-two of the 34 (65%) mosquito-borne viruses and 13 of 17 (107) of the tick-borne viruses can cause disease in humans. Only 5 of the 22 (23%) viruses with no known vector cause human disease. Dengue, yellow fever, the tick-borne encephalitis (TBE) complex, and Japanese encephalitis are the most important viral arboviruses in the world and cause extensive morbidity and mortality across every continent.

HISTORY

Yellow fever virus is the type virus of the family (hence the name, derived from *flavus,* Latin for “yellow”). It was the first filterable agent shown to cause a human disease and the first virus proved to be transmissible by an arthropod vector. Yellow fever virus was the first flavivirus to be isolated (in 1927) and cultivated *in vitro* (in 1932). During the first decade of this century, dengue virus was also shown to be a filterable virus transmitted by arthropods, but it was not isolated until 1943.

A number of diseases characterized by meningoencephalitis were recognized as nosologic entities during the 19th and 20th centuries and later proved to be caused by flaviviruses. Among these are louping ill (a disease of sheep, recognized in Scotland since 1807), JE (Japan, 1873), and Australian X disease (now known as Murray Valley encephalitis [MVE], Australia, 1917). Between 1931 and 1937, the viruses responsible for louping ill, St. Louis encephalitis (SLE), JE, and TBE were isolated. Common features of these viruses included neurotropism and arthropod transmission, but initially they were believed to be unrelated agents. In the late 1930s and early 1940s, relationships were demonstrated by neutralization and complement fixation tests between JE, SLE, and West Nile (WN) viruses. With the advent of the hemagglutination-inhibition (HI) test, which defined the broadest spectrum of antigenic relatedness, Casals and Brown (101) were able to separate the flaviviruses (group B arboviruses) from the alphaviruses (group A viruses) and to define the cross-reactions among a set of 10 flaviviruses. As the flavivirus family grew with continued isolations of new agents from wild vertebrates and arthropods, so did the complexity of their serologic classification (100). Thirteen new flaviviruses were isolated for the first time during the 1970s, and one new virus has been recovered since 1980.

Notwithstanding the lack of a serologic relationship, the group A and B arboviruses were originally linked on the basis of their mode of transmission and physicochemical characteristics into a single family, the family *Togaviridae,* encompassing small RNA viruses with lipid envelopes and cubic nucleocapsid symmetry. As knowledge of the morphogenesis, biochemistry, and replication strategy of the flaviviruses expanded, it was clear by 1984 that their differences when compared with other togaviruses were sufficiently great to place them in a separate family (764). Only members of the genus Flavivirus are discussed in the chapter; the Pestiviruses, Hepaciviruses, and other newly recognized *Flaviviridae*-like viruses (91) are not.

INFECTIOUS AGENTS

Physical and Chemical Properties

Flavivirus morphology, morphogenesis, protein composition, and genome structure are described in detail in Chapter 32 (see also 601). Here we focus on the characteristics of viruses that relate either to interactions with the environment or to laboratory manipulations in antigen and vaccine preparation. In the next section, the chemical and physical properties of gene products interacting with antibody and immunologically specified cells are described.

Flavivirus virions consist of a spherical ribonucleoprotein core surrounded by a lipoprotein envelope with small surface projections. The projections seen in electron micrographs are clarified by x-ray crystallography and represent molecules of envelope glycoprotein, which form rodlike structures anchored to the viral membrane at their basal ends. Envelope lipids constitute about 17% of the virion dry weight (718) and are derived from the host cell lipids.

Mature flavivirus virions contain three structural proteins: a nucleocapsid or core protein (C; 12 kd), a nonglycosylated membrane protein (M; 8 kd), and an envelope protein (E; 53 kd), which is usually glycosylated (718). The M and E proteins are both associated with the lipid envelope by means of hydrophobic membrane anchors. The E protein is the major component of the virion surface; it contains the important antigenic determinants subserving HI and neutralization and thus induces immunologic responses in the infected host. Structural elements of the E protein determinants are assumed to be involved in the binding of virions to cell receptors and in intraendosomal fusion at low pH.

Detergents and proteases have been used to characterize the structure of flaviviruses and to isolate immunologically reactive subunits (695,718). Nonionic detergents, such as Triton X, solubilize the entire envelope, releasing M and E proteins; whereas sodium deoxycholate appears to remove only E, leaving M associated with the nucleocapsid. Protease treatment showed that a portion of the E glycoprotein is located within the lipid bilayer (285). Analysis of the primary structure of the flavivirus glycoprotein has confirmed the presence of a hydrophobic membrane anchor region at the carboxyl terminus of the E protein molecule (535).

The flaviviral envelope protects the genome from cellular nucleases, and naked nucleocapsids released by detergent treatment are degraded by ribonuclease. Flavivirus infectivity and hemagglutinin are optimally stable at pH 8.4 to 8.8 (344). Sensitivity to acid pH (also to bile and proteolytic and lipolytic enzymes) generally precludes infection by the oral route. TBE may, however, be acquired by ingestion of infected milk (560). Flaviviruses are rapidly inactivated at high temperature. At 50°C, 50% of infectivity is lost in 10 minutes. As a practical measure, total inactivation of virus suspended in blood or other protein solutions occurs within 30 minutes at 56°C. Low temperatures preserve infectivity, with stability being greatest at –60°C or below. Aerosols present a hazard of laboratory infection (646). SLE virus is stable for 6 hours in aerosol suspension at room temperature and 23% to 80% humidity (344). For reasons that are not understood, aerosol laboratory infections with tick-borne flaviviruses are more frequent than with mosquito-borne viruses.

Flaviviruses are inactivated by ultraviolet light, gamma-irradiation, and disinfectants, including 3% to 8% formaldehyde,

2% glutaraldehyde, 2% to 3% hydrogen peroxide, 500- to 5,000-ppm available chlorine, alcohol, 1% iodine, and phenol iodophors. The tick-borne viruses appear to be relatively more resistant to these measures than mosquito-borne agents.

Antigenic Composition and Determinants

Antigenic Classification

All members of the genus *Flavivirus* share common antigenic sites, as revealed by HI tests with polyclonal immune sera, and this originally formed the basis for their classification (101). Neutralization tests (NT), on the other hand, are more discriminating and can be used to distinguish individual viruses in the genus and to define subgroups of closely related viruses.

On the basis of cross-neutralization using polyclonal hyperimmune antisera, the flaviviruses have been divided into a number of antigenic complexes. The original studies by de Madrid and Porterfield (150) classified 36 flaviviruses. A recent study classified 68 viruses into 14 clades within 8 antigenic complexes (Table 2). Eleven other viruses were not closely related enough to be included in any of the antigenic complexes (380). Because the envelope protein E is the viral hemagglutinin and the primary target for neutralizing antibodies (reviewed in 283), the cross-neutralization data reflect differences in the antigenic structure of this envelope protein and, together with the results of cross-HI tests, provide evidence for the presence of group-, serocomplex-, and type-specific determinants. This antigenic classification conforms to major biologic and epidemiologic characteristics of the flaviviruses (see Table 1).

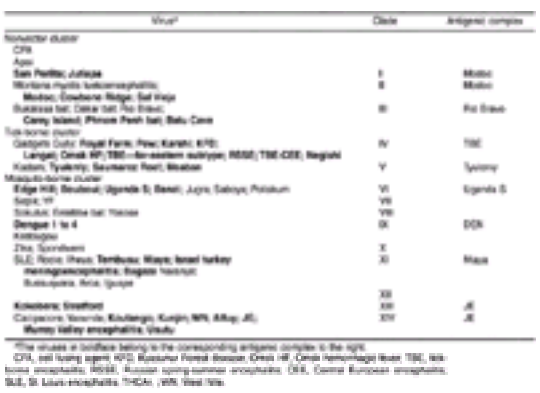

TABLE 2. *Assignment of flaviviruses to clusters and clades*

The complexity of the antigenic relationships among flaviviruses has further been emphasized by the application of protein E–specific monoclonal antibodies (reviewed in 284,291, and 614). These analyses have demonstrated the presence of flavivirus group-, serocomplex-, and type-specific antigenic determinants, generally confirming the relationships shown with polyclonal antisera. Monoclonal antibodies have also been found with subcomplex, subtype, strain, and even substrain specificity, allowing the further distinction of viruses at a level that has been difficult or impossible to demonstrate with polyclonal antisera (38,651). Thirteen different binding sites for monoclonal antibodies have been identified on the E protein of a dengue 2 strain (612).

Monoclonal antibodies have uncovered antigenic relationships at the epitope level that link different flavivirus antigenic complexes or that reveal previously unsuspected relationships between members of the same antigenic complex, thus complicating the simple concept of group-, complex-, and type-specific determinants. For example, among members of the dengue complex, subcomplex specificities were demonstrated for dengue 1 and 4 and for dengue 2 and 3 (294). Relationships were also revealed between dengue and members of other antigenic complexes (e.g., Tembusu virus). Moreover, monoclonal antibodies may show functional reactivity with heterologous, but not homologous, virus strains. For example, monoclonal antibodies prepared against yellow fever 17D virus neutralized the parental Asibi strain but not 17D (651). To complicate matters even further, binding and functional assays with the same monoclonal antibody may show completely different cross-reactivity patterns (283,291). These data are an apparent reflection of the complexity of antigenic determinants recognized by antibodies on the surface of the virion.

The complete or partial sequences of a number of flaviviruses have recently provided a classification based on sequence homologies and the construction of evolutionary trees (Fig. 2). The amino acid sequence comparisons of protein E, like those of other viral sequences (59,77,419), yield a picture that perfectly matches that of the flavivirus serocomplexes defined by cross-neutralization using polyclonal immune sera (see Table 2).

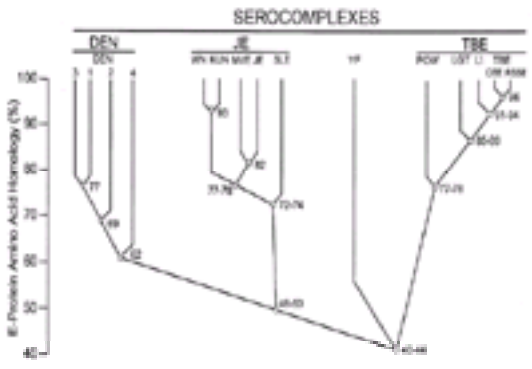

FIG. 2. Phylogenetic tree of the genus *Flavivirus,* using nucleotide sequence. The tree was constructed by the

neighbor-joining method. Each number at the nodes is the percentage of 500 bootstrap replicates supporting the relationships shown; *asterisk* indicates confidence probability higher than 90%. Vertical length is arbitrary. Scale is percentage of genetic distance. (From ref. 380, with permission.)

The TBE complex and yellow fever virus are most distantly related to each other and to the other flaviviruses, with a sequence homology of 40% to 44% (depending on the pair of viruses compared). There is a somewhat closer relationship between members of the JE serocomplex and the dengue viruses (46% to 53%). The different dengue types share 62% to 77% of their amino acids, with dengue 1 and dengue 3 being most closely related (77% homology), followed by dengue 2 (69%) and dengue 4 (62%). An extensive comparative sequence analysis of dengue 2 virus isolates has revealed a significant degree of diversity (up to 10% amino acid differences in protein E) and has allowed the identification of at least four genetic subtypes (419,604). Within the JE and TBE serocomplexes, the degree of nucleotide homology is at least 72% and 77%, respectively. As pointed out by Blok and colleagues (59), the viral proteins are very similar in topology.

The E protein is one of the most slowly evolving viral proteins (together with NS1, NS3, and NS5), indicating that immunologic pressure is not an important driving force in the evolution of flaviviruses.

Role of Structural and Nonstructural Proteins in Immune Response

The envelope protein E plays a dominant role in the generation of neutralizing antibodies and the induction of a protective immune response. This has been conclusively demonstrated by active immunization of animals with defined subviral components (291) and recombinant proteins (72,287,332,365,367,461,484,555,657) and by passive protection experiments with protein E–specific monoclonal antibodies (reviewed in 283 and 614). Protein E–specific nonneutralizing antibodies or neutralizing antibodies at subneutralizing concentrations, however, may also mediate the phenomenon of antibody-dependent enhancement (ADE) of infection, which has been implicated in the pathogenesis of dengue hemorrhagic fever (DHF) and dengue shock syndrome (DSS) (257).

Low-titer neutralizing activity and a significant degree of passive mouse protection has also been observed with monoclonal antibodies against the prM protein of dengue 3 and dengue 4 viruses (346). Mice immunized actively with prM/M also exhibit a degree of protection (70). The prM protein is part of immature virions, and its proteolytic cleavage, presumably by a cellular protease in the trans-Golgi network, generates mature virions. In certain instances, this precursor cleavage can apparently be incomplete, allowing the prM protein to function as an additional target for neutralizing and protective antibodies.

The nonstructural glycoprotein NS1 is expressed on the surface of infected cells (96,182,654,693) but is also secreted and, in this form, was previously designated as soluble complement fixing antigen (183,695). NS1 elicits an immune response in the course of flavivirus infections in humans and in experimental animals (227,385,783a). Its role as a protective antigen is discussed later. In the infected host, secreted forms of NS1 are found in the circulation.

Although passive protection in mice by a monoclonal antibody against the nonstructural protein NS3 of dengue 1 virus has been reported (704), the primary immunologic role of the nonstructural proteins, with the exception of NS1, appears to be their function as targets for cytotoxic T cells (Tc) (301,630).

The Antigenic Structure of Protein E

Protein E is the primary target for neutralization, and its antigenic structure has been extensively studied using both polyclonal and monoclonal antibodies (reviewed in 283,291, and 614). Because the location of disulfide bridges is also known (535), these data together have been used to generate structural models of protein E (94,289,361,448,613,615).

The x-ray structure of a soluble form of the TBE virus protein E has been determined (596). This soluble form was obtained by tryptic cleavage from purified virions (290) and lacked the carboxyl-terminal 80 to 90 amino acids including the membrane anchor. Because the cysteines forming all six disulfide bridges are absolutely conserved among flavivirus E proteins and a common 3D structure can be anticipated, the available data on other flavivirus epitopes will be discussed with reference to the TBE virus protein E.

Unlike the influenza hemagglutinin, this complex is a head-to-tail rather than a head-to-head oligomer. Thus, it apparently does not represent a spike protruding from the surface of the virion, but rather a 170-Å long rod that is probably anchored to the membrane at its distal ends. The side view shows that the dimer has a curved shape consistent with its attachment on the surface of a 500-Å particle. In each monomer, three structural entities are discernible, two of which are related to previously defined antigenic domains (compare Fig. 3**A** and 448). The carboxyl-terminal 100 amino acids (domain III in Fig. 3**A**) correspond to antigenic domain B and form a b-barrel composed of seven antiparallel b-strands resembling an immunoglobulin constant domain. This structure is connected by a flexible region to the central domain I, which is folded as an eight-stranded b-barrel with up-and-down topology. It includes the amino-terminal 50 amino acids as well as a sequence element that carries the single carbohydrate side chain and was previously referred to as antigenic domain C. Two long loops extending from this central part of the protein are primarily involved in dimer contacts (domain II in Fig. 3**A**) and correspond to antigenic domain A.

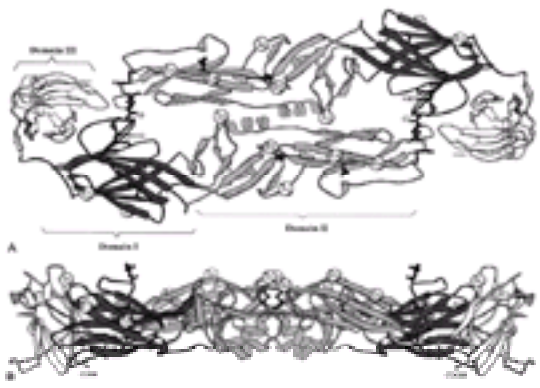

FIG. 3. Ribbon diagram representing the structure of the membrane anchor-free envelope (E) protein dimer isolated from tick-borne encephalitis virus. **A:** Top view. **B:** Side view. The positions of amino acid substitutions in monoclonal antibody escape mutants are indicated by *white circles* and designated according to Mandl and colleagues (448) and Holzmann and associates (311). Disulfide bridges and the single carbohydrate side chain (G) attached to domain I are shown as ball-and-stick representations.

Linear epitopes have been mapped using synthetic peptides and are found in areas of the glycoprotein predicted to be hydrophilic (325); however, the induction of neutralizing antibodies appears to be strongly dependent on the native conformation of protein E (761). Mutations leading to escape from neutralization have been mapped to each of the structural domains shown in Figure 3**A** (102,206,272,311,336,422,448), and the position of such amino acid substitutions in TBE virus mutants are indicated in Figure 3. Consistent with the suggested topology of the dimer on the virion surface, most of these mutations are located on the accessible upper side of the subunit, which also suggests that they indeed form part of the corresponding epitopes. In contrast, two of the mutations in TBE virus (B1 and B4) are not located on top but rather on the side of domain III, and may therefore alter the conformation rather than being part of the epitope itself. Interestingly, one of the mutations (designated O3) does not affect binding of the selecting monoclonal antibody to the virus but nevertheless abolishes its neutralizing activity. The scattered distribution of these neutralization-escape mutations over the entire subunit indicates that antibody binding to any of the structural domains can lead to virus neutralization. Taking into account the known sizes of Fab footprints on protein antigens, which are in the range of 500 to 900 $Å^2$ and involve 15 to 20 contact residues (147,676,752), most of the epitopes are expected to be discontinuous. This is consistent with the denaturation sensitivity of neutralization epitopes (761) and the finding that monoclonal antibodies usually do not react with synthetic peptides unless they recognize an epitope that is present on denatured protein E only (249,311,615).

Antigenic domain B (domain III in Fig. 3**A**) represents an independently folding domain that can be isolated as a trypsin-resistant fragment from purified virions (771) or generated as a recombinant protein by bacterial expression (458). In both cases, however, its reactivity with neutralizing monoclonal antibodies is dependent on the integrity of the single disulfide bridge located within this domain.

Because the dimeric subunit forms part of an as yet undefined lattice on the virion surface, it is likely that certain epitopes are composed of elements from different subunits. Although formal proof is lacking, some neutralization epitopes present on whole virions are lacking on the soluble dimer (290) and on the Triton X-100 solubilized protein. How the two-step process of rearrangement and trimerization of the E protein at low pH for the purpose of fusion alters the antigenic sites available for immune response is not clear (691). The first step is a reversible dissociation of the E dimers, followed by an irreversible formation of trimers involving the a-helical and conserved segments of the stem anchor region of the E protein.

The mechanism of antibody-mediated neutralization remains a matter of speculation. The functional sites of protein E have not yet been mapped, although it has been speculated that domain III may be involved in receptor binding (434) and that the highly conserved sequence from residues 98 to 111 at the tip of one of the domain II loops (see Fig. 3**A**) may be involved in fusion activity (616). Fusion activity requires conformational changes that affect several neutralization epitopes, primarily within the central domain I and domain II (292,616). These changes are apparently associated with a reorganization of the subunit interactions on the virion surface, with trimer contacts being favored in the low pH form, as opposed to dimer contacts in the native form (11). It can be assumed that the interference with these structural rearrangements by antibody binding represents one mechanism leading to virus neutralization.

HI and NT activity are not necessarily linked, and all possible combinations (HI+, NT+; HI–, NT+; HI+, NT) have been observed with monoclonal antibodies (reviewed in 283). Binding of certain monoclonal antibodies is enhanced in the presence of other antibodies (288,296). Such cooperative effects have been demonstrated in binding assays and also in neutralization and passive protection experiments, even with antibodies that are nonfunctional when tested alone.

Monoclonal antibodies have also been identified that do not neutralize the virus but are protective in passive immunization experiments (66,222). Nonneutralizing antibodies may even confer cross-protection between different flaviviruses. For example, a group-reactive nonneutralizing dengue antibody (4G2) provides efficient protection against yellow fever challenge (64). The ability of nonneutralizing antibodies to protect is not associated with complement-dependent lysis of infected cells, but a possible mechanism of protection is suggested by the finding that the protective antibodies inhibited virus replication in a neural cell line, although they showed no neutralization in Vero cells.

The Antigenic Structure of NS1

By the use of polyclonal and monoclonal antibodies, type-specific, subcomplex-specific, complex-specific, and flavivirus–cross-reactive epitopes have been identified (181,381), and a detailed epitope map of the secreted form of

dengue 2 NS1 has been established (295,782). Similar to the situation with protein E, most of the epitopes are conformation-dependent (181). Oligomerization is a general property of flavivirus NS1 proteins. The formation of dimers is favored in certain instances (772) and appears to be necessary for secretion (572).

Although antibodies to NS1 do not react with the virion and exhibit no neutralizing activity, passive transfer can confer protection against dengue and yellow fever virus infection in experimental animals (222,297,652). Enhanced protective efficacy was observed with combinations of monoclonal antibodies (297), suggesting that protection might be due to immunologic recognition and destruction of infected cells expressing NS1 (657). This phenomenon appears to be dependent on the Fc portion of antibodies (656) and could be due to complement-mediated cytotoxicity. However, other mechanisms may contribute as well because protection has also been observed in the absence of complement fixation (297).

Because the phenomenon of ADE of infection by antivirion antibodies has been implicated in the development of DHF/DSS, NS1 has been evaluated as a candidate vaccine for dengue and other flaviviruses (66,783,788). Active immunization experiments using NS1 purified from infected cells or recombinant NS1 demonstrated the induction of a protective immune response in experimental animals against homologous challenge with dengue, yellow fever, or TBE virus (331,652,653). The specific immunogenicity apparently depends on the physical structure of the NS1 preparation. Dimers were superior to monomers (181), and higher protection rates were observed with the soluble NS1 compared with its membrane-associated form.

Specificity and Targets for Cellular Immune Responses

The specificity of T-cell responses to flaviviruses in both the human and mouse systems has been most extensively studied with members of the dengue serocomplex and the JE serocomplex (WN, Kunjin, MVE) (301,398,734). In the course of dengue virus infection of humans, both CD4+, CD8– and CD8+, CD4– T-lymphocyte responses have been detected and characterized. In bulk cultures of CD4+ lymphocytes, as well as with CD4+ T-cell clones obtained from a dengue virus–infected individual, different specific cross-reactivity patterns with other dengue viruses, WN, and yellow fever virus were observed (392,792). Interestingly, these CD4+, CD8– T-cell clones were cytotoxic and exhibited class II major histocompatibility complex (MHC)-restricted cytotoxic activity against infected lymphoblastoid cell lines.

Similar results were also obtained with CD8+ T lymphocytes from infected humans and mice. Bulk responses and those of individual T-cell clones were cross-reactive with other dengue serotypes (82,227,630), supporting the concept put forward by Kurane and Ennis (398) that the activation of memory T cells during secondary infections with a heterologous serotype may contribute to the development of DHF/DSS (see later). In this context, it is of interest to note that the induction of cross-reactive T cells appears to differ in individuals with different genetic backgrounds. A predominantly type-specific CD4+ T-lymphocyte response was observed in an individual vaccinated with an experimental live-attenuated dengue virus type 1 vaccine (228), and the extent to which WN-immune CD8+ cells and CD4+ T cells from mice recognized Kunjin virus–encoded determinants varied considerably between mice of different MHC haplotypes (302,376).

Protein targets for T-cell responses have been identified (6,363). In the dengue virus system, NS3 appears to contain multiple (at least six) dominant epitopes for CD4+ and CD8+ T lymphocytes of both species (reviewed in 398), but T-cell epitopes were also recognized on E and NS1. Epitopes on NS3 have serotype, subgroup, and flavivirus group specificities (391,683). One epitope recognized by a dengue-specific human CD4+ T-cell clone was mapped to a peptide including amino acids 255 to 264 of NS3, which is conserved among all four dengue types (393).

NS3, NS4A, and NS4B are predominant targets for class I MHC-restricted anti-Kunjin, -WN, and -MVE responses in mice (302,431); whereas class II MHC-restricted responses to WN and Kunjin virus were predominantly directed against determinants on structural proteins or NS1 (376). In any case, a limited number of T-cell determinants appears to be recognized by a particular individual, and variation exists between different haplotypes (390,430).

Potential T-cell epitopes in protein E of MVE, JE, WN, and dengue virus were identified by the use of computer predictions and by analyzing *in vitro* T-cell proliferation responses against synthetic peptides (399,408,615). Functional identification of T-helper cell epitopes in protein E was achieved by measuring the B-cell response after immunization with synthetic peptides derived from MVE virus (465,617) and dengue 2 virus (618). T-cell help and enhanced antibody response was dependent on the linkage between the corresponding peptides, and the most efficient T-cell–B-cell epitope interaction occurred when the peptides were colinearly synthesized.

Antibody-Dependent Enhancement

ADE of flavivirus replication in Fc-receptor–bearing peripheral blood monocytes and macrophage-like cell lines has been demonstrated *in vitro* with a number of flaviviruses, including dengue, yellow fever, Wesselsbron, WN, and TBE viruses (260). Increased adsorption of virus particles (751) to host cell plasma membrane (mediated by subneutralizing antibodies), as well as increased efficiency of virion internalization, has been shown to increase viral replication fivefold to sixfold in monocyte- or macrophage-like cells (216,217).

ADE occurs through FcgRI and FcgRII (368,427,648), but a second type of enhancement dependent on the C3 complement receptor has also been described (98). Attempts with monoclonal antibodies to elucidate whether specific epitopes are responsible for ADE have revealed that (a) there is no correlation between serologic specificity and ADE, that is, it can be mediated by broadly cross-reactive as well as type- and even subtype-specific antibodies; and (b) antibodies with different functional activities (i.e., neutralizing, HI, or nonfunctional antibodies) can mediate ADE. Studies with a number of dengue 2 and dengue 4 strains and a panel of monoclonal antibodies have revealed significant heterogeneity, and strain-specific patterns of ADE reactivities have been discerned (262,511). The possible role of ADE in the immunopathogenesis of DHF is discussed later.

Molecular Basis of Virulence

Strain-specific differences in neurovirulence or neuroinvasiveness have been observed with several flaviviruses (38,39,158,314,315,500). Attenuation by serial passaging formed the basis for the development of the yellow fever 17D vaccine (708) and candidate vaccine strains for JE (534,784) and dengue virus (780). Attenuation during serial passage may occur quite rapidly. For example, mosquito-borne flaviviruses become rapidly attenuated after only six passages in HeLa cells (40,173,281). These observations are explained in part by the high rate of mutation of RNA viruses (40,308) and fixation of specific mutations during passage in a specific and homogeneous cell type.

Nucleotide sequencing of pairs of parental and attenuated vaccine derivatives has provided some clues as to the molecular basis of virulence, but the large number of mutations and their localization in many parts of the genome complicate interpretation of these comparative data (59,254,410,534,600). The number of nucleotide changes separating parental and vaccine strains is 67 for yellow fever virus (see later); 53 for dengue type 2 virus (59); and 45 for JE virus (534). In the case of yellow fever, although 67 nucleotide and 31 amino acid differences distributed across the genome were originally noted between 17D-204 vaccine and the parental Asibi virus (254), subsequent analyses of other vaccine strains derived from the 17D lineage and additional wild-type yellow fever viruses have significantly reduced the mutations that may explain attenuation (168a,333). Sequencing of the vaccine substrains 17D-204, 17DD, and 17D-213 and comparison with Asibi showed that only 50 nucleotide changes and 13 nonconservative amino acid substitutions were specific to the vaccine strains, 5 of which occur in the E gene. Because the 5 changes in the E gene occur at sites (amino acids 52, 173, 200, 305, and 380) that are conserved in virulent yellow fever viruses from both Africa (333) and South America (34) isolated many years apart, these mutations are likely to be implicated in attenuation.

The location of these mutations with respect to functional domains of the E gene lend further support to this conclusion (compare Fig. 3**A**). Two of the mutated amino acids (at positions 52 and 200) are present in the fusion sequence in domain II (448). Two changes (at amino acids 305 and 380) are present in domain III, and one (at amino acid 173) in domain I of the E protein. The mutations at positions 173 and 380 are very close to neutralization or virulence determinants mapped by monoclonal antibody escape mutants of TBE virus (309,448). Studies of envelope proteins of yellow fever viruses with monoclonal antibodies supports the notion that antigenic changes in the E protein are implicated in attenuation or virulence (40). In one study, the loss of a substrain-specific epitope, recognized by a monoclonal antibody, resulted in dramatic changes in neurovirulence ranging from avirulence to increased virulence (634,635). The role of protein E specifically in neurovirulence was further supported by studies with mouse and monkey brain tissue. In these tests, two to three mutations in the E protein altered viral ability to bind to monkey brain tissue or markedly enhanced neurovirulence (530,647). In the case of the NS1 gene, a 17D-specific mutation at the N-terminus of NS1 is similar to a change observed between parental and vaccine strains of dengue 2 virus (59). The 17D-specific alteration in NS3 yields a nonconservative amino acid change (D®E) in the C-terminal portion of the protein involved in linking the presumed helicase and RNA triphosphatase functions (762). In summary, a strong rationale exists implicating one or more of seven nonconservative changes in E, NS1, or NS3 in attenuation of yellow fever vaccine, a hypothesis that can now be empirically tested using site-specific mutations of an infectious cyclic DNA (cDNA) clone (599).

Yellow fever virus exhibits two distinct virulence factors reflecting its capability to induce encephalitis (neurotropism) and hepatitis (viscerotropism). The attenuated 17D vaccine virus has lost its capacity to cause hepatitis while retaining a reduced degree of neurotropism, particularly for the immature brain. A single fatal case of human encephalitis due to 17D virus has been reported (21), and the virus recovered from the brain was subjected to careful scrutiny (334). A monoclonal antibody specific for wild-type yellow fever virus recognized the case strain but not the parental vaccine (17D-204 substrain) and was considered a mutant at this epitope. The case strain also differed phenotypically in being neuroinvasive and neurovirulent for mice inoculated intranasally and appeared to be neurovirulent for monkeys inoculated intracerebrally. Sequencing of the E glycoprotein and comparison with other substrains of 17D vaccines revealed a single amino acid change (K®Q) at position 303 that could be correlated with the increased neurovirulence of the virus recovered from brain tissue. Presumably, this mutation arose during replication of the vaccine in the human host. Interestingly, this mutation is spatially close to two other mutations distinguishing wild-type from vaccine virus (including the nonconservative change at amino acid 305), suggesting that this region of domain III may represent an important locus defining neurovirulence.

Other data on the localization of virulence determinants have come from characterization of monoclonal antibody escape mutants (102,309,336,432), host range mutants (434), and virulence revertants (333) and by the engineering of infectious cDNA clones derived from dengue 4 virus and JE virus (702). Single amino acid substitutions in the E protein can have dramatic effects on virulence. A chimeric dengue 4 virus containing the envelope proteins from TBE virus exhibited the neurovirulence phenotype of TBE virus (558). In contrast to TBE virus, however, this chimera was not neuroinvasive, indicating that other regions in the genome contribute to the virulence properties of this virus.

Specific virulence mutations in protein E map to distinct structural elements (compare Fig. 3**A**). Domain III (C-terminal in the crystallized membrane anchor-free fragment), is the element that links the central domain I with the loops of domain II, the tip of domain II, and the carbohydrate side chain. The importance of domain III was directly demonstrated by the analysis of single amino acid mutants of MVE, TBE, louping ill, and JE viruses (102,309,336,434). Amino acid substitutions in the E protein of the yellow fever 17D vaccine strains also cluster within this relatively small domain (168a,254). Because this domain contains an RGD sequence in several mosquito-borne flaviviruses, it has been proposed to form part of the receptor-binding site, and this could explain its role in virulence (434). A mutation in the RGD sequence of MVE virus led to loss of virulence for mice (435).

Specific mutations within the element linking the central domain I with the domain II loops influence virulence with TBE (310), JE (102,272), and MVE viruses. The latter case is especially interesting since the attenuating mutation also lowered the pH threshold and the extent of fusion, suggesting a relationship between fusion activity and virulence (479a).

Using the TBE–dengue 4 virus chimera, Pletnev and associates (559) engineered specific mutations in the conserved

sequence element at the tip of domain II, which led to an increase in neurovirulence. This sequence interacts with domain III of the other monomer and thus forms an important contact point within the dimeric subunit. These interactions may also involve the juxtaposed carbohydrate side chain, the removal of which can reduce (in the case of the TBE–dengue 4 chimera) or enhance (in the case of a dengue 4–dengue 4 chimera) neurovirulence (347). As demonstrated with the TBE–dengue 4 chimera (559), such effects of carbohydrate side chains on virulence are not restricted to protein E but rather apply to the prM protein and NS1 as well. Also, a change in the prM cleavage site resulted in decreased neurovirulence of this chimera, consistent with the importance of prM cleavage to yield fully infectious virus (292,760). The role of the E protein in neurovirulence and neuroinvasiveness has been compared for several of the flaviviruses. The existing data indicate that determinants for both map to identical regions of the E protein, which include the lateral surface of domain III and the base of domain II (481). The attenuation of some of these variants has been associated with changes in binding to cell membrane proteins or changes in the pH-dependent fusion activity.

The development of stable genomic-length cDNA clones of various flaviviruses has accelerated the understanding of virulence factors. A good example of this is a dengue 2 virus that was stably cloned into *Escherichia coli* (236). Once the genome of the virus is stably cloned, infectious RNA can be generated. Although generating infectious clones is like a useful tool to elucidate the impact of mutations, it is not an easy task, as shown by the extensive work needed to generate an infectious Langat TBE clone (95). With a stable cDNA clone, it will possibly engineer mutations, so that the effect of specific alterations can clearly be determined (446).

Other regions of the flavivirus genome have not yet been precisely mapped with respect to virulence determinants, but much more information is expected to become available soon by the further extensive application of the infectious clone technology.

Virus–Cell Interactions

Host cell macromolecular synthesis is not markedly decreased until late in flavivirus infection, when cytopathic effects (CPEs) appear. As discussed further later, many arthropod and vertebrate cultured cells do not exhibit CPEs. In other cell–virus pairings, infection progresses to CPEs within an interval as short as 18 hours or as long as 5 to 7 days. A major change in infected cells is proliferation and hypertrophy of rough endoplasmic reticular membranes within which virus particles accumulate. At the ultramicroscopic level, cellular pathologic changes include mitochondrial damage, fragmentation of reticular membranes, formation of distended vacuoles and inclusion bodies, increase in lysosomal bodies, and rarefaction of cytoplasm (517). Activities of lysosomal enzymes increase in infected tissues. At the microscopic level, susceptible vertebrate cells, such a HeLa, BHK-21, porcine kidney (PS), and primary chick or duck embryo, display cell rounding, shrinkage, pyknosis of nuclei, and dislodgment from the growth surface (Fig. 4).

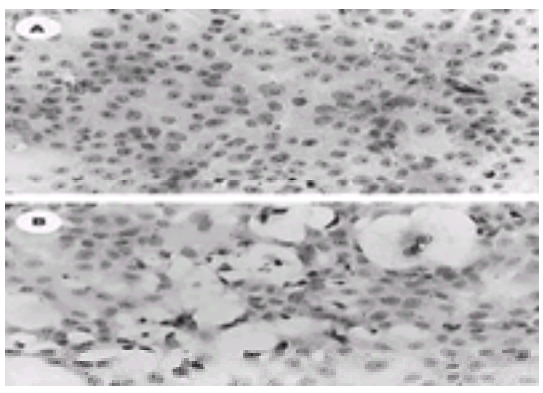

FIG. 4. Cytopathic effects of St. Louis encephalitis virus in Vero cell culture. **A:** Normal culture (Mayer's hematoxylin stain, x220). **B:** Culture after 5 days' incubation, showing focal cytopathic effects, shrinkage, and rounding of cells, pyknotic nuclei, and appearance of hole in the cell monolayer.

Cell fusion and syncytium formation (polykaryocytosis) have been observed in mammalian and arthropod cells. Fusion and infectivity are inhibitable with ammonium chloride, typical of viruses that enter cells by receptor-mediated endocytosis and low-pH–mediated membrane fusion in lysosomes. Fusion from without is demonstrable in mosquito cells after exposure of cell-bound virus to low pH (250,586).

In general, mosquito-borne viruses replicate in mosquito cell culture, and a few (such as SLE and WN, which have been isolated from ticks in nature) will also grow in tick cell cultures. Tick-borne flaviviruses replicate in tick cell cultures, but not consistently in mosquito cells. The antigenic reactivity of some flaviviruses is altered by replication in mosquito cells. For example, dengue and Kunjin viruses lose hemagglutinating activity on passage in *Aedes albopictus* cells (527).

Infected cells stained by the fluorescent antibody technique show viral antigen expression in cytoplasm, typically with a perinuclear concentration of reactivity.

Persistent noncytopathic infections by flaviviruses have been induced in a variety of arthropod and vertebrate cell lines. Depending on the virus–cell pairing, such infections can involve few cells in the culture (658) or nearly 100% of the cells (76). Progeny virus from infected cultures often exhibits altered antigenic reactivity, reduced virulence, temperature sensitivity, or other signs of mutation. The generation of defective interfering particles appears to be an important mechanism underlying persistence (566,658), and interferon production does not play an important role. Expression fo the premembrane protein in mosquito cells renders them resistant to dengue type 2 (203).

Propagation and Assay in Cell Culture

Flaviviruses produce CPEs and plaque formation in a variety of primary and continuous cell cultures derived from human, monkey, rodent, swine, and avian tissues (reviewed in 344). Cell cultures of reptilian, amphibian, and arthropod origin also support replication with or without CPE or plaques. Virus yields and titers, grade of CPE, plaque size and quality, and rate of growth vary with the specific virus and host cell (see discussion of individual viruses). In general, the BHK-21 (baby hamster kidney), SW-13 (human adrenal carcinoma), PS, *Aedes* species mosquito cells, and primary chick and duck embryo cells produce the highest virus yields, in the range of 10^{9}/ml to 10^{10}/ml. In comparison with alphaviruses, the latent period of flavivirus growth is relatively long, and growth is slow. At high multiplicity of infection in BHK-21 cells, SLE virus has a latent period of 11 hours and reaches peak titer at 28 hours. Plaques appear after 4 to 6 days; double overlay procedures are often required for optimal plaque assays in mammalian cell cultures. Addition of neutral red to agar overlay may enhance plaque size. Assay of dengue virus infectivity requires special techniques (see later).

Infection in Experimental Animals: Host Range

The susceptibility of experimental animals and host range vary widely and are considered in the discussion of individual viruses. In general, intrathoracic or intracerebral inoculation of live mosquito adults or larvae provides the most sensitive system for assay of mosquito-borne flaviviruses.

EVOLUTION

The evolution of the flaviviruses appears to have been driven in large part by their arthropod vector. Early in the classification of these viruses, it was recognized that the viruses that shared antigenicity also shared class of vector: mosquito, tick, or no vector. When more complete sequence-based phylogenies were generated, viruses with the similar vectors were more closely related (55,380).

One theory of flavivirus evolution is that the two distinct groups of tick- and mosquito-borne viruses evolved from a common ancestor. This would imply that nonvector progenitor viruses individually entered the tick and mosquito transmission cycle. However, some viruses that are mainly transmitted by one vector can still be competently transmitted by another (SLE, WN, and YF have been isolated from ticks). In addition, none of the nonvector flaviviruses can replicate in mosquito cell culture. This casual association of some mosquito-borne viruses may be a leftover trait from a past association the viruses had with ticks before adaptation to the mosquito vectors (380). This information supports another evolutionary path. Flaviviruses could have evolved from nonvector to tick-borne and finally into the mosquito-borne group. Mosquitoes feeding on viremic tick-borne virus hosts would provide the crossover opportunity. This theory is compromised by the phylogenetic placement of the nonvector Aroa, Entebbe bat, Saboya, and Sokuluk viruses (698,699) in the mosquito cluster. This could be partially the result of incomplete field information on these particular viruses.

There appear to be distinct differences between the evolution of the tick- and mosquito-borne viruses. The tick-borne viruses appear to have dispersed west over most of Asia and Europe and perhaps North America, with the ancestral lineage in the eastern portion of their range and the most recent strain populating the western end of the viral range (786). The mosquito-borne viruses show a much more varied and irregular dispersal and evolution. These differences in range are mirrored at the protein sequence level. The amino acid substitution in TBE viruses would usually be between physicochemically similar or related residues. This is contrasted with the mosquito-borne viruses in which the substitutions are much less conservative (786). Furthermore, the rate of amino acid substitution between the tick and mosquito viruses supports the observation of a lower evolutionary rate in the tick-borne viruses. The differences in vector life cycle, years for ticks and weeks for mosquitoes, and the fact that many of the tick-borne viruses can be transmitted vertically and in the absence of a viremic vertebrate host, supports the general idea of tick-borne viruses evolving at a slower rate. Additionally, it has been observed that the rate of mutation for RNA arboviruses overall is lower than other RNA viruses. This constraint has been explained by the virus having to maintain effective replication in the different environments of the vertebrate host and the arthropod vector (307,308).

The potential rapid rate of evolution is a direct concern to contemporary epidemiology of the flaviviruses. As the mosquito-borne viruses have expanded in range, their diversity has steadily increased (603,786). An expanding and evolving viral population is largely a mosquito-borne virus concern. For many of the mosquito-borne viruses, humans are a relevant host, part of the transmission cycle; therefore, that as the human population expands, the viral population will have a larger range to infect and evolve within. In contrast, for the tick-borne viruses, humans are generally regarded as a dead-end host; hence, the expansion of human populations are predicted to have a less significant effect. An expansion of the tick-borne viruses vertebrate hosts would probably have a more significant impact on their evolution than expansion of the human population. Perhaps it should be anticipated that, year after year, in hundreds of millions of mosquito-borne human flavivirus infections, there may appear a virus with altered tropisms that will develop into a significant public health concern.

PATHOGENESIS AND PATHOLOGY

The greatest body of information about flavivirus pathogenesis is derived from experiments on mice and other laboratory rodents. These animals provide a reasonably good model of flavivirus encephalitis but not of other syndromes associated with human flavivirus infection (i.e., fever, arthralgia, rash, and hemorrhagic fever). Viruses that produce these syndromes in humans, including dengue and yellow fever, cause encephalitic infections in laboratory rodents. The pathogenesis of dengue and yellow fever is discussed in their respective sections. The universal neurotropism of flaviviruses in rodents and even in arthropod vectors (in which brain and ganglia are major sites of replication) may reflect evolutionary conservation of viral polypeptide structures involved in receptor interactions and of cell membrane molecules that subserve virus–receptor interactions.

Three patterns of pathogenesis have been described in flaviviral encephalitis (339,497,524): (a) fatal encephalitis,

usually preceded by early viremia and extensive extraneural replication; (b) subclinical encephalitis, usually preceded by low viremia, late establishment of brain infection, and clearance with minimal destructive pathology; and (c) inapparent infection, characterized by trace viremia, limited extraneural replication, and no neuroinvasion.

Virus- and Host-Specified Factors Influencing Pathogenesis

The course and outcome of infection is influenced by both virus- and host-specified factors. High-dose and intracerebral or intranasal routes of virus infection predispose to fatal encephalitis. Virus strains may differ in neuroinvasiveness, neurovirulence, or both.

Among host factors influencing pathogenesis, the most important are age, sex, genetic susceptibility, and preexisting infection or immunity to heterologous agents. Neonatal animals are more susceptible to lethal encephalitis than older animals. Animals inoculated by the peripheral route are susceptible until 3 to 4 weeks of age, when resistance develops, but they may remain susceptible to lethal encephalitis when inoculated intracerebrally. Immature neurons are more susceptible to infection than mature neurons (538). Parallels are seen in some human flavivirus infections. For example, young infants are more susceptible to encephalitis after yellow fever vaccination. In the case of some flaviviruses (e.g., SLE), however, susceptibility to encephalitis increases with advancing age, with the elderly being most severely affected. The mechanisms underlying the increasing susceptibility with age are not known. Physiologic factors that lead to transient immunosuppression may also be responsible for increased susceptibility to flavivirus encephalitis. For example, mice exposed to cold or isolation stress and challenged with WN virus demonstrated higher virus replication in peripheral tissues and brain and higher mortality rates (44).

Sexually mature female mice demonstrate increased resistance to some flavivirus infections (15). Sex differences in susceptibility of humans (as opposed to exposure to infected vectors) have not been demonstrated, except possibly in the case of DHF, which preferentially affects girls.

Genetic determinants play a central role in the pathogenesis of flavivirus infections (642). Studies by a number of workers (487,636,758) demonstrated genetic resistance of nonimmune mice to flavivirus infection in a number of inbred mouse strains and showed that resistance was determined by a single autosomal dominant allele, currently designated as Flvr. The resistance allele was incorporated into susceptible C3H/He inbred mice to yield the resistant strain C3H/RV (C3H.PRI-Flvr). WN virus yields in brains of resistant C3H.PRI-Flvr mice were significantly lower than in susceptible mice, but there were no differences in interferon or humoral antibody responsiveness between the two mouse strains (219). *In vitro* studies with cells derived from the two mouse strains indicated that (a) macrophages from resistant mice do not support flavivirus replication as well as macrophages from the susceptible strain, and (b) the lower virus yields observed in cells of resistant mice were due to greater production of defective interfering virus particles (143). In the case of Banzi virus infection of C3H.PRI-Flvr mice, genetic resistance did not appear to depend on lack of permissiveness of tissues to virus replication (329), but instead had an immunologic basis (54,330). Virologic mechanisms may also operate in determining resistance in this model, however. Increased interfering virus found in lymphoid tissues of resistant mice may contribute to survival (673).

Studies in inbred mice derived from single subspecies of wild *Mus musculus* suggested that flavivirus resistance genes are carried by many wild mouse strains (735,736). In addition to Flvr, a second autosomal dominant allele at the Flv locus (designated Flvmr) was found to determine resistance. Although not fully mapped, the Flv locus is believed to reside on chromosome 5 (643). Haplotype restriction may also influence the immune response of the host to flaviviruses. Inbred mouse strains of the H-2d, H-2k, and H-2b haplotypes differed with respect to neutralizing antibody response to JE vaccine virus strains (770).

Concurrent infections with unrelated agents may enhance flavivirus neuroinvasion (reviewed in (497), presumably by disturbing the blood–brain barrier. This mechanism has been reported in mice doubly infected with JE, herpesvirus, *Trichinella* species, and visceral larva migrans; a similar phenomenon has been reported to occur in humans with neurocysticercosis (145,663). Impairment of the blood–brain barrier by needle puncture, hypercarbia, microwave radiation, or administration of bacterial lipopolysaccharide or sodium dodecylsulfate renders mice susceptible to lethal encephalitis by virus strains that are inherently neurovirulent but not neuroinvasive (358,406,441).

Extraneural Infection and Routes of Neuroinvasion

A general scheme for the dissemination of flaviviruses in the host is shown in Figure 5. Recent studies with dengue virus infection of humans show that skin Langerhans cells are primary targets (779a). After inoculation into the skin, the virus replicates in local tissues and regional lymph nodes. Virus is then carried through lymphatics to the thoracic duct and into the bloodstream (445). This primary viremia seeds extraneural tissues, which, in turn, support further viral replication and serve as a source for release of virus into the circulation.

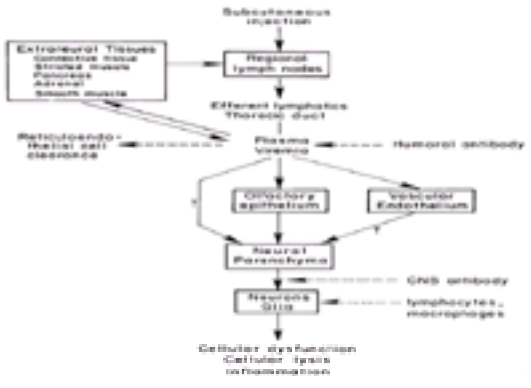

FIG. 5. General scheme of the sequential development of flavivirus infection. *Boxes* indicate sites of virus replication and

dashed arrows show immune defense mechanisms. (Modified from ref. 524, with permission.)

The viremia level is modulated by the rate of clearance by macrophages, and it is terminated by the appearance of humoral antibodies, usually by about 1 week after infection. Major extraneural sites of flavivirus replication include connective tissue, skeletal muscle and myocardium, smooth muscle, lymphoreticular tissues, and endocrine and exocrine glands. In baby hamsters infected with SLE and Rocio viruses, pancreas and heart were the most severely affected organs (269). Virus particles within secretory granules of exocrine and endocrine areas of the pancreas were released by exocytosis. Myocardial necrosis with productive viral infection of myocytes was a prominent finding. Correlations are possible between this experimental model and pathogenesis in clinical hosts. Infection of goat mammary glands, followed by secretion of virus in goat's milk, is an important mode of spread of TBE viruses. Interstitial myocarditis has been reported in WN and JE virus infections of humans and horses, and pancreatitis has been associated with human WN virus infection.

Investigation of experimental flavivirus encephalitis in mice has demonstrated a relationship between level of viremia, development of brain infection, and multisite appearance of viral antigen in nervous tissue (9), supporting the concept of hematogenous spread to the central nervous system (CNS) (339). As pointed out earlier, artificial disruption of the blood–brain barrier potentiates neuroinvasion and encephalitis. The mechanism by which flavivirus particles cross the blood–brain barrier during natural infection remains uncertain. The ability of these viruses to replicate in vascular endothelial cells suggests that they may grow across capillaries in the brain. However, viral antigen has been found only rarely in endothelial cells of brain capillaries *in vivo,* and flaviviruses did not replicate to high titer in brain endothelium cells *in vitro* (170).

The olfactory tract has long been recognized as (a) an alternative pathway to the CNS, and (b) an important mode of spread after aerosol exposure. Intranasal inoculation of flaviviruses may result in lethal encephalitis, presumably by direct infection of olfactory neurons and spread through the olfactory tract to the brain, whereas peripheral inoculation of the same virus strains does not result in neuroinvasion. However, olfactory neurons may also provide a route for CNS infection after peripheral virus infection. In an experimental model, mice and hamsters inoculated by the peripheral route with SLE virus developed low-level or undetectable viremias similar to those occurring in clinical hosts. This resulted in early infection of olfactory neurons (which are unprotected by the blood–brain barrier) and subsequent axonal transport of virions to the olfactory lobe of the brain (501). It is not known whether this pathway operates in humans, but a postmortem study of JE patients indicated a hematogenous, rather than an olfactory, route of neuroinvasion (340). Once in the CNS, virus spreads rapidly.

Neuronal centers vary in susceptibility. In the mouse, the hippocampal formation is particularly sensitive, whereas in monkeys and humans, the thalamus, substantia nigra, and cerebellum are most vulnerable (523,524).

Pathologic Changes

Pathologic changes observed in humans and experimental animals with flaviviral encephalitis include (a) neuronal and glial damage caused directly by viral injury and characterized by central chromatolysis, cytoplasmic eosinophilia and cell shrinkage, and neuronophagia; (b) inflammation, including perivascular infiltration of small lymphocytes, plasma cells, and macrophages (Fig. 6); (c) cellular nodule formation composed of activated microglia and mononuclear cells (Fig. 7); and (d) cerebral interstitial edema. In monkeys and hamsters infected with tick-borne viruses, astrocyte proliferation and hypertrophy appear as a late phenomenon (794). At the ultrastructural level, infection of neurons is characterized by marked proliferation and hypertrophy of rough endoplasmic reticulum (RER), accumulation of vesicular structures derived from the RER and containing virus particles, and progressive degeneration of the RER and Golgi apparatus (270). Neuronal destruction is infrequent, however, suggesting that dysfunction rather than cell death is responsible for lethal outcome of the host (271).

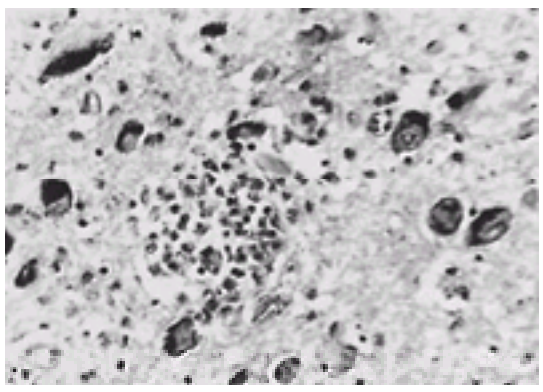

FIG. 7. Glial nodule in the substantia nigra from a fatal human case of St. Louis encephalitis (hematoxylin and eosin, x400). (Courtesy of M. G. Reyes.)

Residual neurologic deficits, electroencephalogram (EEG) changes, and psychiatric disturbances frequently persist after recovery from acute encephalitis. Pathologic lesions in cases with neurologic residua 12 to 67 years after recovery from acute JE were characterized by small areas of rarification (neuronal loss) surrounded by dense microglial scarring and were distributed in areas typically affected during the acute phase. In experimental animals, changes in behavior and learning ability have been documented (see next section).

Persistent and Congenital Infection

Neural tissue is a preferred site for *in vivo* persistence of latent infections with many viruses, and flaviviruses may be no exception. Studies with alphaviruses indicate that antibody may mediate viral clearance from neurons that lack surface class I MHC determinants for recognition by cytototoxic T lymphocytes (417,418). The mechanism of antibody clearance appears to involve intracellular uptake of antibody and restriction of gene expression. Passive administration of antibody to mice with established flavivirus (WN virus) brain infection prevented lethal infection (524). However, the role of antibodies in viral clearance as opposed to a mechanism involving cell killing by Tc cells suggests a mechanism for persistence of viral genomes in neural cells. Because abortive CNS infections with flaviviruses occur in humans and animals in nature, persistent infections may be established in neuronal tissue. In children infected with JE virus, recurrent neurologic disease has been observed (664), suggesting reactivation of latent neural infection. Chronic progressive human encephalitis and seizure disorders (Kozhevnikov's epilepsy) occurring years after infection with TBE virus has been reported (539). Yellow fever 17D virus has been recovered from the brains of monkeys more than 5 months after intracerebral inoculation. Hamsters and monkeys infected with tick-borne flaviviruses have developed progressive neurologic degeneration, with astrocytic proliferation, perivascular granulomas, and neuronal vacuolation (793,794). Chronic infection of neural or lymphoreticular tissues has also been reported with TBE and WN viruses in monkeys and with Kyasanur forest disease and SLE viruses in mice (reviewed in 497). In these models, some persistently infected animals either failed to develop neutralizing antibodies or reverted to seronegative, suggesting that productive viral replication occurred when immune responses were impaired or suppressed. Similarly, persistent infections with SLE, TBE, and JE viruses have been documented in hibernating bats and rodents, with reactivation following arousal, suggesting that immune suppression during hibernation may be responsible for persistence.

Virus isolates from persistently infected animals have exhibited phenotypic changes such as loss of hemagglutinin, reduced neurovirulence, and temperature sensitivity similar to that associated with persistent infection of cell cultures, indicating that persistent infections may be associated with attenuation of the virus phenotype, generation of defective interfering particles, or alteration of viral antigens to escape immune surveillance.

In Asia, JE virus is an important cause of epizootic abortion and stillbirth in swine and has been isolated from brain, liver, and placental tissues of these animals. Mice infected with JE virus show a high incidence of stillbirth and congenital malformations when inoculated 9 to 16 days before parturition. Mice can transmit JE virus to offspring of consecutive pregnancies (115), and immune suppression during pregnancy has been postulated to play a role in establishment of persistent maternal infection (467,468). Splenic T lymphocytes have been shown to harbor the virus in latently infected mice (469). Evidence for latent JE virus infection in humans is reviewed later in the section, Japanese Encephalitis Virus.

Immune Response in Protection, Recovery, and Pathogenesis of Encephalitis

Both humoral antibody and cellular immune responses have been implicated in protection and recovery from infection. Passive transfer of monoclonal antibodies against M and E proteins (284,346,458) as well as antibodies against the NS1 nonstructural protein (652,653,655) protects mice against flavivirus encephalitis. The mechanism of protection of antibodies to NS1, which is expressed on the surface of infected cells, appears to involve Fc-dependent effector functions, but the roles of complement-mediated cytolysis and ADCC *in vivo* are uncertain (656). As mentioned previously, passively transferred antibodies can abort experimental flavivirus encephalitis even when given after neuroinvasion, whereas transfer of immune spleen cells may not be effective at this stage. In severe or lethal infections characterized by high-titer viral growth and rapid accumulation of antigen in the critical target tissues, inflammatory responses may enhance lesions and accelerate death. Characterization of the inflammatory cell populations in brain tissue has shown that both natural killer (NK) cells and Tc cells are responsible for lysis of infected neurons and Tc cells for lysis of infected astrocytes (428,429). Infection of these target cells in the brain appears to result in an interferon-induced increase in class I and II MHC antigen expression, leading to increased recognition by Tc cells. In addition to cell-mediated clearance, antibodies have been implicated in early death in mice infected with yellow fever virus, an effect attributed to complement-mediated cytolysis of infected cells (220,221).

ARTHROPOD INFECTION

The dependency of certain arthropods upon blood feeding for energy requirements and egg development provides a mechanism for salivary transmission of flaviviruses and many other infectious agents. Although mechanical transmission from host to host by simple transfer of virus on the mouthparts of mosquitoes during the process of interrupted feeding may occur occasionally, biologic transmission is the rule. Biologic transmission of flaviviruses by arthropods depends on the following:

1. Ingestion of a blood meal containing virus and infection of epithelial cells lining the mesenteron (midgut)
2. Escape of virus from the midgut epithelium into the hemocele
3. Infection of the salivary gland
4. Secretion of virus in saliva during refeeding on a susceptible vertebrate host (Fig. 8)

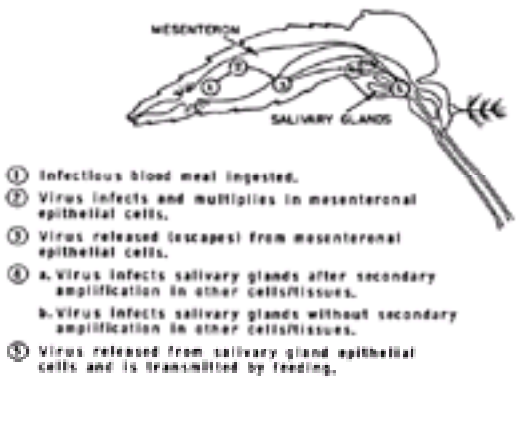

FIG. 8. Steps required for flaviviruses infection and transmission by an arthropod. (From ref. 268, with permission.)

Many flaviviruses exhibit a high degree of specificity in their ability to infect and be transmitted by individual insect or tick species (or even strains of individual species). Vector competence is under genetic control, with the susceptibility of the midgut epithelium being the primary determinant (268,727). In a susceptible arthropod, a sufficient concentration of virus must be ingested to exceed the mesenteronal infection threshold. The time interval between the ingestion of an infectious blood meal and the salivary secretion of virus (extrinsic incubation period) must not exceed the life span of the arthropod. Increased temperature shortens the extrinsic incubation period and may significantly increase the rate of virus transmission in nature. Other extrinsic factors affecting flavivirus transmission by arthropod vectors include (a) mosquito larval crowding and nutritional deprivation, which appear to increase transmission by adult vectors; (b) rearing temperature (349); and (c) co-infection with other infectious agents such as microfilaria, which may induce lesions in the midgut epithelial barrier and thereby facilitate viral dissemination to the hemocoel (728); or natural disasters (521).

Transfer of virus in mosquito saliva occurs during the process of probing host tissues with the piercing mouthparts in an attempt to cannulate a small vessel. The probing process often results in microhematoma formation, which facilitates location and cannulation of the vessel (177). Salivary enzymes play an important role in feeding, particularly apyrase, which prevents ADP-dependent platelet aggregation and coagulation (455). Salivary virus is deposited principally in the extravascular tissues of the host during probing, and saliva that is injected intravascularly is rapidly reingested by the mosquito during blood feeding (729,730). This results in virus replication at the site of inoculation and relatively slow spread of initial infection through lymphatic channels to regional lymph nodes, rather than a rapid viremic dissemination of the inoculum to the bloodstream.

For virus transmission to occur, the vector must find and successfully feed on a vertebrate host. Many factors influence the search for vertebrate hosts, including vector and host behavior and density, chemical signals emitted by the host, and environmental variables (reviewed in 177). By altering vertebrate host behavior, virus infection may itself influence rates of transmission because infected animals may be lethargic and exhibit reduced defense against mosquito and tick bite. This phenomenon has been demonstrated experimentally in the case of SLE virus–infected mice (149), but its relevance under field conditions remains to be demonstrated. Interestingly, the reduced defense against mosquito attack by immature nestling birds appears to be offset by their intrinsically lower attractiveness to blood-seeking mosquitoes (661).

Maintenance of the infection requires that the basic reproductive rate (number of new infections that arise from a single infection) be greater than one; that is, the host infected by one arthropod must serve as the source of infection for more than one new arthropod. Because mosquitoes feed on vertebrate blood for a very brief time, infection requires that the blood meal volume contain a concentration of virus sufficient to establish midgut infection in the vector. Thus, infected vertebrate hosts involved in transmission cycles generally develop viremia titers in excess of 10^5/ml. In contrast to mosquitoes, ticks imbibe blood over a much longer period of time. The requirement for host infection and viremia for virus amplification of tick-borne arboviruses has recently been questioned (402,536) because TBE virus is transmitted efficiently from infected ticks to uninfected ticks cofeeding on a vertebrate host in the absence of detectable viremia. Although the mechanism whereby infection of cofeeding ticks occurs has not been elucidated, it is logical to assume that the virus is blood-borne and below levels detectable by conventional techniques. Because vertebrate hosts are infected by multiple ticks in nature, virus amplification may occur without the requirement for active infection of vertebrate tissues and viremia. A component of tick saliva appears to enhance virus transmission between infected and uninfected ticks, possibly by suppressing early, nonspecific antiviral responses (NK cell activity) in the host (375,401). However, humoral immunity of previously infected vertebrate hosts would limit virus spread by the cofeeding mechanism in nature.

Vertical transmission from female arthropod to her progeny is an important mechanism for overwinter survival of certain mosquito- and tick-borne flaviviruses. Flaviviruses infect the genital tract of female mosquitoes so that the virus may

enter the fully developed egg through the micropyle at the time of fertilization and oviposition (625). As opposed to true transovarial transmission (infection of the egg at the time of development in the ovary), this mechanism allows infection of mature ova during the first ovarian cycle after feeding on a viremic host. Venereal transmission of flaviviruses from male to female mosquitoes has also been demonstrated (626). The mechanism of transovarial transmission of tick-borne flaviviruses remains to be elucidated.

Flaviviruses generally do not damage the vector, and the pathologic changes in the midgut seen in mosquitoes infected with some alphaviruses have not been observed in the case of *Flaviviridae.* In one study, vertical flavivirus infection in *Aedes* species mosquitoes appeared to induce a prolongation of development time from ova to pupa, suggesting a deleterious effect (706). However, no such effect was observed in the case of SLE virus in experimentally inoculated *Aedes* species larvae (731). These results contrast with those observed in the case of alphaviruses, which appear to induce more consistent and severe pathologic effects on mosquito larvae and pupae, possibly explaining the lower efficiency of vertical transmission of alphaviruses than of flaviviruses in their mosquito vectors. There have been conflicting results of studies on the effect that flavivirus infections, specifically dengue, have on the feeding patterns of the common vector *Aedes aegypti.* A study with dengue 2 virus indicated that the only alterations was actually a shorter feeding time, which would not be beneficial to the virus (577). In another study, dengue 3 virus–infected mosquitoes took a significantly longer time to finish their blood meals than did the uninfected mosquitoes, a behavior that could significantly increase the chance of infecting the vertebrate host (556a). The difference in the two studies could result from differences in mosquitoes: the earlier study used mosquitoes that had been colonized for many years and had adapted to feeding on the test animals, whereas the later study used mosquitoes that were between F1 and F3 generations from field-collected mosquitoes.

FLAVIVIRUSES ASSOCIATED PRIMARILY WITH THE ENCEPHALITIS SYNDROME

St. Louis Encephalitis Virus

The history of SLE has been reviewed in detail by Chamberlain (103). The disease was first recognized in 1932, when an outbreak occurred in Paris, Illinois. The following year, there was a large epidemic in St. Louis and Kansas City, Missouri, characterized by CNS infections of variable severity. The causative virus was isolated from human brain tissues inoculated into mice and rhesus monkeys. *Culex pipiens* mosquitoes were suspected to transmit the infection in this outbreak on epidemiologic grounds, but more than 20 years would pass before this species was confirmed as the principal vector in the east-central United States. During the early 1940s, the disease was recognized in the Pacific Coast states, where the virus was isolated from *Culex tarsalis.* A third transmission cycle involving *Culex nigripalpus* mosquitoes was suspected during SLE outbreaks in south Florida between 1959 and 1961, and later confirmed by entomologic studies. Since 1933, there have been numerous outbreaks involving the western United States, Texas, the Ohio-Mississippi Valley, and Florida. The largest epidemic occurred in 1975, with nearly 2,000 recognized cases. Epidemic activity in the subsequent decade is reviewed in reference 504. In the 1980s and 1990s, SLE epidemics occurred in Colorado, California, Florida, Texas, and Arkansas (453,588,723,724).

Infectious Agent

SLE virus is a member of the JE virus antigenic subgroup. Antigenic and structural properties of the virus have been described (344,718), and its nucleotide sequence has been partially elucidated (716). The organization of the genome is similar to all other flaviviruses. As expected, a higher order of sequence homology (about 65%) was found with members of the JE virus antigenic complex than with yellow fever or dengue viruses (about 40%). Cross-protection studies in experimental animals have confirmed the close relationship between SLE and other members of the JE complex, including WN and MVE viruses. However, immunization with dengue virus also confers cross-protection against SLE virus challenge in mice. During an epidemic of SLE in Florida, the incidence of encephalitis was significantly lower in people with prior dengue infection, as determined by the presence of antibodies, than in those lacking dengue immunity (60).

SLE virus produces CPE and plaques in a wide variety of vertebrate cell cultures (reviewed in 344). Mosquito cell cultures (derived from *Aedes, Culex,* or *Toxorhynchites* species) support growth of SLE virus, often with persistent infection and lack of CPE or with syncytium formation (585,586). Interestingly, SLE virus replicates to high titer and causes CPEs in lepidopteran cells (Sf9, *Spodoptera frugiperda*), whereas yellow fever 17D and dengue viruses, alphaviruses, and bunyaviruses do not (787).

Virus strains vary considerably in virulence for mice and may be classified as highly virulent, avirulent, or of intermediate virulence on the basis of the intraperitoneal-to-intracerebral LD_{50} ratio (500). Mouse virulence correlates with pathogenicity for rhesus monkeys inoculated intracerebrally and with the capacity of virus strains to induce viremia in the house sparrow (63). Chickens develop viremia without disease; newly hatched chicks have the highest titers. Young rats inoculated intracerebrally are partially susceptible, and survivors may develop cataracts (266). Guinea pigs, older rats, and rabbits develop antibody but not disease or consistent viremia. The SLE virus infects the chorioallantoic membranes of chick embryos. Horses are frequently infected in nature without known clinical consequences but are susceptible to lethal encephalitis after intracerebral inoculation of the virus.

The SLE virus has been isolated from a variety of wild vertebrate species during field studies, including many species of birds as well as raccoons, opossums, and bats in North America and birds, rodents, nonhuman primates, and the three-toed sloth in tropical America.

Pathogenesis and Pathology

The pathogenesis in experimental animals was described previously. The neuropathology associated with human disease is reviewed by Gardner and Reyes (208). Principal lesions include neuronophagia, cellular nodules, and

perivascular cuffing, most severely affecting substantia nigra, thalamus, and hypothalamus.

Clinical Features

Three clinical syndromes are described: encephalitis, aseptic meningitis, and febrile headache (Table 3). The severity of illness increases with advancing age, and people older than 60 years of age have the highest frequency of encephalitis. The incubation period varies between 4 and 21 days. Onset is characterized by generalized malaise, fever, chilliness, headache, drowsiness, anorexia, nausea, myalgia, and sore throat or cough, followed in 1 to 4 days by the acute or subacute appearance of meningeal and neurologic signs. Early urinary tract symptoms (frequency, urgency, dysuria) occur in nearly one fourth of patients (578). The case fatality rate increases with age, from 2% in young adults to more than 22% in elderly patients. Underlying hypertensive and arteriosclerotic disease, diabetes, and chronic alcoholism predispose to severe infection and fatal outcome. Four of the 41 recognized cases of SLE during an outbreak in Houston, Texas in 1991 were in patients with human immunodeficiency virus (HIV) infection, suggesting that immunosuppression caused by HIV may be a risk factor for expression of symptomatic encephalitis (542).

Encephalitis[a] (including meningoencephalitis and encephalomyelitis)
Acute febrile illness[b]
One or more signs in either of the following categories:
Altered level of consciousness (confusion, disorientation, delirium, lethargy, stupor, coma)
Objective signs of neurologic dysfunction (convulsion, cranial nerve palsy, dysarthria, rigidity, paresis, paralysis, abnormal reflexes, tremor, etc.)
Aseptic meningitis[a]
Acute febrile illness[b]
Signs[c] of meningeal irritation (stiff neck with or without positive Kernig's or Brudzinski's sign)
No objective signs of neurologic dysfunction
Febrile headache[a]
Acute febrile illness
Headache (may also have other systemic symptoms, e.g., nausea or vomiting)
No signs of meningeal irritation or neurologic dysfunction

[a] CSF pleocytosis present in patients with encephalitis and aseptic meningitis; it may also be found in patients with the syndrome of febrile headache.
[b] Oral temperature 100°F, 37.8°C.
From ref. 75, with permission.

TABLE 3. *Clinical syndromes caused by infection with flaviviruses associated with CNS disease*

The cerebrospinal fluid (CSF) shows moderate pleocytosis (£500 cells/mm ^{3}), mainly lymphocytes, although polymorphonuclear cells may predominate early in the infection. The CSF protein may be elevated (usually 45 to 100 mg%, rarely as high as 500 mg%). There are a few reports of hypoglycorrhacia. Hyponatremia and hypo-osmolarity occur in up to one third of the patients as a result of inappropriate secretion of antidiuretic hormone (767). Elevated plasma 17-hydroxycorticosteroids and loss of the normal diurnal pattern of glucocorticoid secretion indicate reaction to stress (169). A disproportionately high cerebral perfusion in relation to metabolic demands has been found, indicating a disturbance in cerebral autoregulation of blood flow, which was unrelated to changes in sensorium of acutely ill patients. Radionuclide brain scans and computed tomography have been normal. The EEG shows diffuse generalized slowing and amorphous generalized delta wave activity (75).

A period of prolonged convalescence occurs in 30% to 50% of cases, characterized by asthenia, irritability, tremulousness, sleeplessness, depression, memory loss, and headaches, lasting up to 3 years. About 20% of these patients have symptoms persisting for longer periods, including gait and speech disturbances, sensorimotor impairment, psychoneurotic complaints, and tremors (187). Old age and severity of acute illness appear to predispose to these sequelae.

Jaundice was reported in two cases of SLE occurring in Brazil (741). Hepatitis has also been a feature of WN virus infections in the tropics, raising the possibility that the clinical spectrum of infection with members of the JE virus complex may be broader than currently appreciated.

Diagnosis

The patient's age, season of the year, place of residence and exposure, and information about the occurrence and serodiagnosis of similar cases in the community are of paramount importance in the differential diagnosis. In the individual case, it is essential to rule out treatable bacterial, mycobacterial, spirochetal, and fungal infections as well as herpes encephalitis. Because SLE often strikes the elderly, it has occasionally been misdiagnosed as stroke.

Virus isolations from serum or CSF are very unusual, and testing is not profitable. In more than half of fatal cases, virus may be recovered by intracerebral inoculation of suckling mice with suspensions of brain tissues; occasional isolates have been made from liver, spleen, lung, and kidney (93). SLE viral antigen has been demonstrated by immunofluorescence (IF) examination of brain frozen sections (597). Flavivirus-like particles have been found by electron microscopy, and SLE antigen has been found by IF in urine sediment (440). Polymerase chain reaction (PCR) assays applied to blood, CSF, or tissue may provide a sensitive approach to early diagnosis in the future.

Specific diagnosis usually relies on serologic tests on appropriately timed acute and convalescent samples. The HI test detects mainly group-reactive antigens and is a useful screening procedure. Antibody titers increase rapidly during the first week after onset. In primary infection, titers to SLE antigen are usually higher than to heterologous antigens. In some areas of the southern United States, cross-reactions due to immunity to dengue virus confuse the diagnosis in older patients. The presence of CF antibody in a single serum sample is presumptive evidence of a recent infection. However, 20% of patients with confirmed SLE virus infections fail to develop detectable CF antibodies (93). Cross-reactions in the CF test are less than by HI. The NT is most specific. Antibodies appear during the first week and persist for many years, usually for a lifetime.

Local production of IgM antibodies in the CNS provides a potential means of rapid and early diagnosis. Demonstration of immunoglobulin M (IgM) antibodies in CSF by enzyme-linked immunosorbent assay (ELISA) is applicable to the diagnosis of SLE as early as 3 to 5 days after onset. The IgM-capture ELISA has replaced classic serologic methods in many laboratories. IgM antibodies in serum appear within the first 4 days after onset, peak at 7 to 14 days, and decline thereafter, generally reaching extinction by 60 days (503). Presence of IgM antibody in a single serum is presumptive evidence of recent infection. However, because IgM antibody may persist for up to a year in up to one fourth of patients, demonstration of a decrease in antibody titer between paired sera is preferable. IgA antibodies parallel those in the IgM class (724).

Treatment

Neither antiviral chemotherapeutic agents nor interferon has been evaluated for therapy of SLE. Treatment is supportive and consists of good medical management and nursing care, especially in the semicomatose and comatose patient.

There have been a number of laboratory accidents in which SLE was contracted through the aerosol route. Recombinant human interferon (IFN) hybrids (IFN-aA/D and IFN-aB/D) was tested to determine whether it could reduce mortality (78). Postexposure prophylaxis was not successful.

Epidemiology

Morbidity and Mortality

The epidemiology of SLE has been reviewed (491,504,588,721). Between 1964 and 1998, there were 4,478 confirmed cases of SLE (Fig. 9). Major outbreaks, which occur every 5 to 15 years, have involved up to 1,815 officially notified cases. Endemic transmission occurs during interepidemic intervals, with small numbers of cases (less than 50 per year). Attack rates in localities affected by epidemics have ranged from 1 to 800 per 100,000 population. The overall case fatality rate is about 7%, but it is significantly influenced by age. The ratio of inapparent to apparent SLE infection varies with age, from 806:1 in children to 85:1 in elderly patients.

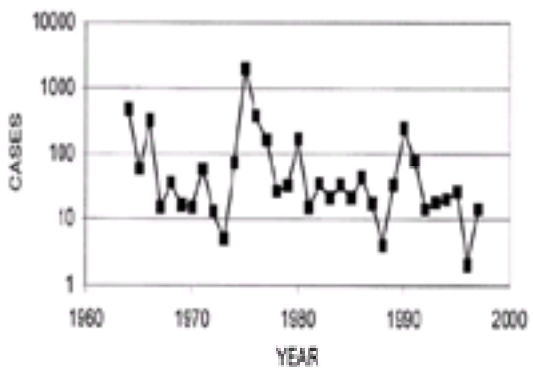

FIG. 9. Annual incidence of St. Louis encephalitis in the United States, 1964 to 1997. (Data from the Centers for Disease Control and Prevention.)

The disease appears in July, with the peak incidence in August and September, but outbreaks may occur later in the year at southern latitudes. SLE predominantly affects the Ohio-Mississippi Valley, eastern Texas, Florida, Kansas, Colorado, and California (Fig. 10). The primary transmission cycle involves wild passeriform and columbiform birds and the *Culex* spp. mosquitoes (Fig. 11). Mammals do not participate in the primary transmission cycle, but occasional isolates have been made from carnivores, and bats have been suggested to play a role in overwinter maintenance. The vectors responsible for virus amplification between birds and transmission from birds to humans vary regionally. In the Ohio-Mississippi basin and eastern Texas, the distribution of cases is urban-suburban, corresponding to high densities of the principal vectors, *Culex pipiens,* and *Culex quinquefasciatus,* which breed in polluted water (especially where poor sanitation exists). In Florida, the tropical mosquito *Culex nigripalpus* is the epidemic vector. In the western states, the principal vector, *Culex tarsalis,* breeds in irrigated or flooded dryland areas; its wide distribution leads to frequent human exposures in rural areas. *C. tarsalis* is also the vector of western equine encephalitis virus, and transmission of this virus and of SLE are often concurrent (588). SLE generally occurs as a rare, sporadic disease in many areas of tropical America (684).

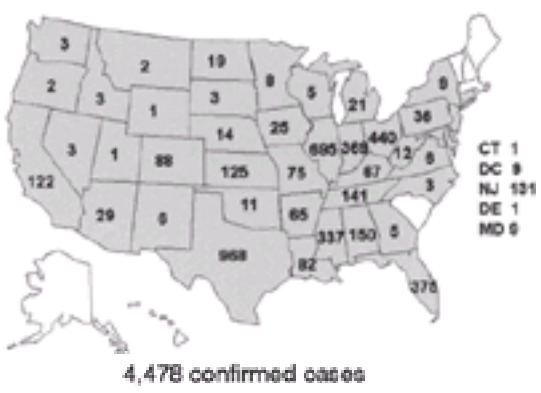

FIG. 10. State-by-state distribution of St. Louis encephalitis cases in the United States, showing cumulative number of

cases for the period 1964 to 1998. (Data from the Centers for Disease Control and Prevention.)

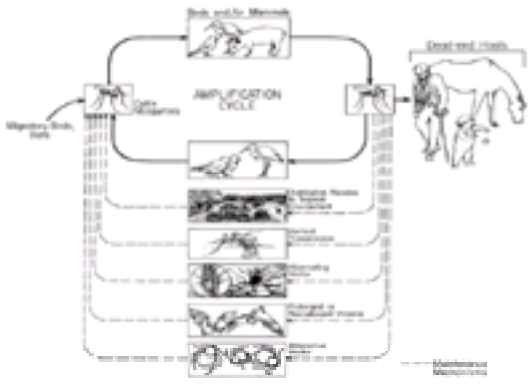

FIG. 11. Generalized transmission cycle of mosquito-borne flaviviruses causing encephalitis, showing summertime amplification and presumed overwintering mechanisms. Humans are dead-end hosts and do not participate in perpetuation of virus transmission. Vector species vary, but culicine mosquitoes are responsible for amplification cycles. Wild birds are the most important viremic hosts for most viruses, but in the case of Japanese encephalitis, pigs play an important role. The pattern shown applies to St. Louis, Japanese, Murray Valley, and Rocio encephalitis viruses as well as West Nile, Kunjin, space Usutu, and possibly other flaviviruses (see Table 1).

In the eastern and central United States, the incidence of disease and the case fatality rate are significantly higher in individuals older than 55 years of age than in younger people. Altered behavioral patterns of the human population (use of air-conditioning and television) may be responsible for decreased exposure to mosquitoes, as well as a decline in infection and immunity, in these endemic areas (200).

In rural areas of the western states, where *C. tarsalis* is the principal vector, cases in males outnumber those in females nearly 2:1 because of the greater exposure of males working outdoors. A predominance of cases in females has been found in the central and eastern states, where exposure to the household mosquito vectors (*C. pipiens, C. quinquefasciatus)* is responsible for infection. *Culex restuans* may be involved in early transmission during the cool spring months, preceding amplification by *C. pipiens* or *C. quinquefasciatus.* Risk factors for infection associated with low socioeconomic status include living in homes near open storm sewers and without screens and air conditioning, and sitting outside in the evening (453,491). In Florida, however, the black population was relatively spared during epidemics between 1959 and 1962; the higher prevalence of antibodies to dengue virus in the elderly black population may have provided a degree of protection (60).

Although historically a disease of rural agricultural communities in the western United States, SLE appeared in epidemic form in Los Angeles in 1984 (588). Subsequent investigations showed that virus transmission occurred principally in residential habitats, parkland, and vegetated undeveloped areas, with *C. tarsalis* as the principal vector (593).

Immunity

Surveys in several urban areas in the eastern United States have shown a 6% incidence of SLE virus infection during epidemics (299). A survey of urban and rural Indiana residents showed an overall seroprevalence of 3.6% and an estimated annual infection rate of 0.32% (233). A serologic survey in Los Angeles County during the outbreak in 1984 indicated evidence of infection in 1.6% of the human population.

Origin and Spread of Epidemics

Evidence indicates that SLE virus is maintained in local winter reservoirs in North America, but the possibility of annual reintroduction from warm regions of year-round transmission by migratory birds or bats cannot be excluded. The virus has been isolated from hibernating adult female *C. pipiens* (33), and there is annual recrudescence of virus activity throughout much of North America. Vertical transmission of virus has been experimentally shown in *C. pipiens, C. quinquefasciatus, C. restuans*, and other species. The virus can also be transmitted venereally in *Culex* species, providing a potential mechanism for virus spread from vertically infected males to female mosquitoes (669). SLE virus has been isolated from the gizzard of a cowbird 38 days after experimental infection (107) and from the blood of bats for prolonged periods (698). Transplacental passage of virus in bats has also been demonstrated. Despite these observations, the mechanism whereby SLE virus is maintained locally over the winter will require further elucidation.

Wild passerine birds serve as the main viremic hosts in these cycles of transmission. A comprehensive review of the avian species involved is given by McLean and Bowen (479). If the rate of virus transmission between birds and mosquitoes is sufficiently high, humans and other mammals (e.g., horses, dogs) may be tangentially infected but do not serve as viremic hosts. Many factors influence the rate of spread of virus (Table 4) and determine the course and extent of epidemics.

Virus	
	Strain differences in infectiousness for vectors and hosts
Vectors

TABLE 4. *Some factors that affect rates of flavivirus transmission in nature*

In some areas in which there is an established enzootic cycle of SLE attempts have been made to determine the extent of transmission to humans and factors that affect the level of transmission (148,371,593). The use of sentinel birds has provided warning of an increase in the amount of SLE in circulation, which increases the potential for viral transmission to humans.

Molecular Epidemiology

SLE virus strains exhibit extensive genomic variability (717). Strains can be classified by their geographic origin; moreover, within a given area, both genetic drift and introduction of other geographic types have been demonstrated over time. Genome analysis thus provides a possible means of determining the origin and source of outbreaks. The presence of three unique genotypes was defined by RNAase T1 oligonucleotide fingerprinting: (I) Florida (associated with the *C. nigripalpus* cycle); (II) the Ohio-Mississippi River basin and eastern Texas (*C. pipiens* or *C. quinquefasciatus*); and (III) the western United States (*C. tarsalis*) suggests that the virus is maintained in each area in local reservoir hosts or vectors. Although relatively few strains from tropical America have been studied, they appear to represent distinct genotypes, again suggesting that the annual recrudescence of SLE virus transmission in North America is not dependent on reintroduction by migratory birds or bats. The segregation of North American virus genotypes by mosquito vector has evolutionary implications, and the selective forces have been partially elucidated (63,500,717). Virus genotype III is transmitted principally by *C. tarsalis,* despite the sympatric distribution of ample populations of *C. quinquefasciatus* in the western United States. This virus genotype is, however, less virulent than genotype II for a variety of hosts, including avian species, which develop relatively low viremias. Since *C. tarsalis* is highly susceptible to oral infection, whereas *C. quinquefasciatus* exhibits lower susceptibility, the former species is capable of amplified transmission of genotype III, whereas the latter is not. In the central United States, virus genotype II elicits high viremias in birds, sufficient to infect readily the more refractory *C. pipiens* and *C. quinquefasciatus.* Because *C. tarsalis* is not prevalent in this region, selective pressure for virulence is maintained on the virus genotype by the restricted vector competence of *C. pipiens* and *C. quinquefasciatus.*

Prevention and Control

Reduction of vector populations remains the most widely used method for prevention and control of SLE epidemics. Surveillance programs focus on early detection of increased levels of virus activity by testing avian sera for antibodies or mosquitoes for virus or viral genome by PCR. Sentinel flocks of chickens followed at frequent intervals for serologic conversions provide a sensitive indicator of SLE virus activity and have accurately predicted impending human epidemics.

Presently, there is no licensed SLE vaccine. However, there have been efforts to develop subunit, recombinant vaccinia, and DNA vaccines against this virus (554,743). One study tested the use of recombinant vaccinia virus expressing PreM/E protein and baculovirus-produced PreM/E proteins. In mice, the recombinant vaccinia virus followed by a boost with the purified baculovirus-produced proteins as 100% effective against viral challenge (743). An SLE DNA vaccine coding for the PreM/E protein has been tested. Although effective in mice, the level of protection varied (60% to 75% survival rate), with DNA dose and did not have the efficacy of the vaccinia-baculo immunization (554).

Japanese Encephalitis Virus

A disease resembling JE was recognized in horses and humans as early as 1871. A severe epidemic occurred in Japan in 1924, and a filterable agent was extracted from human brain and passed to rabbits, but the agent was not identified or characterized. In 1934, Hayashi reproduced the disease in intracerebrally inoculated monkeys. In 1935, the agent was recovered from the brain of a human in Tokyo and was virologically and serologically established as the prototype (Nakayama) strain. The virus was first recovered from brain tissue of a sick horse in 1937. Mosquito transmission was suspected during the early 1930s; in 1938, Mitamura and colleagues reported isolation from *Culex tritaeniorhynchus.* Classic studies in Japan by Scherer and associates (81,645) established that pigs and birds were the principal viremic hosts and that *C. tritaeniorhynchus* was responsible for transmission between these vertebrates and from them to humans.

Infectious Agent

Japanese encephalitis virus is the prototype of the JE antigenic complex (565). Cross-reactions in NT and cross-protection in animals have been demonstrated between JE and other flaviviruses, particularly members of the JE complex. The complete nucleotide sequence of the JE viral genome has been determined (472,701), and JE viral antigens have been expressed in recombinant systems (198,364,459,687). A full-length infectious clone was constructed

by *in vitro* ligation of cDNA fragments (702). Antigenic variation among JE strains has been shown by antibody-absorption HI, agar gel diffusion, CF, kinetic neutralization, antibody-absorption neutralization (537), and monoclonal antibody analysis (357). At least two immunotypes have been repeatedly distinguished: Nakayama (representing the prototype strain isolated from human brain in Japan in 1935) and JaGAr 01 (from *Culex* species mosquitoes, Japan, 1959). Virus strains isolated in 1969 to 1970 were immunologically placed between these types. Geographic variation between JE virus strains has been demonstrated by examination of RNA fingerprints and nucleotide sequencing (see later section, Molecular Approaches).

Considerable variation exists in neurovirulence and peripheral pathogenicity for mice among JE virus strains (314,315). Virus strains recovered from brain tissues of fatal human cases in Thailand differed by RNA fingerprint analysis from contemporary strains from pigs and mosquitoes (89), suggesting that the human isolates represent distinct neuroinvasive phenotypes. Virus strains from Malaysia and Indonesia, where JE occurs as a endemic infection with sporadic cases, are distinguishable by nucleotide analysis (122) from strains elsewhere in Asia, where the disease causes epidemic disease, suggesting that the Indonesian strains may have reduced virulence for humans. A comparison of highly neurovirulent and neuroinvasive JE strains and two strains that were neurovirulent and not neuroinvasive suggested that only a few differences distinguished the phenotypes. The different strains had 99% amino acid identity (529). The amino acid changes were centered on the E protein, which is suggestive that the envelope protein is responsible for the neuroinvasive qualities.

The virus replicates in a wide variety of primary and continuous cell cultures of hamster, porcine, chicken, monkey, and mosquito origin. Vero and LLC-MK2 cells are useful for plaque assays (692). Infant mice are highly susceptible to lethal infection by all routes of inoculation. Weanling mice succumb to intracerebral virus inoculation, but there is virus strain variation in pathogenicity by the intraperitoneal route. Hamsters and monkeys die after intracerebral or intranasal inoculation but develop asymptomatic viremia after peripheral infection. Rabbits and guinea pigs have asymptomatic infections by all routes of inoculation. The virus is pathogenic for embryonated chicken eggs. It produces disease in horses and swine (see later), whereas cattle are not susceptible.

Pathogenesis and Pathology

Sites of replication and dissemination of virus in the mouse have been described (315). During the acute stage, congestion, edema, and small hemorrhages are found in the brain. Microscopic lesions include neuronal degeneration and necrosis, neuronophagia, microglial proliferation forming glial nodules, and perivascular inflammation. These changes occur in gray matter and predominantly affect diencephalic, mesencephalic, and brainstem structures. Destruction of cerebellar Purkinje cells may be prominent.

In one study of fatal human cases, JE viral antigen was localized to neurons, with no evidence for glial cell infection (340). The highest concentration of infected neurons was in thalamus and brainstem. Among inflammatory cells recruited into perivascular infiltrates, CD4 T cells predominated, but a minority were CD8 T cells. Macrophages predominated among cells recruited into the brain parenchyma.

JE virus can gain access to the CNS at sites of blood–brain barrier disruption caused by herpesvirus (278). A similar role has been implicated for *Toxocara canis* and *Trichinella* species in experimental dual infections (141,550) and for *Taenia solium* (neurocysticercosis) in humans (145,663).

The pathways JE uses to cross over from circulation into the CNS are not well defined. A series of electron micrographs illustrate one possible pathway (426). The JE virion is transported across the cerebral blood vessels by attaching to the endothelial cell and being transported through an endocytotic vesicle. Then the virion is taken up a perivascular cell and transported into the CNS. The use of endocytotic vesicles means that the virus does not lose its own surface proteins and lipid bilayer by fusing with a cell.

Transplacental infection in swine results in fetal encephalitis, abortion, and stillbirth. The virus also produces hypospermia and aspermia in boars (253). Histopathologic changes include epididymitis, spermatogenic arrest, and inflammation of the tunica testis. Pregnant mice inoculated intraperitoneally also transmit JE virus to the fetus, with subsequent abortion (467,468). A curious feature of this model is that infected mothers, when mated again after 6 months, transmitted virus to the second litter. Latent infections of pregnant mice could be reactivated by cyclophosphamide or subsequent pregnancy. In other studies, latent infections were detected by cocultivation of mouse spleen cells and virus located principally to Lyt-1 (CD5+) cells (469).

There is also evidence for congenital and persistent infections in humans. In a series of nine pregnant women infected during an epidemic, four women infected during the first and second trimesters aborted, and virus was isolated from fetuses, whereas none of the five women infected in the third trimester miscarried or had abnormal babies (722). No other reports of human congenital infection are extant, and the frequency of this complication is unknown. Most women of child-bearing age in endemic areas of Asia are naturally or artificially immunized during childhood and are therefore not at risk. Evidence for latent infections of humans has been reported. By use of cocultivation techniques, JE virus was recovered from peripheral blood mononuclear cells of several children who developed recurrent disease as well as symptom-free children 9 months after an acute JE infection (664). Virus has been recovered from CSF samples as late as 117 days after onset of clinical symptoms (587). The frequency with which latent or persistent extraneural or neurologic infection occurs, whether such infections are associated with cytopathology or clinically relevant syndromes, and how the immune response modulates such infections remain to be elucidated.

Clinical Features

The incubation period is 6 to 16 days. As in SLE, illness may manifest as a febrile headache syndrome, aseptic meningitis, or encephalitis (163,210). In the full-blown encephalitic form, onset is rapid, beginning with a 2- to 4-day prodromal phase of headache, fever, chills, anorexia, nausea and vomiting, dizziness, and drowsiness. In children,

abdominal pain and diarrhea may be prominent. These symptoms are followed by the appearance of nuchal rigidity, photophobia, altered states of consciousness, hyperexcitability, and varying objective neurologic signs, including dull, masklike facies, muscular rigidity, cranial nerve palsies, tremulous eye movements, coarse tremors of the extremities, involuntary movements, generalized and localized paresis, incoordination, and pathologic reflexes. Sensory deficits are rare. Paralysis of the upper extremities is more common than paralysis of the legs. Spinal cord involvement (lower motor neuron deficits) may occur, and a bulboparetic syndrome has been described. Convulsions are frequent in children but occur in less than 10% of adult patients. Death occurs on the fifth to ninth day or during a more protracted course with cardiopulmonary complications. A poor prognosis is associated with respiratory dysfunction, positive Babinski's sign, frequent or prolonged seizures, prolonged fever, albuminuria, and evidence for high levels of virus replication in the brain, including infectious virus in CSF, high levels of IFN-a in CSF, and low levels of IgM antibodies in serum and CSF (84).

The peripheral white blood cell (WBC) count is mildly elevated. Urinary tract symptoms are common during the acute phase of illness and may be accompanied by sterile pyuria and microscopic hematuria and albuminuria. The CSF pressure may be elevated; microscopic examination shows 10 to 500 (rarely, up to 1,000) WBCs, with neutrophils predominating early, followed by lymphocytes. Cell counts fall gradually over 8 to 9 weeks. The CSF protein concentration is mildly elevated (50 to 100 mg%). The EEG is abnormal, with decreased electrical activity, slowing, and dysrhythmia. Brain echo and cranial tomography performed during the acute phase have shown characteristic thalamic and basal ganglia abnormalities correlating with poor prognosis.

The case fatality rate is 5% to 40%. Higher rates during epidemics (up to 70%) are reported but reflect poor medical care and recognition of only the most severe cases. Case fatality rates in affected American servicemen varied between 2% and 11%. Children and elderly patients are at highest risk for fatal infection. Neuropsychiatric sequelae occur in 45% to 70% of survivors and are particularly severe in children (378). Sequelae include parkinsonism, convulsive disorders, paralysis, mental retardation, and psychiatric disorders. The social prognosis of survivors is generally poor. Sequelae are more frequent in patients whose acute disease is severe, prolonged, and associated with coma and localizing neurologic signs. Magnetic resonance imaging in patients with sequelae has revealed abnormal-intensity areas in thalamus, globus pallidus, hippocampus, and substantia nigra, providing anatomic correlates of the emotional lability, memory impairment, and parkinsonism.

Diagnosis

Definitive diagnosis is similar to that described for SLE. In fatal cases, virus isolation and demonstration of viral antigen in brain tissue are feasible. Rapid diagnosis may be achieved by staining for antigen in mononuclear cells recovered from CSF (470). Virus isolation from blood is infrequent. However, virus may be isolated from CSF in up to one third of patients during the acute phase, and isolation is correlated with a poor prognosis. Serologic diagnosis depends on the demonstration of a fourfold or greater rise (or fall) in appropriately timed serum specimens. The HI, CF, and NT are applicable. Cross-reactions with heterologous viruses, particularly WN, may complicate the serodiagnosis in tropical areas of Asia. Serum IgM antibodies appear early, usually disappear by 3 to 6 months after onset, and are usually serologically specific (85). The IgM-capture ELISA is especially well suited for diagnosis by detection of locally synthesized antibody in the CSF (85,88,140), separating patients with virus infection of the CNS from those with other etiologies of encephalitis but serologic evidence for systemic (extraneural) JE infection. Intrathecal antibody synthesis can also be estimated by use of an IgG index or CSF IgG–to–CSF albumin ratio. The kinetics of the systemic and local CNS antibody response have prognostic importance; patients who survive have earlier and more vigorous responses. IgM antibody synthesis may persist in CSF for weeks after recovery, indicating persistent antigenic stimulation (587). Monoclonal epitope-blocking immunoassays may be used to identify JE-immunity among patients with cross-reactive flavivirus antibodies (86).

Treatment

There is no specific treatment. Good supportive care (as discussed for SLE) is essential. Vigilance should be maintained for severe hyperthermia and convulsions, and specific countermeasures should be applied. Cerebral edema has been postulated to be an important factor in pathogenesis. However, a controlled trial of high-dose corticosteroid therapy failed to show improvement in clinical outcome, mortality, or sequelae (306). There have been a few modest tests to determine whether there are any effective drug therapies for JE. In a Vero cell culture system, a furanonaphthoquinone derivative, FNQ3, showed some antiviral activity (703). Suramin, an antitrypanosoma drug, showed good antiviral activity against JE replication. Although these drugs are promising, their safety and *in vivo* effectiveness are still unknown. A technical guide to the clinical diagnosis and management of patients has been prepared by the World Health Organization (WHO) (777).

Epidemiology

Morbidity and Mortality

Japanese encephalitis virus is widely distributed in Asia, including Japan, China, Taiwan, Korea, Philippines, far-eastern former Soviet Union, all of Southeast Asia, and India (Fig. 12). About 50,000 cases and 10,000 deaths are recognized annually throughout Asia, but the disease is greatly underreported (732). The incidence in Japan, South Korea, and Taiwan has declined dramatically since the 1980s. Large numbers of cases (more than 10,000 per year) occur in China, but the annual incidence is also declining. In contrast, epidemic activity in northern and central India, Nepal, and the northern part of Southeast Asia has increased since the early 1970s (204). In one study of 740 consecutive hospital admissions with encephalopathy in India, 23% were due to JE virus, and 37% of these patients died (377). In northern Thailand and in Vietnam, outbreaks occur with attack rates of up to 10 to 20 per 100,000, an incidence similar to that of poliomyelitis in the United States before the advent of vaccines (305). The increase in JE virus transmission in these areas is linked to deforestation, agricultural development, and irrigation schemes for rice cultivation, leading to high-density breeding of *C. tritaeniorhynchus* (552). A recent episode in the island of Saipan illustrated the dynamics of JE infection after introduction of the virus into a susceptible area outside of the endemic zone (549). Virus introduction

was followed by intense amplification, universal infection of the pig population, infection of 4.2% of the human population, and a disease attack rate of 25 per 100,000.

FIG. 12. Distribution of Japanese encephalitis virus in Asia.

Children are primarily affected by the disease; attack rates in the 3- to 15-year age group are 5 to 10 times higher than in older individuals because of high background immunity in the older age groups. Epidemics in nonendemic regions have affected all age groups, but a bimodal age distribution (young children and the elderly) has appeared, indicating an increased risk in elderly people, as seen in SLE.

In endemic areas, nearly all people have sustained infection by young adulthood. The ratio of inapparent to apparent infections is 200:1 to 300:1 (45). Among factors that influence this ratio are age, differing virus strain virulence, and cross-protective immunity to other flaviviruses, especially dengue.

In tropical areas, there is an endemic pattern of infection, with occurrence of sporadic cases throughout the year. In temperate zones and in the northern part of the tropical zone, outbreaks have a marked seasonal incidence during the rainy (monsoon) season (July to September). Precipitation and temperature are important determinants of vector density and rate of virus transmission. The incidence is highest in rural agricultural areas. An excess of cases has been noted in males in many outbreaks, presumably because of increased exposure in areas of rice cultivation.

The reasons for the absence of epidemics in tropical countries are poorly understood. In southern Thailand, intense JE virus transmission to pigs has been demonstrated in the absence of epidemic human disease (89). The RNA genome of virus isolates from this area differed significantly from northern Thai epidemic strains, suggesting that a difference in virulence may be responsible. Other factors to be considered include vector–host relationships, vector abundance, vector competence, and cross-protecting heterologous immunity to dengue.

Transmission Cycle

Birds and pigs are effective viremic amplifying hosts, serving as the source for infection of mosquito vectors (see Fig. 11) (645). Cattle are frequently infected but have low viremias and do not perpetuate virus transmission (323). In temperate regions, virus transmission is detectable in July in mosquitoes, pigs, and birds, principally ardeid species (egrets, black-crowned night herons) and possibly ducks. Human infections occur several weeks later. The main epidemic vectors are *Culex* species, of which *C. tritaeniorhynchus* is the most important. It breeds in irrigated rice fields, shallow ditches, and pools, with peak population densities during the monsoon season. Infection rates in *C. tritaeniorhynchus* may exceed 1% during periods of peak transmission. Other species implicated in transmission include *Culex vishnui* (India), *Culex gelidus* and *Culex fuscocephala* (India, Malaysia, Thailand), *Culex annulus* (Taiwan), and *Culex annulirostris* (Guam). Isolations have been made from many other species of *Culex, Anopheles,* and *Aedes.*

The overwinter maintenance of JE in temperate areas has not been fully elucidated. Vertical transmission of JE virus by *Culex* and *Aedes* species has been demonstrated in the laboratory and by field studies (545,622,628). The virus is also sexually transmitted from male to female mosquitoes. Japanese encephalitis virus and antibodies have been found in bats in Japan. Experimentally infected bats held in simulated hibernation develop persistent infections and, upon warming, have viremias sufficient to infect mosquitoes. Japanese encephalitis virus and antibodies have been found in reptiles (668), but their role in the ecology of JE remains unknown. Certainly, the demonstration that latent and recrudescent infections occur in experimentally infected mice as well as in humans lends credence to the view that wild or domestic vertebrate hosts could play a reservoir role in overwinter maintenance. In tropical regions, year-round transmission of the virus among mosquitoes, birds, and pigs probably occurs (235).

Japanese Encephalitis in Travelers

Cases of JE have occurred among travelers to Asia. Between 1978 and 1992, 24 such cases were reported (24). Although the risk for overt disease among travelers is low (estimated to be 1 in 5,000 to 1 in 20,000 per week of travel, varying with location of travel, season, and rural exposure), the severity of the disease has encouraged use of vaccine (see Control, later). Among JE cases with known outcome among travelers, 40% died, and 36% had residual disabilities.

Molecular Epidemiology

Japanese encephalitis virus diversity has been determined by primer-extension sequencing of a region in the *C/prM* gene (122,321). These analyses demonstrated four geographically distinct genotypes of JE virus in Asia differing by more than 12% at the nucleotide level. Genotype I consists of virus strains from a broad region encompassing northern Asia (Japan,

China, Taiwan), Vietnam, Nepal, India, and Sri Lanka. Genotype II consists of strains from northern Thailand and Cambodia. A third genotype contains strains from Indonesia (Sarawak, Java), Malaysia, and southern Thailand. A fourth comprises isolates from eastern Indonesia (Java, Bali, and Flores) (213). It is of considerable interest that an epidemic pattern of disease expression prevails in areas where genotypes I and II circulate, but an endemic pattern is seen in areas represented by genotypes III and IV. Whether this reflects a difference in virus virulence or in epidemiologic and ecological factors remains uncertain. The very large and continuous geographic distribution of genotype I (from Japan to Sri Lanka) suggests the possibility of gene flow, but the virus distribution does not appear to fit patterns of bird migration.

Control

Vaccination

Vaccines have been used to prevent (a) encephalitis in horses and humans and (b) abortion and stillbirth in swine. Vaccination of horses with formalin-inactivated vaccines was the first successful application and afforded significant protection during an epizootic in Japan during 1948 to 1949. Since 1972, live attenuated vaccines have been licensed in Japan for use in pigs (722,781). Although immunization of pigs is a theoretical means of interrupting transmission and amplification of JE virus and thereby of preventing human infections, difficulties arise in practice. In many parts of Asia, pigs are only semidomesticated, and wide-scale immunization is difficult. In areas such as Japan, where swine husbandry is highly developed, pigs are born after the epidemic period, have interfering maternal antibody for 4 months, and are killed the following summer, leaving a narrow interval for vaccination.

Formalin-inactivated vaccines for use in humans are prepared from infected adult mouse brains or infected primary hamster kidney cell cultures in Japan and China, respectively (reviewed in 17 and 722). The mouse brain vaccine produced by the Research Foundation for Microbial Diseases (Biken), Osaka, Japan, is purified by protamine sulfate precipitation and ultracentrifugation and has been in wide use since the 1960s. A controlled trial of Biken vaccine in Thailand showed an efficacy of 91% (305). Mass vaccination campaigns have been carried out in Japan, Taiwan, and China, with children as the target population. Primary immunization requires at least two doses of 1.0 mL (0.5 mL in children younger than 3 years of age) at a 7- to 14-day interval. Although booster doses are recommended after 12 months, antibodies from the three-dose regimen have been shown to persist at protective levels for up to 3 years (202).

Because of the antigenic diversity of JE virus strains, efforts were made by Biken to improve on the original mouse brain vaccine produced from the 1935 Nakayama virus by incorporating a more recent isolate, Beijing-1 virus, representing a distinct (JaGAr-01) antigenic variant. Immunization of mice with Beijing-1 vaccine raised antibodies that were cross-reactive at higher titer with JE strains of different geographic origin. The Beijing-1 strain also replicates to higher titer in mouse brain. It is more potent and may be administered at a dose half that of Nakayama or bivalent vaccine. A monovalent Beijing-1 vaccine is currently produced for use in Japan, and it may ultimately replace the bivalent product for export. A comparison of Nakayama and Beijing vaccines in nonimmune Thai schoolchildren showed about 94% seroconversion against the homologous virus strain (620). At this time, there is no evidence to suggest that antigenic variation of vaccine or wild virus has a significant effect on vaccine efficacy.

Since 1981 when JE was proved to be a threat to travelers, there has been an international interest in vaccines. The Biken vaccine is licensed for use in the United States (marketed by Connaught Laboratories) and in Europe (Pasteur-Merieux). Studies in adults have shown that three (rather than two) inoculations are required to achieve protective immunity (neutralizing antibody titers of more than 10) in more than 90% of the vaccinees. Booster doses are recommended after 12 months. Side effects are generally inconsequential, consisting of local tenderness or mild systemic symptoms in 10% to 30%. Although produced from brain tissue of mice, the purified vaccine contains less than 2 ng/mL of myelin basic protein, an amount far below that capable of eliciting allergic encephalomyelitis in the sensitive guinea pig model. Only rare cases of postvaccinal encephalitis have been reported (540), and in such cases, a clear etiologic role for JE vaccine has been difficult to establish. Surveillance for postvaccinal neurologic events in Japan has not demonstrated an association between JE and neurologic complications.

Use of JE vaccine in adult travelers recently has resulted in a number of cases of allergic reactions, including urticaria, angioedema, bronchospasm, and erythema nodosum and multiforme (24). These reactions occurred acutely or after an interval of up to 7 days. The delay in onset appeared to lengthen when reactions followed the second or third vaccine inoculation. The incidence of these allergic phenomena has varied in different reports from 2 per 1,000 to as high as 1%. Allergic reactions in Western adult vaccinees appear to have increased in recent years, a phenomenon that was not explained by changes in vaccine manufacture or by use of specific vaccine lots.

Two other JE vaccines are currently in use in China: formalin-inactivated vaccine produced from primary hamster kidney (PHK) cells, and a live attenuated vaccine designated SA14-14-2, also prepared in PHK cell culture. Both vaccines are extensively used in China (719). Immunogenicity of the live vaccine in children exceeds 95%, but antibody titers appear to wane rapidly, and a booster dose is given at 12 months.

Efforts are underway to produce genetically engineered JE vaccines. Recombinant vaccinia (including the NYVAC vector, a highly attenuated strain of vaccinia suitable as a vaccine) encoding prM and E (or preM, E, and NS1) of JE virus elicited neutralizing antibodies and conferred a high level of protection against challenge of rhesus monkeys, mice, and pigs (366,367,581). Recombinant vaccinia vaccines expressing only the NS1 protein showed low levels of protection (364). The *PreM* and *E* genes were also inserted into a highly attenuated MVA strain of vaccinia virus (520), and immunized animals were completely protected against a lethal challenge of JE virus. Infection of mammalian cell cultures with recombinant vaccinia virus expressing the *prM* and *E* genes of JE virus results in the production of extracellular 20-nm subviral particles. These particles, composed of the prM/M and E viral proteins in a lipid bilayer, are free from nucleic acid, are easily purified, and are highly immunogenic, providing a practical approach to vaccine development (461). This type of extracellular particle has been effective in generating immunity to infection in Balb/c mice (367a). A full-length infectious clone of JE virus has been developed, allowing the introduction of attenuating mutations (702) and a potential means of constructing new live vaccines. Novel carrier and delivery systems for subunit or purified virion JE

vaccines have been investigated in preliminary studies, including polylactide-coglycolide–encapsulated vaccine and JE peptides linked to meningococcal proteosomes. In an attempt to simplify vaccination, a protocol calling for oral administration of an attenuated JE strain has been tested. Depending on the preparation, mice immunized in this manner showed 70% to 76% seroconversion. Although this shows that oral administration has potential, the level of protection needs to be improved for it to be a practical alternative.

DNA vaccinatons, one of the newest techniques in vaccinology, has been pursued in an attempt to generate new JE vaccines that will increase coverage. To date, three general strategies have been used in making DNA JE vaccines. One, the genes *PreM* and *E* are expressed by the DNA vaccine. This leads the cells transfected to secret virion-like particles, which are excellent immunogens. Tests with these vaccines have induced excellent and, in some cases, long-lived protection from challenge (109,360,362). In the second approach, only the E protein is encoded by the DNA vaccine. The E protein is either present in the cytoplasm of transfected cells or can be secreted as a dimer. These DNA vaccines have also demonstrated good protection against JE viral challenge (27,118). Third, some studies have involved DNA vaccines coding for the nonstructural protein NS1 (423). In previous studies, purified NS1 protein injected into test animals elicited varying levels of immunity. A slightly truncated version of NS1 (designated NS1') was able to induce good protection against challenge.

A chimera yellow fever 17D JE virus has also been designed (105). The virus has the yellow fever PreM/E proteins replaced by the JE preM/E protein. Therefore, this virus theoretically has the immunogenicity of JE and attenuated phenotype (determined by the nonstructural proteins) of the yellow fever 17D strain. Preliminary tests in animal models indicated that the chimera is immunogenic and safe (247,489). Potentially, any flavivirus preM/E protein, as long as a viable virus results, could be exchanged for the native 17D strain proteins, creating a number of immunogenic and safe vaccines.

Mice have been effectively immunized with live JE virus administered orally (583).

Vector Control

Field trials of organophosphate larvicides and adulticides have proved effective against vectors of JE. Use of agricultural pesticides in rice-growing areas has also reduced populations of *C. tritaeniorhynchus.* Integrated programs, which include use of chemical larvicides, larvicidal fish, and biologic larvicides (*Bacillus thuringiensis*), elimination of aquatic vegetation in irrigation canals, and spraying of residual insecticides in livestock pens have reduced the case incidence in China (314). Emergency epidemic control requires aerial ultralow-volume (ULV) spraying of organophosphate adulticides.

Murray Valley Encephalitis Virus

Epidemics of encephalitis (Australian X disease) in southern Australia in 1917, 1918, 1922, and 1925 are now believed to have been due to MVE virus. In 1917 and 1918, an infectious agent was recovered by inoculation of monkeys (73), but the virus was not established or characterized. During an outbreak in 1951, the virus was isolated from human brain and was shown to be a flavivirus related to, but distinct from, JE virus (195). *C. annulirostris* was suspected to be the vector in 1951, and the virus was subsequently isolated from this mosquito in 1960 (168). Epidemics occurred in southeastern Australia in 1956, 1971, and 1974. Small outbreaks also occurred in the Kimberley and Pilbara regions of western Australia in 1971, 1978, 1981, and 1984. The disease was recognized in New Guinea in 1956 (197).

Infectious Agent

MVE virus is a member of the JE antigenic complex. Antigenic comparison of five MVE virus strains isolated in Australia and New Guinea by HI, kinetic HI, and plaque-reduction NT showed four strains to be similar and showed the fifth to have minor but reproducible antigenic differences. Strains from the 1974 epidemic were indistinguishable by standard serologic tests from isolates recovered during previous outbreaks (164).

Mapping of the E glycoprotein of MVE virus with monoclonal antibodies and synthetic peptides has elucidated T- and B-cell epitopes (274,464). The nucleotide sequence of MVE has shown it to be most closely related to JE virus (142,411).

Many vertebrate and mosquito cell culture systems propagate the virus. Plaque assays can be performed in primary chick embryo and continuous lines of pig kidney, monkey kidney, and hamster kidney cells (763). Immune enhancement of virus growth has been demonstrated in primary chick embryo fibroblast cultures mediated by a subpopulation of macrophages having Fc receptors (353). The host range of MVE virus has been reviewed by French (196). Infant mice are highly susceptible by all routes of inoculation. Mice develop clinical resistance to peripheral (but not intracerebral) inoculation between 17 and 28 days of age. Hamsters 6 to 10 weeks old are susceptible to lethal infection by all routes. Monkeys, horses, sheep, and some birds develop encephalitis after intracerebral inoculation. Pigeons and chickens infected subcutaneously develop viremic infections without clinical illness. Rabbits and guinea pigs have subclinical infections after intracerebral and peripheral inoculations. Chicken embryos are highly susceptible and have been used for primary isolation from human cases (195).

MVE virus is suspected to cause neurologic disease in horses, but field and experimental studies have failed to incriminate the virus conclusively (457). During epidemics of MVE, there are reports of dogs dying; dogs are susceptible to infection, as shown by a high antibody prevalence, but no evidence has been obtained for a pathogenic role of MVE virus.

Pathogenesis and Pathology

There is little available information on the experimental pathology of MVE in animals. One study compared the spread of MVE strains of high and low neuroinvasiveness in mice (583). The high invasive strain infection quickly spread to the

lymph nodes and produced viremia and then a CNS infection with infection through the olfactory bulb. In contrast, the low invasive strain did not infect the lymph nodes, had a 20-fold lower viremia, and caused a much less intense infection of the CNS, also invading through the olfactory bulb. The main difference in the two strains is the speed and magnitude of infection. Thus, the neuroinvasion by MVE could be seen as a race between the magnitude and breadth of viral replication and invasion in comparison to the host immune response. Pathologic findings in human cases of fatal encephalitis are similar to those in JE (607).

Clinical Features

The disease begins with a 2- to 5-day prodrome characterized by fever, headache, myalgia, generalized malaise, anorexia, and nausea, followed by the appearance of nuchal rigidity and neurologic signs. In infants, the disease progresses rapidly, and patients are frequently comatose when first brought to medical attention. Bennett (46) divided patients into three groups on the basis of severity of illness: (a) mild cases with altered level of consciousness and variable neurologic abnormalities but without coma or respiratory depression, accompanied by stabilization of neurologic changes within 5 to 10 days; (b) severe cases with coma, paresis, and paralysis, including respiratory and pharyngeal impairment requiring respiratory assistance; and (c) fatal cases with spastic quadriplegia and progressive CNS damage or severe disease with superimposed bacterial infection. Neurologic sequelae occur in up to 40% of the mild cases and in all of the severe cases that recover.

Attempts to associate MVE virus with mild febrile illnesses without neurologic signs have failed (164).

Diagnosis

Specific diagnosis depends on isolation of virus from brain tissue or serologic tests. Virus isolation from blood or CSF has not been successful. Isolations from brain have been made in chick embryos and suckling mice. For serodiagnosis, the ELISA, HI, CF, and NT are useful. Cross-reactions with dengue and with Kunjin virus may confuse interpretation. An epitope-blocking ELISA with MVE monoclonal antibodies proved useful in distinguishing MVE infections from those with other flaviviruses (276). Some patients with encephalitis (presumably MVE) have shown rising antibody titers to Kunjin (165), possibly on the basis of a previous Kunjin infection and the original antigenic sin phenomenon. IgM antibodies appear to be quite specific and useful for early diagnosis (769). There has been some recent development of reverse transcription–polymerase chain reaction (RT-PCR) assays for MVE (482). These could provide earlier and more specific diagnosis than the conventional tests.

Treatment

Treatment is as described for SLE and JE.

Epidemiology

Epidemics have occurred principally in the Murray Valley region of New South Wales and Victoria, involving up to about 50 human cases (457). The most notable recent outbreak, in 1974, was unusual in its geographic extent, with patients also infected in east central Queensland, Northern Territory, northern and southeastern South Australia, and the Ord River Basin of Western Australia. Sporadic cases were reported in New Guinea. Outbreaks in Australia occur during the summer (January to May) and appeared to follow periods of abnormally high rainfall for two consecutive years. Water impoundment and irrigation schemes were responsible for the emergence of MVE in Western Australia in the 1970s. A mathematic model of MVE has provided hypotheses regarding amplification and dissemination of the virus in southern Australia (350).

Population-based incidence data on MVE are not available. Before 1974, children were predominantly affected. In the 1974 epidemic, however, 35% of the patients were younger than 10 years old, and a similar proportion were older than 50 years of age (165). A serologic survey conducted after the 1951 epidemic in various localities in Victoria showed 4.5% to 36% positive CF tests; the rate in children was about half that in adults (16). A statistically valid HI antibody survey conducted 8 months after the 1974 epidemic showed 4.5% positive overall. Follow-up surveys indicated no MVE virus activity after 1974, despite a high incidence of human infection with other flaviviruses (275). MVE is endemic in the tropical Kimberley area of Western Australia (675). Between 1978 and 1991, there were 26 reported cases of Australian encephalitis in Western Australia, of which 16 occurred in the Kimberley region (443). Of 20 cases serologically diagnosed, 18 had MVE, and 2 had Kunjin virus infections. Sixty-five percent of the encephalitis cases were in Aboriginal children, and 85% were male.

The principal vector is *C. annulirostris,* a transient pool breeder. The virus has also been isolated from *Aedes normanensis, C. tritaeniorhynchus,* and *C. pipiens. C. pipiens,* once considered to be a potential vector on epidemiologic grounds, has proved to be poorly susceptible or refractory to oral infection in experimental studies, whereas *C. annulirostris* is a highly efficient vector (348).

Large water birds (herons, egrets, and pelicans) appear to be the most important viremic hosts. However, mammals (including rabbits and kangaroos) may contribute significantly to the transmission cycle.

The overwintering mechanism and origin of intermittent epidemics are unknown (reviewed in 457).

Molecular Epidemiology

MVE viruses analyzed by mapping restriction enzyme digests and by nucleotide sequencing showed a remarkable homogeneity of strains from widely separated areas of Australia over a 23-year period (433). This finding suggests continuing gene flow, possibly by widely ranging water bird hosts. Strains from New Guinea differ, suggesting that this

area represents a separate focus.

Prevention and Control

In parts of Australia, MVE is a significant health risk to infants. Animal tests indicate that passive immunization with gammaglobulin of patients who were sublethally infected with MVE or JE can be an effective prophylactic measure (79,113). However, sera from patients who were immunized with the JE vaccine are not protective and instead appear to enhance the infection.

Recently, two types of vaccines have been investigated in a murine model: a DNA vaccine and a Semliki Forest virus–vectored vaccine (133,171,480). Both vaccines use the PreM/E proteins as immunogens and induce. In areas prone to recurrent epidemics (e.g., the Murray River basin), reduction of *C. annulirostris* breeding by use of larvicides is practiced. Use of rainfall data and surveillance of virus activity in mosquitoes and sentinel fowl to predict risk for epidemic allows targeted mosquito control efforts.

Central European and Russian Spring-Summer (Tick-borne Encephalitis) Viruses

TBE was clinically described in the far-eastern Soviet Union in 1934. In 1937, the causative virus was isolated from the human brain and demonstrated to be transmitted by ticks (679). The disease was first recognized in eastern Europe (Czechoslovakia) during an epidemic in 1948, and a virus isolated from a patient was shown to be similar to the Far Eastern virus. Transmission by ingestion of unpasteurized goat's milk occurs in both Russia and Europe. The disease has been recognized in all Central and Eastern European countries and Scandinavia as well as in France, Italy, Greece, and Albania.

Infectious Agents

The TBE complex consists of 17 antigenically closely related viruses, 13 of which cause human disease (see Table 1). Russian spring-summer encephalitis (RSSE) and Central European encephalitis (CEE) viruses are closely related antigenically and have been considered subtypes of the same virus. They share about 96% of their amino acids in the E protein and can be distinguished by means of protein E–specific monoclonal antibodies (312). No significant difference, however, has been observed in cross-protection experiments when mice were immunized with the European subtype and then challenged with different European and Far Eastern strains (312). As discussed below, the two subtypes also differ in their tick vectors and clinical expression. Remarkable stability of the CEE genome and antigenic determinants has been demonstrated among strains from different areas of Europe (248,312,766). The morphology, chemistry, and antigenic composition of TBE complex viruses are similar to those of other flaviviruses (285,293). Although the E protein of TBE virus undergoes specific conformational changes at acidic pH, which are associated with a reduction in infectivity (292), a significant degree of resistance to acid pH in sour milk (232) and gastric juice (560) has been reported. This feature is apparently responsible for oral infections through milk.

TBE complex viruses grow in a variety of cell cultures, including pig, bovine, and chick embryo, HeLa, Detroit 6, human amnion, Hep 2, Vero, and primary reptilian and amphibian cells (573), but CPE and plaquing are variable. Chicken embryos and a variety of animals are susceptible to infection. Infant and weanling mice develop fatal encephalitis by all routes of inoculation. Rats, guinea pigs, sheep, monkeys, and swine succumb to encephalitis after intracerebral inoculation. Hamsters are less susceptible to intracerebral and peripheral challenge than mice. Experimental inoculation of wild vertebrate species (including rodents, insectivores, foxes, birds, hares, and bats) results in viremia and antibody formation (230). Cows, goats, and sheep experimentally infected by inoculation or tick bite develop viremia and secrete virus in their milk. Mice can also be infected by the oral route, with subsequent shedding of virus in feces and milk (561).

The Far Eastern virus type (RSSE) is more virulent for sheep and monkeys inoculated intracerebrally than the Western (CEE) virus (789). However, no distinct difference has been noted in pathogenicity for mice or cell cultures (37). Variation has been found between wild virus strains in their ability to produce viremia in a natural host species, *Clethrionomys glareolus* voles (127).

Pathogenesis and Pathology

The pathogenesis in mice was reviewed by Albrecht (9) and does not differ significantly from the general scheme presented earlier. In monkeys, the anterior horn cells of the spinal cord and cerebellar cortex appear to be selectively more vulnerable to tick-borne viruses than other neuronal centers (525). An apparently unique feature of members of the TBE virus complex may be their propensity to cause persistent infections in experimental animals (and possibly also in humans). Mice infected with Kyasanur Forest virus may survive for months with paralysis, low titers of virus in the brain, and absence of detectable neutralizing antibodies (570). Hamsters infected with CEE virus develop late CNS lesions, including proliferation and hypertrophy of astrocytes (794), and have detectable viral antigen in tissues for up to 4 months. Louping ill virus persists in immunosuppressed guinea pigs for 50 days (793). Monkeys infected intranasally or intracerebrally with CEE virus develop a chronic encephalitis with degenerative spongiform lesions and astrocytic proliferation (794). The virus has been isolated from monkey tissues by cocultivation and explant procedures as long as 383 days after inoculation (563). Chronic progressive human encephalitis and seizure disorders (Kozhevnikov's epilepsy) have been associated with RSSE virus on serologic grounds (539), and virus has been isolated from the CSF of a patient with a disease clinically resembling amyotrophic lateral sclerosis (515). These observations support the notion that flaviviruses produce persistent infection in sequestered neuronal tissues of human hosts (see Pathogenesis and Pathology, earlier).

The neuropathology of experimental infection in mice has been reviewed by Vince and Grcevic (746), and the pathology of infection in humans has been reviewed by Zilber and Soloviev (790). Findings are generally similar to those of other flaviviral encephalitides. Gross changes include swelling, congestion, and petechial hemorrhages. Histopathologic alterations include meningeal and perivascular inflammation, neuronal degeneration and necrosis, neuronophagia, and

glial nodule formation involving cerebral and cerebellar cortex, brainstem, basal ganglia, and spinal cord. The anterior horn cells of the cervical cord are especially vulnerable, explaining the predominance of lower motor neuron paralyses of the upper extremities seen in many cases.

Clinical Features

The Central European form (CEE) is milder than RSSE and typically takes a biphasic course. The first phase is an uncharacteristic influenza-like illness with fever (temperature usually not exceeding 38°C), headache, malaise, and myalgia that arises after an incubation period of 3 to 7 days and lasts for about a week. After an asymptomatic period of up to a week, 20% to 30% of those affected develop the second phase of the disease, which involves the CNS. It may take the form of aseptic meningitis, meningoencephalitis, meningoencephalomyelitis, or meningoencephaloradiculitis (579,580). The case fatality rate is 1% to 2%, and the disease in children is less severe than in adults. Meningitis usually resolves completely. However, 10% to 20% of patients with the more severe clinical forms have long-lasting or permanent neuropsychiatric sequelae. These tend to be minor in degree, and motor defects are rare; CSF changes are similar to those in the other flavivirus encephalitides.

The disease in the Far East (RSSE) differs clinically from CEE. Onset of illness is more often gradual than acute, with a prodromal phase including fever, headache, anorexia, nausea, vomiting, and photophobia. These symptoms are followed by stiff neck, sensorial changes, visual disturbances, and variable neurologic dysfunction, including paresis, paralysis, sensory loss, and convulsions. In fatal cases, death occurs during the first week after onset. The case fatality rate is about 20% (229) but may be biased by the lack of hospitalization of mild cases. In contrast to CEE, the disease in children is more severe than in adults. Neurologic sequelae occur in 30% to 60% of survivors, especially residual flaccid paralyses of the shoulder girdle and arms.

Diagnosis

Fewer than half of patients give a history of tick bite. At the time of admission to hospital (i.e., after onset of CNS symptoms), specific antibodies are almost always detectable. Diagnosis is most often made by serologic tests, especially the detection of IgM antibodies by ELISA (304,619). Using sensitive tests, IgM antibodies may be detectable for up to 10 months after disease onset. The virus may be isolated from the blood during the first phase of illness and from brain tissue of patients dying during the early phase of the disease.

Epidemiology

TBE occurs in an endemic pattern over a wide area of Europe and the former Soviet Union, corresponding to the distribution of ixodid tick vectors (Fig. 13). The annual incidence is several thousands of cases, with considerable variation from year to year. In Europe, the highest morbidity has been recorded in Austria, Slovenia, Hungary, and the Czech and Slovak Republics, with several hundred cases occurring annually in these countries (57,230). In the former Soviet Union, 5,500 cases were reported in 1990. The disease occurs in foci characterized by ecological habitats favorable for ticks, and very little variation in geographic distribution is observed. The intensity of transmission varies from year to year; increases in small mammal populations (the principal hosts for immature ticks), with subsequent migration, are followed within 1 to 2 years by increased tick populations and a higher risk for human infections.

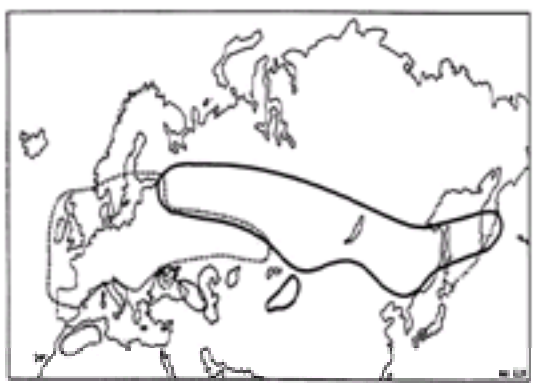

FIG. 13. Distribution of *Ixodes ricinus* (vector of Central European encephalitis and louping ill viruses; *dotted line*) and *Ixodes persulcatus* (vector of Russian spring-summer and encephalitis; *solid line*). (From ref. 57, with permission.)

The virus is maintained in nature in a cycle involving ticks and wild vertebrate hosts (Fig. 14). At least 10 species of rodents have been implicated as amplifying hosts (229,230). Insectivores (shrews, moles, and hedgehogs, which have relatively stable populations, in contrast to rodents), are believed to be important reservoirs. Large mammals, such as goats, sheep, and cattle, are important blood-feeding hosts for adult ixodid ticks but have low viremias and are not considered to be important sources of tick infection. The virus is excreted in the milk, however, and human infection may result from consumption of unpasteurized goat or sheep milk or cheese. Small outbreaks, involving all age groups and often in family groups, result from consumption of raw sheep or goat milk or cheese (231). Vertebrate hosts may also be involved in overwintering. Prolonged viremic infections have been demonstrated in hibernating dormice and hedgehogs, bats, and ducks.

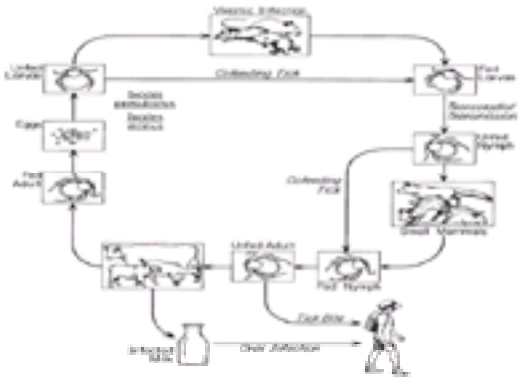

FIG. 14. Generalized transmission cycle of tick-borne flaviviruses, showing hosts for larval, nymphal, and adult ticks. Virus is passed to succeeding tick stages during molting as well as transovarially to progeny of adult ticks. Both male and female ticks are involved in transmission. Tick-borne encephalitis virus (and possibly other tick-borne flaviviruses) may be transmitted to uninfected ticks cofeeding on a vertebrate host without the requirement for active viremic infection of the host.

Ixodes ricinus and *Ixodes persulcatus* are responsible for transmission in Europe and the Soviet Union, respectively (see Fig. 13). Other tick species, of the genera *Dermacentor* and *Haemaphysalis,* have also been implicated in transmission, especially in areas that do not support *Ixodes* species ticks. Pre-imago ticks acquire infection by feeding on small mammals and pass the virus transtadially to the adult stage. Transtadial and transovarial virus transmission has been demonstrated in *Ixodes, Dermacentor,* and *Haemaphysalis* species. Considerable losses of virus occur with tick molting from stage to stage. About 1% of the progeny of an infected female *Ixodes* species tick acquire the virus. Although ticks may serve as a natural reservoir and overwintering mechanism, horizontal transmission between vectors and vertebrates is required for endemnicity. A mathematic model has been described that predicts age-specific infection rates and infection risk in hyperendemic foci (215).

The propagation of the TBE viruses does not appear to follow the classic model of the vertebrate host acting as an amplification and reservoir from which vectors are infected. Compared with other tick-borne diseases, such as Lyme disease, TBE has a far more focal distribution. This pattern suggests that the conditions of its maintenance are much more narrowly defined (584). When this pattern and the low and transitory nature of TBE viremia are considered, the persistence of TBE would seem to be very tenuous. Three factors help to define an alternative cycle in which TBE is propagated. First, the well-known, overall, synchronous seasonal activity of the vector. Second, TBE virus can be transmitted efficiently between infected and uninfected ticks cofeeding on the same host without the host supporting an infectious viremia. Finally, this transmission can occur at a high level, 89% (400), even on immune hosts.

In Central Europe, the activity of adult ticks occurs in two peaks (May to June and September to October), that are followed by two peaks of human disease at a 3- to 4-week interval, whereas in Scandinavia, only one peak is seen in late summer. Forestry workers, farmers, and others working in forest or scrub areas are at highest risk. In recent years, however, the infection has increasingly affected people in their leisure and travel activities. An imported case of TBE occurred in a child in Ohio (138).

Before the availability of an effective vaccine and biosafety precautions, laboratory infections with TBE virus were not uncommon (646).

Molecular Epidemiology

A phylogenetic analysis of the E protein of 25 TBE viruses revealed three genetic lineages. These correspond to European, Far Eastern, and Siberian subtypes (175). The variation between subtypes within strains was low, with a maximum of 2.2% at the amino acid level; between strains, the variation was 5.6%. This range is similar to that reported for other flaviviruses. The new Siberian subtype is more related to the Far Eastern than to the European subtype, which geographically makes intuitive sense. Although the differences between the subtypes are minor, they do have a significant effect on TBE virulence (277). Disease caused by TBE is more severe in Asia than in Europe, with case fatality rates of up to 30% and 1% to 2%, respectively. As with other flaviviruses, relatively few amino acid changes can have a significant effect on virulence (750).

Prevention and Control

Using Far Eastern strains of TBE virus, formalin-inactivated mouse brain vaccines were in used before World War II in the former Soviet Union. A live, attenuated heterologous (Langat) vaccine developed in Czechoslovakia was investigated (471) and abandoned. Formalized cell culture–derived vaccines were developed in Russia, and at the present time, an unpurified and a partially purified inactivated chick embryo cell vaccine are in use (180). An experimental vaccine has also been prepared using virus grown in a green monkey kidney cell line (126).

In Europe, a partially purified formalin-inactivated vaccine based on an Austrian virus isolate grown in chick embryo cells became commercially available in 1976 (372,388). This vaccine gave satisfactory seroconversion rates but caused a significant rate of side reactions, such as headache, malaise, and fever. This reactogenicity was almost completely eliminated when the vaccine was prepared in a highly purified form (286,386), which is licensed in several European countries. It contains Al(OH) as an adjuvant and has an efficacy of about 97% to 98% in the field. In Austria, mass vaccination was initiated in 1981 and resulted in a dramatic decline in the annual incidence of disease (389). A second European TBE vaccine has more recently been registered in Germany (267,355), and demonstration of efficacy will have to await results from longer-term usage. Vaccination may be warranted in people living in endemic areas, those working

under high-risk conditions (foresters, woodcutters, farmers, military personnel, laboratory workers), or travelers engaged in high-risk activities (e.g., field work, camping).

For passive immunization, a specific TBE-immunoglobulin is also available in several European countries that can be used for preexposure and postexposure prophylaxis (124). When given within 4 days after tick bite, protective efficacy was estimated to be 60% to 70% (387).

A difficulty in achieving complete TBE vaccination coverage has been the higher level of adverse reactions in children. In a controlled trial, a reduced amount of the Ecepur (TBE) vaccine was shown to induce an effective immune response and to have a much lower level of side effects (213). Another study showed that rapid vaccination protocols using inactivated vaccines could be successful in protecting recipients. This sort of rapid vaccination would be useful for individuals, such as those involved in military or relief operations, who have received short notice of a trip into an endemic area (689).

The high degree of relatedness of the TBE complex would seem to allow a vaccine against one subtype to be effective against another. This was confirmed in a murine study in which immunization with a vaccine against a European strain induced antibodies against a Far Eastern strain. Inactivated TBE vaccines have adjuvant/carrier activities for unrelated antigens and have been proposed as components of multivalent vaccines containing weak antigens (412).

Several new types of TBE vaccines are under development (282). A vaccinia virus vector expressing the PreM/E proteins induces protective immunity against challenge with virulent TBE virus (313). A chimera Langat/dengue type 4 attenuated vaccine induces neutralizing antibodies and resistance to fatal Langat virus–induced encephalitis (557). Naked DNA vaccines expressing PreM/E proteins of RSSE and CEE induced protective immunity against RSSE and CEE challenge (659). Another DNA vaccine study looked at how different forms of the E protein would effect its immunogeneity. In this study, the E protein was either intracellular, secreted as an E dimer, or secreted as a recombinant subviral particle (3). The best immunogen was the RSP. The E-dimer DNA vaccine elicited suboptimal protection, whereas the RSP DNA vaccine induced 100% protection. Synthetic infectious RNA has been used to immunize mice in a model system (447), and recombinant adenovirus carrying the gene for NS1 has also been tested in mice (712).

The use of repellents or protective clothing may reduce the risk for tick bite, although this is not a practical prophylactic measure, especially for people at permanent risk for exposure. In the past, widespread use of pesticides, including aerial applications of pesticides, was undertaken in some areas in attempts to interrupt transmission.

Other Viruses Causing Encephalitis

Rocio Virus

Rocio virus, a classic emerging virus, was first isolated from fatal human cases in 1975 during an explosive outbreak of encephalitis on the south coast of Sao Paulo State, Brazil (437,438). The virus is not placed in any of the flavivirus antigenic complexes, but it cross-reacts most closely with members of the JE subgroup, especially Ilheus virus. A plausible explanation for its sudden appearance is a mutation in a strain of Ilheus virus, which has a wide geographic range, including Brazil and Argentina. However, at this writing, neither Rocio nor Ilheus virus has been sequenced in an attempt to elucidate the origin of the epidemic.

The pathologic changes in humans are similar to those of JE and SLE infections: the most severely affected structures in seven patients studied were thalamus, dentate nucleus of the cerebellum, hypothalamic nuclei, and substantia nigra (629). In experimentally infected suckling hamsters, Rocio virus produced severe necrosis of myocardium and pancreas (269).

The clinical features in human cases are similar to those of SLE (713). The case fatality rate in hospitalized patients was 4%. Sequelae, including persistent cerebellar, motor, and neuropsychiatric signs, were noted in 20% of survivors. Diagnosis is by virus isolation from brain tissues of fatal cases or by serology.

Epidemics in coastal Sao Paulo State in 1975 and 1976 resulted in 971 cases, with attack rates of up to 38 per 1,000 inhabitants (326,327,438). The disease appears to have virtually disappeared, suggesting that the emergent virus may not have been well adapted for sustained transmission. Since 1976, only one serologically diagnosed case has been reported (a fatal case in an infant in 1980) (328), although other, clinically suspect cases continue to occur. The highest disease incidence during the outbreak of 1975 to 1976 was in young adult males engaged in outdoor work in impoverished agricultural areas. Wild birds are presumed to be viremic hosts in the transmission cycle. A single virus isolation was made from *Psorophora ferox* mosquitoes. *Aedes serratus* and *Aedes scapularis* were implicated as epidemic vectors of Rocio virus on epidemiologic grounds (194). Both *P. ferox* and *A. scapularis* transmit Rocio virus experimentally, whereas *A. serratus* does not (486). A mouse brain vaccine lacked potency (439).

Louping Ill Virus

Louping ill was recognized as a neurologic disease of sheep in Scotland during the late 19th century. Isolated in 1929 (567), the virus is a member of the TBE virus complex. By monoclonal antibody analysis, louping ill and CEE viruses belong to a distinct western subtype of the TBE virus complex (207,690). Phylogenetic analysis using the envelope gene sequence from various isolates revealed the presence of three major geographic populations the Irish, Welsh, and British variants (473). Louping ill is different from the other TBE viruses in that it is associated with a forest environment. This analysis also suggests that an ancestral virus was originally introduced to Ireland from Continental Europe and emerged as the distinct louping ill virus 800 years ago. From Ireland the virus dispersed, mostly in the last 130 to 300 years. There is suggestive evidence that the dispersal of louping ill followed the export of cattle from Ireland to England and spread further along routes of cattle transit. Although impossible to substantiate, this would be a classic dispersal of a viremic host into a virgin area, where the local arthropods feed off of the imported host and then form a new transmission cycle.

Louping ill virus kills suckling mice by all routes of inoculation; weanling mice, hamsters, and guinea pigs develop fatal encephalitis after intracerebral inoculation. Many cell cultures propagate the virus, and plaque assays may be performed in PS, Vero, and LLC-MK2 cells.

Experimentally infected sheep develop prolonged viremia followed by ataxia, paralysis, and tremors (591). Pathologic changes include diffuse meningoencephalitis with severe chromatolysis and destruction of Purkinje cells, reactive gliosis, and astrocytosis. Although clinical disease has been described in cows, horses, pigs, goats, deer, and dogs, louping ill is predominantly a disease of sheep, which develop a biphasic illness; the first phase is characterized by fever and weakness, followed by a neurologic illness with prominent cerebellar ataxia, hyperexcitability, and progressive paralysis. Epornitics of fatal disease in wild red grouse have been described (592). Experimentally infected red grouse also develop fatal infection and viremias sufficient to infect tick vectors (590).

The human disease was first described in a person with a laboratory infection (605). Thirty-nine human cases have been reported, of which 26 resulted from laboratory exposure (146,674). Of the natural infections, some followed tick bites, whereas others followed direct exposure of abattoir workers, butchers, and veterinarians to sick sheep. Shepherds and crofters are also occupational risk groups. Infection by the oral route has been documented in animals ingesting infected milk or lamb carcasses.

The human disease is biphasic and resembles CEE. The incubation period is 4 to 7 days. The first phase is influenza-like, lasting 2 to 11 days, followed by a remission of 5 to 6 days and then the reappearance of fever and a meningoencephalitic syndrome that last 4 to 10 days. There is leukopenia during the first phase and leukocytosis during the encephalitic phase. No deaths have been reported. The clinical features are reviewed by Smith and Varma (674) and Webb and colleagues (756). Asymptomatic infections are not infrequent, and abortive, influenza-like illness also occurs. In one laboratory-acquired case, a hemorrhagic diathesis developed, and the disease closely resembled Kyasanur Forest disease. Treatment is symptomatic. Diagnosis is by virus isolation from blood during the first phase of illness, from CSF during the early encephalitic phase, or by serologic tests (HI, CF, neutralization). Antibodies are produced locally in the CNS. The serum-to-CSF antibody ratio has been employed in human diagnosis (756).

Louping ill virus is distributed in Scotland, northern England, Wales, and Ireland. A virus serologically identical to louping ill virus was recovered from sick sheep in Norway (589). A closely related but distinct agent in Turkey has been associated with louping ill–like disease in sheep (Turkish sheep encephalitis) (205). The transmission cycle of louping ill involves *I. ricinus* ticks and both sheep and grouse (319). As with other TBE viruses, transmission can occur between infected and uninfected ticks that are cofeeding on the same host (341). Spread in this manner can occur on immune or nonimmune host animals, although it seems to be much more efficient on nonimmune animals. Control of the disease in sheep is by vaccination, dipping with residual acaricides, and environmental control of ticks. The vaccine now in general use is grown in sheep kidney cell cultures, is formalin inactivated, and is concentrated by methanol precipitation (80). A killed vaccine for use in laboratory and abattoir workers was once used on an experimental basis (178). It is likely that the TBE vaccine (prepared against the western subtype) would cross-protect against louping ill infection. A louping ill virus vaccine using Semliki Forest virus particles for delivery appears to provide excellent protection in several of the combinations (189).

Modoc Virus

Modoc virus was first isolated in 1958 from white-footed deer mice (*Peromyscus maniculatus*) collected in Modoc County, California. Isolations have subsequently been made from the same species in Oregon, Montana, and Alberta, Canada. The virus is antigenically related to other flaviviruses recovered from rodents (Cowbone Ridge, Jutiapa, Sal Vieja, and San Perlita viruses), and is probably transmitted by contact. Virus isolations have been obtained from throat swab specimens of deer mice trapped in the wild. It has not been possible to infect mosquitoes experimentally. The compartmentalization of virus transmission in a rodent–rodent cycle probably accounts for the scarcity of human infections. A single human case of illness attributed to Modoc virus was reported in California in 1966 (588). The patient was a 10-year-old boy who presented with a clinical picture of aseptic meningitis. The infection may have been acquired in Tulare County, where the patient played with deer mice near a rural cabin.

Powassan Virus

Powassan virus was first isolated in 1958 from a fatal case of encephalitis in Ontario (478). It is a member of the TBE virus complex but is more distantly related than other viruses in the complex both antigenically (92) and genetically (449). The virus is pathogenic for infant and weanling mice by the intracerebral and intraperitoneal routes; hamsters and rabbits develop subclinical infections. Experimental encephalitis has been demonstrated in rhesus macaques. Continuous cell lines of monkey kidney origin are useful for virus assay by CPE and plaque formation. Pathologic changes in the brains of mice, monkeys, and humans are typical of other flavivirus infections. Powassan infection is characterized by a variable period of fever and nonspecific symptoms, followed by neurologic signs of meningeal irritation and encephalitis, which are often severe. Serious neurologic sequelae have occurred in 35% of the reported cases, and in one, these resembled RSSE with shoulder-girdle involvement (134). In another case, the acute disease closely mimicked herpes encephalitis with temporal lobe involvement. In cases reported from the former Soviet Union, a characteristic syndrome with prominent cerebellar signs differentiated the disease from RSSE (414).

The disease occurs in Russia, Canada, and the United States. In North America, Powassan encephalitis has been reported in Ontario, New York, and Pennsylvania, with a total of 20 cases, 18 in people younger than 20 years of age, and one death (25,721). Most cases have been in males, probably reflecting increased outdoor activity and exposure to ticks. Human infections are rare; antibody surveys in the United States and Canada have generally shown prevalence rates of 0.5% to 4%. The virus has a much wider geographic distribution than indicated by case reports, and Powassan infection should therefore be suspected in cases of encephalitis throughout the United States and Canada. Treatment is

symptomatic; diagnosis is by serology or virus isolation from brain tissues of fatal cases.

In North America, the virus is transmitted in a cycle involving small mammals principally squirrels and ground hogs) and *Ixodes* species ticks, including (a) *Ixodes marxi* and *Ixodes cookei* in the East and (b) *Ixodes spinipalpus* in the West (25,26). The virus has also been isolated from *Dermacentor andersoni* in South Dakota. *I. scapularis* (the vector of Lyme disease) is a competent experimental vector. The widening geographic distribution of *I. scapularis* and its role in the spread of Lyme disease may herald an increased risk for human Powassan infection. Serologic surveys and virus isolations have shown infections in wild mammals, including rodents, hares, dogs, skunks, and foxes. In an experimentally infected lactating goat, virus secreted in the milk resulted in infection of the offspring; antibody has been demonstrated in naturally infected goats in New York State, indicating the possibility of milk-borne transmission to humans (775). The virus has been isolated from ixodid ticks (e.g., *Haemaphysalis neumanni*) and from mosquitoes in Russia (413). There is no evidence for mosquito transmission in North America.

Negishi Virus

Negishi virus was isolated from the CSF of a fatal human case in Tokyo in 1948 during an outbreak of JE. The virus is a member of the TBE virus complex (129). Monoclonal antibody analysis and nucleotide sequencing showed that the virus is most closely related to louping ill virus (744). Infant and weaned mice are highly susceptible to peripheral and intracerebral infection. A second fatal case occurred in 1948, and in 1950, a laboratory infection was reported with fever but no neurologic signs (541). Human cases of Negishi encephalitis have been recognized in China.

FLAVIVIRUSES ASSOCIATED PRIMARILY WITH FEVER, ARTHRALGIA, AND RASH

Dengue Fever Viruses

The first epidemic of a disease that is believed to have been dengue was described in Philadelphia in 1780 by Benjamin Rush. Epidemics were common during the 18th and 19th centuries in North America, the Caribbean, Asia, and Australia (99,670). The earliest recorded illness found thus far whose symptoms resemble dengue were found in a Chinese encyclopedia first published in the Chin Dynasty (265 to 420 A.D.). Outbreaks of an illness in the French West Indies in 1635 and a similar illness in Panama in 1699 could quite possibly have been dengue (237). These outbreaks and descriptions show that long before it became a significant health concern, dengue had a global distribution.

Dengue transmission by *A. aegypti,* first described by Bancroft in 1906, was later proved by Siler and colleagues (670) and Simmons and associates (671). Ashburn and Craig found a filterable, infectious agent in human blood in 1906; in 1926 and 1931, respectively, Siler and colleagues (670) and Simmons and associates (671) transmitted the virus to human volunteers and established the incubation period in mosquitoes. The virus was isolated in mice by Sabin and Schlesinger in 1944 (638), and the existence of more than one serotype was established by cross-protection studies in human volunteers (637).

In the years following World War II, the slow spread of dengue began. The number of nations and people affected have steadily increased, and today dengue is considered a critical global health concern; epidemics involving thousands of people and multiple strains recur in areas of tropical Asia, Africa, Australia, and the Americas where *A. aegypti* is present. Since the 1980s, dengue fever and a severe form of the disease described for the first time in 1954, DHF (see later, Dengue Viruses), have emerged as the most important arthropod-borne viral diseases of humans (238,241,506). More than 2.5 billion people inhabit tropical areas where they are at risk for dengue infection, and an estimated 100 million cases of dengue fever and 250,000 cases of life-threatening DHF occur annually on a worldwide basis.

Infectious Agents

Four serologic types (1 through 4) are recognized on the basis of plaque reduction NT (633) and constitute a distinct antigenic complex (92). Dengue 1 and 3 form a subcomplex defined by monoclonal and polyclonal antibodies (294). Some antigenic heterogeneity is apparent between strains of each type by conventional NT (632). However, monoclonal antibodies have also shown unexpected relationships at the subcomplex level (e.g., between dengue 1 and 3, 2 and 4, and between dengue and viruses of the JE and TBE complexes) (reviewed in 283 and 614). At a more detailed level, antigen signature analysis of dengue 2 strains by monoclonal radioimmunoassay (RIA) has revealed antigenic variation that correlates with genomic variation demonstrated by RNA oligonucleotide fingerprinting (505). The latter technique has now defined multiple geographic variants of dengue 1 and 2 virus (see Epidemiology, later).

Nucleotide sequences of all four dengue types have been reported (157,255,460). Within the dengue virus group, amino acid sequence positional homology of 63% to 68% was found, compared with 44% to 51% between dengue, yellow fever, and WN viruses. Genetic variants of dengue 2 show more than 90% similarity. A genetic relationship was found between dengue 2 virus and Edge Hill virus (58).

Dengue viruses grow in a variety of primary and continuous cell cultures; high yields and demonstration of CPE are difficult to obtain in many systems without adaptation and passage. Cells of human (BSC-1 and HL-CZ, a promonocyte cell line), monkey (LLC-MK2, Vero, primary monkey kidney), hamster (BHK-21), and mosquito origin are most susceptible. Yields of up to 10^7/ml to 10^8/ml, CPE, and plaque formation are obtained under appropriate conditions.

Dengue viruses replicate in the brains of suckling mice and hamsters inoculated intracerebrally (65). Neurovirulence for mice and monkeys increases with sequential passage in mouse brain. Guinea pigs, rabbits, cotton rats, adult hamsters, chickens, and lizards are not susceptible to infection (345,649). Embryonated eggs replicate some strains only after repeated passage. Adult mice inoculated with highly adapted dengue types 1 and 2 viruses become infected with or without overt encephalitis (61). Old World and New World monkeys and apes develop subclinical infection and viremia (621,671,768). Dengue viruses replicate to high titer in *Aedes* and *Toxorhynchites* species mosquitoes inoculated

intrathoracically or intracerebrally (627).

Protein E binds to Vero, CHO, endothelial, and glia cells in culture in a dose- and time-dependent manner and can be saturated (119). The cellular receptor used by dengue in this experiment is a highly sulfated type of heparan sulfate (121). The dengue envelope protein sequence has two putative glycosaminoglycan-binding motifs at the carboxyl terminus. Other members of the flavivirus family have similar motifs in their envelope proteins. Differences in the E protein and the differences among heparin sulfate structure and sulfation among cells may be the factors responsible for tissue tropism (320,409).

The CD14 receptor of monocytes and macrophages appears to be involved in dengue virus attachment to these cells because lipopolysaccharide, which binds to the CD14 receptor, is able to block dengue virus entry into monocytes and macrophages (120). The understanding of what surface receptors the flaviviruses use for cellular entry is expanding (575), but the diverse nature of the pathology and tropism within and between strains makes it possible that there are many different receptors (421).

Recently, it has been demonstrated that the initial target cells for dengue virus infection in humans are skin dendritic cells. Studies of virus growth in human cadaveric skin explants and in skin biopsy specimens from an infected human have demonstrated that a high proportion (60% to 80%) of local dendritic cells expressed dengue antigens (779a).

Pathogenesis and Pathology

Neuroadapted dengue virus produces typical encephalitic lesions, predominantly in the rhinencephalus of infant, weanling, and adult mice. Viral antigen is detectable by IF in reticuloendothelial cells of liver, lymph nodes, and spleen of intraperitoneally infected mice (61). Dengue infects liver cell lines *in vitro* and appears to induce cellular death or apoptosis, which could be involved in the disease pathology (425,454). Dengue viral antigens are detectable by Western blotting in suckling mouse brain or liver examined 7 days after intracerebral inoculation (114). Athymic nude mice peripherally infected with adapted dengue virus develop fatal encephalitis and viral antigen in neurons, skeletal muscle, myocardium, and Kupffer's cells. In mice, dengue replicates within and induces apoptosis in neurons of the cortical and hippocampal regions of the CNS (152).

In experimentally infected nonhuman primates, the role of mononuclear phagocytes as principal sites of dengue viral replication has been established by tissue titration and immunofluorescent staining of cells in skin, spleen, lymph nodes, liver, lung, and thymus; *in vitro* infection of monocytes supports these findings. Mild inflammatory lesions are found in the brain of monkeys inoculated by the intracranial route.

Classic dengue fever produces self-limited infection in humans. Biopsy specimens of skin lesions show swelling of endothelial cells of small vessels, perivascular edema, and infiltration of mononuclear cells.

Dengue viruses multiply in the midgut epithelium, brain, fat body, and salivary glands of mosquitoes (627). No detectable pathologic changes result from infection, and mosquitoes remain infectious for life. Dengue virus replicates in the female mosquito genital tract and may enter the ovum at the time of fertilization, thereby infecting a portion of her progeny (625). Sexual transmission also occurs from male *Aedes* species with inherited infections to susceptible females, which may subsequently pass the virus to their progeny (626).

Clinical Features

The clinical manifestations of dengue fever are described by Siler and colleagues (670), Simmons and associates (671), and Sabin (637). In the typical case, the disease begins abruptly, after a 2- to 7-day incubation period, with high fever, headache, retrobulbar pain, lumbosacral aching pain, conjunctival congestion, and facial flushing. Fever may be sustained for up to 6 to 7 days or may have a biphasic (saddle-back) course. Initial symptoms are followed by generalized myalgia or bone pain that increases in severity, anorexia, nausea, vomiting, weakness, and prostration. The pulse rate may be slow in relation to the fever. Respiratory symptoms (cough, sore throat, and rhinitis) are not uncommon, especially in children. A transient, generalized macular or mottled rash may appear on the first or second day. Coincident with defervescence (day 3 to 5) or shortly thereafter, a secondary rash, maculopapular or morbilliform in nature and nonirritating, appears first on the trunk and then spreads centripetally to the face and limbs but spares the soles and palms. The rash may desquamate. Fever may rise again, creating the second phase of the saddle-back course. Generalized lymphadenopathy, cutaneous hyperesthesia, and altered (metallic) taste sensation may accompany this step of the disease. The peripheral WBC count is depressed with an absolute granulocytopenia, and the platelet count may fall to less than 100,000/mm^3. Hemorrhagic phenomena are noted in a few cases and include petechiae, epistaxis, intestinal bleeding, menorrhagia, and a positive tourniquet test. Myocarditis and various neurologic disorders, including encephalopathy and peripheral mononeuropathy, polyneuritis, and Bell's palsy, have been associated with dengue fever (243,337,548). Central neurologic disorders appear to be more common in DHF than in classic dengue. Reye's syndrome has also been reported to follow dengue infection.

Convalescence may be prolonged, with generalized weakness, depression, bradycardia, and ventricular extrasystoles. Persistent arthritic symptoms are not a feature of dengue and suggest other viral etiologies, including alphavirus (Ross River or chikungunya) infection.

Diagnosis

Exposure by residence or travel in dengue-endemic areas and knowledge about the occurrence of other cases in the community are important clues to the diagnosis. Other infections that clinically may be confused with dengue include influenza, rubella, rubeola, malaria, scrub typhus, leptospirosis, and a variety of other arboviral infections. Rash is a helpful differential sign, but it may be difficult to discern in dark-skinned patients. Epidemic arboviral infections that resemble dengue fever and may be accompanied by rash include chikungunya, O'nyong nyong, WN, Sindbis, Mayaro,

and Ross River virus diseases.

Specific diagnosis depends on virus isolation or serologic tests. Virus may be recovered from the blood during the early febrile phase of the illness. Viremia titers in dengue 1, 2, and 3 infections range from barely detectable to 10^8 for 3 to 5 days; titers in patients infected with dengue 4 are about 100-fold lower (244,245). *Toxorhynchites* species mosquitoes are sensitive hosts for dengue virus isolation by intrathoracic inoculation; virus can be identified by IF staining or CF tests on mosquito tissues within 10 to 14 days after inoculation (374). Larval *Toxorhynchites* species inoculated intracerebrally are also useful for primary virus isolation. *Toxorhynchites amboinensis* (TRA-284), *A. albopictus* (C6/36), and *Aedes pseudoscutellaris* (AP-61) cell lines are now widely used for primary dengue virus isolation (384). The TRA-284 line adapted to serum-free medium provides the most sensitive assay. Syncytial CPE may be present, but it is an unreliable marker of infection; moreover, cultures must be examined by IF to detect virus. Monoclonal antibodies are used for type-specific identification by IF. These techniques allow isolation and identification in as short a period as 2 days, depending on titer of virus in the test sample.

Direct detection of dengue viral antigen in human serum has been reported by use of countercurrent immunoelectrophoresis and by monoclonal RIA. Rapid diagnosis has been achieved by immunocytochemical staining of peripheral blood mononuclear cells obtained during the acute phase of illness (518), and this method is more sensitive than virus isolation. RT-PCR has been applied to the rapid diagnosis of dengue infections, using serotype-specific primers and analysis of amplified sequences by agarose gel electrophoresis or hybridization with serotype-specific digoxigenin-labeled probes (159,404). This technique has permitted detection of viremia levels of less than 2 dex/ml.

Serologic diagnosis depends on the demonstration of a fourfold or greater rise (or fall) in antibodies by HI, CF, or NT. It is frequently difficult to establish the specific infecting serotype because of cross-reactions, especially in patients with preexisting heterologous immunity. In the case of sequential dengue infections, the antibody response to the initial infecting virus type may exceed that to the current infecting type (original antigenic sin) (261), but this is not a uniformly reliable method for retrospectively determining the identity of an earlier infection (383). The plaque-reduction NT is more specific than other tests. During the convalescent period after a sequential infection, cross-reactions make specific diagnosis difficult, but after about 6 months, the presence of neutralizing antibodies to multiple dengue serotypes is a reliable marker of prior infection with those serotypes. Epitope-blocking immunoassays employing monoclonal antibodies provide diagnostic specificity similar to the NT (86). The IgM antibody–capture ELISA is the favored assay for serologic diagnosis. IgM antibodies appear shortly after defervescence and wane after 1 to 2 months (324).

Because of the association between sequential infection and DHF, it is important to distinguish primary from secondary dengue infections. The HI test has been used to classify dengue infections. Secondary infections are characterized by the presence of HI antibodies in the acute phase sample and by high titers (more than 1:1,280) in convalescent sera. The ratio of IgM to IgG antibodies determined by ELISA is useful for distinguishing primary from secondary infections (324,382); in primary infections, the IgM-to-IgG ratio (expressed in optical density [OD] units) in acute sera or convalescent sera obtained during the first month after onset generally exceeds 1.5, whereas secondary infections are characterized by an excess of IgG. Western blotting of sera from patients with primary dengue infections reveals antibodies against the E glycoprotein and the NS3 and NS5 nonstructural proteins, whereas sera with high titers owing to secondary infections reveal a broader array of viral protein bands (113,114).

In recent years, several commercial kits have been designed to make dengue diagnosis simpler and more efficient. A good assay will allow dengue diagnosis without the need for a large, well-developed laboratory and highly skilled personnel, resources at a premium in dengue endemic areas. The clinical usefulness of one of these tests, a capture ELISA specific for IgM and IgG antibodies in distinguishing between primary and secondary infection, was demonstrated (140a). This distinction is important for the epidemiology of DHF.

Treatment

Treatment is supportive and includes bed rest, antipyretics, and analgesics. In case of dehydration, fluid and electrolyte replacement are used in addition. Perspectives on possible future antiviral treatments are reviewed by Leyssen, Declercq, and Neyts (420). Ribavirin has marginal value (444).

Animal Models

One of the problems in developing a better understanding of dengue infection and the various complications thereof has been the lack of a good animal model. Only humans, mosquitoes, and some primates are naturally infected.

Human cell lines have been engrafted into SCID mice, and some of the characteristics of systemic dengue infection are produced (13,424).

Epidemiology

Dengue virus is transmitted in a cycle involving humans and mosquitoes, *A. aegypti* being the most important vector (Fig. 15). Dengue occurs principally in tropical areas of Asia, Oceania, Africa, Australia, and the Americas. Temperate areas within the range of *A. aegypti* are susceptible to summertime introduction and spread of the virus. In areas having year-round vector activity and large human populations, one or more dengue virus types may be maintained endemically. Elsewhere, especially in small, insular populations, epidemics result from the introduction of a new type. Because most dengue cases are subclinical, many cases go unnoticed and can be silently transmitted, as was seen recently in Taiwan (117). Environmental changes can increase human infection and lead to outbreaks (110). Therefore, a long-term active surveillance system is needed to determine accurately the risk for a dengue outbreak.

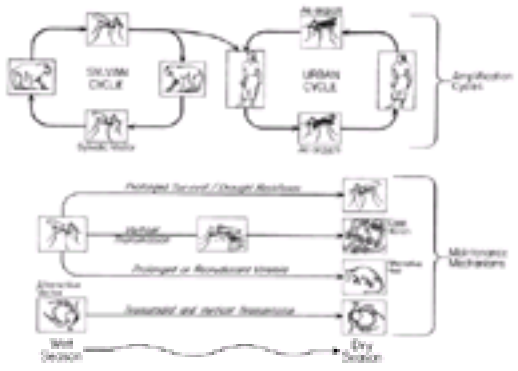

FIG. 15. Transmission cycles of yellow fever and dengue viruses. These viruses have enzootic maintenance cycles involving tree-hole breeding *Aedes* species vectors and nonhuman primates. Dengue viruses are transmitted principally between humans and *Aedes aegypti* that breed in domestic and peridomestic water containers. A sylvatic cycle has been documented in Southeast Asia and West Africa, but it is presently uncertain to what extent this cycle contributes to human infections. In the case of yellow fever, sylvatic transmission is widespread throughout the distribution of the virus. In tropical America, human yellow fever cases derived from contact with forest mosquito vectors, and no urban (*Aedes aegypti* mosquito-borne) yellow fever has occurred since the 1950s. In Africa, sylvatic vectors are responsible for intermonkey and interhuman virus transmission, and there is frequent involvement of *Aedes aegypti* in urban and dry savannah regions.

Protection against homotypic reinfection is complete and probably lifelong, but cross-protection between dengue types lasts less than 12 weeks (637). Consequently, it is possible to sustain multiple, sequential infections. In general, however, most clinically overt illness probably occurs during primary or secondary infections. Clinically apparent tertiary infections do occur, but infection with a fourth serotype is nearly always subclinical. Experimental infection in nonhuman primates has also shown incomplete cross-protection between pairs of dengue viruses, and sequential infection with three or four dengue types is required to achieve complete protection. The background of homotypic immunity in a human population group determines the incidence and age distribution of infections. In virgin-soil outbreaks, dengue attack rates are generally similar among age groups. In some outbreaks, a higher incidence of dengue fever has been found in females (22,343), probably indicating risk for infection around the home by the domestic, daytime biting vector, *A. aegypti.*

Vector density and factors determining exposure to infected female mosquito vectors are important determinants of the rate of dengue virus transmission. The domestic habits of the principal vector, *A. aegypti,* ensure that infection occurs in and around human habitations. Inhabitants of screened houses are at significantly lower risk for epidemic dengue (356). Where dengue is transmitted, it is not uncommon to find 10 to 20 female *A. aegypti* per room, of which 5% to 10% may be infected (512). *A. aegypti* commonly exhibit interrupted feeding behavior, and most females feed multiple times between egg laying; these factors contribute to the rapid transmission of dengue virus and the explosive nature of dengue epidemics.

The worldwide incidence of dengue has increased dramatically in the period following World War II, owing to expanding urban human populations and a coincident increase in *A. aegypti* density as well as the advent of air travel and rapid movement of viremic people. These changes are underscored in the Americas (241,506), where the frequency of epidemics has increased dramatically and multiple dengue serotypes have been introduced. Since the mid-1990s, the continent of South America was reinvaded by *A. aegypti* (Fig. 16), with the result that large dengue outbreaks, some involving more than 1 million people, occurred in immunologically naive populations. Attack rates in outbreaks in the Americas have ranged from 20% to 90% (179,186,242,369). In many areas, dengue has become established in endemic patterns of infection. In Puerto Rico, for example, dengue serotypes 1, 2, and 4 have circulated continuously since 1985 (512,611).

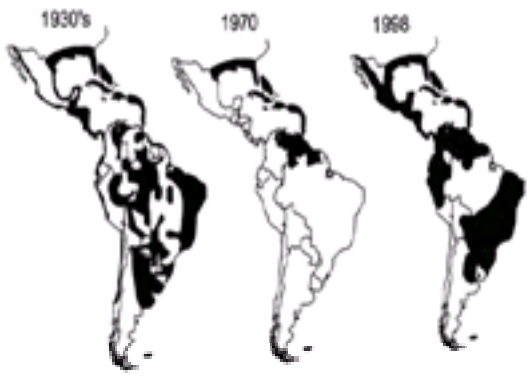

FIG. 16. Distribution of *Aedes aegypti* in the Americas in the 1930s, the 1970s, and in 1998. Reinvasion of the South American continent by *Aedes aegypti* occurred in the late 1970s and 1980s due to collapse of vector control programs, the increase inbreeding sites due to urbanization, and other factors. The result has been the emergence of epidemic dengue and dengue hemorrhagic fever in the continent, and an increased risk of urban outbreaks of yellow fever. From Gubler (237).

In hyperendemic areas of Southeast Asia, more than half of children experience infection with one or more dengue

serotypes by 7 years of age. In tropical areas, epidemics tend to occur during the monsoon or rainy season (18,322). Although increased rainfall results in expansion of vector mosquito breeding, human disease incidence does not correlate closely with vector population density. Other factors (in particular, increased temperature, which shortens the extrinsic incubation time of dengue virus in the vector) appear to be more important (191,594,754).

In the United States, most cases of dengue fever have been acquired abroad. Between 1980 and 1989, 1,457 cases of clinical dengue were reported in the United States, and 276 were confirmed by laboratory tests. There were several small outbreaks of dengue along the Texas–Mexico border in the mid-1990s, involving about 50 cases (587a).

In addition to *A. aegypti,* other species, including *A. albopictus, Aedes polynesiensis,* and *Aedes scutellaris,* play a role in rural and insular areas of Asia and the Pacific. *A. albopictus* was introduced from Asia into the United States and Brazil in 1985; an isolation f dengue virus has been made from this species in Brazil, but it has not yet been clearly implicated in epidemic dengue transmission (241,506). *A. aegypti* breeds in artificial containers with clean water in and around human habitations and bites principally during the daytime. In addition to biologic transmission, mechanical spread by *A. aegypti* and other mosquitoes may occur. Geographic variation exists between strains of *A. aegypti* and *A. albopictus* in terms of their vector efficiency (susceptibility to oral infection), but the epidemiologic importance of this variation has not been clearly established (240). In general, *A. aegypti* strains display low susceptibility to oral infection. This requires that virus titers in the blood of human hosts be high, exceeding 10^5/ml, for infection and transmission to be sustained. Thus, the vector serves as an important selection mechanism or biologic filter for maintaining virus virulence at a high level because only virus strains that replicate efficiently in humans and produce high viremias are transmissible by this mosquito.

Zoonotic cycles of dengue virus transmission involving monkeys and forest *Aedes* species have been documented in Malaysia (631), Sri Lanka (154), and West Africa (136,609) (see Fig. 15). The vector in Malaysia is *Aedes niveus;* the species implicated in West Africa are *Aedes furcifer, Aedes taylori, Aedes luteocephalus, Aedes opok,* and *Aedes africanus.* The possibility of a forest cycle in South America deserves study.

The maintenance of dengue viruses between epidemics has not been clearly defined, especially in rural areas with relatively sparse human populations (11). An alternative mechanism to year-round horizontal human–mosquito–human transmission, such as vertical transmission in *Aedes* species vectors, must be considered. Similar considerations apply to the maintenance of the sylvatic cycle over the dry season. Experimental studies have documented vertical transmission of dengue virus in *Aedes* species, and the virus has been isolated from field-collected larvae of *A. aegypti* and males of *A. furcifer-taylori* in West Africa (reviewed in 239 and 240). There is also evidence of a sylvatic cycle whereby jungle primates and mosquito vectors perpetuate the virus. This type of cycle is well known in jungle yellow fever. Dengue types 1 and 2 have been isolated from monkeys and sylvatic *Aedes* species in West Africa, and dengue 1, 2, and 4 have been isolated from monkeys in Malaysia (631). However, limited genetic studies of sylvatic dengue viruses in Africa appear to indicate that they are not involved in outbreaks of human dengue (604). The persistence of dengue in a jungle cycle would make it nearly impossible to eliminate the virus. However, once a good multistrain vaccine is available, the effect of the virus on the human population will be limited. As with yellow fever, any significant level of dengue introduction from a jungle cycle may require future vaccine program to continue in perpetuity.

Molecular Epidemiology

Nucleotide sequencing of the entire *E* gene has replaced the traditional techniques of RNA fingerprinting, RNA-DNA hybridization, antigenic analysis, short RNA oligonucleotide fingerprinting, and limited nucleotide sequencing of short regions of the genome as tools for determining the origin and spread of dengue epidemics (111,160,241,405,505,604,715). Phylogenetic and nucleotide sequence signature patterns of the *E* gene permit classification of each dengue serotype into a number of E genotypes, which generally correlate with geographic origin (Table 5). However, the current classification will expand as more strains of each dengue serotype are examined. Within a single geographic area, genetic changes in the virus population may be found over time (749), with the appearance of new variants by mutation and selection as well as by introduction from afar. Inconsistencies in the geographic classification, such as the finding of sequence homology between a virus genotype from one region and a strain from a widely separated region, imply that a new strain has been introduced by viremic humans or possibly by virus-infected mosquitoes or mosquito ova. Thus, genotypic classification has been useful as a tool to determine the origin and spread of epidemics. Two distinct genotypes of dengue 1 virus (see E genotypes I and II in Table 5) coexist in Thailand. Genotype II has been recovered in Africa. In 1977, it was introduced into the American region, where it caused a pandemic. The genotype has persisted in the Americas, and its distribution has expanded to include most Latin American countries except Argentina and Chile. Another example of a stably transmitted virus is the E genotype I of dengue 2 virus. This genotype, represented by the New Guinea C strain, the prototype dengue 2 virus, isolated in 1944, has persisted to the present day in Asia and was introduced into the Americas in 1981, causing the first epidemic of DHF in Cuba (252). This genotype now coexists in multiple areas with E genotype III, which had been present in the Caribbean since at least 1969. Similarity between the Caribbean E genotype III strains and dengue 2 strains isolated in the South Pacific between 1971 and 1976 indicated a potential route of spread.

Virus	Genotype[a]	Geographic distribution
Dengue 1	I	Japan (single isolate, 1943), Hawaii (single isolate, 1944), Thailand, Indonesia, Philippines, Taiwan, South Pacific
	II	Thailand, Malaysia, Burma, West Africa, Americas (introduced in 1977)
Dengue 2	I	New Guinea (prototype), Sri Lanka (before 1968), Philippines, Taiwan, Thailand, Malaysia, SE China, Americas ("Jamaica 'genotype'" introduced in 1981)
	II	Seychelles, Sri Lanka, Africa (introduced to East Africa in 1980–1981), Indonesia, Saudi Arabia
	III	India, South Pacific, Americas ("Puerto Rican genotype" introduced in 1969)
	IV	West Africa (sylvan cycle)
Dengue 3	I	Philippines, Indonesia, Malaysia, South Pacific (1980s)
	II	Thailand
	III	Sri Lanka, India, Africa
	IV	South Pacific (1960s), Americas (1960s, 1970s)
Dengue 4	I	Indonesia, South Pacific, Americas
	II	Thailand, Philippines

[a]Genotypes are defined on the basis of phylogenetic relationships of the E gene nucleotide sequence. The classification is a synthesis of several studies (see 111,405,604), and will change as sequences of other strains are reported and evolution of dengue virus genomes continues. The geographic distribution reflects virus importations and movements, and patterns of epidemic spread (see examples in text).

TABLE 5. *Classification of dengue viruses into E genotypes*

The dengue 4 virus, circulating in an endemic and epidemic pattern in the Americas since 1981, is closely related to strains from Niue Island and the Gilbert Islands, again indicating virus transfer between the Americas and Oceania. Comparison of dengue 2 strains isolated in the 1980s in Africa demonstrated that enzootic strains associated with sylvatic vectors and nonhuman primates in West Africa were genetically distinct from strains causing human epidemics. The West African epidemic strains were genetically related to isolates from Indonesia, Sri Lanka, the Seychelle Islands, and Somalia, suggesting a route of spread across the Indian Ocean to East Africa and thence to West Africa; the epidemics thus arose by introduction by viremic travelers rather than from a local jungle cycle (241,604).

Genetic analysis of strains has also suggested that dengue viruses vary in virulence (see later section, Dengue Viruses).

Evolution

Dengue viruses need to be able to survive in two different hosts, the vector and the reservoir. This dual requirement is thought to limit the degree of evolution because the virus must conserve amino acids that are critical to survival in the vector or reservoir.

A recent study indicates, however, that recombination may be an important aspect of dengue viral evolution (779). In a comparison of some 70 full-length dengue sequences, 7 were determined to have been the result of recombination. In the analysis, there were representatives of all four dengue types, but the recombination only appeared to take place within the same types. Recombination is difficult to detect because the complete sequences of many different isolates need to be compared. Questions about dengue recombination that need to be answered include the role it plays in dengue evolution and the degree of sequence homology needed for recombination.

ADE may play a role in the persistence of multiple strains of dengue. Computational-model analysis of dengue transmission dynamics determined that the ADE frequency plays a role in generating a persistent cycle of epidemic behavior (185,251). When modeled, the coexistence of all strains furthers the existence of the four distinct strains, whereas in its absence, there would be only one strain. Although this model is not definitive, it is interesting to note that among the other flavivirus (in which there is little or no ADE), even though there are many different isotypes, the same type of distinct strains as with dengue have not evolved. Nucleotide sequencing studies have been used to track the molecular epidemiology of specific dengue strains (602,672).

Prevention and Control

The development of a safe, effective dengue vaccine is a high priority of WHO, health ministries in some affected countries, the U.S. military, and at least one major pharmaceutical company, but has been an elusive goal (97,106). Classic live vaccines prepared by serial passage of dengue 1 and 2 in mouse brain were tested in humans 50 years ago (637,773) and found to be attenuated and immunogenic; however, the unacceptable substrate for these vaccines and the observation that neurovirulence of dengue viruses increased with continued mouse brain passage led efforts in a different direction (69,641). Propagation of mouse-adapted virus in chicken embryos (a technique similar to that used to develop yellow fever 17D vaccine) was successful and the passaged virus-induced abortive illness in human subjects (650). Although promising at the time, this approach was not pursued into development. In the 1970s, efforts to produce a live, attenuated vaccine by serial passage and cloning in cell culture (fetal rhesus lung or primary dog kidney) were initiated by the U.S. Army. By this time, it was clear that a combination vaccine that simultaneously induced protective immunity against all four serotypes would be required to avoid sensitizing the vaccinee to more severe disease (DHF). Candidate vaccines developed against the four serotypes had various markers of attenuation (small plaque size, temperature sensitivity, reduced viremia in monkeys) and were eventually tested in humans. All were found either to be overattenuated and poorly immunogenic or to induce dengue-like illness of varying severity. The dengue 2 vaccine (PR-159/S-1) was satisfactorily attenuated (660), but it elicited durable immunity only in subjects who had been immunized previously with yellow fever 17D, presumably on the basis of ADE (35). The experience gained in these studies suggested that *in vitro* (and even *in vivo* nonhuman primate) markers of attenuation were not reproducibly predictive of the response in humans, and current efforts are thus focused on stepwise testing of selected passage levels in small numbers of human volunteers.

Live, attenuated, small-plaque, temperature-sensitive dengue vaccines produced by serial passage in primary dog kidney cells without biologic cloning were developed in Thailand and have shown promise in human trials (50,52,53,737). The candidate vaccines have been administered to nonflavivirus-immune human subjects first as univalent and ultimately as tetravalent vaccines. Studies are currently underway in adults with prior dengue and JE virus immunity and in seronegative children. The results indicate that the quadrivalent vaccine is safe and immunogenic and that prior flavivirus exposure enhances the immune response to dengue. The precise dose requirements for each of the four serotype components of the vaccine mixture are still being refined, and it appears that children require significantly lower doses than adults to achieve adequate immunogenicity. Commercial production of the live dengue vaccine is expected in the near future.

Various strategies are also being explored toward the development of genetically engineered vaccines. Underlying assumptions of this work are that the immunity to protein E (and possibly also NS1) is required for durable protection; both humoral antibodies (especially neutralizing anti-E antibodies) and cytotoxic T-lymphocyte responses mediate protection; immunization with dengue virus is serotype specific (228), and, therefore, simultaneous immunization against all four serotypes is required. The major approaches are listed subsequently, with selected examples.

1. Recombinant subunit vaccines: expression of dengue structural proteins in eucaryotic systems has yielded immunogenic and protective antigens. Recombinant baculovirus expressing a fusion protein of E (lacking the C-terminal transmembrane domain) with MalE has been constructed. The fusion protein is secreted as a soluble product by *Spodoptera frugiperda* cells and is readily purified by maltodextrin affinity chromatography. The recombinant truncated E protein elicited neutralizing antibodies and protection in mice (151). In other studies, dengue *E* genes expressed in baculovirus also induced neutralizing antibodies and were protective (576,742). However, similar recombinant proteins have not always resulted in retention of conformational dengue epitopes required for neutralization (184). Immunization of monkeys with recombinant baculovirus-expressed structural and nonstructural proteins elicited binding antibodies but poor neutralizing antibody responses and poor protection against challenge (174). Other vaccines based on the highly immunogenic E protein have been tested. One vaccine was a fusion protein that combined 204 amino acids of E protein and 65 amino acids of NS1 protein from the Den-2 strain. This chimera protein was expressed as a fusion protein with staphylococcal protein A in *E. coli* and then administered to mice, where it was found to be very effective in protecting against lethal challenge by Den-2 virus (686). Another preparation involved the E protein with a six-histadine tag in place of the C-terminal amino acids expressed by recombinant baculovirus in *S. frugiperda* insect cells. The protein was purified under nondenaturing conditions and then administered to mice. These mice were able to survive a lethal Den-2 challenge (688). Subunit vaccines are of particular interest in generating successful dengue vaccine because of the difficulty in developing live-attenuated vaccines.
2. Production of recombinant noninfectious subviral particles: cells infected with recombinant vaccinia virus expressing the prM-E or prM-E-NS1 of JE virus were found to secrete the encoded proteins, which self-assemble into noninfectious, virus-like particles (461). The subviral particles appear to be highly immunogenic and protective (365). A similar approach to the production of dengue particles is now under investigation. A serious concern for the use of subunit vaccines (methods 1 and 2) is their ability to elicit sustained humoral immunity because waning antibody levels may precipitate aggravated disease as a result of ADE. The ability of subunit vaccines to induce protective responses based on cellular immunity is uncertain. Given classic concepts of antigen processing and presentation, such vaccines should induce predominantly CD4+ T-cell responses and would not be expected to elicit CD8+ class I MHC-restricted cytotoxic T cells that may play a role in clearance of infection. Nevertheless, protection has been demonstrated in mice immunized with recombinant structural proteins in the absence of detectable neutralizing antibodies (184), suggesting that linear T-cell epitopes inducing CD4+, CD8– class II MHC-restricted T cells (397,398) may be responsible.
3. Live attenuated, genetically engineered vaccines: full-length genomic cDNA of a Caribbean strain of dengue type 4 virus has been used to transcribe infectious RNA (403) and to produce stable progeny virus. The cDNA can be genetically manipulated to introduce deletions or substitutions. Mutations introduced in the 3'-noncoding region and at the NS1/NS2a cleavage site resulted in reduced replication of dengue 4 virus, suggesting that the virus had become attenuated. Other potential target sites of the genome for the introduction of attenuating mutations and deletions are under investigation. The infectious clone has been used to construct intertypic chimeric viruses in which the *C-prM-E* genes of dengue 1 or 2 or the *prM-E* genes of dengue 2 were inserted into the dengue 4 genomic framework (68,71). In animals, the chimeric viruses elicited protective homotypic immunity to the insert. Similar chimeras have been constructed using the *prM-E* structural genes of TBE virus in the dengue 4 genomic framework (559). Work is underway in several laboratories to use a similar approach, but with dengue virus structural genes inserted into the backbone of yellow fever 17D virus. In another approach, the structural gene of a dengue 1 vaccine strain, passive level PDK-13, were combined with the nonstructural proteins of the dengue 2 vaccine strain, passive level PDK-53. The initial mouse studies indicate that the resultant chimera dengue 1/dengue 2 vaccine induced higher levels of neutralizing antibodies to dengue 1 than the dengue 1 PDK-13 strain vaccine (316). Although this general approach shows considerable promise as a means of preparing rationally designed live vaccines, the genetic changes required to achieve the appropriate level of attenuation and immunogenicity in such constructs remain to be defined.
4. Live vectored vaccines: various prokaryotic and eukaryotic vectors expressing dengue genes are under investigation, including salmonella, vaccinia, rubella virus, and adenoviruses. Immunization of mice with recombinant vaccinia expressing dengue 1 *prM-E* genes elicits protective responses (70,192), which may depend on the expression of subviral particles (see previous paragraph number 2) during *in vivo* replication of the recombinant vaccinia.
5. DNA vaccine: the dengue 2 *PreM* and 92% of the *E* genes have been cloned into various expression vectors and administered to ALB/c mice (359). All of the mice developed antidengue neutralizing antibodies specific for dengue 2. However, when challenged with dengue 2, the immunized mice demonstrated no protection.

Until the successful development and implementation of dengue vaccines, prevention of epidemics will continue to rely on reduction or eradication of *A. aegypti* by breeding site elimination, use of larvicides, and perifocal spraying of insecticides. Eradication achieved 20 years ago in many countries of Latin America has now been reversed by repeated reinfestations, economic development with attendant expansion of *A. aegypti* breeding, reduction in program support, and insecticide resistance (see Fig. 16).

There are several different paths that mosquito eradication programs can follow. The most effective is to eliminate the mosquitoes at the larval stage. To accomplish this, there must be a complete understanding of the water containers in the community used by the mosquitoes. A small number of containers can support the majority of mosquito larva. In a study in Queensland, Australia, in one village, 13% to 29% of the water containers supported 60% to 63% of the immature forms (726). If access to these containers could be restricted, the mosquito population could be significantly decreased. It is also possible to treat these containers with larva-eating copepods that consume the larva while leaving the water in the tanks potable. Copepods of the genus *Mesocyclops* have been successfully used in mosquito control programs in areas as disparate as New Orleans, Louisiana and Phanboi, Vietnam. In both areas, the population of *A. aegypti* were significantly reduced or eliminated (519).

For the emergency control of epidemics, it is necessary to interrupt transmission by killing infected adult female *A. aegypti.* ULV aerial or ground applications of organophosphate insecticides have been used with variable success. Recent field studies in the Caribbean and South America suggest that ULV applications are relatively ineffective and do

not suppress vector populations long enough to interrupt transmission (526).

A reason for the inconsistent results of spraying are the flawed rationales in their application. The spraying is designed to kill the adult mosquitoes and halt the life cycle. Typically, the spraying is done 50 to 100 meters around the residence of the presumed or confirmed cases. This approach assumes that the adult mosquito's flight range is 50 to 100 meters. However, a recent study that marked eggs showed that the ovipositioning females can cover an area 840 meters in diameter (595). Therefore, limiting or stopping an epidemic in progress requires spraying over a larger area than was previously indicated.

West Nile Fever Virus

Infectious Agent

WN virus is a member of the antigenic complex of flaviviruses, which includes MVE, SLE, and JE viruses. The structures of the WN virus genome and glycoprotein spike have been partially analyzed (535). Kunjin virus (another agent in the virus complex) is more closely related to WN than to other members of the complex (132). A high degree of cross-protection was found in hamsters immunized with JE or SLE viruses and challenged peripherally with WN (265). Monkeys immunized with WN were partially protected from lethal intranasal JE virus challenge, whereas JE-immune animals were fully protected against WN challenge (223).

There is a considerable body of research on antigenic variation and restriction-length polymorphism analysis of WN virus. Strains from Africa, Europe, the former Soviet Union, and the Middle East as far east as Pakistan form one group distinct from strains isolated in India and the Far East (201,571). Other studies have shown considerable heterogeneity among strains isolated within a single region (49). In Madagascar, for example, monoclonal antibody analysis identified five antigenic variants, of which four represented the African-European antigenic group and one the India–Far East group (513). A Madagascan strain was found to be distinct from other WN viruses at the nucleotide sequence level (569). Additionally, similar subtypes have been identified in France, Senegal, and Central Africa (47). These antigenic and genomic analyses agree well with the model of migrating birds as important vertebrate hosts of WN that spread the virus to local mosquito populations at the site of infection and along their migratory routes. Even with long-distance travel, which gives rise to distant, but related virus populations, viruses with this method of dispersal still have local segregation of distinct genotypes in some areas. In the Central African Republic, for example, where human disease has been characterized by hepatitis, virus strains recovered from humans, mosquitoes, and ticks differed from the Egyptian prototype and from local avian isolates by monoclonal antibody analysis and restriction digest profiles (466). A mosquito isolate from the Central African Republic was placed (together with an East African strain) in a distinct group based on nucleotide sequence (569). The results suggest that the distinctive human disease pattern in this part of Africa may be caused by a local WN variant with a nonavian transmission cycle.

WN virus grows and produces CPE or plaques in a wide variety of cell cultures (including primary chick and duck embryo) as well as in continuous lines of human, primate, swine, rodent, and amphibian origin. It multiplies in *A. aegypti* and *Drosophila* species cells and produces CPE in *A. albopictus* cells.

Mice and hamsters of all ages are susceptible to lethal infection by the intracerebral route. Resistance to peripheral routes of inoculation develops with age; some virus strains are pathogenic for adult animals. Lethal oral infection of adult mice has been described. Hamsters transmit virus to their young through the milk. Rabbits, guinea pigs, and cotton rats develop antibodies without overt illness by all inoculation routes; rats succumb to intracerebral infection only. Rhesus and bonnet macaques develop fatal encephalitis after intracerebral or intranasal inoculation (223,523). Almost all birds tested develop viremia, including wild species, chickens, and pigeons (474,705). Generally, encephalitis and death appear to be rare, but in the recent American outbreak, there were numerous deaths among the American crow population, which have been used to track the geographic expansion of the virus (15a). Whether crows or other birds are instrumental in the virus spread through the eastern American seaboard is not known.

The developing chick embryo is highly susceptible to the virus. With one exception (namely, *Arvicanthus abyssinicus*), wild African rodents do not develop viremia.

Sporadic cases of naturally acquired WN encephalitis have been reported in horses in Egypt, France, and the United States (246); however, low-level viremia, antibody production, and absence of clinical illness are the rule. Bovine species do not develop viremia after experimental inoculation, but antibodies in cattle are prevalent. Dogs are susceptible to infection, and some develop mild illness, but low viremia levels appear to preclude a major role in transmission cycles (56).

Strain variation exists in the pathogenicity of WN virus for cell cultures, mice, pigeons, and lemurs (733). Experimental infections in various arthropods have been reported (reviewed in 280). *Culex univittatus,* the principal vector in Africa, is a highly efficient vector. The virus has been found to infect soft and hard ticks under natural and experimental conditions.

Pathogenesis and Pathology

The pathogenesis of WN virus is similar to that of other flaviviruses (379,450,524). WN virus is reported to produce persistent infection and a subacute inflammatory-degenerative process in the CNS of monkeys (562). Several studies have examined the role of intracellular adhesion molecule-1 up-regulation in virally infected cells as a mechanism associated with enhanced viral spread (665,666 and 667). Up-regulation of surface adhesion molecules leads to the attraction of important immune cells (667). Paradoxically, cell–cell adhesion may promote further viral infection of these cells and continued replication of the virus. Identification of sites where amino acid substitutions have significant effects on viral virulence and specificity has shown that the determinants for neuroinvasiveness are on the E protein, similar to other flaviviruses (104).

Pathologic observations in humans are limited to a small number of patients with fatal encephalitis and showed lesions of diffuse inflammation and neuronal degeneration. Autopsies performed on patients who died within 4 weeks after inoculation of WN virus (used as an experimental treatment for cancer) resulted in WN virus isolation from spleen, lymph nodes, liver, and lungs (681,682), a distribution similar to that described in laboratory animals.

Clinical Features

The incubation period is 1 to 6 days. The typical case is mild, characterized by fever, headache, backache, generalized myalgia, and anorexia. The course of fever may be biphasic. Rash occurs in about half of cases; onset of rash is either during the febrile phase or at the end of it. The rash is roseolar or maculopapular, is nonirritating, and principally involves the chest, back, and upper extremities. Rash may persist for up to a week and resolves without desquamation. Generalized lymphadenopathy is a common finding. Pharyngitis and gastrointestinal symptoms (nausea, vomiting, diarrhea, abdominal pain) may occur. The disease runs its course in 3 to 6 days, followed by rapid recovery (451). Children generally experience milder illness than adults. Infection may also result in aseptic meningitis or meningoencephalitis in a small proportion of patients, especially in elderly patients (28). Other neurologic presentations include anterior myelitis resembling poliomyelitis and encephalopolyradiculitis (83,224). In an outbreak of encephalitis in 12 of 49 aged patients who acquired the infection in Israel, four patients died. Three cases of encephalitis in young people were described by Flatau and associates (188); one patient had papillitis. Eleven percent of cancer patients inoculated with the prototype (Egypt 101) strain showed clinical signs of encephalitis (682), an incidence much higher than expected from experience in naturally acquired infection, probably owing to the altered susceptibility and poor immune responsiveness of the patient population. Nonneurologic, rare complications include myocarditis (8) and pancreatitis (553). In the Central African Republic, WN virus has been responsible for cases of hepatitis, including fatal disease resembling yellow fever (211).

Clinical laboratory findings include leukopenia and, in cases with CNS signs, CSF pleocytosis and elevated protein.

Inapparent and very mild infections are common. In the series of cancer patients intentionally inoculated by Southam and Moore (682), 89% of 78 infected patients had no clinical signs or symptoms other than fever; in 27%, temperature was never elevated more than 1°F.

Diagnosis

On clinical grounds, WN fever resembles dengue and other dengue-like fevers. Other manifestations include meningoencephalitis and (in Central Africa) hepatitis. Unlike SLE, JE, and MVE viruses, WN virus can be isolated from the blood of as many as 38% of patients (77% when the specimen is taken on the first day of illness) (214). In patients naturally infected, viremia was detectable up to 5 days after onset; titers were low (maximum titer, 3.3 dex/mL). In cancer patients inoculated with the Egypt 101 strain, viremias were more prolonged and of higher titer (682). Viremia has been demonstrated by chance during the incubation period. The reverse passive hemagglutination test has been used to detect viremia in the blood of nestling birds. Neither this technique nor immunoassays have been evaluated for detection of virus in human clinical specimens.

Serologic diagnosis is possible using any of the usual tests; cross-reactions with heterologous flaviviruses complicate the interpretation. In addition to standard serologic tests, the indirect IF and ELISA tests are applicable to the diagnosis of WN infection (704a). Radial hemolysis-in-gel has been used for the detection of IgG antibodies, has a similar sensitivity to the HI test, and has the advantage that there is no need to remove nonspecific inhibitors. RT-PCR has been effectively used to detect WN RNA from human clinical specimens, field-collected mosquitoes, and avian samples (74a,405a)

Treatment

Treatment is supportive.

Epidemiology

WN virus is widely distributed throughout Africa, the Middle East, parts of Europe and the former Soviet Union, India, and Indonesia, and during the summer of 1999, was introduced to the American Eastern seaboard. During the 1950s, classic studies on the epidemiology of WN virus in Egypt and the Sudan revealed that human infections were extremely common in the Nile Delta (705), where 22% of children and 61% of young adults were immune. A survey conducted 10 to 15 years later showed that the infection prevalence in adults had decreased somewhat (to 50%) (144). In a study conducted in 1968, 14.6% of febrile children attending the fever hospital in Alexandria were diagnosed as having WN infection (488). A survey showed that 6% of schoolchildren and 40% of young adults had been infected (137). The hyperendemic virus circulation has precluded sharp epidemics but places a high burden of infection on childhood populations, which experience largely unrecognized and clinically undifferentiated febrile disease. The risk for epidemic may increase (especially in areas such as Cairo) as endemic transmission declines and a larger segment of the adult population becomes susceptible.

Summertime epidemics of WN fever were recognized as early as 1950 in Israel and recurred there at frequent intervals during the 1950s (451). These epidemics involved hundreds of recognized cases, but the true incidence was undoubtedly much higher, and attack rates of more than 60% were reported in some localities. The epidemics were the result of amplified virus transmission and spillover to a human population with a low background of immunity.

In an area of South Africa with relatively low immunity to WN virus (13% to 20%), an outbreak in 1974 resulted in infection of 55% of the population. The epidemic involved an area of 2,500 km ^{2} of central and northern Cape Province. Hundreds to thousands of clinical cases occurred, but they were mild and without any recognized cases of encephalitis (476). Few clinical cases have been reported from West and Central Africa (211,714). In the central highlands of

Madagascar, a high annual incidence of WN virus infection (15%) has been documented, and the virus is suspected to be responsible for grippe-like illness in the population (513,514). A small outbreak of WN virus infection occurred between 1962 and 1964 in the Camargue region of France, in which 13 cases were documented, some with encephalitic complications (546). Infections in tropical Asia are frequent, and the virus appears to be hyperendemic in many areas.

The incidence of CNS infection has not been clearly defined, but this complication appears to be rare. Cases have been described in Israel, India, France, and Egypt. In Egypt, four of 133 patients with aseptic meningitis or encephalitis admitted to one hospital between 1966 and 1968 were shown to have WN infection (2).

In 1996, there was a major epidemic in Romania around Bucharest and the Danube valley. Between 1996 and 1997, 500 clinical cases were identified, and the case fatality rate approached 10% (317,318,720). WN virus was detected in the Czech Republic in 1997, and although several people were infected, the outbreak was not widespread (318).

In 1999, WN virus was first detected in the Western Hemisphere when it appeared in the New York City area. The initial outbreak affected about 60 people, 100 birds, and about a dozen horses, with 7 human fatalities (335). Although the overall numbers are small, the introduction and establishment of a new pathogen is a troubling occurrence. The strain responsible for the American outbreak is closely related to a Middle Eastern isolate (335). This could indicate that the introduction was a single event, whether it was an infected person, unlikely because of low viremia, or an imported animal is unknown.

Despite efforts to eliminate WN virus, it reappeared in the summer of 2000 (20). The geographic distribution of the virus is steadily increasing. The virus has been detected in sick birds as far north as Massachusetts and as far south as North Carolina. This spread is consistent with the infection of migratory birds and would appear to indicate that this virus has established itself in the northeastern part of the United States and will continue to spread along the migration routes of the birds it infects.

WN virus has been isolated from various mosquito species; *C. univittatus* and *C. pipiens molestus* appear to be the most important vectors in Africa and the Middle East (280). The virus has been isolated from an extensive list of *Culex, Aedes, Anopheles, Mimomyia,* and *Mansonia* species mosquitoes in Africa. *C. tritaeniorhynchus* is an important vector in tropical Asia. In the American outbreak, the virus was detected in *C. pipiens,* other *Culex* species, and *Aedes exans* mosquitoes (15a). A subspecies of *C. pipiens* is considered to be the primary vector. Isolations of the virus have been made from ticks, especially in bird rookeries in the former Soviet Union. There have been numerous isolations from wild birds in many areas, and high antibody rates in birds have been reported in Israel, Egypt, and South Africa. Birds sustain high viremia after experimental infection and are the only known amplifying host (474). WN virus has been isolated from a camel and a grass mouse in Nigeria and from a frugivorous bat in India (280,345). Bats have also been implicated as possible hosts in Madagascar. Humans and horses susceptible to clinical infections are incidental hosts and are not thought to play a role in the mosquito transmission cycle. The mechanism of virus survival over the winter or dry season has not been elucidated. Vertical transmission of WN virus in *Culex* and *Aedes* species has been demonstrated under laboratory conditions (42). Transtadial transmission by ticks may play a significant role in virus maintenance. It will be of interest to determine whether the phenomenon of nonviremic, saliva-enhanced transmission of WN virus occurs between cofeeding ticks (536).

Prevention and Control

There is no vaccine for WN virus, but experimental work is ongoing. In a chimera virus approach, the *Pre-M* and *E* genes of WN virus have been combined with the nonstructural gene portion of the attenuated yellow fever vaccine.

Until a successful vaccine is developed, space sprays and aerial sprays of insecticides are the only real option for attempts at control. As with any control program, a thorough understanding of the vector and its lifecycle is critical for efficient control.

Other Viruses

Several other flaviviruses cause human diseases but are not at present of major public health concern. These agents must be considered in the differential diagnosis of febrile illness in people inhabiting or traveling in endemic areas. Furthermore, with the spread of viruses formerly considered to be minor problems, such as dengue was before World War II, these viruses must be studied so that any increase in virulence or geographic distribution can quickly be recognized and appropriate response mounted.

Banzi Virus

Banzi virus was first isolated from the blood of a febrile child in South Africa in 1956 (678). Analysis of *NS5* gene sequences suggests that the virus is most closely related to the mosquito-borne flaviviruses, particularly yellow fever (199). It has been associated with human febrile disease in Tanzania and has been isolated from *Culex rubinotus* and other species of mosquitoes, rodents, and sentinel hamsters in Kenya, South Africa, Zimbabwe, and Mozambique. The virus is pathogenic for infant and weaned mice by all routes of inoculation; it causes CPE in HeLa and primary hamster kidney cells and causes plaques in Vero and LLC-MK2 cells. It has been used as a model to study the pathogenesis of flaviviruses in mice (329).

Bussuquara Virus

Bussuquara virus was originally isolated from a sentinel monkey in Brazil in 1956 (218). The virus is distinct from other flaviviruses by NT (92,139,150). Infant mice are susceptible to intracerebral and intraperitoneal infection, but older mice are susceptible only to intracerebral infection. Adult hamsters inoculated by all routes develop viremia and antibodies but no illness (345). Bussuquara virus replicates and produces plaques in a wide variety of cell cultures, including primary

duck and chick embryo, BHK-21, Vero, LLC-MK2, MA-104, and MA-111. Histopathologic lesions resembling yellow fever were found in the sentinel monkey from which the original isolation was made, but subsequent experimental infection failed to reproduce these findings. The virus is known in Brazil and Colombia, where it has been isolated from various mosquito species, and in Panama, where it was recovered from the blood of a patient with fever, anorexia, and joint pain lasting 4 days (the only known human case) (685). Antibody prevalence rates of 12% have been found in humans in Panama. The virus has been repeatedly isolated from *Proechimys guyannensis* rodents in Brazil; experimentally inoculated *Proechimys* rodents develop viremia. Mosquitoes of the genus *Culex* are the principal vectors. No control measures are applicable.

Edge Hill Virus

Edge Hill virus is a flavivirus that was isolated in 1961 from *Aedes vigilax* mosquitoes collected at Edge Hill, a suburb of Cairns, Queensland, Australia (166). On the basis of subsequent isolations and serosurveys, Edge Hill virus has a wide distribution in eastern Australia (167,273). By antigenic analysis, the virus was placed in the Uganda S virus complex (92). However, by nucleic acid hybridization, the virus is related to dengue 2 virus (58). Edge Hill virus causes CPE and plaque formation in PS, BHK-21, and Vero cell cultures. The virus is pathogenic for newborn mice inoculated intraperitoneally and intracranially and for weanling mice inoculated intracranially.

Human infections have been recognized by serologic surveys in eastern Australia. A single case of human disease occurring in 1990 was attributed to Edge Hill virus on the basis of IgM serologic responses (1). The patient, a 64-year-old farmer from southeast Queensland, had a syndrome resembling epidemic polyarthritis (Ross River virus disease), with fever, myalgia, arthralgia, and fatigue. Symptoms recurred when medication (prednisone) was withdrawn but finally resolved after 12 months. Sporadic cases must be distinguished from dengue fever (which cross-reacts serologically) and Ross River virus infection.

Edge Hill virus is transmitted between *A. vigilax* mosquitoes and mammals, principally wallabies and bandicoots. Virus isolates have been made also from *Cx annulirostris* and *Anopheles meraukensis.*

Ilheus Virus

Ilheus virus was first isolated from a pool of *Aedes* and *Psorophora* species mosquitoes collected in Brazil in 1944. It was originally placed in the WN virus antigenic complex but was shown to be distinct from other members of the complex by NT (92,150). The virus is pathogenic for infant and weanling mice by the intracerebral and intraperitoneal routes but not for other laboratory animals. It produces plaques in primary rhesus kidney cells and various continuous cell lines (BHK-21, Vero, LLC-MK2, and PS) but not in avian cells. Pathologic features are described only in mice, which develop typical encephalitis. A total of eight human infections have been documented by virus isolation, five with mild febrile illness, headache, and myalgias; one with encephalitis; and two without symptoms. These cases occurred in Brazil, Trinidad, Columbia, and Panama (345). The virus was inoculated into 20 cancer patients by Southam and Moore (681); three individuals developed CNS signs. Diagnosis is by virus isolation from blood or serologic tests, which are complicated by cross-reactions with other flaviviruses. The transmission cycle in nature involves wild birds and mosquitoes; at least eight genera of mosquitoes have yielded virus, but most isolations have been made from *Psorophora* species. The potential link to the emergence of Rocio virus was discussed previously. No control measures are applicable.

Kokobera Virus

Kokobera virus was first isolated in 1960 from *C. annulirostris* mosquitoes collected in northern Queensland. The virus is a member of the JE virus complex and is thus related to the other Australian pathogens MVE and Kunjin viruses. Kokobera virus causes CPE and plaques in BHK-21, Vero, and PS cells and is pathogenic for infant and weanling mice by the intracranial route and for infant mice inoculated intraperitoneally. Serologic surveys in New South Wales have demonstrated presumed human infections (273,275). Evidence for human disease was provided by serologic analyses of three patients from this region in 1984 and 1985 (62). The disease was characterized by fever; fatigue; headache; neck pains; painful, stiff, and (in one case) swollen joints; and (in two of three cases) maculopapular, slightly pruritic, desquamating rash. In all three patients, there was a prolonged convalescence, with joint pains persisting for months.

The virus is probably transmitted between *A. vigilax* and wallabies and kangaroos. However, virus isolations have also been made from *C. annulirostris.* Kokobera is distributed in widely separate areas of Australia, including New South Wales, Queensland, Western Australia, the Northern Territory, and Papua New Guinea. The use of molecular epidemiology has found that isolates of Kokobera cluster according to geographic location and time (564). There are three general topotypes covering Queensland and New South Wales, Papua New Guinea, and the Northern Territory and Western Australia. This distribution is different from the other Australian flaviviruses, MVE and Kunjin, which exist as single genetic types across the entire continent. MVE and Kunjin infect birds, which have large ranges and distribute the virus broadly, whereas Kokobera has macropods as its main host, so that the range over which a single isolate can spread is limited.

Koutango Virus

Koutango virus was isolated from a gerbil (*Tatera kempi*) in Senegal in 1968. Subsequent strains have been recovered from other rodent species (*Mastomys, Lemnyscomys*) and from several genera of ticks (*Rhipicephalus, Hyalomma, Alectorobius*) in Senegal and the Central African Republic. No naturally acquired human disease is reported, but a laboratory infection characterized by fever, headache, joint pains, and rash occurred in Senegal.

Kunjin Virus

Kunjin virus was first isolated from *C. annulirostris* mosquitoes in Australia in 1960. It is a member of the JE virus

antigenic complex and is thus antigenically closely related to MVE virus. The virus is pathogenic for infant mice by intracerebral and intraperitoneal routes and for weaned mice by intracerebral inoculation. It forms plaques in primary chick embryo, Vero, and PS cell cultures. Kunjin virus strains isolated in widely separated regions of Australia are genetically homogenous (4,190,436). The nucleotide sequence has a very high level of homology with respect to WN virus, implying an evolutionary relationship (132). Human disease has been reported from Australia. Two accidental laboratory infections were characterized by mild febrile illness, one with rash and one with lymphadenopathy (10). The first severe case with encephalitis mimicking MVE was described in 1986 (516). Of 45 cases diagnosed as MVE during the 1974 epidemic, five cases may in fact have been due to Kunjin virus infection. Cases of Kunjin encephalitis have been reported from Western Australia. Of 20 encephalitis cases diagnosed between 1978 and 1991, two (10%) were due to Kunjin and 18 were caused by MVE virus (443). The clinical disease resembles MVE but is probably less severe. Serologic diagnosis is complicated by cross-reactions with MVE. Kunjin virus was isolated from the spinal cord of a horse with severe encephalomyelitis in New South Wales (32). *C. annulirostris* is believed to be the principal vector, and wild birds and mammals are viremic hosts. The virus has also been isolated in Sarawak and Thailand.

Rio Bravo Virus

Rio Bravo virus was first isolated from a Mexican free-tailed bat (*Tadarida brasiliensis mexicana*) in California in 1954. Subsequently, many other isolations have been made from bats in California, Texas, New Mexico, and Sonora, Mexico (345). The virus is pathogenic for infant mice. Experimentally inoculated monkeys and hamsters develop infection but no illness. A single naturally acquired human case with febrile illness was reported. Laboratory infection (699) resulted in moderately severe illness in three of five patients who experienced aseptic meningitis, orchitis, or oophoritis. The virus is not arthropod borne and does not multiply in inoculated mosquitoes. It is probably transmitted bat to bat by direct contact or aerosol.

Sepik Virus

Sepik virus was isolated from *Mansonia septempunctata* mosquitoes in New Guinea in 1966. Several other isolates have been made from *Ficalbia* and *Armigeres* species mosquitoes in New Guinea. Antigenically, Sepik virus is a close relative of Wesselsbron virus. A single human case of febrile illness with headache, requiring hospitalization, has been recorded (345).

Spondweni Virus

Spondweni virus was originally isolated from *Mansonia uniformis* mosquitoes collected in Northern Zululand, South Africa, in 1955 (345). It is ungrouped but is most closely related antigenically to Zika virus. The virus is pathogenic for infant and weanling mice inoculated intracerebrally, produces CPE in primary hamster and monkey kidney cells, and produces plaques in Vero and LLC-MK2 cells. A virus isolated from the blood of an anicteric child with fever and headache and first thought to be Zika virus was later identified as Spondweni virus; however, recent analysis of this virus strain by monoclonal antibodies suggests that it is a mixture of yellow fever and another flavivirus most closely resembling Spondweni. A volunteer inoculated with this virus developed a mild febrile illness (43). During investigations in South Africa, two people acquired laboratory infections characterized by fever, chills, aches and pains, nausea, and epistaxis (477). Wolfe and colleagues (774) reported a case in an expatriate living in Burkino Faso; symptoms were fever, dizziness, nausea, myalgia, headache, photophobia, and a maculopapular pruritic rash. Treatment is symptomatic. Diagnosis is by virus isolation from blood or serology. Spondweni virus has been isolated from at least seven mosquito species, but most isolates have come from *Aedes circumluteolus* in South Africa. Antibody has been found in cattle, sheep, and goats in South Africa, but the vertebrate hosts involved in transmission are unknown. No control measures are applicable.

Usutu Virus

Usutu virus was first isolated from *Culex naevei* mosquitoes in South Africa in 1959. Newborn and weaned mice are susceptible to fatal encephalitis by the intracerebral route. A case of human infection with fever and rash was reported from the Central African Republic in 1982. The virus has a wide distribution in sub-Saharan Africa. *Culex* mosquitoes and birds are responsible for transmission in nature. *Culex perfuscus* appears to be an important vector. Isolations of the virus have also been made from *Mansonia africana* and *Praomys* species mice in the Central African Republic and from *Coquilletidia aurites* mosquitoes in Uganda.

Wesselsbron Virus

Wesselsbron virus was first isolated from a dead lamb during an epizootic in South Africa in 1955. It is antigenically closely related to Sepik virus and shows some cross-reactivity with yellow fever virus. Wesselsbron virus–immune monkeys develop reduced viremias when challenged with yellow fever virus (298). The virus kills infant and weanling mice by all routes of inoculation. It produces CPE in BHK-21 cells and plaques in Vero and LLC-MK2 cells. Wesselsbron infection in sheep is of veterinary public health importance in southern Africa, where it causes abortion and death of newborn lambs and pregnant ewes (759). Some goat strains are highly susceptible to lethal infection. A mild, febrile disease occurs in cows. A syndrome of hydrops amnii in pregnant ewes, with prolonged gestation, maternal deaths, and fetal malformation (arthrogyphosis, hydranencephaly, hypoplasia, or segmental aplasia of the spinal cord, neurogenic muscular atrophy, and inferior brachygnathia), has been associated with both wild virus infection and use of a live attenuated vaccine (130). Pathologic changes in lambs include jaundice, focal necrosis of liver cells, Councilman-like bodies, and mild periportal inflammation (416). The clinical features, epidemiology, and pathologic changes in livestock resemble Rift Valley fever, from which it must be distinguished. Naturally acquired human cases of febrile illness occurred in South and West Africa, and there have been several reports of laboratory infections. Human illness is characterized by a short incubation period (2 to 4 days) and sudden onset of fever, chills, myalgia, hyperesthesia of the skin, hepatosplenomegaly, and maculopapular rash. In severely ill patients, signs of CNS involvement have been noted (475). There have been no fatalities, nor have signs of severe liver dysfunction similar to those seen in livestock been

observed in humans. Clinical laboratory studies show leukopenia and elevated serum transaminase levels. Treatment is supportive. Diagnosis is by virus isolation from blood or by serology (30,31). The virus has been recovered from pharyngeal swabs. Serologic cross-reactions present difficulties in patients with prior flavivirus infection. The transmission cycle involves mosquitoes. Species incriminated most frequently are *Aedes caballus-juppi, Aedes lineatopennis,* and *A. circumluteolus* in South Africa and numerous other *Aedes* species elsewhere in Africa. The virus is known to occur in Zimbabwe, Cameroon, Nigeria, Senegal, Ivory Coast, Central African Republic, Uganda, Kenya, Madagascar, and Thailand (345). The vertebrate hosts involved in transmission are uncertain; domestic livestock and ostriches (12) develop high viremias, as do experimentally infected gerbils.

No specific control measures are recommended for prevention of human infection. Special care is required when manipulating this virus in the laboratory. Because of the veterinary hazard, work with the virus in the United States is restricted by the Department of Agriculture.

Zika Virus

Zika virus was first isolated from a sentinel monkey in Uganda in 1947. The virus is not assigned to a subgroup but is most closely related to Spondweni, yellow fever, and Uganda S viruses. Zika immunity suppressed viremia in monkeys challenged with yellow fever (298). The virus kills infant and weanling mice by all routes of inoculation. It produces viremia but no illness in monkeys. Rabbits and guinea pigs inoculated by peripheral routes develop antibodies. Plaque assays may be performed in primary chick or duck embryo cell cultures. Pathologic changes in infected mice include encephalitis, myocarditis, and myositis. Serologic surveys reveal a prevalence of human infection of up to 50% in many areas of Africa and in parts of Asia, but human disease has been rarely reported. Of about 14 diagnosed human cases, one was in a mosquito collector working in Senegal, 12 were naturally acquired cases that occurred in Senegal, Central African Republic (508), Nigeria (509), and Indonesia (543), and two were laboratory acquired. Illness is characterized by fever, malaise, headache, and a maculopapular rash. Treatment is supportive. Diagnosis is by virus isolation from blood or serology; cross-reactions confuse interpretation, especially in people with prior flavivirus exposures. The virus has been isolated from primatophilic *Aedes* species that also play a role in yellow fever transmission (e.g., *A. africanus, A. luteocephalus, A. vittatus, A. furcifer-taylori, A. metallicus,* and *A. opok*). Although the vertebrate hosts involved in transmission are not fully defined, it is likely that both nonhuman and human primates play a role and that the transmission cycle is similar to that of yellow fever. Multiple isolations have been made from *Cercopithecus* and *Erythrocebus* species monkeys in West and East Africa. Explosive epizootics (without recognized disease) occur in monkey populations in East and West Africa. A single isolate has been recovered from a rodent (*Taterillus* species) in Senegal, and isolations have been made from a large number of mosquitoes other than those listed previously, raising the likelihood that the ecology of Zika virus is considerably more complex. No control measures are applicable.

FLAVIVIRUSES ASSOCIATED PRIMARILY WITH HEMORRHAGIC FEVER

Yellow Fever Virus

Historical aspects of yellow fever have been reviewed by Strode (697) and Monath (493). The disease was recognized as a clinical entity in 1648 in Yucatan. Tropical areas of the Americas were subject to large outbreaks in the 17th, 18th, 19th, and early 20th centuries, and the disease occurred in epidemic foci as far north as Boston and Halifax; it also appeared during the 18th century in Italy, France, Spain, and England. As late as 1905, there was a significant outbreak in New Orleans, with 5,000 cases and 1,000 deaths.

Mosquitoes were suggested as the vector of yellow fever by Nott in 1848, but this theory was not seriously proposed until 1881 by Carlos Finlay. In 1900, Walter Reed demonstrated a filterable agent in the blood of patients and showed transmission by *A. aegypti* mosquitoes. Despite suggestions to the contrary, yellow fever was thought to be transmitted exclusively between humans by *A. aegypti.* Investigations by Soper (680) resulted in the concept of jungle yellow fever, later shown in both tropical America and East Africa to involve wild monkeys and sylvatic mosquito species.

In 1927, Mahaffy and Bauer first isolated the virus by inoculation of a rhesus monkey with the blood of a patient in Ghana; this was the source of the Asibi strain, parent of the 17D vaccine (694). In 1937, Theiler and Smith (708) reported attenuation of the Asibi strain by passage in chick embryo tissue and demonstrated use of the modified virus (17D) for human immunization.

Yellow fever continues to be a major public health problem in the Americas. Most cases are a result of humans intruding on the jungle or sylvatic cycle (41,740). Although there have not been any outbreaks in urban areas where the vector *A. aegypti* would be involved, there are some disturbing trends. The collapse of the *A. aegypti* control program has allowed this vector to reinfest Central and South America, and yellow fever has appeared in areas where it has been long absent. In 1998, the first case of yellow fever since 1902 occurred in French Guiana (300), and there is evidence of the urbanization of yellow fever. In 1996 and 1997, there were six cases reported in Santa Cruz, Bolivia (739). These cases were almost all localized to one neighborhood, and several of the subjects had not recently left the city, suggesting that transmission had occurred within the city limits and that *A. aeypti* was responsible. Although this particular incident was transient, all the factors to facilitate a significant outbreak are in place: a competent widespread urban vector, a natural sylvatic reserve that urbanites travel to and from, and a low level of immunization in many places in the Americas (about 34% to 41% in Santa Cruz).

In Africa, there continue to be epidemics involving large numbers of cases, such as the 1996 Kaffrine, Senegal outbreak (710). The disease incidence has risen dramatically in recent years (23) with the urban vector, *A. aegypti,* and sylvatic vectors have been responsible for epidemic transmission in Africa. At one time, yellow fever was an example of a successful public health policy with a reduced incidence in many countries. Today, 33 sub-Saharan countries with 450 million people are at risk, and yellow fever continues to be endemic in nine South American countries. WHO estimates, with adjustments for underreporting, that there are 200,000 cases of yellow fever each year, most in sub-Saharan Africa (606). Yellow fever can be prevented by vaccine, and its urban vector was almost eradicated. Today, the vector has

reinfested many areas, and many at-risk populations go unimmunized (490).

Infectious Agent

Yellow fever virus is the prototype of the *Flavivirus* genus. It has been used as a model for elucidation of the flavivirus genome structure and replication strategy (see Chapter 30) and for studies on the molecular basis of antigenic structure, function, and virulence.

Yellow fever is not placed within an antigenic subgroup or complex by plaque-reduction NT (92,150); however, it is antigenically more closely related to Banzi, Wesselsbron, Bouboui, Zika, and Uganda S viruses than to other flaviviruses. By virtue of its relationship to Zika virus, Spondweni virus may be considered indirectly linked to yellow fever. Cross-protection between yellow fever and many flaviviruses can be demonstrated using the sensitive intraperitoneal test in infant mice. In more epidemiologically meaningful tests of cross-protection, prior immunization with Wesselsbron, Zika, and dengue viruses causes a significant reduction in viremias of monkeys challenged with virulent yellow fever virus (298,707).

Antigenic differences have been shown between strains of yellow fever virus. By polyclonal antibody absorption techniques, strains from tropical America and Africa are distinct, as are 17D vaccine and parent Asibi viruses (128). Monoclonal antibodies have been described that are specific for yellow fever virus, for the 17D vaccine strain, or for vaccine substrains 17D-204 and 17DD (38,651). Monoclonal antibody analyses suggest that yellow fever virus is closer to mosquito-borne viruses than to tick-borne viruses. Some of these relationships (e.g., to Banzi, Uganda S, and Zika) fit previous concepts from polyclonal antibody analyses, but many others do not.

Monoclonal antibodies have not provided an antigenic classification of wild yellow fever strains by geographic origin, and further studies in this direction are required. In one limited analysis, Central and West African strains could be distinguished by immunoprecipitation of NS1 protein by anti-NS1 monoclonal antibodies (158). RNA fingerprinting and limited sequencing have delineated four yellow fever topotypes (see later section, Molecular Epidemiology). Strains from South America and Africa are also distinguishable by the electrophoretic migration and carbohydrate content of their E proteins.

Differences have been found between wild yellow fever virus strains in terms of their virulence for mice and monkeys and infectivity for mosquitoes (39,156), but some results are conflicting and reflect multiple variables, including mouse strain, virus passage level, and heterogeneity of virion subpopulations in virus stocks.

The molecular basis for yellow fever virulence has been partially elucidated by comparison between wild-type and vaccine viruses at the sequence level (254) and between vaccine strains with differing virulence patterns (168a,333,334). For a review, see previous section, Molecular Basis of Virulence.

Yellow fever virus can be propagated in a wide variety of primary and continuous cell cultures. Vaccine strains (17D and French neurotropic viruses) grow to higher titer and produce more evident CPE and plaques than do wild strains in various continuous monkey kidney (MA-104, Vero, LLC-MK2), rabbit kidney (MA-111), baby hamster kidney (BHK), and PS cell lines, as well as in primary chick and duck embryo fibroblast monolayers. Wild yellow fever virus strains can also be propagated in these cell cultures, but plaque formation is inconsistent and variable from strain to strain. Viral growth can be detected by IF in advance of the appearance of plaques. Both 17D vaccine and the parent Asibi virus grow in cell cultures of human origin (e.g., Chang liver cells, Henle embryonic intestine, HeLa, KB). Persistent infection of these cells has been described. The virulence properties of virus from carrier cultures can be altered; passage in HeLa cells, in particular, has been associated with a loss of viscerotropism for monkeys (40,172,173,281).

Mosquito cell cultures are useful for primary isolation and are more sensitive than Vero cells or infant mice. *A. pseudoscutellaris* (AP-61), cloned *A. aegypti,* and *A. albopictus* cells are susceptible; infection is generally assessed by IF or subpassage to mice or Vero cells. AP-61 cells consistently show CPE. Intrathoracic inoculation of mosquitoes (*Toxorhynchites* species or *A. aegypti*) is also useful for isolation or assay of yellow fever virus. After a 10- to 16-day incubation period, mosquitoes can be examined directly for virus by IF or can be subpassaged to a susceptible host (e.g., suckling mice). Passage of some wild-type and vaccine strains in C6/36 cells resulted in the appearance of temperature-sensitive virus.

In vertebrate species, yellow fever virus produces both neurotropic and viscerotropic patterns of infection. Viscerotropism reflects the pathogenicity of yellow fever virus for human or nonhuman primates infected by the peripheral route; disease is principally characterized by hepatic pathology. Rhesus and cynomolgus macaques, as well as certain neotropical monkeys, are highly susceptible. Monkeys intracerebrally inoculated with wild-type virus develop encephalitis but die of viscerotropic yellow fever.

The European hedgehog (*Erinaceus europaeus*) is the only nonprimate experimental animal that develops severe visceral lesions in response to yellow fever infection. Hamsters inoculated intraperitoneally with some virus strains (e.g., Asibi) are partially susceptible (scattered deaths), but they resist lethal infection with other virus strains. Rabbits resist intracerebral and peripheral challenge but form antibodies. Newly hatched chickens develop viremic infection without disease.

The neurotropic properties of yellow fever virus are most apparent in mice; infant mice are highly susceptible to encephalitis after intraperitoneal or intracerebral inoculation. Considerable variation in neuropathogenicity for mice exists between virus strains (39). Older mice are susceptible by the intracerebral route, as are guinea pigs.

Pathogenesis and Pathology

Neurotropic yellow fever infection of mice has been used as a model system for studies on the pathogenesis of flavivirus

encephalitis (see General Pathogenesis and Pathology, earlier). The discussion to follow deals solely with the viscerotropic disease in humans and nonhuman primate models.

The typical yellow fever lesion is marked by cloudy swelling, then by coagulative necrosis of hepatocytes in the midzone of the liver lobule, sparing cells bordering the central vein (Fig. 17). Eosinophilic degeneration of hepatocytes results in the formation of Councilman's bodies and intranuclear eosinophilic granular inclusions (Torres' bodies). On an ultrastructural level, Councilman's and Torres' bodies consist of amorphous material without any viral structures. Multivacuolar and microvacuolar fatty change is nearly always present, especially after the eighth day of illness. An inflammatory response is absent or mild. The reticulin framework is preserved, and healing is complete in recovered cases. Typical changes have been seen in biopsy specimens taken as early as the third day of illness; interpretation of biopsy or necropsy material obtained after the 10th day is often difficult. In cases in which death is delayed, partially disintegrated Councilman's bodies consisting of small, irregular, granular, ochre-colored bodies (Villela bodies) may be found, especially in the midzone.

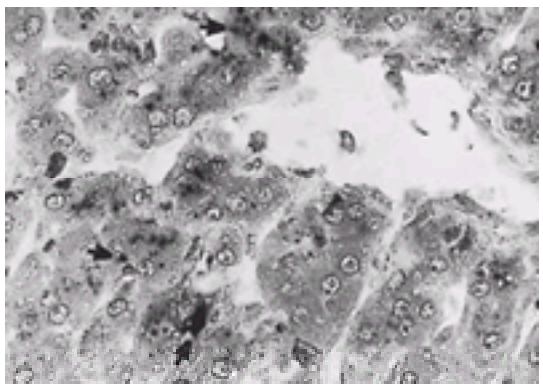

FIG. 17. Postmortem liver sample from a patient with yellow fever, showing midzonal necrosis and hemorrhage, as well as sparing of cells bordering the central vein. Yellow fever viral antigen (*arrows*) is demonstrated by immunohistochemistry (alkaline phosphatase–antialkaline phosphatase technique) and is present both in cells undergoing necrotic change and in the cells preserved around the central vein (×500).

Renal glomerular changes are relatively insignificant compared with acute tubular necrosis and fatty metamorphosis, which may be marked. Schiff-positive transformation of the glomerular basement membrane has been described and has been linked to altered permeability to proteins and albuminuria (496). The myocardial fibers show cloudy swelling, degeneration, and fatty infiltration. The brain may show edema and petechial hemorrhages. Lymphocytic elements in the spleen and lymph nodes are depleted, and large mononuclear or histiocytic cells accumulate in the splenic follicles.

Our present understanding of yellow fever pathogenesis and pathophysiology relies extensively on experimental observations in rhesus monkeys (498,711). After inoculation, the virus replicates in regional lymph nodes and then spreads to other tissues, including liver, spleen, bone marrow, and cardiac and skeletal muscle. The hepatic parenchyma is the principal target organ, and hepatocellular damage is undoubtedly mediated directly by viral infection. Serial examination of liver tissue from infected rhesus monkeys reveals the earliest cytopathologic changes and appearance of immunofluorescent viral antigen in Kupffer's cells (711). Lymphocytic necrosis in the germinal centers of the splenic periarteriolar lymphocytic sheath and necrosis of germinal centers in lymph node follicles are prominent findings in the rhesus monkey (498). Yellow fever (17D) virus replicates to high titer in human peripheral monocyte cultures and in peripheral blood lymphocytes stimulated by phytohemagglutinin (765).

The pathogenesis of the renal lesion is uncertain. In the experimentally infected rhesus monkey, changes in renal function are most revealing during the interval between 36 and 12 hr before death (498). Oliguria was interpreted to reflect intrarenal changes in blood flow secondary to decreased effective blood volume, whereas the development of acute tubular necrosis very late in the infection was the result of the generalized circulatory collapse. Acid-base disturbances, as well as changes in the distribution of water and electrolytes, in cardiac muscle and brain have been described and may be important pathophysiologic events.

The pathogenesis of the bleeding diathesis in yellow fever is also complex. Decreased synthesis of vitamin K–dependent coagulation factors by the diseased liver is an important part of the hemorrhagic disorder, but disseminated intravascular coagulation and altered platelet function may play a role in severe and fatal cases.

Genetic factors may be important in determining individual host responses to yellow fever infection but have not been well defined. Older reports emphasize the severity of the disease in whites compared with blacks, but it is not possible to separate genetic from acquired resistance factors (e.g., immunity to yellow fever or heterologous flaviviruses). Descendants of Dutch colonists in Surinam who survived typhoid and yellow fever epidemics had gene frequencies that were significantly different from those of a large Dutch control group, possibly indicating selection through genetic control of survival (161).

Clinical Features

The incubation period is usually 3 to 6 days. The clinical spectrum varies from very mild, nonspecific, febrile illness to a fulminating, sometimes fatal disease with pathognomonic features (496,697).

Severe yellow fever begins abruptly with fever, chills, severe headache, lumbosacral pain, generalized myalgia, anorexia, nausea and vomiting, and minor gingival hemorrhages or epistaxes. Despite a persistent or rising temperature, the pulse

may decrease (Faget's sign). This syndrome, lasting about 3 days, corresponds to the period of infection, during which yellow fever virus is present in the blood. It may be followed by a period of remission, with defervescence and mitigation of symptoms, usually lasting up to 24 hours. Fever and symptoms reappear with more frequent vomiting, epigastric pain, prostration, and the appearance of jaundice (period of intoxication). Viremia is generally absent, and antibodies appear during this phase. The bleeding diathesis is manifested by “coffee-ground” hematemesis (vomito negro), melena, metrorrhagia, petechiae, ecchymoses, and diffuse oozing from the mucous membranes. Dehydration results from vomiting and increased insensible losses. Renal dysfunction is marked by a sudden increase in albuminuria and diminishing urine output. Death (in 20% to 50% of severe yellow fever cases) occurs usually on the 7th to 10th day of illness and is preceded by deepening jaundice, hemorrhages, rising pulse, hypotension, oliguria, and azotemia. Hypothermia, agitated delirium, intractable hiccups, hypoglycemia, stupor, and coma are terminal signs. Leukopenia occurs during the acute phase of illness. Other laboratory abnormalities include elevation of bilirubin and serum transaminase levels, thrombocytopenia, prolonged clotting and prothrombin times, and ST-T wave changes in the electrocardiogram.

Convalescence is sometimes prolonged, with profound asthenia lasting 1 to 2 weeks. Late death, occurring at the end of convalescence or even weeks after complete recovery from the acute illness, is a rare phenomenon attributed to cardiac complications or renal failure. The duration of icterus in surviving cases is unknown. Elevations of serum transaminase levels have been documented to persist for at least 2 months after onset of yellow fever.

Diagnosis

Mild yellow fever cannot be distinguished clinically from a wide array of other infections, including viral hepatitis, falciparum malaria, leptospiral infections, Rift Valley fever, typhoid, Q fever, typhus, and surgical, drug-induced, and toxic causes. The other viral hemorrhagic fevers, which usually present without jaundice, include dengue, Lassa, Marburg, and Ebola virus diseases; Bolivian and Argentine hemorrhagic fevers; and Congo and Crimean hemorrhagic fever.

Specific diagnosis depends on histopathologic study, isolation of the virus, or demonstration of viral antigen or a specific antibody response. The virus is most readily isolated from serum obtained during the first 4 days of illness, but it may be recovered from serum up to the 14th day and, occasionally, from liver tissue at death. Isolation attempts from clinical specimens can be made by intracerebral inoculation of mice, intrathoracic inoculation of *Toxorhynchites* species mosquitoes, or inoculation of mosquito cell cultures. The *A. pseudoscutellaris* cell line has the advantage of high sensitivity and a relatively short incubation time (3 to 6 days) to detection of virus (by IF using polyclonal or monoclonal reagents). PCR or nucleic acid hybridization may find application for early detection of virus in such samples (574). Viral antigen or IgM–antigen complexes in serum may be detected by immunoassay (502), affording a rapid, early diagnosis. A comparison of various techniques showed that the antigen-capture ELISA has a sensitivity of about 70%, and it may detect noninfectious antigen in poorly handled specimens. RT-PCR has shown promise for rapid detection of viral genome in serum. A definitive postmortem diagnosis may be made by detection of yellow fever antigen in liver tissue sections by immunocytochemical staining (507). It should be emphasized that in living patients, liver biopsy is contraindicated as a diagnostic procedure due to the high risk for hemorrhage.

Serologic methods useful in the diagnosis of yellow fever include the usual HI, CF, and NT, single radial hemolysis, indirect IF, ELISA, and RIA. The HI, IFA, and neutralization antibodies appear within a week of onset; CF antibodies appear later. Paired acute- and convalescent-phase specimens are required to establish the diagnosis by the rise in antibody titer. Cross-reactions complicate serodiagnosis in cases with prior exposure to heterologous flaviviruses.

Antigens suitable for serologic assays are prepared from infected mouse brain tissue, cell culture fluids, or extracted mosquito cell culture membranes. Determination of IgM antibodies by the indirect fluorescent antibody technique or ELISA may indicate recent infection. The duration of IgM antibodies is uncertain, however, and appears to be quite variable. In people vaccinated with 17D virus, detectable IgM neutralizing antibodies are present as long as 18 months after immunization. IgM antibodies show relative specificity, but cross-reactions in ELISA are sometimes found in patients with prior flavivirus exposure.

The use of yellow fever 17D vaccine may confound serodiagnosis. In people without prior flavivirus exposure, the vaccine induces an NT seroconversion with a low titer (1:10 to 1:40) of HI antibodies and no detectable IF or CF antibodies. However, in people with preexisting flavivirus antibodies, vaccination may result in marked rises in yellow fever and heterologous HI and CF antibodies. The patterns produced may be broad or heterotypic; in some cases, however, homotypic responses are seen (a specific rise in yellow fever HI or CF antibodies), similar to those seen in recent natural infection.

Treatment

Treatment is supportive. Most patients with yellow fever have not benefited from the availability of modern intensive care, and it is unknown to what extent fluid management and correction of hypotension and electrolyte and acid-base disturbances would reverse the apparently inexorable course of severe yellow fever. A number of compounds with antiviral activity *in vitro* have been described, including ribavirin and derivative compounds (reviewed in 496). Ribavirin suppresses yellow fever replication *in vitro* but at concentrations higher than those achievable *in vivo.* Trials of ribavirin in experimentally infected monkeys showed no therapeutic effect. IFN-g treatment of monkeys resulted in delayed onset of viremia and illness but had no effect on survival.

Epidemiology

Yellow fever is a zoonotic disease. The primary transmission cycle involves wild nonhuman primates and various sylvatic (tree-hole–breeding) aedine mosquitoes. Humans may be tangentially exposed when they encroach on this cycle (so-called jungle yellow fever), and epidemic spread from human to human can subsequently be continued by sylvatic vectors (see Fig. 15). Alternatively, the domestic mosquito, *A. aegypti,* which lives in close relationship with humans, may

transmit the virus, with humans being the sole viremic hosts in the cycle (*A. aegypti*-borne yellow fever or urban yellow fever). Detailed reviews of the ecology of yellow fever are available (135,212,492).

Yellow fever occurs throughout much of tropical South America and sub-Saharan Africa. Within this region, viral activity may be intermittent and quite localized (19). The distribution of reported cases gives only a partial picture of the natural circulation of yellow fever virus and gives a misleading estimate of risk to travelers. The virus is potentially present throughout the tropical rainforest and bordering grassland areas of South America and Africa.

As previously mentioned, the annual global incidence of yellow fever is estimated to be about 200,000. These numbers include adjustment to estimate the true impact of the disease and are far above the reported confirmed cases, which are 50 to 300 per year in tropical America and up to 5,000 per year in Africa (Fig. 18). These data represent a significant underestimate of the true morbidity, as shown by investigations of various epidemics. The incidence in Africa has increased dramatically in recent years, principally owing to a series of annual outbreaks in Nigeria between 1986 and 1991 that probably involved hundreds of thousands of cases (Fig. 19) (493). The virus spread from Nigeria to Cameroon in 1990, causing an epidemic that may have involved up to 20,000 cases and 1,000 deaths (745). The most recent outbreak in West Africa occurred in Ghana (1993). In East Africa, the first yellow fever epidemic in more than 25 years occurred in 1992 to 1993 in western Kenya.

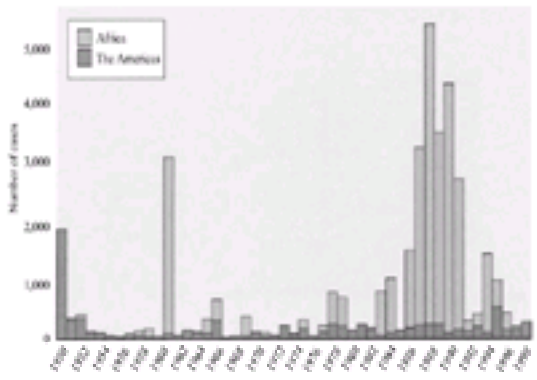

FIG. 18. Officially reported cases of yellow fever in South America and Africa, 1950 to 1998, showing the increase in incidence in Africa in recent years, owing to a series of epidemics in West Africa and (in part) to improved reporting.

FIG. 19. Countries in South America and Africa with officially reported yellow fever outbreaks. Areas considered to be at risk are also shown.

In tropical America, the incidence of jungle yellow fever is highest during months with peak rainfall, humidity, and temperature (January to March). In Africa, transmission by *A. aegypti* and tree-hole–breeding mosquitoes peaks during the late rainy season and early dry season. In tropical America, jungle yellow fever principally affects young adult males. The age and sex distribution reflects the higher incidence of exposure to *Haemagogus* species vectors during woodcutting and forest-clearing activities in the forest. In Africa, background immunity (natural and vaccine-induced) is the principal factor determining the age distribution of cases. In outbreaks affecting immunologically virgin populations (e.g., in Ethiopia, 1960 to 1962), all ages are equally affected. In West Africa, a high level of acquired immunity in adults has resulted in high attack rates in children. A slight excess of cases in males is typical of African epidemics and is probably due to increased exposure to sylvatic vectors during the period around sunset. The ratio of infections to clinical cases ranges between 2:1 to 20:1. Prior infection with one or more heterologous flaviviruses appears to mitigate severity and increase the infection-to-case ratio (499). The case fatality rate has varied widely in different epidemics, possibly reflecting virus strain variation in virulence.

Yellow fever has never occurred in Asia. Possible explanations include (a) cross-protection afforded by dengue immunity, and (b) low vector competence of Asian strains of *A. aegypti;* experimental evidence in support of both hypotheses has been presented (reviewed in 492).

Ecology of Yellow Fever in Tropical America

Howler monkeys (*Alouatta* species), spider monkeys (*Ateles* species), squirrel monkeys (*Saimiri* species), and owl monkeys (*Aotus* species) are effective viremic hosts and commonly develop fatal infections, whereas capuchin monkeys (*Cebus* species) and wooly monkeys (*Lagothrix* species) are susceptible to viremic infection but usually do not develop

clinical signs. This unstable host–parasite relationship may reflect the relatively recent introduction of the virus, possibly at the time navigation was established between Africa and America during the 15th century. Other South American vertebrates, including edentates, marsupials, and rodents, are now believed to play a negligible role in the yellow fever transmission cycle, although further study appears warranted.

Mosquitoes of the genus *Haemagogus* are the principal vectors of jungle yellow fever in tropical America. *Haemagogus* species mosquitoes breed in tree holes and feed in the forest canopy during the midday hours, but they also have been found biting humans in forest clearings and even inside houses in villages near the forest. Transovarial transmission of yellow fever virus in *Haemagogus* species has been experimentally demonstrated. This phenomenon may explain, in part, maintenance of the virus during prolonged dry seasons, when adult vector populations are diminished. The relatively drought-resistant mosquito *Sabethes chloropterus,* a relatively inefficient vector, may also play a role in virus survival.

The development of anti–*A. aegypti* campaigns in Latin America during the 20th century culminated in eradication of the vector from most countries surrounding the Amazon Basin and the disappearance of urban yellow fever after 1942. However, within the last 15 years, *A. aegypti* has reinvaded many areas (see Dengue Fever Viruses) (241,494). The urban vector again exists in or near areas of enzootic yellow fever, raising the specter of future urban outbreaks.

Ecology of Yellow Fever in Africa

All species of cercopithecid and colobid monkeys, and some prosimians tested have proved to be effective viremic hosts, circulating virus for several days or more at sufficient titers to infect mosquitoes (492,610). Infection infrequently results in illness or death, indicating a balanced host–parasite relationship.

A. africanus is responsible for year-round virus transmission in the humid equatorial African forests (see Fig. 15). The ecologic zones bordering equatorial forest have assumed great importance in yellow fever ecology. Appropriately named the *zone of emergence* by Germain and associates (212), the savannah vegetational zones support large and concentrated populations of monkeys and vector mosquitoes. Viral activity intensifies during the rainy season and wanes during the dry season, when vector populations virtually disappear. The principal species involved in sylvatic transmission and transmission to humans are *A. furcifer, A. africanus,* and *A. luteocephalus.* These species are responsible for interhuman spread during epidemics. Depending on location, other vectors that play a role in yellow fever transmission cycles include *A. vittatus, A. metallicus, A. opok, A. neoafricanus,* and *A. keniensis.* Surveillance of virus activity in sylvatic vectors collected in eastern Senegal over a 17-year period (1976 to 1993) has shown an impressive correlation with epidemics occurring throughout the West African region (23). The ecological events underlying the periodicity of virus amplification are unknown but may reflect regional fluctuations in rainfall patterns (494).

In areas subject to extreme drying (e.g., in the dry northern Sudan and Sahel savannah zones of West Africa), yellow fever occurs in intermittent epidemic form, and human immunity patterns indicate little or no infection during interepidemic periods. In these areas, domestic water storage is intensively practiced, domestic *A. aegypti* populations are high, and introduction of yellow fever virus may result in explosive outbreaks. Urban areas along the West African coast are also susceptible. A large urban epidemic occurred in western Nigeria in 1987.

Vertical transmission of yellow fever virus has been documented experimentally in *A. aegypti* (7). Evidence for vertical transmission in nature has been obtained by virus isolation from male *A. furcifer* and *A. aegypti* in West Africa (193). This mechanism ensures virus survival over the long dry season. Yellow fever virus has been isolated from *Amblyomma variegatum* ticks in the Central African Republic (640), raising the possibility that alternate vectors may play a role in dispersal or dry-season maintenance of the virus.

Yellow fever virus has been rarely isolated from other arthropods, including *Aedes dentatus, Coquilletidia fuscopennata,* and phlebotomine flies. Virus has been isolated from a bat in Ethiopia. These observations are of interest but probably bear little relationship to the ecology of yellow fever.

Molecular Epidemiology

The complete sequence of the E protein from 20 different isolates of yellow fever has been used to examine its evolution (108). Two major evolutionary lineages, E genotypes I and II, were characterized. Genotype I contains viruses isolated from East and Central Africa. Genotype II contains two sublineages: IIA from West Africa and IIB from America. One isolate from Trinidad was not characteristic of the IIB group, but it was related to African genotypes suggesting a recent introduction. The relationship between viruses supports the idea that yellow fever was introduced to the Americas from West Africa possibly through the slave trade. The recent reintroduction of an African subtype to the Caribbean shows that intercontinental transmission still occurs (112).

When yellow fever was transmitted to the Americas, it adapted to the local vectors and hosts. There are more unique amino acid substitutions relative to the nucleotide substitutions in the E protein in the American viruses than in the African subtypes (556). Five uniquely American amino acid signatures may possibly be the result of pressure by the new virus–host interaction. This evolution has altered the mouse virulence, antigenic character, and monoclonal antibody reactivity (9,21,155).

All of the African yellow fever virus genotypes are capable of rapid amplification, epidemic spread, and induction of highly lethal human infections, and all have demonstrated the capacity to cross from sylvan to urban (*A. aegypti*–borne) transmission cycles.

Prevention and Control

Vaccination

Yellow fever 17D is a safe, effective live viral vaccine prepared from infected chicken embryos under standards developed by WHO (608,677). Demonstrable immunity occurs in more than 95% of vaccinees within 10 days. For the purposes of international certification, immunization is valid for 10 years, but various studies have shown persistence of antibodies for as long as 30 to 35 years; immunity is probably lifelong (568). Many countries in South America conduct immunization campaigns, and a high vaccine coverage in enzootic areas has limited the incidence of human disease. Vaccination coverage in African countries is highly variable (608). In 1988, a strong recommendation was made to include 17D vaccine in the Expanded Program on Immunization. In 1992, coverage in 11 African countries ranged between 20% and 80%. Cost-effectiveness of routine preventive immunization of infants compares favorably to emergency mass immunization for epidemic control (495).

Serious adverse reactions to 17D vaccine are extremely uncommon. No abnormalities in liver function tests are associated with 17D vaccination. Fewer than 10% of vaccinees experience headache and malaise. Allergic reactions occur at a very low rate (about 1 in 1 million), predominantly in people with an allergy to eggs. The vaccine should not be given to patients with immunodeficiency states (including clinically overt HIV infection) or in those taking immunosuppressive drugs.

Neurologic accidents are extremely uncommon, and 14 of 20 such cases involved infants younger than 6 months of age (485,495); vaccine is now contraindicated in this age group. Encephalitis following yellow fever vaccine is due to virus neuroinvasion and direct viral injury; in all but one fatal case (21), the encephalitis resolved without sequelae.

The safety of yellow fever vaccination during pregnancy is a subject for debate. Taking the results of two studies into consideration, the risk for congenital infection (assessed by IgM antibody present in cord blood) approximates 1% to 2% and is not associated with fetal abnormality or illness (522,725). The stage of pregnancy during which vaccine was administered was uncertain in many cases, and further studies are warranted. Given the susceptibility of the immature nervous system to 17D virus, as noted by the occurrence of postvaccinal encephalitis in infants, and the fact that transplacental infection occurs in a small number of cases, immunization during pregnancy should be avoided. This recommendation must, however, take into account the relative risk for natural infection, which may be as high as 20% to 30% during epidemics.

Vaccination results in a low-level viremia lasting 1 to 2 days and beginning 3 to 4 days after inoculation. The low magnitude of viremia and the fact that *A. aegypti* is refractory to oral infection with 17D virus preclude the possibility of natural transmission (and possible reversion) of vaccine virus.

Factors that may affect seroconversion to the vaccine include (a) nutritional state, (b) simultaneous administration of other vaccines, (c) preexisting heterologous flavivirus immunity, and (d) pregnancy. Children with kwashiorkor showed marked impairment in antibody production after 17D vaccination. People administered 17D yellow fever and cholera vaccines simultaneously or 1 to 3 weeks apart showed reduced antibody responses to both vaccines (209). Other vaccine combinations and immune serum globulin can be used without interference. Studies with 17D vaccine produced in mouse brain and administered by scarification have shown a reduction in vaccine seroconversion in African population groups with prevaccination heterologous flavivirus antibodies. In patients given 17D chick embryo vaccine by the subcutaneous route, however, preexisting heterologous immunity did not interfere with the immune response. In one study (522), only 38% of pregnant women seroconverted, compared with 82% to 90% of nonpregnant controls. There are no data on the safety or efficacy of yellow fever vaccination of HIV-infected patients. Present recommendations are for vaccination of infected individuals without signs or laboratory parameters indicating immunosuppression.

At the present time, vaccines produced by some of the world's 12 manufacturing institutes are contaminated with avian leukosis virus. Although undesirable, this contaminant has not been associated with the development of leukemia, lymphoma, or other cancers (753). Fully effective 17D vaccine virus can be genetically cloned and recovered (452). Intranasal administration of the 17D vaccine (531) induces an immune response in rhesus monkeys. Although there has been no pathogen challenge, if this intranasal route were as successful as the injection, immunization would become much easier, and vaccine coverage would be simplified.

The French neurotropic vaccine, produced from infected suckling mouse brains, is no longer manufactured. The vaccine had the advantage of high stability and ease of administration (by scarification or multiple puncture). However, about 20% of vaccinees developed systemic symptoms, 3% to 4% developed meningeal signs, and 0.5% to 1.3% developed postvaccinal encephalitis. Neurologic accidents were more frequent in children than in adults; fatalities and permanent neurologic sequelae have been reported.

Other Preventive Measures

Areas infested with the domestic form of *A. aegypti* are at risk for the introduction and urbanization of yellow fever. Elimination of breeding sites (e.g., tires, artificial containers), treatment of potable water with temephos (Abate), perifocal spraying with organophosphorus insecticides, and use of Gambusia minnows are effective if applied in a well-administered and continually supported program.

In the case of an outbreak of *A. aegypti*-borne yellow fever, ground or aerial ULV application of adulticides may be used. The control of yellow fever epidemics involving wild vector species is more difficult, and little experience with vector control has been accumulated.

Aerial ULV applications of malathion are effective for the control of the yellow fever vector *Aedes bromeliae* breeding in false banana (*Musa ensetta*) plantations in Ethiopia. Ground and aerial applications of malathion rapidly suppressed populations of *A. africanus* in forest habitats in West Africa for a period of time believed sufficient to interrupt virus

transmission. Aerial ULV was also used for the control of *Haemagogus* species vectors in forested areas in eastern Panama in 1974.

Dengue Viruses (Dengue Hemorrhagic Fever)

Cases of hemorrhage and death had been described during outbreaks of classic dengue fever in Australia (in 1897), Greece (1928), and Formosa (1931) (338). In 1954, a febrile disease with hemorrhagic signs (Philippine hemorrhagic fever) occurred in epidemic form in Manila and was shown to be caused by dengue 3 and 4. DHF was subsequently described in many other areas of Southeast Asia (264). The disease was first reported in China in 1985. The incidence of DHF in Asia has risen steeply since the 1980s, and more than 450,000 cases are now reported annually, making it a leading cause of morbidity. Case fatality rates currently range from 1% to 10%, depending on the availability and sophistication of hospital care. Sporadic cases of DHF were recognized in the Americas during the 1970s, and epidemic DHF appeared in the 1980s. The pathogenesis of DHF remains incompletely understood. Halstead proposed that the severe form of the disease had an immunopathologic basis and occurred in individuals previously sensitized by infection with a heterologous dengue serotype (257,259).

Infectious Agents

All four dengue virus serotypes cause DHF and DSS. In Thailand, dengue type 2 was the predominant virus associated with these syndromes until the 1980s, when dengue 3 and 4 emerged as important serotypes. In Indonesia, dengue 3 was most frequently isolated and associated with fatal cases between 1976 and 1978. In Cuba, Venezuela, and Brazil, DHF epidemics occurred when a specific strain of dengue 2 was introduced 3 to 4 years after an outbreak of dengue 1. The sequence of infecting serotypes, the interval between infections, and strain differences in virulence may be important determinants of the clinical and epidemiologic patterns of DHF (87,153,240,257,258,639). Because an animal model of DHF has not been found, this question has eluded study. Two studies have indicated that viral replication in human mononuclear cells may provide a correlate of virulence (354,510). Comparison of strains associated with different disease outcomes at the genome level have also provided clues that virus-specified factors may contribute to the pathogenesis of DHF (506,604).

Pathogenesis and Pathology

The development of a satisfactory animal model of DHF has been an elusive goal. Unsuccessful attempts to develop models have included the sequential infection of nonhuman primates and of SCID mice reconstituted with human cells. The human disease is characterized principally by diffuse capillary leakage of plasma and a hemorrhagic diathesis. Increased vascular permeability results in hemoconcentration, decreased effective blood volume, tissue hypoxia, lactic acidosis, and shock. These pathophysiologic events are probably mediated by cytokines, and pathologic findings in fatal human cases consequently reveal little evidence of direct viral injury (51,90,598). Gross pathological findings include petechiae, ecchymoses, and focal visceral hemorrhages; serous and bloody effusions; retroperitoneal edema; and, in some cases, hepatic enlargement. On histopathologic examination, there are diffuse small-vessel changes in viscera and soft tissues with leakage of plasma (perivascular edema) and erythrocytes. The spleen and lymph nodes show proliferation of immature and mature lymphoid cells and plasmacytoid elements. Necrosis of thymus-dependent areas of the spleen may be prominent. Hepatic lesions similar to other hemorrhagic fevers, although generally less severe, consist of central or paracentral focal necrosis, sinusoidal acidophilic (Councilman's) bodies, hypertrophy of Kupffer's cells, variable and mild fatty change, and patchy portal mononuclear cell infiltration. Bone marrow changes include maturational arrest of megakaryocytes. Focal dengue viral antigen has been demonstrated in skin, liver, and mononuclear leukocytes.

Prospective studies in Thailand have shown that more than 90% of cases of DHF occur in patients who have previously been infected with at least one heterologous dengue serotype (87,259,639). Children with secondary immune responses were at significantly higher risk for DHF than those experiencing their first infection. About 3% of people who ustain secondary dengue infections develop DHF, whereas less than 0.2% of those with primary infections develop the syndrome. In infants who develop DHF as a consequence of primary dengue infection, the disease occurs mainly between 6 and 12 months of age in the presence of waning, passively acquired maternal antibody. The concept of antibody-dependent immune enhancement of dengue viral replication in monocytes has been proposed (257,258,259 and 260) to explain these observations (see previous section, Antibody-Dependent Enhancement). Dengue viruses were shown to replicate to higher titer in human mononuclear cells in the presence of cross-reactive nonneutralizing dengue antibodies than in the absence of antibodies. Infectious complexes of virions and IgG antibody gained access to monocytic cells through their Fcg receptors. These findings led to the concepts that the presence of enhancing antibodies increased the number of dengue-infected cells and that lysis or immune clearance of these cells led to the release of vasoactive mediators and procoagulants (738). Attempts to model this phenomenon *in vivo* by studying viremia levels in immunologically sensitized nonhuman primates provided equivocal results (256,623). However, recent evidence for the occurrence of ADE *in vivo* has been obtained from studies on the presence of NS1 antigen in the sera of patients with primary and secondary dengue infections (783a). Acute-phase sera from patients with secondary, but not primary, dengue infections were found to contain high levels of NS1 antigen, indicating enhanced numbers of infected cells in secondary infections.

Recent studies have focused on the role of T-cell activation and cell-mediated immunologic clearance of dengue-infected monocytes in the pathogenesis of DHF. Both CD4+, CD8– and CD4–, CD8+ T cells have been detected in people naturally infected with dengue viruses or immunized with live attenuated vaccines (396,397). Cytotoxic CD4+, CD8– T-cell clones established from immune donors have demonstrated dengue serotype-specific, dengue serotype–cross-reactive, and flavivirus cross-reactive specificities (791). The CD4+ clones lyse autologous dengue virus-infected cells in an HLA class II–restricted fashion; proliferate; and produce IFN-g, interleukin-2 (IL-2), and granulocyte-macrophage colony-stimulating factor when stimulated with dengue virus antigens (396,544). Memory CD4–, CD8+ cell clones with HLA class I–restricted cytotoxicity also show dengue serotype cross-reactivity (82). The NS3, NS1, and E proteins appear to contain important epitopes for recognition by both CD4+ and CD8+ T cells (392). Further complicating the model, it has been shown that there can be a partial agonist effect on the cytotoxic T-lymphocyte

response to the homologous protein of different dengue serotypes (791). Under this assumption, the effector cells are partially activated, thus producing some of the soluble mediators, which could be involved in the DHF pathogenesis. But the limited nature of activation induces an ineffective viral clearance. Although seemingly counterintuitive to the present model of DHF development, there has been some evidence of impaired T-cell proliferation during an acute dengue infection (462).

A unifying hypothesis linking ADE of virus replication and T-cell activation has been proposed by Halstead (258) and Kurane and Ennis (398) (Fig. 20). In this model, the host has been previously infected with a dengue serotype and has cross-reactive serum antibodies and memory T cells. Upon infection with a heterologous dengue serotype, the formation of virus–antibody complexes leads to complement activation and enhanced infection of Fcg receptor–bearing monocytic cells. Memory CD4+ T lymphocytes activated by dengue antigens proliferate and produce IFN-g, which in turn up-regulates both the expression of Fc receptors on monocytic cells (augmenting the infection of these cells by immune complexes) and the expression of HLA class I and II molecules involved in recognition of these cells by Tc cells. The dengue-infected monocytic cells are targets for CD4+ and CD8+ Tc cells, resulting in the release of cytokines or cell lysis and release of intracellular enzymes and activators. Evidence for enhanced CD4+ and CD8+ T-cell activation in DHF patients was provided by the finding of higher levels of soluble IL-2 receptor, soluble CD4, and soluble CD8 in sera of DHF than in dengue fever patients (394). However, the precise role of cytokines and tissue factor mediators of capillary leakage, shock, and hemorrhage in DHF remains a subject of research. Although several lines of evidence suggest that T-cell activation and release of mediators are key to the pathophysiology of DHF, it has proved difficult to demonstrate clear correlations with disease severity (226). Elevated levels of IL-2 have been found in children with both dengue fever and DHF (394). IL-2 induces capillary leakage and complement activation when administered to humans. Elevated levels of tumor necrosis factor (TNF), IL-6, C3a and C5a, and histamine have been described in DHF (303,747). In children with DHF, levels of TNF-a and IL-6 were highest on the day of appearance of shock. TNF-a is released from activated monocytes and macrophages, is implicated in septic shock induced by bacterial endotoxins, and is thus a potentially important mediator in DHF and DSS. Bradykinin has not been implicated (176) as a mediator in DHF. High IFN-a levels are sustained for a week or more after onset (395), but the role of this molecule in immunoregulation and pathogenesis, clinical symptomatology, and control of dengue infection in the host remains to be defined.

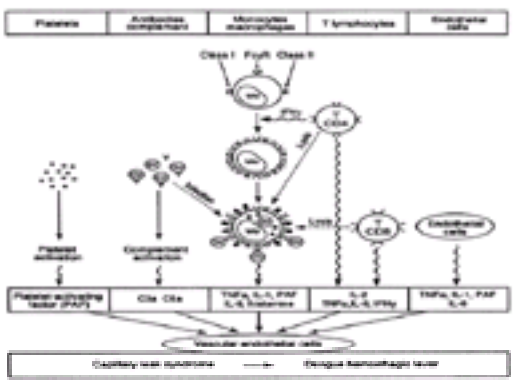

FIG. 20. Diagram of the immunopathogenesis of dengue hemorrhagic fever induced by cytokines and other chemical mediators of increased vascular permeability. (From ref. 398, with permission.)

The role of cytokine mediators in DHF has been investigated in mice by Chaturvedi and colleagues. These investigators described a unique cytokine called *cytotoxic factor* (CF) produced by splenic T cells. When administered to uninfected mice, cytotoxic factor induced vascular and blood–brain barrier permeability and lymphoid cell depletion, effects mimicking elements of DHF pathophysiology (116,162). Immunization of mice with cytotoxic factor prevented these effects. A recent study has demonstrated that the CF was found only in the CD4+ T cells (5,662) and that the amount of CF correlated with the degree of illness. Although implicated in the pathogenesis of DHF, the exact nature and properties of CF need to be determined so that its role can be better defined.

Another uncertainty in the DHF puzzle is the role of infected endothelial cells (14,29). Human umbilical vein endothelial cells become activated when exposed to culture fluids from infected monocytes and up-regulated expression of adhesion molecules VCAM-1 and ICAM-1. Infected human endothelial cells also up-regulate the production and secretion of chemokines RANTES and IL-8 (342), which can increase vascular permeability through transient recruitment and local activation of neutrophils. Additionally, cross-reactive antibodies activate complement on infected endothelial cells. In addition, it was shown that in the absence of outside influence, dengue-infected endothelial cells die, possibly through programmed cell death. All of these factors could contribute to the development of DHF. It is possible that these particular effects play a role along with the various cross-reactive T cells.

The etiology of the hemorrhagic disturbance in DHF appears to be complex. Microvascular injury, thrombocytopenia, platelet dysfunction, and disseminated intravascular coagulopathy have been variously implicated (reviewed in 258). Liver injury of significant degree may impair synthesis of vitamin K–dependent coagulation factors. Increased platelet turnover has been attributed to the direct attachment of dengue virus to platelets and to the presence of antiplatelet antibodies, with subsequent immune elimination. At a cellular level, it is probable that procoagulants are released from infected monocytic cells or endothelial cells activated by IL-2 or other cytokines. In one study, dengue-infected monocytes were found to contain significantly higher levels of plasminogen activator-inhibitor, suggesting a mechanism for interference with the fibrinolytic system (373). A possible link between the immune response to dengue infection and the hemorrhagic diathesis has been suggested (456) on the basis of homology between the amino acid sequence of plasminogen and a 20-residue region of the dengue E glycoprotein. Cross-reactive antibodies between the dengue E peptide and the corresponding site of plasminogen were demonstrated in sera of dengue patients.

Why only a small subset (about 3%) of people with secondary infections develop DHF remains uncertain. Both virus-specified and host-related factors may operate. Virus strains may vary with respect to the presence of enhancing epitopes or other intrinsic virulence factors. In the Americas, dengue 2 has been responsible for repeated outbreaks of classic dengue fever as well as by the explosive appearance of DHF in Cuba, Venezuela, and Brazil. This apparent paradox could be explained solely on the basis of the epidemiologic events leading to the establishment of hyperendemic transmission of multiple serotypes and an increased incidence of sequential infections. However, circumstantial evidence from molecular analysis suggests that the dengue 2 strain responsible for the occurrence of severe disease may represent a variant with increased virulence for humans.

A comparison of the gene sequences of dengue 2 viruses from the Caribbean region indicate that two distinct variants were cocirculating over a period of many years (604). One genetic variant represented the Puerto Rican strain, that had been introduced into the region in 1969 and has persisted in an endemic and epidemic pattern, associated with classic dengue fever. A second variant represented a strain first isolated in Jamaica in 1981. The Jamaican genotype was responsible for the DHF epidemics in Venezuela (1989) and Brazil (1990). Sequence homology between the Jamaican variant and virus strains from Southeast Asia suggested the original source of introduction. In contrast, the Puerto Rican genotype resembled contemporary virus strains from Polynesia, where for the most part disease was mild. These observations infer that the Jamaican genotype of dengue 2 is more likely to cause DHF than the Puerto Rican genotype. The virus responsible for the large DHF epidemic in Cuba in 1981 was distinct from the Jamaican genotype, and more closely resembled older strains from Southeast Asia (252).

Several workers have noted an apparent increase in the severity of disease expression during the chronologic progression of dengue epidemics (623,624). For example, during the 1981 Cuban epidemic, the incidence of severe grades of DHF, and the case fatality rate increased with time and was highest in the later stages of the outbreak (370). During an epidemic of dengue fever in Queensland, the incidence of hemorrhagic phenomena rose as the epidemic progressed (696). These observations suggested that dengue viral virulence may have been enhanced by rapid passage through the human population. No comparisons of early and late virus strains by sequencing or virus growth in human cells or mosquitoes have yet been reported to support this hypothesis.

A preliminary analysis demonstrated variation in the ability of dengue virus strains to replicate in human peripheral blood mononuclear cells and higher replication of isolates from DHF patients than from dengue fever patients (354). A second study of dengue 2 isolates also demonstrated higher replication in human peripheral blood mononuclear cells of strains from DHF patients than those from dengue fever patients (510). These studies were performed in human peripheral blood mononuclear cells and in the presence of enhancing antibodies from donors unrelated to the subject from whom the virus isolate was obtained.

Host genetic factors may influence severity of dengue infection (463). An association between HLA haplotype and disease expression was found in Cuban patients with DHF. HLA-B “blank,” HLA-A1, and HLA-Cw1 were more frequent and HLA-A29, less frequent than in control subjects (547). In Thailand, HLA-B blank and HLA-A2 were associated with DHF (125). In the Cuban epidemic, whites had a higher incidence of DHF than blacks, a finding that could not be explained on the basis of the background of immunity (67). Among acquired factors that influence disease expression, nutrition and underlying diseases may play a role. The prevalence of malnutrition is lower in children with DHF patients than in the general population (709), possibly reflecting the requirement for robust immunologic responsiveness in the genesis of DHF. Chronic diseases such as sickle cell disease, diabetes mellitus, and bronchial asthma appear to increase the risk for severe disease (67).

Clinical Features

The clinical manifestations of DHF and DSS are described by Cohen and Halstead (131) and by Nimmannitya and associates (532). DHF is distinguished from dengue fever by the presence of fever, thrombocytopenia (platelet count less than 100,000 per mm^3), and hemoconcentration (hematocrit increased by more than 20%). DSS is a more severe form of the disease, characterized by hypotension (pulse pressure, 20 mm Hg; cold and clammy extremities), or profound shock (Table 6). The disease initially presents in a manner similar to that of classic dengue fever (see previous section, Dengue Viruses) but progresses after 2 to 5 days to a rapidly progressive, severe form with prostration, restlessness, irritability, shock with cold clammy extremities, diaphoresis, circumoral and peripheral cyanosis, rapid respiration, rapid pulse, and hypotension. Spontaneous hemorrhages occur, including petechiae, ecchymoses, oozing from venipuncture sites, epistaxis, and so forth. Clinically relevant hemorrhage occurs in 10% to 15% of cases. Gastrointestinal hemorrhages and intracerebral bleeding may be life-threatening. Physical findings include skin hemorrhages, pleural effusions, changes in vital signs, and hepatomegaly. Jaundice is a rare manifestation (528). Neurologic abnormalities have been reported in some cases, the most frequent manifestation being encephalopathy (stupor, coma, convulsions, paresis), generally with normal CSF. Cases meeting the criteria for Reye's syndrome have been described. Laboratory abnormalities in DHF include elevated hematocrit and hypoproteinemia (reflecting the capillary leakage), thrombocytopenia, elevated serum transaminases, depression of complement (especially C3) and fibrinogen levels, and the presence of fibrin split products in plasma. The progression of shock is rapid; without physiologic treatment, up to 50% of patients with profound shock die. However, early recognition and appropriate treatment have resulted in overall case fatality rates of less than 1%.

Grade	Hemo-concentration[b]	Spontaneous hemorrhage	Hypotension[c]	Shock

TABLE 6. *Clinical grades of dengue hemorrhagic fever*[a]

Diagnosis

Geographic location and epidemiologic setting are important clues to the diagnosis. DHF has generally not occurred in areas affected by other viral hemorrhagic fevers. An exception is the recent appearance of DHF in South America, where individual cases of the disease resemble and have been confused clinically with yellow fever. Chikungunya occasionally produces an illness with minor hemorrhagic manifestations similar to those of classic dengue fever, but cases with severe hemorrhage, hemoconcentration, thrombocytopenia, and shock are rare or do not occur. Nonviral causes must be considered in the individual case, including bacterial sepsis, scrub and epidemic typhus, leptospirosis, severe malaria, and typhoid fever.

Virus isolation from tissues of fatal cases is less often successful than in classic dengue (533). Techniques for virus isolation from blood of acutely ill patients were discussed in a previous section, Dengue Viruses. Serodiagnosis is possible, but identification of the infecting subtype is difficult because most cases of DHF occur in people with prior dengue exposure. Secondary antibody responses characterized by high HI, CF, and ELISA antibody titers, which are broadly cross-reactive, are typical in cases of DHF. Various attempts to examine the patterns of antibody responses to individual dengue proteins have not revealed consistent differences between dengue and DHF patients. In general, antibodies to the nonstructural proteins, including NS1, NS3, and NS5 are more prominent in sera of patients with secondary infections (113,385).

DHF has a sudden onset and thus can be difficult to predict and treat quickly and efficaciously. It is believed that cytokines play a key role in the pathology; if this is true, it should be possible to predict the course of the disease by the production of different cytokines. There are several detectable factors that appear to predict DHF. CF, IL-8, soluble tumor necrosis factor receptor, and transforming growth factor are all elevated during DHF (48,407,582).

Treatment

WHO has formulated specific guidelines for the management of cases (778). Principles of treatment are dictated by the need to monitor closely the patient's vital signs and hematocrit and to replace plasma volume by judicious fluid replacement. Oxygen should be administered; moreover, if disseminated intravascular clotting is documented, consideration may be given to heparin therapy. Blood transfusion is indicated only in the case of severe hemorrhage. Salicylates and hepatotoxic drugs should be avoided. Corticosteroids are widely used; evidence for their usefulness is conflicting, but some studies indicate that they are of no value (700).

Specific, antiviral therapy has not been extensively evaluated. An uncontrolled trial of IFN was conducted during the 1981 epidemic in Cuba, with some indication that deaths may have been averted. Although ribavirin shows *in vitro* activity against dengue virus, concentrations required for *in vivo* efficacy are not achievable without toxicity. A study of ribavirin in dengue-infected monkeys failed to show an antiviral effect (444).

Epidemiology

Nearly 3 million cases of DHF have been officially reported worldwide through 1990, most cases occurring in Asia. In Thailand alone, 874,207 cases of DHF were reported between 1958 and 1990, with a case fatality rate of 1.57%; in Thailand, the disease ranks fifth as a cause of morbidity, third as a cause of death, and fifth as a cause of years of productive life lost (225). Factors responsible for the emergence of DHF as an epidemic disease in Asia in the 1950s and 1960s and for its recent dramatic rise in incidence (Fig. 21) include the following:

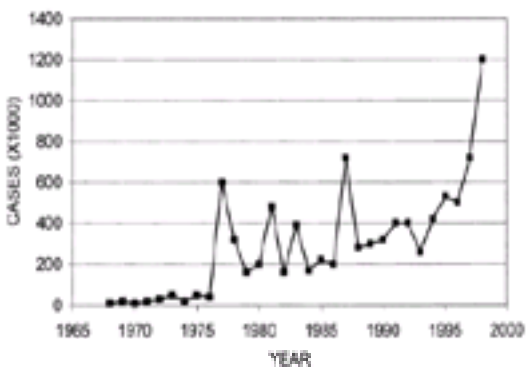

FIG. 21. Incidence of reported cases of dengue hemorrhagic fever, worldwide, 1968 to 1998, and showing a dramatic

increase in incidence in the recent past. The factors responsible are described in the text and include changes in human and vector ecology leading to increased intensity and geographic expansion of virus transmission and cocirculation of multiple dengue serotypes.

1. Demographic changes (human population growth and urbanization) favoring contact with the domestic mosquito vector, *A. aegypti*
2. Ecologic changes linked to urbanization (poor sanitation, inadequate piped water, necessitating domestic water storage) favoring *A. aegypti* breeding
3. The rapid rise in air travel, providing the means for movement of viremic humans and dissemination of multiple dengue serotypes
4. Establishment of hyperendemic dengue infection and increasing frequency of sequential infections of children (241,506)

The factors responsible for the emergence of DHF in Asia have recently come to bear on the Americans. The distribution of *Aedes aegypti* changed dramatically, due to the collapse of mosquito control efforts (see Fig. 16). The pattern of dengue infections changed from outbreaks at intervals of multiple years caused by a single serotype to annual outbreaks and cocirculation of three of the four dengue serotypes. Sporadic cases of DHF were recognized in the 1970s, and major epidemics occurred in Cuba, Venezuela, and Brazil in the 1980s. Eleven countries in the region have now reported the occurrence of DHF (Fig. 22).

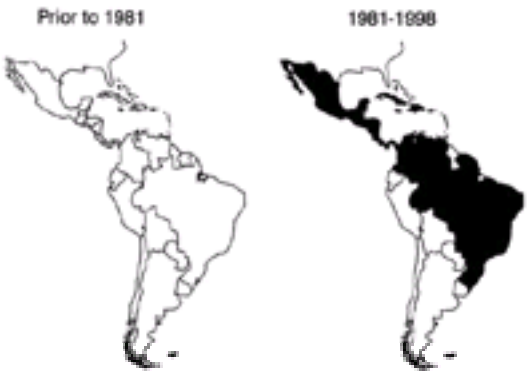

FIG. 22. Distribution of dengue hemorrhagic fever in the Americas before 1981 and during the period from 1981 to 1998, showing spread of the disease as a result of reinvasion of the region by the *Aedes aegypti* vector and the introduction and transmission of multiple dengue serotypes. (From ref. 237, with permission.)

DHF in Asia is a disease of childhood. Two peaks have been noted in age-specific incidence rates: children younger than 1 year of age and children 3 to 5 years of age. The disease in infants is associated with primary infection in the presence of maternal antibody, whereas most cases in older children are the result of secondary infections. Studies in Thailand have estimated the frequency of DHF and DSS in children 1 to 14 years of age to be 31 and 11 cases per 1,000 secondary dengue infections, respectively, whereas the incidence of DHF and DSS in primary infections is 1.9 and 0.07 per 1,000, respectively (87). An age-dependent excess in cases of severe DHF with shock syndrome in girls, compared with boys, has been noted and appears to be related to host factors because serosurveys have shown no difference in sex-specific antibody prevalence.

Other Flaviviruses Associated with Hemorrhagic Fever

Kyasanur Forest Disease Virus

Kyasanur Forest virus was isolated from a sick monkey (*Presbytis entellus*) in the Kyasanur Forest, Shimonga District, Karnataka (then Mysore) State, India, in 1957 (36,776). The virus belongs to the TBE virus antigenic complex. No antigenic differences between strains have been found. The virus is lethal to infant and weanling mice by both the intracerebral and intraperitoneal routes; produces CPE or plaques in chick embryo, hamster, and monkey kidney cell cultures; and replicates without CPE in a continuous cell line of *Haemaphysalis spinigera* tick cells. Pathologic findings in human patients include parenchymal degeneration of the liver and kidneys, hemorrhagic pneumonitis, and an increase in reticuloendothelial tissue in liver and spleen, with marked erythrophagocytosis (442). Similar changes have been seen in experimentally infected monkeys. Bonnet macaques are susceptible to severe or lethal infections and demonstrate necrosis of lymphoid tissues (351). Some primate species also develop encephalitic lesions (chromatolysis of neurons and focal demyelination) (755). Lactating monkeys shed small amounts of virus in their milk. The clinical illness in humans is characterized by fever, headache, myalgia, cough, bradycardia, dehydration, hypotension, gastrointestinal symptoms, and hemorrhages (551). In some patients, a biphasic course is seen; the first phase, as described previously, lasts 6 to 11 days, followed by an afebrile period of 9 to 21 days and then the reappearance of fever and signs of meningoencephalitis. In such patients, the disease closely resembles Central European TBE (757). Leukopenia is a frequent finding during the acute phase of illness, and serum transaminase levels are raised. The cause of hemorrhage is unknown, but disseminated intravascular coagulation has been suspected. Diagnosis is by virus isolation from blood or serology. Standard serologic tests and enzyme-linked immunoassays are applicable. Viremia is detected between the 2nd and 12th days of illness and is maximum between the 3rd and 6th days, with a mean titer of 3.0 dex/mL. The disease is limited to Mysore State, India, but is gradually spreading. Epizootics occur in wild monkeys. Human infections occur

principally during the dry season and in people with close contact with forested areas.

Thousands of cases have been reported since the recognition of the disease in 1957; the annual incidence of virologically diagnosed cases varies between 400 and 500 cases. The case fatality rate is 3% to 5%; no sequelae are reported. The basic transmission cycle involves ixodid ticks and wild vertebrates, principally rodents and insectivores (36). Bats and ground-dwelling birds may play a role in transmission. Large animals (goats, cows, sheep) become infected, but viremias are low, and their importance is principally as hosts sustaining tick populations. At least 10 species of ixodid ticks have been implicated in transmission; *Haemaphysalis spinigera* is a major vector. Transtadial and transovarial transmissions occur in ticks. The density of tick vectors in a given year correlates with the incidence of human disease. A formalin-inactivated vaccine produced in chick embryo fibro-blasts has been licensed and is currently in use in the endemic area.

Omsk Hemorrhagic Fever Virus

Omsk hemorrhagic fever (OHF) virus was first isolated in 1947 from the blood of a patient with hemorrhagic fever during an epidemic in Omsk and Novosibirsk Oblasts, former Soviet Union. As demonstrated by serologic relationships and nucleotide sequence homology (234), OHF virus is a member of the TBE virus complex. Strain heterogeneity has been noted in virulence and antigenic characteristics. The virus is pathogenic for infant and weanling mice by all routes of inoculation. Guinea pigs inoculated by the subcutaneous route develop fever and scattered deaths; rabbits develop antibodies only. Unlike Kyasanur Forest disease, OHF virus does not induce disease or significant pathology in experimentally inoculated bonnet macaques (351). The virus causes hemorrhagic disease and death in experimentally inoculated muskrats and narrow-skulled voles (*Microtus gregalis*). The virus has been propagated in pig kidney, Hela, and Detroit G cells. The disease in humans closely resembles Kyasanur Forest disease except that sequelae (hearing loss, hair loss, neuropsychiatric complaints) are relatively frequent. The case fatality rate is 0.5% to 3%. Between 1945 and 1958, a total of nearly 1,500 cases were recorded in the Omsk region (352). Small numbers of cases acquired by tick bite continue to occur among rural residents engaged in field work during the spring and summer. Muskrat hunters are at risk for the disease by direct contact with blood and tissues, and such cases may occur during the winter months.

The basic transmission cycle remains uncertain. The ixodid tick vector *Dermacentor reticulatus* has been incriminated by field evidence and experimental infection (352). Other species, especially *Ixodes apronophorus,* are suspected to play a role in virus maintenance. Rodents, particularly water voles (*Arvicola terrestris*), are the principal viremic hosts. Direct rodent-to-rodent transmission may occur. Muskrats are epizootic hosts, and human infections occur by direct contact with urine, feces, or blood. No specific Omsk hemorrhagic fever vaccine has been developed, but TBE vaccines apparently provide cross-protective immunity and have been used in high-risk population groups.

CHAPTER 34 Hepatitis C Viruses

Marian E. Major, Barbara Rehermann, and Stephen M. Feinstone

HISTORY

Recognition of the Disease

Viral hepatitis had been separated into two distinct diseases termed *infectious hepatitis* and *homologous serum hepatitis* during World War II (211). Later, the terms *hepatitis A* (HA) and *hepatitis B* (HB), respectively, were applied, and the infectious agents associated with these diseases were named *hepatitis A virus* (HAV) and *hepatitis B virus* (HBV). Until sensitive and accurate tests became available to distinguish patients who were infected by these viruses, however, the diagnosis was based on the clinical and epidemiologic features of the individual patient. With the discovery of Australia antigen, later termed *hepatitis B surface antigen* (HBsAg), in 1965 (37) and its association with hepatitis B in 1968 (244,266), a clearer picture of viral hepatitis began to emerge. In 1971, a radioimmunoprecipitation test for antibody to HBsAg was developed that reached a sensitivity sufficient to identify virtually all patients who had previously been infected with HBV (186). Soon after, highly sensitive radioimmunoassays (RIAs) for HBsAg became available as well as a test for antibody to the hepatitis B core antigen (HBcAg). With these three tests, virtually all patients infected by HBV in the present or past could be identified and their current clinical status determined.

Surprisingly, using these assays, it was found that most patients with transfusion-associated hepatitis did not have hepatitis B (12). Because the only other known hepatitis agent was HAV, which did not fit well with the epidemiologic or clinical picture of posttransfusion hepatitis, there began to emerge the belief that there may be other, yet to be identified, hepatitis agents. In 1973, the hepatitis A virus was identified by immune electron microscopy (IEM) (96). Although this assay was cumbersome, not only was it capable of detecting in HAV some clinical samples but also it was reasonably sensitive for detecting antibody to HAV. To determine the role of HAV in posttransfusion hepatitis, a study was undertaken in which very well characterized patients from the National Institutes of Health (NIH) Clinical Center prospective trials of posttransfusion hepatitis were examined for the development of antibody to HAV after their acute hepatitis. Of 22 patients whose pretransfusion and posthepatitis sera were studied, none developed new antibody to HAV or rising levels of preexisting antibody as measure by IEM (97). A similar group of patients was characterized by Prince and colleagues, who also concluded that these cases were not hepatitis A based on clinical characteristics (261). Finally, in a study of 13 patients with a total of 30 distinct multiple bouts of community-acquired hepatitis, only 2 cases could be diagnosed as hepatitis A, 12 were hepatitis B, and the remaining 16 were termed *non-A, non-B hepatitis* (NANBH) (230). From these studies, the concept of NANBH became accepted, and the search began for the causative agent.

Identification of the Virus

During the ensuing 15 years, a large number of reports appeared claiming to have discovered the virus, a viral antigen, or a specific antibody associated with NANBH. None of these reports proved accurate. Nevertheless, many things were learned about the etiologic agent, the disease, and the epidemiology of NANBH. The agent was passed to chimpanzees (13,137). It was clearly shown that NANBH caused chronic infections, as would be predicted by the fact that it was frequently transmitted by blood transfusion from presumably chronic carriers. It was shown that NANBH could be a very serious disease that could result in chronic liver disease and cirrhosis, whereas the acute disease was often relatively mild compared with that of transfusion-associated hepatitis due to HBV (11). The pathology was described at both the

light and electron microscopic levels (83,255). Several viral characteristics were also described using the chimpanzee model for the infectivity readout. It was shown that the virus could be inactivated by lipid solvents, suggesting that the virus was enveloped (98). The virus was also shown to be able to pass through a 50-nm filter (126). Thus, a picture of a small, enveloped virus emerged.

With the development during the 1980s of increasingly powerful and sensitive molecular biologic techniques, the detection of previously unrecognized infectious agents became possible. Using a large volume of plasma that had been collected over time from a chronically infected chimpanzee and that had a relatively high titer of infectious virus (40), a group of scientists at the Chiron Corporation, led by Michael Houghton, made a lambda phage complementary DNA (cDNA) expression library from the nucleic acid extracted from the plasma (64). This library was screened with serum from a patient with chronic NANBH as a likely source of antibody to the virus. They identified a clone termed *5-1-1* that expressed an antigen that was shown to be specific for NANBH. They were able to show that the origin of the clone was a single-stranded RNA molecule of about 10,000 nucleotides in length and that the RNA had one continuous long open reading frame (ORF). The expression product of clone 5-1-1 became the basis for the first serologic assay for antibody to the NANBH agent, which was now termed *hepatitis C virus* (HCV) (181). The specificity of the clone and the antibody assay was determined by testing sera from patients who had previously been used to transmit NANBH to chimpanzees, implicated blood donors, and transfusion recipients who developed NANBH. They found that at least 80% of patients with posttransfusion NANBH developed antibody to 5-1-1, and 58% of patients with chronic NANBH without a known exposure to blood had antibody. The 5-1-1 antigen remains a part of the commercial multiantigen test for HCV antibody in use today.

Later, sequence analysis of clones representing nearly the complete HCV genome showed that the virus most closely resembled the Flaviviridae. Since the discovery of HCV by the technology of modern molecular biology, many of the fine details of this virus have been determined, even though it still has not been grown to useful levels *in vitro.*

INFECTIOUS AGENT

Classification

HCV has a similar genomic organization and polyprotein hydrophobicity profile as the pestiviruses and flaviviruses (65) and has been classified as a separate genus in the family Flaviviridae (102). The HCV viral particle is about 50 nm in diameter (126,292) and consists of an envelope derived from host membranes into which are inserted the virally encoded glycoproteins (E1 and E2) surrounding a nucleocapsid and a positive-sense, single-stranded RNA genome of about 9,500 nucleotides (65). The genome contains highly conserved untranslated regions (UTRs) at both the 5' and 3' termini (127,173,315), which flank a single ORF encoding a polyprotein of 3,000 amino acids (67,313). This is processed cotranslationally and posttranslationally by cellular and viral proteases to produce the specific viral gene products outlined in Figure 1. The structural proteins, core, E1 and E2, are located in the N-terminal quarter, with the nonstructural (NS) proteins (NS2, NS3, NS4A, NS4B, NS5A and NS5B) in the remaining portion of the polyprotein (117,131).

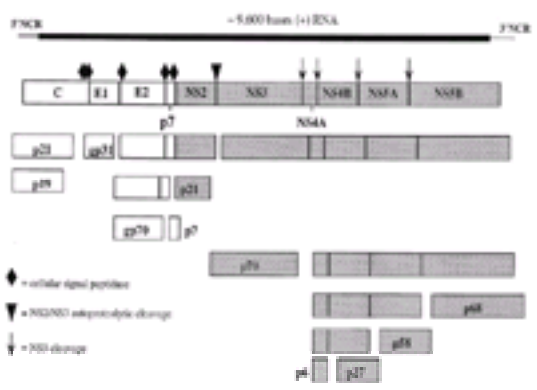

FIG. 1. Structure and processing of the hepatitis C virus (HCV) polyprotein by cellular signal peptidases and virally encoded proteases (NS2/3 and NS3). The viral coding region is represented across the *top. Boxes* below indicate precursors and mature proteins generated by proteolytic processing events. Approximate sizes by sodium dodecyl sulfate-polyacrylamide electrophoresis of the mature proteins (*p*) and glycoproteins (*gp*) are indicated. See Table 1 for nucleotide and amino acid locations of the mature products and Table 2 for the amino acid sequences of the cleavage sites.

Genome region, protein	Nucleotide location[a]	AA location of the mature product in the HCV polyprotein[a]	Approximate size by SDS-PAGE	Function
5' UTR	1–341		None[b]	Initiation of translation, replication[b]
C	342–914	1–191/ 29/182	p21/19	Structural, encapsidation of viral RNA[c]
E1	915–1490	192–383	gp31[c]	Structural, receptor binding, cell entry[c]
E2	1491–2579	384–746	gp70[c]	Structural, receptor binding, cell entry[c]
E2-p7	1491–2755	384–809	gp70[c]	NK, possible precursor or structural function
p7	2580–2755	747–809	p7	NK
NS2	2756–3419	810–1029	p21	Part of NS2-3 protease
NS3	3420–5312	1027–1657	p70	Part of NS2-3 protease, serine protease, helicase, NTPase
NS4A	5313–5476	1658–1711	p6	Cofactor for NS3 serine protease activity
NS4B	5477–6257	1712–1972	p27	Replicase component[c]
NS5A	6258–7600	1973–2420	p56	Replicase component[c]
NS5B	7601–9374	2421–3011	p68	RNA-dependent RNA polymerase
3' UTR	9375–9621		None	Replication,[b] packaging of viral genome[b]

[a]Based on HCV-H strain nucleotide and amino acid sequence (145).
[b]5' UTR contains several short open reading frames (ORFs), whether there is production of polypeptides or their possible functions is unknown.
[c]Indicates proteins are N-glycosylated.
[d]Designates putative function based on comparisons with other viruses.
AA, amino acid; SDS-PAGE, sodium dodecyl sulfate-polyacrylamide electrophoresis; NTPase, nucleoside triphosphatase; NK, not known.

TABLE 1. *Features of the HCV genome and polyprotein products*

Cleavage site	Amino acid sequence[a]	Protease	cis/trans	Cotranslational (Co) or posttranslational (Post)	Cofactor requirement

[a]Based on the HCV-H published sequence (145).
[b]No cofactor requirement has been demonstrated.
[c]Cleavage at these sites still occurs in the absence of NS4A but at a lower efficiency.

TABLE 2. *Clevage in the HCV polyprotein*

Nomenclature and Genotypes

HCV strains show extensive genome heterogeneity, although the variation is not uniform throughout. Relatively well-conserved regions of the HCV genome (core, E1, and NS5) have been extensively studied and used as the basis for classification of isolates into six distinct genotypes (1 to 6) and more than 50 subtypes (1a, 1b, 1c, and so forth) (296; reviewed in 46). It has been shown that antibodies to the core or NS4 regions can be used to distinguish between some HCV genotypes due to variation in the amino acid sequence at the sites of reactive B-cell epitopes (299). These serologic differences, however, do not equate with distinct serotypes based on antibody neutralization as generally defined for most viruses. As yet, there is no classification of HCV on the basis of serotyping, the antibody data for HCV merely represents type-specific antibody that can represent a simpler and quicker way to determine the genotype of a virus. Other genotyping methods include (a) restriction fragment length polymorphism of the 5' UTR (298); (b) reverse dot blot hybridization analysis of 5' UTR, or LIPA (Line Probe Assay, Innogenetics, Zwijnaarde, Belgium) (303); and (c) nested polymerase chain reaction (PCR) amplification of the core gene using type specific primers (242). Overall, however, PCR amplification and sequence analysis is the most reliable method for determining genotype differences of HCV isolates.

Through sequence analysis, as many as 11 genotypes had been defined, although these were not always accepted as distinct from previously existing genotypes. A broader system was recently proposed to unify the nomenclature for HCV, define the requirements for classification, and accommodate isolates that did not fit into the Simmonds scheme, which is based on phylogenetic analysis of the NS5 region (274,297). The concept of six major groups for HCV based on sequence homology would remain, but these would be distinguished phylogenetically and described as *clades.* Genotypes 1, 2, 4, and 5 would be identified as clades 1, 2, 4, and 5, respectively; genotypes 3 and 10 would become members of clade 3, and genotypes 6 to 9 and 11 would be members of clade 6. Despite the discussions surrounding the classification of HCV sequences, clinical and virologic data have not uncovered significant phenotypic differences between genotypes. It appears that patients infected with types 1a and 1b respond somewhat less well to interferon (IFN) treatment and are associated with more rapid progression to chronic liver disease than those infected with other genotypes (reviewed in 46). It must be remembered that all types so far isolated have the potential to cause serious liver disease.

Virologic and Molecular Characteristics

Most of the reports regarding the processing of HCV proteins and genome function are based on *in vitro* studies using mammalian, insect cell, or bacterial expression systems. Kolykhalov and colleagues demonstrated an essential requirement for the enzymatic activities of the NS2/3 protease, the NS3-4A serine protease, the NS3 nucleoside triphosphatase (NTPase) and helicase, and the NS5B polymerase for chimpanzee infection (172). In addition, a requirement for elements contained within the 3'-UTR of the HCV genome for successful replication of the virus has also been shown using the chimpanzee (172,340). These observations suggest that the *in vitro* data provide a good representation of events occurring during productive viral infection.

The 5'-Untranslated Region

The complete 5'-UTR consists of 341 nucleotides (125), the proposed secondary structure (138) of which is shown in Figure 2**A**. This is one of the most conserved portions of the HCV genome (47,300), and while nucleotide variations characteristic of different HCV types exist and have been used in PCR-based genotyping assays (300), the overall secondary structure is still conserved. Several groups have confirmed an internal ribosome entry site (IRES) that can direct translation in a cap-independent manner (104,273,327). This occupies most of the HCV 5'-UTR, as depicted in Figure 2**A**, with a requirement for sequence downstream of the initiator AUG for efficient IRES function. In the genome, coding sequence from the core region of 12 to 30 nucleotides is sufficient for this IRES function (140,273), but some reporter gene sequences can be substituted (104,139). It has been suggested that specific sequences in this region downstream of the initiating AUG contribute to IRES function through RNA–RNA interaction (138,139). The 5'-UTRs from different genotypes have been shown to direct translation with different efficiencies (72,141), which may be dependent on subtle sequence variations within this region affecting RNA–RNA interactions or RNA–protein interactions. Several cellular proteins have been shown to bind the 5'-UTR of HCV and play functional roles in HCV internal initiation (8,123,301), including polypyrimidine tract–binding protein and the eukaryotic translation initiation factor eIF3 (7,49). However, the precise mechanism of translational control in HCV infection is still to be determined.

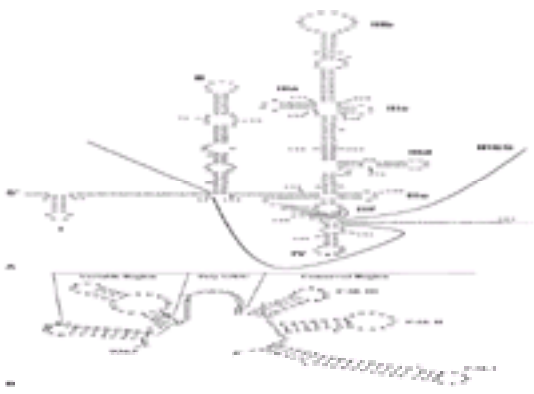

FIG. 2. A: Model showing the predicted RNA secondary and tertiary structure of the hepatitis C virus (HCV) 5'untranslated region (H strain) and the adjacent core coding sequence showing the individual stem-loop stuctures important for internal ribosome entry site (IRES) function. The minimal region required for IRES function (nucleotides 43 to 354) is indicated. *Solid lines* indicate base pair interactions within the pseudoknot (loop IIIf); *highlighted* AUG indicates the site of translation initiation. (From ref. 138, with permission from American Society for Microbiology). **B:** Computer-predicted secondary structure of the HCV 38UTR (H strain) and limited upstream sequence. Stem-loop (SL) structures and individual regions are labeled. The open reading frame UGA termination codon is located at nucleotide 9375. (From ref. 171, with permission of the American Society for Microbiology).

The 3'-Untranslated Region

After the ORF stop codon is the 3'-UTR. This contains, in the 5' to 3' direction, a region of about 30 nucleotides, which shows nucleotide variability between genotypes, a poly(U) tract of variable length, a polypyrimidine C(U)n stretch, and a highly conserved 98-base sequence, thought to represent the 3'-terminus of the genome (171,313). Computer predictions of the secondary structure and cleavage analyses show that the region can form stable stem-loops (36,148,171) (see Fig. 2**B**), although the upstream two stem-loops have not been confirmed experimentally. Specific interactions between the 3'-UTR, in particular the conserved 98 base region at the 3'-terminus, and cellular proteins, including polypyrimidine tract–binding protein (148,323) suggest that this region is involved in viral replication and possibly translation (149). Studies in chimpanzees using infectious clones of HCV deletion mutants have shown that the poly(U/UC) region and the conserved 98 base region are critical for infectivity but that the variable region, or its secondary structure, is not (172,340). This further confirms the involvement of the proximal 3' region of the HCV genome in replication.

The Viral Proteins

The functional HCV proteins are generated from the polyprotein following cotranslational and posttranslational cleavage by cellular and viral proteases (see Fig. 1). The amino acid sequences and positions of the cleavage sites at each junction are listed in Table 2). The structural proteins are characterized by hydrophobic domains at the C termini that are important for membrane association and subsequent cleavage by the signal peptidases, localized in the lumen of the endoplasmic reticulum (ER) (117,131). Cleavage at the junction between NS2 and NS3 occurs autoproteolytically by a protease encoded by NS2 and the N-terminal portion of NS3 (115,132), whereas the cleavages of the other downstream NS proteins are mediated by a distinct virus-encoded serine protease located in the N-terminal third of NS3 (27,88,116,132).

The Core Region

The first 191 amino acids of the HCV polyprotein represent the putative nucleocapsid or core protein with a molecular weight of 21 to 23 kDa (131). This region is highly conserved (48) and includes several T-cell and B-cell epitopes (114,162). Different molecular weight forms representing C-terminally truncated products have been identified in sodium dodecyl sulfate polyacrylamide electrophoresis (SDS-PAGE) analysis (131,279,341). The truncated form of 19 to 21kDa is thought to represent the mature protein (202,341), terminating at amino acid 173 to 174 (202,279). Some of these truncated forms have been identified in the nucleus (202,203,307,341). The basic nature of the core N-terminus, which contains several putative nuclear localization signals and a DNA-binding motif (59), may result in translocation to the nucleus, but there are no clinical data indicating the presence of the core in the nuclei of infected liver cells (24). The RNA-binding activity has been localized to the N-terminus, amino acids 1 to 75 (279), and is characterized by a cluster of basic residues showing a high degree of conservation, suggesting an important biologic function. *In vitro,* it has been shown to interact with cellular proteins and other viruses (264,290) performing multiple functions in cells, such as transactivation and suppression (217,342). These numerous reports have implications for possible adverse effects of core on cellular functions, which may contribute to pathogenesis (see Pathogenesis).

The Envelope Region

The glycoproteins (gp) E1 (gp31) and E2 (gp70), representing the putative viral envelope proteins, are targeted to the ER by aminoterminal signal peptides and are N-terminally glycosylated at 5 or 6 and 11 sites, respectively (87,117,263). It has been shown that the proteins are retained in the ER rather than retrieved from the Golgi complex during processing through the C-terminal hydrophobic transmembrane domains (73). The sequence of cleavage events from the viral polyprotein appears to be such that two possible precursors for E2 are produced (see Fig. 1 and Table 1), E2-NS2 and E2-p7 (87,117,197,226). Signalase cleavage at the p7 site is inefficient, leading to the presence of two forms of the second envelope protein, E2 and E2-p7 (197,226), differing only in their C-termini (see Fig. 1). Neither the function of p7 nor the role of the E2-p7 protein in viral particle formation is known.

Kinetic studies show that E1 and E2 interact slowly to form a stable complex (80,87,117). Properly folded complexes

require N-linked glycosylation (67,221) and are noncovalently bonded into heterodimers (80,87,263), a proportion of disulfide-bonded complexes have been identified that are thought to represent misfolded structures (80,87). The interaction seems to be totally membrane associated as the proteins remain localized to the ER and are not transported to the cell surface (87), although deletion of the E2 C-terminal hydrophobic domain results in secretion of this protein from cells (222).

An unusually high degree of amino acid variation has been observed in the N-terminus of the E2 protein (329). This hypervariable region, referred to as *HVR1,* is located between amino acids 384 to 410 of the polyprotein (amino acids 1 to 27 of E2). The HVR1 varies within any one isolate (231,289), generating a form of quasi-species, and between different genotypes. It should be stressed that no one HVR1 sequence pattern has been associated with any particular genotype, and therefore, this region cannot be used to make distinctions at this level.

Observations that specific antibodies to HVR1 epitopes change during the course of a chronic infection suggest that this region is subject to immune pressure, with the potential for escape mutants (reviewed in 101). Puntoriero and associates, however, developed a consensus profile of HVR1 sequences and indicated that there may be more cross-reactivity between variants than previously thought (262). These data provide important considerations for prophylactic vaccine development.

The NS2 Region

The NS2 protein is cleaved from the polyprotein at its N-terminus by a cellular signal peptidase and at its C-terminus by an HCV protease encoded by most of the NS2 region and part of the NS3 domain. This NS2-3 protease is believed to mediate autoproteolytic cleavage at the 2/3 site (115,132), appears to be zinc dependent (132), and can function in *trans,* although inefficiently (115,267). The region that is required for processing at the 2/3 site in mammalian cells lies between residues 849 and 1207 of the HCV polyprotein (115,280). This cleavage event, however, is not required for NS3-serine protease–dependent cleavages downstream, and mutations inactivating the NS3-serine protease have no effect on 2/3 cleavage (115,132). Residues His-952 and Cys-993 of the NS2 region are essential for the NS2/3 cleavage and are thought to be involved in zinc binding (115,132), whereas mutations of Cys-1123, Cys-1125, and Cys-1171 in the NS3 region significantly decrease autoproteolytic activity (132). *In vitro* studies on NS2-3 have shown that the efficiency of processing is at least partially dependent on the presence of microsomal membranes (115,280), suggesting the involvement of a cellular cofactor in this event. The exact mechanism of autoproteolysis at the 2/3 site is still to be determined, alternate zinc protease or cysteine protease mechanisms have been suggested (334); however, further structural and biochemical studies are still required to characterize this viral protease fully.

Whether NS2 itself plays a separate role in viral replication is still to be determined. It has a hydrophobic profile and is a transmembrane protein with the C-terminus located in the ER lumen and the N-terminus in the cytoplasm (280). It has been suggested that NS2 may play a role in virus assembly because it has been coprecipitated with the envelope proteins and the cleavage between E2-p7 and NS2 occurs after the complete folding of E2 (87). Whether this is the case remains to be determined and requires the analysis of NS2 in the context of productive viral replication, as opposed to *in vitro* expression systems.

The NS3 Region

The NS3 encodes serine protease, NTPase, and RNA helicase activities. The serine protease activity has been particularly well characterized and probably plays an essential role in HCV processing because a flavivirus homolog has been previously shown to be indispensable for viral growth (56), making it a desirable target for antiviral drugs. The activity resides in the N-terminal third of the NS3 protein and functions independently in two sets of processing events: first, the cleavage of the NS2/3 site, in conjunction with NS2 (115,132), and second, the release of the remaining downstream NS proteins, by mediating cleavage at the 3/4A, 4A/4B, 4B/5A, and 5A/5B sites (Table 2) (27,115,132,139). The first 181 amino acids of NS3 (amino acids 1027 to 1207 of the polyprotein) have been shown to contain the domain necessary for all of these cleavages (198), with the minimal protease region narrowed down to amino acids 1059 to 1204 (336). Amino acid sequence comparisons of several HCV isolates showed that the NS3 protein contains three highly conserved residues, His-1083, Asp-1107, and Ser-1165, which are known to represent the catalytic triad of the serine proteinase family (56). Substitutions at any one of these residues abolish processing at the downstream sites (27,116,319). The cleavage between NS3/4A occurs in *cis* (28), and although those at the other sites can occur in *trans* (27,198,319), it is yet to be established which type of cleavage dominates during viral replication.

Each of the NS3-dependent cleavage sites contains certain residues, which are conserved both between sites and genotypes, suggesting an importance for substrate specificity (see Table 2) (132,173). These residues include an Asp or Glu at P6, a Cys or Thr at P1, and a Ser or Ala at P1', although *in vitro* studies show that certain sites are more tolerant of substitutions than others (29,170,345). This is distinct from the flaviviruses, in which the NS3-dependent cleavages usually occur after dibasic amino acids (56).

The NS4A protein functions as a cofactor in NS3 activity. It is essential for the NS3/4A and NS4B/5A cleavage events and enhances cleavage at the NS4A/4B and NS5A/5B sites (91,198,134). The N-terminal 22 amino acids of NS3 have been shown to interact with NS4A (30,91,314), creating a stable complex between the two proteins.

The crystal structure of the NS3 protease has been elucidated (160,219,337), and the solution structure of the N-terminal domain has been solved by NMR (25) (reviewed in 27). The protein has a structural zinc-binding site coordinated by residues Cys-1123, Cys-1125, Cys-1171, and His-1175 (160,209,302), mutation of any of which reduces protease activity (132,302). These analyses of the NS3 structure indicated that the substrate-binding pocket (SBP) is primarily determined by residues Leu-1161, Phe-1180, and Ala-1183, with Phe-1180 forming the bottom of the SBP. Substitutions at several sites around the SBP showed that only mutations of Phe-1180 substantially affected specificity (166), confirming the importance of this residue in substrate recognition.

The RNA helicase (157,309) and NTPase (306) activities of NS3 reside in the C-terminal 465 amino acids of the NS3 protein. These functions are less well characterized than the serine protease, although NS3 appears to possess properties similar to the helicases of other positive-stranded RNA viruses and to contain characteristic sequence motifs (306). The helicase unwinds double-stranded RNA (dsRNA) and RNA–DNA heteroduplexes in the 3' to 5' direction using any NTP or deoxyribonucleoside triphosphate (dNTP) as an energy source (121,309). Biochemical characterizations (256,259) and the x-ray crystallographic structure (159) of the helicase have recently been reported, confirming structural features common to other helicases. Mutations of certain residues within the conserved sequence motifs severely affect the functions of the enzymatic activities (128,158,196). These data, combined with biochemical and structural analyses, provide an understanding of the mechanism of action for the helicase and the basis for therapeutic drug design.

The NS4 Region

The NS4 region encodes two viral proteins designated *NS4A* and *NS4B.* The function of NS4B, a very hydrophobic protein, is unknown, although it is required for the phosphorylation of NS5A together with NS4A and NS3 (232,315). NS4A has also been shown to act as a cofactor in NS3 protease activity (see earlier).

NS4A is 54 amino acids in length and has a hydrophobic N-terminal region followed by a hydrophilic C-terminus (90). NS4A enhances the NS3 serine protease cleavages in *cis* and in *trans* (28,90,198,314). The precise region of NS4A essential for the activation of NS3 has been mapped to the central, hydrophobic portion of the protein encompassed by amino acids 21 to 34; a peptide spanning this region is sufficient to enhance cleavage by NS3 (28,91,199,291). A stable, physical interaction occurs between the two proteins that can be destabilized by mutations in NS4A (91,199) and inhibited by a peptide carrying a single residue mutation at position 28 in the 21– to 34–amino acid stretch (291). Although NS4A is not essential for all the processing functions of the serine protease, it appears to form an integral part of the protease complex (160), possibly stabilizing the protein in an active conformation and directing it to membranes where proteolytic processing and RNA replication take place (91,160,199). NS4A has also been shown to form a complex with the NS4B/NS5A polyprotein product (200), in which the NS4A central hydrophobic region is again essential. This interaction may explain the requirement of NS4A as a cofactor for cleavage by NS3 at this site.

The NS5 Region

The NS5 region is processed into the proteins NS5A and NS5B. The primary function of NS5A is unknown, although from comparative studies with other viruses, it is predicted to play a role in RNA replication. The mature NS5A exists as a phosphoprotein (p56); the phosphorylation occurs primarily on serine residues through the action of unknown cellular kinases (268,269). Two phosphoproteins (p56 and p58), termed *phosphorylated* and *hyperphosphorylated* forms, respectively, have been identified for 1b genotypes (20,167,232), for which the production of p58 requires NS3, NS4A, and NS4B expression in *cis* (167,232). A requirement of two domains for phosphorylation of NS5A has been shown (19,315), located around the center (amino acids 2200 to 2250) and C-terminus (amino acids 2350 to 2419). The major phosphorylation site for HCV H strain (genotype 1a) has been mapped to Ser-2321 (268), whereas mutation analysis has identified residues Ser-2197, Ser-2201, and Ser-2204 as putative hyperphosphorylation sites for p58 production by HCV J strain (type 1b) (315).

In addition to its potential involvement in RNA replication, clinical studies suggest that NS5A may play a role in conferring sensitivity to IFN-a through interaction with the IFN-induced cellular protein kinase PKR (106) (see Mechanisms of Persistence).

NS5B forms the C-terminal protein of the HCV polyprotein. It contains a GDD motif, residues 2737 to 2739, common to other RNA-dependent RNA polymerases (RdRps) (254) and appears to be a membrane-associated phosphoprotein (144). RdRp activity has been demonstrated for recombinant NS5B expressed in insect cells (34,205) and *Escherichia coli* (99,240), and RNA-binding domains have been identified within this region (61,205). Four amino acid motifs have been shown to be essential for polymerase activity (205). These were designated A (amino acids 2640 to 2645), B (amino acids 2702 to 2711), C (amino acids 2737 to 2739), and D (amino acids 2762 to 2766) and appear to be important for nucleotide binding and catalysis (A), template/primer positioning (B), and NTP binding and catalysis (C and D).

Most of the recombinant NS5B proteins studied direct replication of RNA in a primer-dependent manner (35,205). The primer may be an exogenous RNA molecule or generated through folding of the input RNA at the 3' end. A full-length, *E. coli*–expressed form of NS5B, however, was able to synthesize genome-length HCV in a primer-independent manner (240). This protein also recognized specific sequences at the 3' end of positive- and negative-stranded HCV RNAs for the initiation of RNA synthesis, suggesting this may more closely represent the authentic HCV RdRp (240). It is probable that replication of the HCV genome involves negative-stranded RNA synthesis initiated by interaction between the NS5B polymerase or replicative complex and the 3'-terminus of the viral genome. Specificity of binding by recombinant NS5B is not limited to RNA templates containing the 3'-UTR of HCV (35,205,240), although conserved stem-loop structures within the 3'-coding region of the HCV RNA have been shown to interact specifically with NS5B (61). The mechanism of HCV replication is still to be determined, as are the other components of the replicative complex; these analyses of the RdRp provide important contributions toward understanding this process and the development of possible antiviral agents targeting this protein.

Virion Morphology
