RNA segment 6 of influenza C virus contains 1,180 nucleotides and contains a single ORF of 374 residues (259,386) (Fig. 11). This RNA segment gives rise to two mRNA species. One is a colinear mRNA that contains a 374–amino acid residue ORF (seg 6 ORF) that is translated to yield the precursor protein, p42. Synthesis of the p42 protein has been detected in influenza C virus–infected cells (122). Proteolytic cleavage of p42 at an internal signal peptidase cleavage site gives rise to the p31 and CM2 proteins (124,259). The second mRNA species that results from splicing of the colinear mRNA (386) encodes the matrix (CM1) protein, consisting of the N-terminal 242 residues of the seg 6 ORF followed by a stop codon introduced through mRNA splicing. The N-terminal product of p42 cleavage, p31, is identical in amino acid sequence to the CM1 protein except for the presence of 17 amino acids at its C-terminus that are mostly hydrophobic. The p31 protein binds tightly to lipid membranes with properties more like those of the integral membrane protein CM2 than those of the peripheral membrane protein CM1, and it is rapidly degraded in virus-infected cells (259,260).

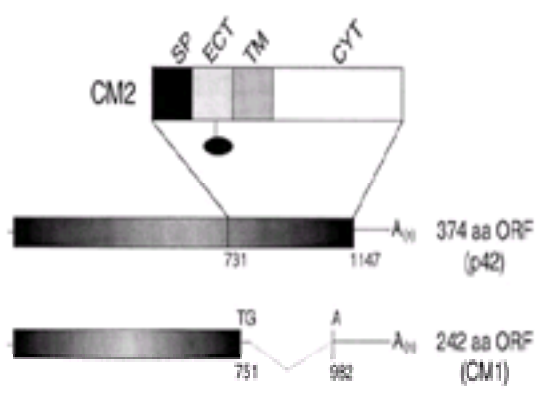

FIG. 11. The CM2 glycoprotein is a translation product of the full-length, colinear mRNA derived from influenza C virus RNA segment 6. Schematic diagram depicting the mRNAs derived from influenza C virus RNA segment 6 and their encoded proteins. The CM2 protein is processed from p42, and CM2 has been shown to contain a cleaved signal peptide (*SP*), an amino-terminal extracellular domain (*Ect*) modified by addition of N-linked carbohydrate (*black oval*), a hydrophobic transmembrane domain (*TM*), and an intracellular cytoplasmic tail (*Cyt*). (Data from ref. 259, with permission.)

The influenza C virus CM2 protein is a small glycosylated integral membrane protein (115 residues) that spans the membrane once. The CM2 protein forms disulfide-linked dimers and tetramers and is oriented in membranes in a NoutCin orientation. CM2 contains a single site for N-linked carbohydrate addition, which is frequently further modified with lactosaminoglycans. The CM2 protein is abundantly expressed at the cell surface of virus-infected and cDNA-transfected cells and is incorporated into influenza C virions (123,258) (see Fig. 6).

The Matrix Protein

It is now virtually dogma that the matrix protein underlies the viral lipid envelope and provides rigidity to the membrane. In addition, it is widely believed that the M_1 protein interacts with the cytoplasmic tails of the HA, NA, and M_2 proteins and also interacts with the RNP. However, experimental evidence for these very plausible interactions has been difficult to obtain. Solubility properties of purified M_1 protein (i.e., soluble in chloroform-methanol and 0.5 M KCl) are consistent with the protein being a peripheral membrane protein. An interaction between M_1 and lipid has been shown *in vivo* using light-activated cross-linking and *in vitro* using purified M_1 protein and liposomes (reviewed in 171). Contacts between the M_1 protein and the RNPs are suggested by finding that purified RNPs often contain M_1 protein; and by using immunoelectron microscopy, it has been found that the RNPs are heavily labeled with M_1 antibody (221). Purified M_1 protein inhibits transcription *in vitro* (390,402), and if M_1 protein is not dissociated from the RNPs *in vivo,* the RNPs fail to be transported to the nucleus (208). At late times after infection, transport of the M_1 protein into the nucleus is required

for exit of the newly assembled RNPs from the nucleus (208) (see later). An interaction between the M_1 protein and RNA has been demonstrated by using filter-binding assays and blotting procedures (351,390). An NLS has been mapped to residues 101 to 105 (RKLKR) (389).

The x-ray crystal structure of the N-terminal portion of the M_1 protein (residues 2 to 158) at low pH has been determined (304) (Fig. 12). Under these conditions the M_1 protein fragment forms a dimer related by a noncrystallographic twofold axis at pH 4.0. Each monomer consists of nine a-helices, eight loop regions, and no b-strands (304). A highly positively charged region (10 residues from each monomer) on the dimer surface is well positioned to bind RNA, whereas the hydrophobic surface opposite the RNA-binding region is hypothesized to be involved in membrane interactions. It is possible that the hydrophobic surface could be buried or exposed after a conformational change (304). The M_1 protein contains a zinc-binding motif (Cys-Cys-His-His type, residues 148 to 162 of influenza virus A/PR/8/34 M_1 protein). However, the x-ray crystallographic structure indicates this sequence does not form a functional zinc finger (304).

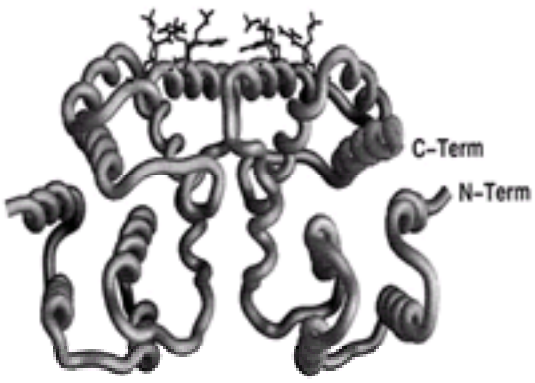

FIG. 12. Three-dimensional structure of the influenza A virus matrix protein. The structure shown is a dimer of M_1 residues 1 to 158. The 9 helical regions in each monomer are clearly visible, and the 10 positively charged residues at the top of the structure that are thought to interact with RNA are shown. (This figure was produced using Protein Data Bank coordinate file 1AA7.)

An interaction between M_1 and the M_2 protein has been suggested based on the observation that virus growth restriction by anti-M_2 antibodies can be overcome by mutations in M_1 (394) (see later). Finally, an interaction has been observed between M_1 and the NS_2 protein found in purified virions (388).

The M_2 Protein and Its Ion Channel Activity

As discussed previously, the M_2 integral membrane protein (97 amino acids) is encoded by a spliced mRNA derived from genome RNA segment 7 (173,183). The M_2 protein is abundantly expressed at the plasma membrane of virus-infected cells but is greatly underrepresented in virions because only a few (on average, 20 to 60) molecules are incorporated into virus particles (185,395,396). In polarized cells, the M_2 protein is expressed at the apical cell surface (128), the surface at which influenza virus particles bud. The M_2 protein spans the membrane once; by using domain-specific antibodies and specific proteolysis, it has been shown that M_2 protein is orientated such that it has 24 N-terminal extracellular residues, a 19-residue TM domain, and a 54-residue cytoplasmic tail (185). The presence of an N-terminal extracellular domain in the absence of a cleavable signal sequence indicates that the M_2 protein is a model type III integral membrane protein that is dependent on the signal recognition particle for cotranslational insertion into the ER membrane (130) (see Fig. 6). The M_2 protein cytoplasmic domain is posttranslationally modified by phosphorylation on a serine (residue 64) (119) and palmitoylation on cysteine (residue 50) (119,333,346), but neither posttranslational modification is required for the function of the M_2 ion channel (38,119,340).

The native form of the M_2 protein is minimally a homotetramer consisting of either a pair of disulfide-linked dimers or disulfide-linked tetramers (9,117,298,334) that form a left-handed four-helix bundle with an interhelix tilt of 20 to 30 degrees (161,262) (Fig. 13).

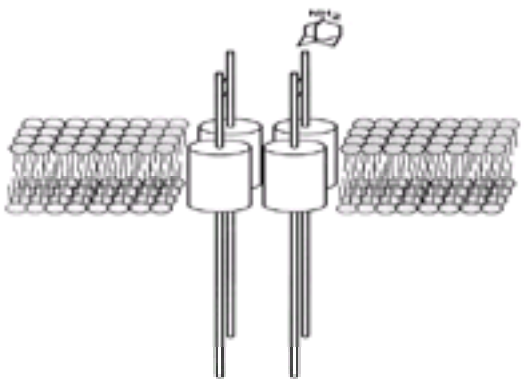

FIG. 13. Schematic diagram of the influenza virus M_2 protein ion channel in a membrane. The influenza virus M_2 protein is a disulfide-linked homotetramer with each chain consisting of 97 amino acid residues with 24 residues exposed extracellularly, a 19-residue transmembrane domain, and a 54-residue cytoplasmic tail. The disulfide bonds can form between the same subunit partners, as shown; otherwise, after the first bond is made, the second disulfide can link to

another partner to form the fully disulfide-linked tetramer. The M_2 protein has a pH-activated ion channel activity that conducts protons. The channel is specifically blocked by the antiviral drug amantadine hydrochloride. The pore of the channel has been shown to be the transmembrane domain of the M_2 protein. The ion channel activity is essential for the uncoating of influenza virus in endosomal compartments in the infected cell. (Drawn from data in ref. 185, with permission.)

The M_2 protein TM domain was deduced to be the target of the anti–influenza virus drug amantadine. Amantadine (1-aminoadamantane hydrochloride) displays a specific anti–influenza A virus action (60) and has been used in the prophylaxis and treatment of influenza A virus infections (reviewed in 243). Mutants that were resistant to amantadine were found to contain amino acid changes in the M_2 protein TM domain (108).

From studies on the effect of amantadine on virus replication (see later), it was hypothesized that the M_2 protein functions as an ion channel that permits ions to enter the virion during uncoating and also to act as an ion channel that modulates the pH of the Golgi apparatus (334; reviewed in 104).

It has been established that the M_2 protein has ion channel activity by experiments in which the M_2 protein was expressed in oocytes of *Xenopus laevis* and in mammalian cells, and measuring membrane currents. This M_2 ion channel activity is blocked by amantadine and is regulated by changes in pH. The channel is activated at the lowered pH found in endosomes and the TGN (43,118,263,352,353 and 354). The ion selectivity of the M_2 ion channel activity indicated the M_2 channel is highly specific for H^+ ions (43,219).

RNA Segment 8 of Influenza Virus: Unspliced and Spliced mRNAs Encode the NS_1 and NS_2 Proteins

RNA segment 8 of influenza A and B viruses and the smallest RNA segment of influenza C virus (RNA 7) encode two proteins, NS_1 and NS_2. NS_1 is encoded by a colinear mRNA transcript, whereas NS_2 is encoded by a spliced mRNA. The finding of a spliced NS_2 mRNA was the first evidence for splicing with an RNA virus that does not use a DNA intermediate in its replication.

RNA Segment 8 Gene Structure and Encoded Proteins

RNA segment 8 of influenza A virus is 890 nucleotides in length and contains a large ORF encoding the NS_1 protein (M_r about 26,000), ranging from 202 to 237 residues depending on the virus. In addition to the NS_1 protein, genetic and biochemical evidence has shown that RNA segment 8 encodes a second protein, NS_2 (M_r about 14,000) and that NS_2 is translated from a small mRNA (350 nucleotides) (131,132,174,177,178). Nucleotide sequencing studies indicated that the NS_1 mRNA is unspliced, directly encoding the NS_1 protein, whereas the NS_2 mRNA contains a 473-nucleotide intron. NS_1 and NS_2 share a 56-nucleotide leader sequence that contains the AUG codon used for initiation of protein synthesis. Consequently, the NS_1 and NS_2 proteins share 9 N-terminal amino acids before the intron; translation of the body of the NS_2 mRNA then continues in the +1 ORF, which overlaps the NS_1 frame by 70 residues (181). The arrangement of the NS_1 and NS_2 mRNAs and their ORFs is shown in Figure 14.

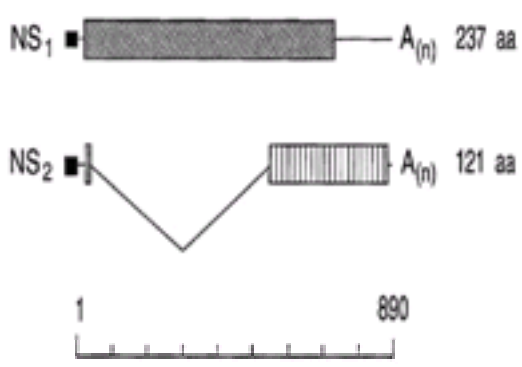

FIG. 14. Model for the arrangement of the influenza A virus NS_1 and NS_2 mRNAs and their coding regions. Thin lines at the 5'- and 3'-termini of the mRNAs represent untranslated regions. *Shaded* or *hatched areas* represent coding regions in 0 or +1 reading frames, respectively. The intron is shown by the *V-shaped line.* Rectangles at the 5' ends of the mRNAs represent heterogeneous nucleotides derived from cellular RNAs that are covalently linked to viral sequences. (Adapted from ref. 177, with permission.)

RNA segment 8 of influenza B virus is 1,096 nucleotides in length and contains a large ORF of 281 residues encoding NS_1 (281 residues; M_r, 32,026). An analogous arrangement of unspliced and spliced mRNA transcripts is found to encode NS_1 and NS_2, as described previously for influenza A virus. The NS_2 mRNA has a 5' leader sequence of 75 nucleotides, which is shared with the NS_1 mRNA, and contains the AUG codon used for initiation of protein synthesis, such that 10 N-terminal residues are shared between NS_1 and NS_2. The 350-nucleotide body region of the NS_2 mRNA encodes in the +1 reading frame 112 residues, overlapping the NS_1 ORF by 52 residues (25,26).

RNA segment 7 of influenza C virus (the equivalent of RNA segment 8 for influenza A and B viruses) contains 934 nucleotides. The NS_1 protein contains 286 residues (225). The NS_2 protein (122 residues) is encoded by a spliced mRNA: 62 N-terminal residues are shared by NS_1 and NS_2, and after the splice junction, translation continues in the +1 ORF for 59 residues. The second ORF of influenza virus RNA segment 7 is completely overlapped by that of the NS_1 protein (226).

The NS_1 Protein

The NS_1 protein (M_r about 26,000) is expressed in large amounts in influenza virus–infected, cells but it has not been detected in virions, hence the designation NS for *nonstructural* (166,188,317). NS_1 is found in infected cells in the nucleus and is associated with polysomes (50,166,168,188). The NLS within NS_1 has been mapped, and it has been found that the protein contains two separate signals (residues 34 to 38 and within residues 203 to 237) (99). The NS_1 protein also contains a nuclear export signal (NES), a short leucine-rich sequence that mediates the nuclear export of proteins (reviewed in 91). The NS_1 NES has been mapped to residues 138 to 147 (198).

Where the NS_1 and NS_2 ORFs overlap (in NS_1 proteins of 237 residues), the amino acid sequences indicate that NS_2 is conserved at the expense of NS_1 (reviewed in 171). These observations support the original suggestion (385) that NS_1 and NS_2 may have been colinear on the vRNA but not overlapping and that read-through of a termination codon at the C-terminus of NS_1 allowed the NS_1 protein to become longer.

NS_1 protein is a multifunctional protein, and many of its functions in the influenza virus life cycle have been determined as described later.

The NS_2 Protein

The NS_2 protein (M_r about 11,000), originally thought to be nonstructural, is now known to exist in virions (130 to 200 molecules on average) and to form an association with the M_1 protein (282,388). The subcellular localization of NS_2 has been indicated to be nuclear (98) and cytoplasmic (324). The NS_2 protein has an NES sequence, and its role in the export of RNPs out of the nucleus is discussed later.

STAGES OF REPLICATION OF INFLUENZA VIRUSES

Virus Adsorption, Entry, and Uncoating

Influenza viruses bind to sialic acid residues present on cell surface glycoproteins or glycolipids through the receptor-binding site in the distal tip of the HA molecules (see Three-Dimensional Structure of Hemagglutinin, earlier). Different influenza viruses have different specificities for sialic acid linked to galactose by a2,3 or a2,6 linkages, and this is dependent on specific residues in the HA receptor-binding pocket (367) (see Fig. 3). Carbohydrate chains of avian intestine contain predominantly sialic acid linked to galactose by a2,3 linkages, pig trachea contain sialic acid linked to galactose by a2,3 and a2,6 linkages, and human trachea carbohydrate chains contain predominantly sialic acid linked to galactose by a2,6 linkages (134). The specificity of HA for sialic acid in a2,3 or a2,6 linkages to galactose is a key determinant in restricting the transfer of influenza virus directly from avian species to humans without mutations in the HA sialic acid–binding site occurring (see Chapter 47). Although the interaction of HA with sialic acid is of fairly low affinity, a high avidity of the virus for cell surfaces is probably achieved by multiple low-affinity interactions.

Influenza viruses enter cells by receptor-mediated endocytosis, the high-capacity endocytic activity by which components of the medium are internalized in clathrin-coated membrane-bound vesicles, formed by invagination of specialized coated-pit domains of the plasma membrane. After internalization, the clathrin coat is removed, and vesicles fuse with endosomes (a series of organelles of increasingly acidic pH), beginning with mildly acidic primary endosomes and progressing to late endosomes. The acidification of endosomes is brought about by H^+-ATPases. The uncoating of influenza virions in endosomes is dependent on the acidic pH of this compartment, and agents such as acidotropic weak bases (ammonium chloride, chloroquine) and carboxylic ionophores (monesin and nigericin) raise the pH of endosomes and block influenza virus uncoating (211). However, these acidotropic weak bases do not have a specific anti–influenza virus effect: raising the intraluminal pH of endosomes blocks the uncoating of most viruses that enter cells by the endocytic pathway (reviewed in 207). For the influenza virus RNPs to penetrate into the cytosol, they have to cross the membrane of the virion and that of endosomes. This is accomplished by HA-mediated fusion of the viral membrane with the cellular membrane (see The Low-pH–Induced Hemagglutinin Conformational Change, earlier) (Fig. 15 and Fig. 16). The precise time and location of penetration depends on the pH dependence of the transition of HA to its low-pH–induced form. For human strains such as A/Japan/305/57, the transition to the HA low-pH form occurs at pH 5.3, which is found in late endosomes and occurs with a half-life of 20 to 35 minutes after virus entry (328).

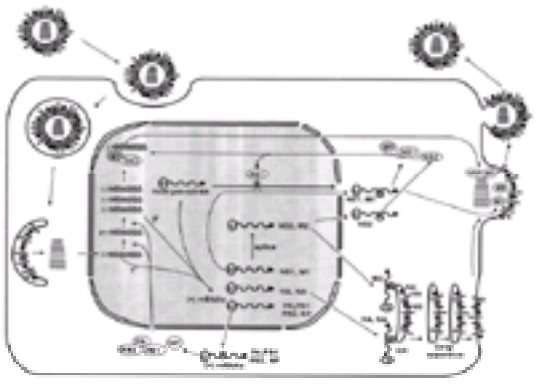

FIG. 15. Schematic diagram of the life cycle of influenza virus. See text for details of the model.

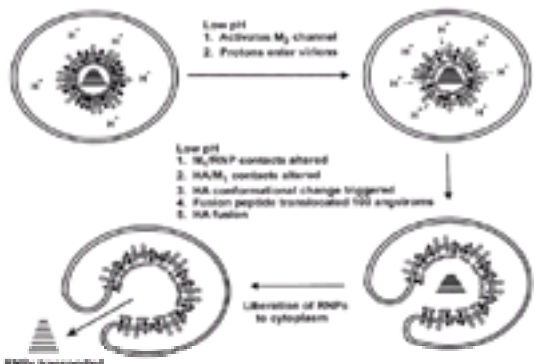

FIG. 16. Schematic diagram of the proposed role of the M_2 ion channel activity in virus entry. The M_2 ion channel activity is thought to facilitate the flow of protons from the lumen of the endosome into the virion interior, bringing about dissociation of protein–protein interactions between the HA cytoplasmic tail and M_1, M_1, and lipid or RNPs and M_1 from the RNPs.

Studies with the antiviral drug amantadine led to the hypothesis that the M_2 ion channel activity is essential for the uncoating process. For all influenza A virus strains, the amantadine block to viral replication occurs at an early stage in the virus life cycle between the steps of virus penetration and uncoating (32,320). In the presence of the drug, the influenza virus M_1 protein fails to dissociate from the RNPs, and transport of the RNPs to the nucleus is blocked (208). Once a virion particle has been endocytosed, the low-pH–activated ion channel activity of the virion-associated M_2 protein (118,263,354) permits the flow of ions from the endosome to the virion interior, to disrupt protein–protein interactions and free the RNPs from the M_1 protein (see Fig. 16) (reviewed in 104,110, and 179). Support for this idea comes from detergent solubilization studies that demonstrate that the interaction between M_1 and the RNPs can be disrupted by mildly acidic pH (397,399). An attractive feature of this hypothesis for virus uncoating is that the low pH of endosomes where uncoating occurs, in contrast to the neutral pH at the plasma membrane where assembly occurs, would push the equilibrium of the disassembly–assembly process in favor of uncoating. Another consequence of the M_2 protein ion channel activity in virions during the uncoating process may be to prepare HA for the fusion process. It has been found that fusion of influenza virus with liposomes is slowed in the presence of amantadine, and it was suggested that intraviral low pH facilitates influenza virus fusion, possibly by weakening interactions of the cytoplasmic tail of HA with the M_1 protein or RNPs (28,369).

Microinjection and immunoelectron microscopy experiments indicate that the RNPs enter the nucleus through the nuclear pore as an intact RNP after the M_1 protein has been dissociated from the RNP. All four proteins that are in the RNP (NP, PB1, PB2, and PA) contain NLS, and the RNPs are actively transported into the nucleus (reviewed in 374). The M_1 protein that has dissociated from the RNP, or newly synthesized M_1 protein, may enter the nucleus by passive diffusion because it is below the 50-kd cutoff for energy-dependent selective nuclear uptake mechanisms, but as discussed previously, a putative NLS in the M_1 protein has been identified. An examination of the fate of the proteins of the infecting virion indicates that whereas HA is degraded in lysosomes (half-life, 120 minutes), more than 30% to 35% of M_1 and NP persists for many hours (209).

Messenger RNA Synthesis and Replication of Virion RNA

Distinctive Feature of Influenza Virus mRNA Synthesis

Unlike other RNA viruses, influenza virus mRNA synthesis has a unique dependence on host cell nuclear function. One early observation was that a-amanatin, at concentrations that specifically inhibit the cellular DNA-dependent RNA polymerase II, inhibits influenza virus mRNA synthesis in infected cells, but not the virus mRNA synthesis that is catalyzed *in vitro* by the virion-associated transcriptase (175,205,325).

The discovery of the role of this host nuclear function came from studies of the virion-associated polymerase (reviewed in 163). The important observation was that this enzyme is incapable of initiating viral mRNA synthesis *in vitro* unless a primer is supplied. The primers are capped (m^7GpppX^m-containing) RNA fragments derived by cleavage of host cell RNA polymerase II transcripts. Hence, influenza virus scavenges host cell RNA polymerase II transcripts to supply the primers

for its own mRNA synthesis. A cap-dependent endonuclease that is intrinsic to the influenza virus polymerase cleaves capped RNAs 10 to 13 nucleotides from their 5' ends, preferentially at a purine residue (266) (Fig. 17). The resulting capped fragments serve as primers for the initiation of viral mRNA synthesis. Priming does not require hydrogen bonding between the capped primer fragments and the 12-nucleotide sequence that is found at the 3' ends of all eight virion (vRNA) segments of influenza A viruses (165). Rather, priming requires the presence of a 5'-methylated cap structure (20,265,266). Transcription is initiated by the incorporation of a G residue onto the 3' end of the resulting fragments, directed by the penultimate C residue of the vRNAs (20,21,114,164,265,266). This process has been called *cap snatching*.

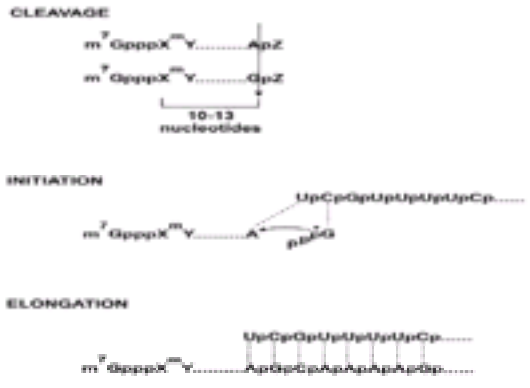

FIG. 17. Influenza virus messenger RNA (mRNA) synthesis requires initiation by capped RNA primers cleaved from cellular nuclear RNAs (see text for details).

Overview of mRNA Synthesis and Virion RNA Replication

Most of our knowledge concerning influenza virus gene expression and RNA replication has been gained from studying influenza A viruses. After priming with 5' capped host-derived mRNA fragments, the mRNA chains are elongated, copying the template up to a point at which a stretch of uridine residues is reached, 15 to 22 nucleotides before the 5' ends of the vRNAs. At this uridine (u) stretch, which ranges in length from 4 to 7 residues in the vRNA segments, transcription terminates, and polyadenylate residues [poly(A)] are added to the mRNAs (105,286) (Fig. 18). Termination occurs apparently as a result of stuttering or reiterative copying of the stretch of U residues, thereby adding a poly(A) tail to the 3' ends of the viral mRNAs (203,273,286). For replication to occur, an alternative type of transcription is required that results in the production of full-length copies of the vRNAs. The full-length transcripts, or *template RNAs,* are initiated without a primer and are not terminated at the poly(A) site used during mRNA synthesis (105,106 and 107). The second step in replication is the copying of the template RNAs into vRNAs (163). This synthesis also occurs without a primer because the vRNAs contain 5' triphosphorylated ends (393). The three types of virus-specific RNAs—mRNAs, template RNAs, and vRNAs—are all synthesized in the nucleus (305,306,323). In the nucleus, the viral mRNAs undergo at least some of the same processing steps as cellular RNA precursors. Internal adenosine residues of influenza virus mRNAs are methylated (167,227), and two of the viral mRNAs are spliced.

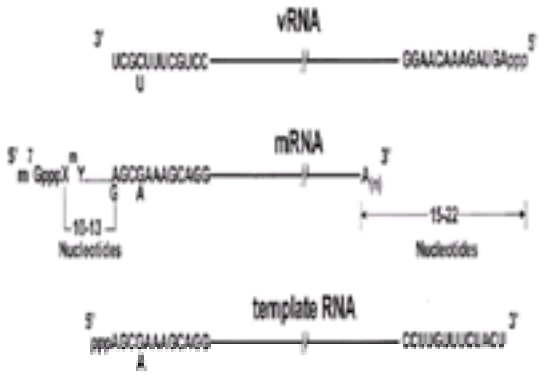

FIG. 18. Schematic diagram to illustrate the differences between influenza virus virion RNA (vRNA) segments, mRNAs, and full-length cRNA or template RNA. The conserved 12 nucleotides at the 3' end and 13 nucleotides at the 5' end of each influenza A virus vRNA segment are indicated. The mRNAs contain an m^7GpppN^m cap structure and, on average, 10 to 13 nucleotides derived from a subset of host cell RNAs (see Fig. 17 and text). Polyadenylation of the mRNAs occurs at a site 15 to 22 nucleotides before the 5' end of the vRNA segment. The template RNA contains at its 5'-terminus pppA, and it is a complete copy of the vRNA segment. Depending on the RNA segment, there is a U/A or C/G at position 4.

Viral mRNA Synthesis

The initial information about the mechanism of viral mRNA synthesis was obtained from *in vitro* studies of the polymerase complex isolated from virions by detergent disruption. The nucleocapsids consist of the individual vRNAs associated with four viral proteins: the NP protein and the three P proteins (PB1, PB2, and PA) (133,343). The P proteins catalyze viral mRNA synthesis, and some of their roles were determined by analyses of the *in vitro* reaction catalyzed by virion nucleocapsids. By using ultraviolet (UV) light–induced cross-linking, it was shown that the three P proteins exist in the form of a complex and that the PB2 protein in this complex recognizes and binds to the cap of the primer RNA

(16,22,343). Cap recognition by PB2 was verified by analysis of the *in vitro* transcription activity of the nucleocapsids derived from PB2 ts mutants (342). The UV–cross-linking experiments also indicated that the PB1 protein most likely catalyzes nucleotide addition (22). No specific role for PA in viral mRNA synthesis has been found.

New insights into the mechanism of mRNA synthesis have been provided by experiments in which viral polymerase complexes are formed using recombinant gene expression, specifically vaccinia virus vectors encoding the three P proteins. When cells are co-infected with three vaccinia viruses encoding the PB2, PB1, and PA proteins, the polymerase complexes that are assembled are inactive in all *in vitro* assays designed to measure the various activities of the polymerase. The polymerase complexes acquire cap-binding and endonuclease activities only when influenza vRNA is present (45,100,194,341). First, binding of the common 5'-terminal sequence of the vRNA segments (AGUAGAAACAAG) activates the capped RNA-binding activity of the PB2 protein. Subsequent binding of the common 3' terminal sequence of the vRNA segments (UCGU/CUUUCGUCC) activates endonuclease activity, thereby enabling the polymerase complex to catalyze capped RNA-primed mRNA synthesis. Consequently, vRNA molecules function not only as templates for mRNA synthesis but also as essential cofactors that activate the catalytic functions of the polymerase that produce capped RNA primers. By means of this control mechanism, the production of primers is activated only when the template for viral mRNA synthesis, namely vRNA, is present.

By using these recombinant polymerase complexes, the sequences of five active sites of the viral polymerase have been identified (194,194a) (Fig. 19). As indicated previously, in the absence of vRNA, the complex of the three P proteins is enzymatically inactive. However, the PB1 subunit of these complexes contains a functional binding site for the 5'-terminal sequence of vRNA. This binding site is composed of an amino acid sequence that is centered around two essential arginine residues at positions 571 and 572. This amino acid sequence, which is conserved in all sequenced influenza A virus PB1 proteins, does not exhibit significant homology to any sequence in the database.

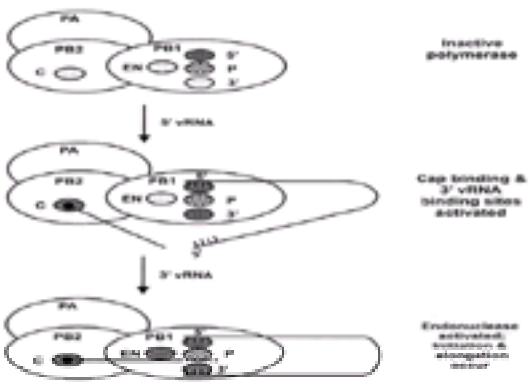

FIG. 19. Activation of the catalytic functions of the influenza virus polymerase by specific vRNA sequences. This model is described in the text. 5', the binding site for the 5' end of vRNA; 3', the binding site for the 3' end of vRNA; C, the binding site for capped RNA; EN, endonuclease active site; P, polymerase active site. *Light gray* denotes an inactive site, and *dark gray* denotes an active site. The P site is shown with interior dots because it is not known whether it is constitutively active or requires activation. The 5' cap structure of the capped RNA is denoted by a *black circle.* (Modified from ref. 194, with permission.)

As a result of binding the 5'-terminal sequence of vRNA, two new functions of the polymerase are activated:

1. An allosteric change occurs in PB2 to activate the cap-binding activity (45,100,194,194a,341), and the region of PB2 important in the process is a tryptophan-rich domain, thought to be analogous to the cap-binding domain in the eIF4E translation initiation factor (206,212).
2. An allosteric change occurs in PB1 to activate the RNA-binding activity specific for the 3'-terminal sequence of vRNA. The region of PB1 involved in this activity is located in a sequence 300 amino acids distant from the PB1 sequence that binds the 5'-terminal sequence of vRNA (194).

When the 3'-terminal sequence of vRNA subsequently binds to PB1, a second allosteric alteration causes the activation of the enzymatic activity that endonucleolytically cleaves capped mRNAs 10 to 13 nucleotides from their 5' end sequences (45,100,194,341). The endonuclease active site, which is in the PB1 protein subunit, contains at least three essential acidic amino acids, comparable to the active sites of other enzymes that cut polynucleotides to produce 3'-OH ends, including RNase H and polynucleotidyl transferases, such as retroviral integrases and bacteriophage Mμ transposase (387).

The capped RNA fragments that are produced by the endonuclease serve as primers for the initiation of viral mRNA synthesis. Nucleotide addition is catalyzed by the PB1 protein, which contains the four conserved sequence motifs of RNA-dependent RNA polymerases (14,269). Mutagenesis experiments established that a core sequence of one of these motifs, namely the SDD sequence at amino acids 444 to 446 of the PB1 protein, is part of the active site for nucleotide addition (14). Thus, the PB1 protein plays a central role in the catalytic activity of the viral polymerase, both in the activation of the enzyme activities that produce capped RNA primers and in the subsequent catalysis of RNA chain elongation.

A key feature of this system is the requirement that the 5' and 3' ends of vRNA bind to the PB1 protein sequentially as ssRNA sequences that are not hydrogen-bonded to each other. These results are not consistent with the original “panhandle” hypothesis, which postulated that the 5' and 3' ends of vRNA, which exhibit considerable complementarity, are hydrogen-bonded to each and that this extensively double-stranded structure binds to the viral polymerase and functions as the “promoter” for the initiation of viral mRNA synthesis (120,127). The existence of such a panhandle

structure requires that the viral polymerase possess a helicase activity that is capable of melting out this structure so that the polymerase can access and copy the bases at the 3' end of the vRNA. However, when the 5' and 3' ends of vRNA are in the form of a hydrogen-bonded structure, the addition of this RNA species to the functional polymerase complexes formed using vaccinia virus vectors does not activate either cap-binding or endonuclease activity (341), indicating that these polymerase complexes lack the requisite helicase activity. Other experiments have also led to modifications of the original “panhandle” model; for example, in the “RNA-fork” model, most of the 5'- and 3'-terminal bases are not hydrogen-bonded to each other (81). Finally, biochemical experiments have shown that the 5' and 3' ends of vRNA molecules in the activated nucleocapsids that are isolated from influenza virions are not juxtaposed unless the polymerase is present (159).

The model for the initiation and subsequent elongation of influenza virus mRNA chains suggests a mechanism for the polyadenylation and termination of synthesis that occur before the 5' end of the vRNA is reached (Fig. 20). It can be postulated that the specific binding of the 5' end of vRNA to the PB1 subunit of the polymerase persists throughout mRNA synthesis. Consequently, the vRNAs would be threaded through the polymerase complex, in a 3' to 5' direction, during mRNA synthesis. Eventually, the polymerase itself would act as a physical barrier to continuation of mRNA synthesis through its site of attachment. This block would result in the reiterative copying of the stretch of U residues in the vRNA template that is adjacent to the polymerase-binding site, thereby producing the poly(A) sequence followed by termination.

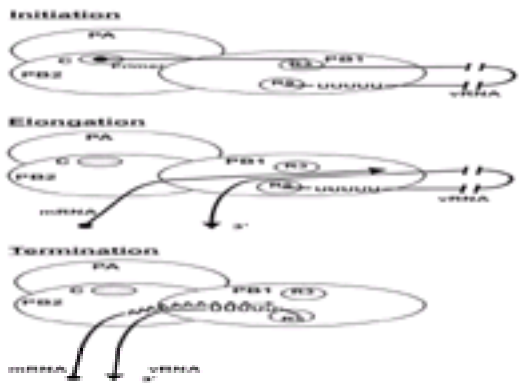

FIG. 20. Model for the elongation and termination of influenza virus mRNA chains. The specific binding of the 5' end of vRNA to the PB1 subunit of the polymerase persists throughout mRNA synthesis, so that the vRNA is threaded through the polymerase complex, in a 3' to 5' direction, during mRNA synthesis. R3 and R5 are the sites on PB1 to which the 3' and 5' ends of the vRNA bind. As a consequence of binding both the 3' and 5' ends of the RNAS, the polymerase itself acts as a physical barrier to continuation of mRNA synthesis, resulting in the reiterative copying of the 5- to 7-U residues that is adjacent to the polymerase-binding site, followed by termination.

Replication of Virion RNA

Replication of virion RNA occurs in two steps: the synthesis of template RNAs, the full-length copies of the vRNAs; and the copying of template RNAs into vRNAs (163). To switch from the synthesis of viral mRNAs to that of template RNAs, it is necessary to change from capped RNA-primed initiation to unprimed initiation and to prevent termination and polyadenylation (antitermination) at the poly(A) site, 15 to 22 nucleotides from the 5' ends of the vRNA templates, that is used during viral mRNA synthesis.

Antitermination requires NP proteins that are not associated with nucleocapsids (11), and this antitermination activity is found in the soluble fraction of infected cell nuclear extracts and can be specifically depleted using an antiserum directed against the NP protein (11). In addition, using a virus containing a ts mutation in the NP protein, template RNA, but not mRNA synthesis, is ts both *in vivo* and *in vitro* (215,306). The most likely explanation for these results is that the nonnucleocapsid NP protein molecules bind to the common 5' ends of the nascent transcripts (11). It seems possible that as additional NP protein molecules are added to the elongating RNAs, they bind to the sequence of 4 to 7 A residues in the mRNA that are copied from the stretch of U residues in the vRNA template. As a consequence, this mRNA sequence is prevented from slipping backward along the vRNA template, and reiterative copying of the stretch of U residues in the vRNA template would be blocked. Supporting data for this hypothesis are awaited, however, and it is not clear how this process would eliminate the physical barrier to the copying of the 5' ends of the vRNAs caused by the polymerase itself. This mechanism predicts that the number of NP protein molecules in infected cells regulates the levels of mRNA synthesis versus genome RNA replication because full-length template RNAs are synthesized only when NP protein molecules are present.

The next step in replication, copying the full-length template RNAs to produce negative-stranded vRNAs, also requires the addition of NP protein molecules to the elongating RNA molecules (306). No vRNA-sense RNAs of discrete sizes are made in the absence of these soluble NP molecules, indicating that elongation of vRNA chains most likely ceases at any time at which NP is not available. Consequently, the newly synthesized vRNAs are in the form of nucleocapsids that can be readily packaged into progeny virus particles.

As noted previously, the switch from mRNA synthesis to the synthesis of full-length template RNAs requires that the polymerase switch from capped RNA-primed initiation to unprimed initiation. The biochemical process by which this occurs is not known, but one hypothesis for this change in initiation is that the form of the polymerase that carries out vRNA replication differs from the one that carries out mRNA synthesis (163). According to this hypothesis, the mRNA synthesis polymerase produces only subgenomic, polyadenylated mRNAs, even in the presence of NP protein molecules. This polymerase requires the PB2 cap-binding protein to produce capped RNA primers, but apparently does

not require the PA protein. In contrast, the replication polymerase, which is present only in infected cells and not in virus particles, requires NP protein molecules to produce full-length template and vRNA strands. This provides an explanation for the fact that vRNA and template RNA are encapsidated with NP subunits, whereas mRNAs are not encapsidated with NP subunits (105,270; reviewed in 163). The replication polymerase initiates the unprimed synthesis of either full-length template RNAs or vRNAs, and presumably requires the PA protein, but not the PB2 cap-binding protein.

Nuclear Export of Ribonucleoproteins

The original model for vRNP nuclear export proposed that the M_1 protein promoted vRNP nuclear export by forming a vRNP-M_1 complex in the nucleus (209) with export occurring through the NES on M_1. Confirming evidence that M_1 is a mediator of vRNP nuclear export was provided when it was found that expressed M_1 can induce the export of nuclear-trapped vRNPs (31). However, vRNP export can occur even when the vast majority of M_1 is trapped in the nucleus by altered hyperphosphorylation (281,373). The M_1 protein lacks an NES, and evidence has been presented that the NES is provided by the NS_2 protein and that vRNP export is mediated by a vRNP-M_1-NS_2 protein complex (236,358) (Fig. 21). The NES in the NS_2 protein would overcome the NLS sequences in the NP and P proteins, a phenomenon that has been observed in other examples of nuclear export (91). The NS_2 protein, which has been shown to bind to the M1 protein (358), contains a leucine-rich region at residues 97 to 105, which is a putative NES for interacting with an exportin, a family of cellular proteins that mediate nuclear export (236); and microinjection of anti-NS^2 antiserum inhibits vRNP export in infected cells (236). There is also the possibility that the NLS sequences in the NP and P proteins are overidden by a different mechanism mediated by the tight binding of NP to actin (64). Thus, in the life cycle of influenza virus, RNPs from input virions are transported into the nucleus, where their transcription and replication occurs, and new RNPs are transported back from the nucleus to the cytoplasm. Thus, knowledge of the switch required for nuclear import and nuclear export of the RNPs is crucial to understanding viral replication.

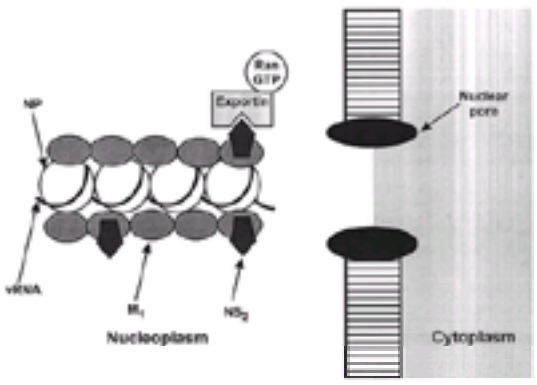

FIG. 21. An M_1-NS_2 protein complex mediates the nuclear export of vRNA-containing nucleocapsids. The current model for export of vRNPs from the nucleus is shown. A nuclear export signal in NS_2 interacts with a member of the cellular exportin family of proteins. The exportin is most likely associated in a complex with RAN-GTP protein to mediate export of the RNP–M_1–NS_2 protein complex from the nucleus. (Modified from ref. 236, with permission.)

Regulation of Viral Gene Expression in Infected Cells

Influenza virus infection can be divided into an early and late phase of gene expression. However, unlike DNA viruses, in which specific patterns of transcription occur before and after DNA replication, the phases of influenza virus gene expression entail quantitative changes of transcription of individual RNA segments as opposed to qualitative changes (176,305,316).

During the early phase, the synthesis of specific vRNAs, viral mRNAs, and viral proteins are coupled (106,305,323). The first event detected after primary transcription is the synthesis of template RNAs, presumably copied off the parental vRNAs. About equimolar amounts of each of the template RNAs are made. The peak rate of template RNA synthesis occurs early and then sharply declines. Specific template RNAs are then selectively transcribed into vRNAs. Specifically, the NS and NP vRNAs are preferentially synthesized early, whereas the synthesis of M segment vRNA is delayed. The rate of synthesis of a particular vRNA correlates with, and therefore most likely determines, the rate of synthesis of the corresponding mRNA and of its encoded protein. The NS_1 and NP mRNAs and proteins are preferentially synthesized at early times, whereas the synthesis of the M_1 mRNA and protein are delayed. Thus, the control of viral protein synthesis during the early phase is predominantly a direct consequence of the regulation of vRNA synthesis, that is, the selective copying of specific template RNAs into vRNAs.

During the late phase, the relationships between the syntheses of vRNAs, viral mRNAs, and viral proteins change dramatically (305). The synthesis of all the viral mRNAs reaches its peak rate at the beginning of the late phase, and the rate of synthesis of all the mRNAs then decreases precipitously. In contrast, the rate of synthesis of all the vRNAs remains at or near maximum during the second phase. Thus, vRNA and viral mRNA synthesis are not coupled during the second phase. In addition, viral mRNA and protein synthesis are not coupled because the synthesis of all the viral proteins continues at maximum levels during the second phase. Previously synthesized viral mRNAs undoubtedly direct viral protein synthesis during the second phase. The pattern of protein synthesis during the second phase differs from that in the first phase. During the second phase, two structural proteins, M_1 and HA, which are poorly synthesized in the first phase, are synthesized at high rates along with the other structural proteins.

As discussed previously, the synthesis of all three types of virus-specific RNAs occurs in the nucleus (163). The template

RNAs, which are synthesized only at early times, remain in the nucleus to direct vRNA synthesis throughout infection (305). In contrast, the vRNAs, which are in the form of nucleocapsids, are efficiently exported to the cytoplasm, particularly at later times (73,306).

A significant part of the replication control system established by influenza virus in infected cells is directed at the preferential synthesis of the NP and NS_1 proteins early and at delaying the synthesis of the M_1 protein (306). The NP protein is synthesized early presumably because it is needed for the synthesis of template RNAs and vRNAs. The NS_1 protein is needed for other early functions (as discussed later). It is likely that the synthesis of the M_1 protein is delayed because this protein stops the transcription of vRNA into viral mRNA (402) and functions in the transport of vRNA-containing nucleocapsids from the nucleus to the cytoplasm (208).

Posttranscriptional Processing of Viral mRNAs

Most pre-mRNAs in higher eukaryotes contain introns that must be precisely removed to generate functional mRNAs (reviewed in 307). Several conserved sequence elements have been found in all introns: 5' splice site, 3' splice site, and the branch site. In mammalian systems, an additional requirement is a polypyrimidine tract, which lies between the branch site and 3' splice site. Influenza virus exploits the host nuclear machinery that splices cellular pre-mRNAs. As discussed previously, in influenza A virus–infected cells, two full-length viral mRNAs, the NS_1 and M_1 mRNAs (encoding the influenza A virus NS_1 protein [NS_{1A}] and the M_1 protein, respectively) are spliced by the cellular splicing machinery in the nucleus to form smaller viral mRNAs that encode two other proteins, NS_2 and M_2, respectively. Whereas the entirety of the population of cellular pre-mRNA molecules is usually spliced, only a portion of the influenza viral precursor NS_1 and M_1 mRNA molecules are spliced, and both the unspliced and spliced viral mRNAs are exported to the cytoplasm (163). Incomplete splicing and nuclear export of unspliced viral pre-mRNAs is not restricted to influenza virus; it also occurs in cells infected with retroviruses, both “simple” retroviruses (such as avian and murine leukemia viruses) and “complex” retroviruses (*Lentiviridae,* which include human immunodeficiency virus type 1) (see Chapter 59).

Regulated Splicing of Viral NS_1 and M_1 mRNAs

In influenza A virus–infected cells, splicing is regulated such that the steady-state amount of the spliced mRNAs is only about 10% of that of the unspliced mRNAs (177,180). It is likely that the extent of splicing of NS_1 (or M_1) mRNA is determined by competition between the splicing rate and the rate of nuclear export of NS_1 (or M_1) mRNA.

The rate of splicing of NS_1 mRNA in influenza virus–infected cells appears to be controlled solely by cis-acting sequences in NS_1 mRNA itself. This conclusion stems from the observation that the rate of splicing of NS_1 mRNA encoded in an adenovirus recombinant is not significantly different from the splicing rate of NS_1 mRNA in influenza virus–infected cells (4 hours after infection) (3).

In contrast to the rate of splicing, the rate of nuclear export of NS_1 mRNA is not intrinsic to the NS_1 mRNA sequence, but rather varies depending on whether the NS_1 mRNA is expressed through a DNA vector or through influenza virus machinery in infected cells. When NS_1 mRNA is expressed with an adenovirus vector (3), its nuclear export is totally blocked because NS_1 mRNA is committed to the splicing pathway (in accordance with the splicesome retention theory). In contrast, in influenza virus–infected cells, nuclear export of NS_1 mRNA is efficient, and the rate of splicing of NS_1 mRNA largely, if not totally, determines the extent of splicing. It is not known how the nuclear export of unspliced NS_1 mRNA is facilitated in influenza virus–infected cells. Viral proteins do not appear to be required for the facilitated nuclear export of unspliced NS_1 mRNA (4).

Control of the Alternative Splicing of M_1 mRNA by Both Viral and Cellular Proteins

The splicing of M_1 mRNA of influenza A virus is complicated by the use of alternative 5' splice sites (183,312) (Fig. 22; see Fig. 10). When the 5' splice site at position 11 (the first virus-coded nucleotide at the 5' end of the mRNA is assigned position number 1) is used, mRNA3 is produced. The mRNA3 5' splice site, CAG\GUAGAU, fits the consensus sequence for 5' splice sites (C/AAAG\GUA/GAGU) closely. By contrast, the 5' splice site for the M_2 mRNA (at position 51), AAC\GUAUGU, does not fit the consensus as well because there is a C rather than a G at the 3' end of the 5' exon. The common 3' splice site, G7G(A)4(U)3GCAG\G, deviates from the consensus (U/CnNC/UAG\G) in that it does not contain an immediately adjacent polypyrimidine tract. When the M_1 gene is expressed in uninfected cells using a transient transfection DNA vector, only the strong mRNA3 5' splice site and not the weaker M_2 5' splice site is used (4,182). This raised the question of how the M_2 mRNA 5' splice site and the mRNA3 5' splice site are used in influenza virus–infected cells.

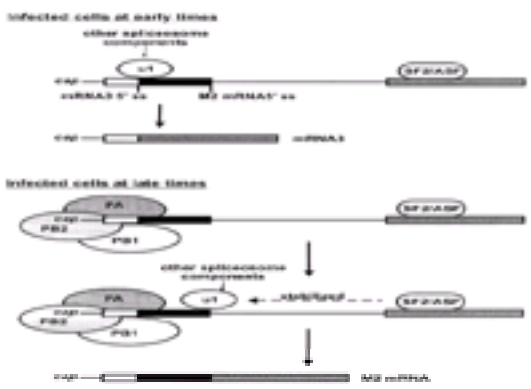

FIG. 22. Mechanism by which the viral polymerase complex and the cellular SF2/ASF splicing factor control the alternative splicing of influenza virus M_1 mRNA. See text for details of the mechanism. (Redrawn from ref. 310, with permission.)

It has been shown that the alternative splicing of influenza viral M_1 mRNA is controlled by both viral and cellular proteins (310,312) (see Fig. 22). The weaker M_2 5' splice site of M_1 mRNA is not used in infected cells at early times of infection because of the presence of the stronger mRNA3 5' splice site. The switch to the M_2 5' splice site occurs at later times in infected cells because the viral polymerase complex binds to a sequence near the 5' end of M_1 mRNA, thereby blocking the mRNA3 5' splice site (312). The polymerase complex binds to the sequence (AGCAAAAGCAGG), which is the complement of the first 12 nucleotides found at the 3' end of each of the virion RNA segments, and it is located immediately 3' to the 5' terminal 10 to 13 nucleotides that are “snatched” from host cell RNAs during viral mRNA synthesis. As a result of this binding, the polymerase protein complex acquires cap-binding activity, thereby enhancing the binding of the polymerase complex to the capped M_1 mRNA. As the cap-binding activity of the polymerase complex is also activated by the common 3'-terminal sequence during the initiation of viral mRNA synthesis (as discussed previously), it is likely that the 5'-viral mRNA sequence and the 3'-terminal sequence of vRNA bind to the same site on the PB1 subunit even though these two RNA sequences differ at 4 out of the 12 positions. Thus, the production of M_2 mRNA is delayed until sufficient amounts of the polymerase complex are synthesized, so that the time course of synthesis and assembly of functional polymerase complexes controls the time at which the M_2 5' splice site can be used in infected cells.

Although the binding of the viral polymerase to the 5' end of the M_1 mRNA causes the M_2 5' splice site to be the only available 5' splice site in the M_1 mRNA molecule, the weak M_2 5' splice site is poorly used unless the cellular SF2/ASF splicing factor is present (310). SF2/ASF is an SR protein, a member of a family of proteins containing a domain rich in serine and arginine and functioning in both alternative and constitutive splicing (83,162). The SF2/ASF protein binds specifically to a purine-rich sequence, called a *splicing enhancer sequence,* in the 3' exon of M_1 mRNA, and this binding, through a series of protein–protein interactions, results in the activation of the M_2 5' splice site (310) (see Fig. 22). Consequently, the control of the alternative splicing of influenza viral M_1 mRNA involves the viral polymerase complex, which determines the time at which the M_2 5' splice site can be activated in infected cells, and the cellular splicing factor SF2/ASF, which controls this activation. The latter function is totally dependent on the former function: SF2/ASF does not activate the M_2 5' splice site of M_1 mRNA when the mRNA3 5' splice site is unblocked. As a consequence of this alternative splicing mechanism, influenza virus has ceded the control of the level of expression of one of its gene products, the M_2 ion channel protein, to a cellular nuclear protein, the SF2/ASF splicing factor. Nonetheless, most of the M_1 mRNA molecules are not spliced, and these M_1 mRNA molecules are transported to the cytoplasm to direct the synthesis of the M_1 protein.

Viral mRNAs Are Not Cannabilized for Their 5' Caps

The viral polymerase exhibits selectivity by “snatching” caps from cellular pre-mRNAs, but not viral mRNAs (163). This selectivity is essential because if the 5' ends of viral mRNAs were also cleaved and used as primers, net synthesis of viral mRNAs would not occur. The mechanism for the selectivity emerged from studying the mechanism of alternative splicing of the viral M_1 mRNA, when it was found that the viral polymerase complex binds to the specific sequence 5' AGCAAAAGCAGG 3' found in all mRNAs that is complementary to nucleotides 1 to 12 of the 3' end of each vRNA segment. This polymerase binding also serves a common function: selective protection of the 5' ends of viral mRNAs, but not cellular pre-mRNAs, from endonucleolytic cleavage catalyzed by the polymerase complex (311). Thus, the three influenza virus P proteins carry out two disparate, opposing functions: the endonucleolytic cleavage of all capped mRNAs, and the selective protection of viral mRNAs, but not cellular pre-mRNAs, against this cleavage (311). The acquisition of these two very different functions stems from the fact that the complex of the three P proteins lacks any detectable activity in the absence of specific vRNA sequences (45,100,194,341) (Fig. 23; see Fig. 22). Influenza virus mRNAs lack the sequence complementary to the 5' end of vRNA; therefore, mRNAs can activate only cap-binding activity and not the endonuclease activity.

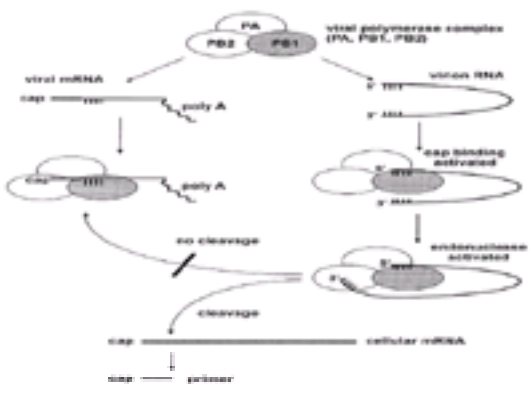

FIG. 23. The influenza viral P protein complex carries out two disparate, opposing functions. The viral P protein complex lacks any detectable activity in the absence of a specific RNA sequence. One specific RNA sequence to which it binds is the 5'-terminal AGUAGAAACAAG sequence present on all eight virion RNA segments. As a result of this binding, the viral P protein complex acquires cap-binding activity. Subsequent binding of the 3' end of the virion RNA results in the acquisition of cap-dependent endonuclease and transcriptase activities. The other specific sequence to which it binds is the AGCAAAAGCAGG sequence that is found both in viral template RNAs, where it is located at the 5' ends (not shown),

and in viral mRNAs, where it is located immediately 3' to the 5' sequence “snatched” from host cell–capped RNAs (shown). As a result of the latter binding, the 5' ends of viral mRNAs are protected against cleavage by the viral cap-dependent endonuclease. In contrast, the 5' ends of host cell mRNAs are not protected and are cleaved by the viral endonuclease. (Redrawn from ref. 311, with permission.)

Splicing in Cells Infected with Influenza B and C Viruses

Splicing also occurs in cells infected with influenza B and C viruses. As with influenza A virus, the NS_1 mRNA of influenza B virus is spliced to form a smaller NS_2 mRNA (25). Both the ORF and the intron of the NS_1 mRNA of influenza virus B/Lee/40 are larger than those of the NS_1 mRNA of influenza virus A/Udorn/72; the sizes of the NS_2 mRNAs of the two virus strains are similar. The 5' splice site, GAG\GUGGGU, of the NS_1 mRNA of influenza B virus fits the consensus sequence closely, whereas the 3' splice site, GAUCGGACAG\U, deviates from the consensus sequence in two ways: (a) absence of a pyrimidine tract immediately upstream of the 39-terminal AG of the intron; and (b) presence of a U rather than a G at the 5' end of the 3' exon. The extent of splicing of the influenza B virus NS_1 mRNA is regulated like that of the influenza A virus NS_1 mRNA; the steady-state level of the spliced influenza B virus NS_2 mRNA is only about 5% to 10% of that of the unspliced influenza B virus NS_1 mRNA (25). In contrast to the M_1 mRNA of influenza A virus, the M_1 mRNA of influenza B virus is not spliced.

Influenza C virus differs from both influenza A and B viruses in that its M_1 protein is not encoded by an unspliced mRNA that is colinear with the virion RNA, but rather is encoded by the mRNA that arises by splicing of the colinear RNA transcript (386). In cells infected with influenza C virus, only a small amount of a colinear M transcript has been detected. This transcript encodes p42, which is processed to p31 and CM2 proteins.

Translational Control Mechanisms

Two major translational controls operate in influenza A virus–infected cells: (a) suppression of the interferon (IFN)-induced block against all protein synthesis, thereby ensuring the efficient translation of virus-specific proteins in infected cells (141,163); and (b) shutoff of the translation of cellular mRNAs, resulting in the selective translation of viral mRNAs (163,176,188,316,317).

Unless a virus-specific defense mechanism were established, overall translation in influenza virus–infected cells would be inhibited because of the production of virus-specific RNA molecules that contain double-stranded regions. The potential for the formation of such double-stranded RNA (dsRNA) molecules stems from the presence of both positive-sense and negative-sense RNAs that are synthesized in the nucleus during infection (163). These viral dsRNA molecules would activate the cellular kinase PKR (141). This dsRNA-activated kinase is expressed constitutively in eukaryotic cells at low levels, and its synthesis is substantially induced by IFN (141,210). Because virus-specific dsRNA also induces IFN (reviewed in 141), increased levels of PKR would be expected to be present in influenza virus–infected cells, and it has been shown that PKR is initially activated during infection (141). Continued activation of PKR would lead to a global shutdown of protein synthesis because activated PKR phosphorylates the a-subunit of the initiation factor eIF-2 (141,210). This initiation factor forms the ternary complex (eIF-2) á g GTP á (met-tRNAi) that binds to the initiating 40S ribosomal subunit before mRNA is bound (135). Phosphorylation of the a-subunit of eIF-2 prevents the recycling of eIF-2–g GDP to form the functional form of eIF-2, eIF-2-GTP (reviewed in 296). Recycling has been shown to be catalyzed by the factor eIF-2B, which is trapped in an inactive complex with eIF-2-GDP when the a-subunit of eIF-2 is phosphorylated (reviewed in 296). Without this recycling of eIF-2 by eIF-2B, protein synthesis initiation is effectively blocked.

Influenza virus mounts a two-pronged attack against the action of PKR. The virus-specific NS_1 protein binds to, and hence sequesters, viral dsRNA molecules, thereby blocking the activation of PKR (102,202). In addition, a 58-kd cellular protein that inhibits PKR function is activated in influenza virus–infected cells (191,192). The experimental evidence indicates that this 58-kd cellular protein interacts directly with PKR, and that influenza virus activates the inhibitory activity of the 58-kd protein by dissociating it from its own natural inhibitor.

In contrast, the mechanism by which viral mRNAs are selectively translated over cellular mRNAs in infected cells is poorly understood. One of the key elements in the shutoff of host cell protein synthesis takes place in the nucleus of infected cells: newly synthesized cellular pre-mRNAs are degraded (143). This degradation is probably initiated by the cleavage of the 5' ends of cellular pre-mRNAs transcripts by the viral cap-dependent endonuclease (163). The resulting decapped RNAs would be more susceptible to degradation by cellular nucleases, as it has been shown that the 5' cap structure stabilizes RNAs against nucleolytic degradation both *in vivo* and in cell extracts (6). This degradation is probably significantly enhanced by the action of the viral NS_1 protein, which blocks the nuclear export of cellular mRNAs (as discussed later). As a consequence, the mRNAs in the cytoplasm of influenza virus–infected cells are composed of cellular mRNAs synthesized before infection (“old cellular mRNAs”) and viral mRNAs synthesized after infection (“new viral mRNAs”). Nonetheless, high levels of these old cellular mRNAs are found in the cytoplasm of infected cells (143). These cellular mRNAs are stable and also functional, as assayed by their efficient translation in reticulocyte extracts *in vitro* (143). Consequently, the shutoff of host cell protein synthesis, which is complete by about 3 hours after infection in several cell lines, probably does not result from the degradation or modification of cytoplasmic old cellular mRNAs. Based on the polysome distribution of several representative cellular mRNAs in uninfected and infected cells, it has been concluded that both the initiation and the elongation step in the translation of old cellular mRNAs are blocked in infected cells (142).

A molecular mechanism for a selective block against the elongation of cellular, but not viral, proteins has not been established. However, selectivity at initiation is probably due at least in part to the fact that influenza viral mRNAs are

efficient initiators of translation (79,142,143). Other possible mechanisms for the selective translational initiation of viral over cellular mRNAs include the following:

1. The inhibition of the activation and activity of PKR may be partial, rather than complete (142,163). Under such conditions, the translation of viral mRNAs would be favored over the translation of cellular mRNAs because influenza viral mRNAs are better initiators of translation (142,143).
2. The NS_1 protein may bind to the 5'-untranslated regions (5'-UTRs) of viral mRNAs, thereby causing, in a manner unknown, the selective translation of these mRNAs (61,74,251). However, no binding of the NS_1 protein to the 5'-UTR in full-length viral mRNAs has been detected (278). Nonetheless, the NS_1 protein may play a role in translation in infected cells because the NS_1 protein appears to be associated with the polysomes of virus-infected cells (50,78,166).
3. Cellular proteins function in the selective translation of influenza virus mRNAs in infected cells. It has been reported that: (a) the cellular RNA-binding protein GRSF-1 specifically binds to the 5'-UTRs of viral mRNAs (252); and (b) the human homologue of the Stauffen protein, which binds to dsRNA, interacts with the NS_1 protein that is associated with polysomes in infected cells (78).
4. One or more cellular protein initiation factors may be modified in influenza virus–infected cells (79), a strategy employed by some other viruses to ensure that their mRNAs are selectively translated (89).

Roles of the NS1 Protein

The nonstructural protein NS_1 of influenza A virus (NS_{1A} protein) was first identified in 1971 (188), but only recently have its multiple functions in the influenza virus life cycle become evident. The observation that provided the initial insight into these functions was that the NS_{1A} protein inhibits the nuclear export of poly(A)-containing mRNAs in transient transfection experiments (4,82,275). Subsequent experiments established that the NS_{1A} protein is a posttranscriptional regulator that has several activities.

Functional Domains of the NS_{1A} Protein

Two major functional domains of the 237–amino acid NS_{1A} protein have been identified. The first is a sequence near the N-terminus that constitutes the RNA-binding domain. The NS_{1A} protein binds with similar dissociation constants to three RNAs: poly(A), a specific stem-bulge in U6 snRNA, and dsRNA (202,278,279). This domain is also required for dimerization of the NS_{1A} protein, the state in which it exists both *in vivo* and *in vitro* (229).

Structural analysis of the RNA-binding domain of the NS_{1A} protein was facilitated by the demonstration that a fragment of the NS1 protein containing the first 73 N-terminal residues (NS_{1A} residues 1 to 73) possesses all the RNA-binding and dimerization activities of the full-length protein (276). Both nuclear magnetic resonance imaging and x-ray crystallography studies demonstrated that the dimeric NS_{1A} residues 1 to 73 RNA-binding domain in the absence of RNA adopts a novel six-helical chain fold (42,200) (Fig. 24). Mutagenesis studies demonstrated that any alanine replacement that causes disruption of the dimer also leads to the loss of RNA-binding activity, indicating that the dimer structure is essential for RNA-binding. Surprisingly, only one amino acid side chain is absolutely required for RNA-binding without significantly affecting dimerization, namely, the arginine side chain at position 38, which is in the second helix of each monomer (see Fig. 24). This result indicates that this arginine side chain probably interacts directly with the RNA target. This interaction is primarily electrostatic because replacement of this arginine with lysine had no effect on RNA binding. A second basic amino acid, the lysine at position 41, which is also in helix 2 (see Fig. 24), makes a strong contribution to the affinity of binding.

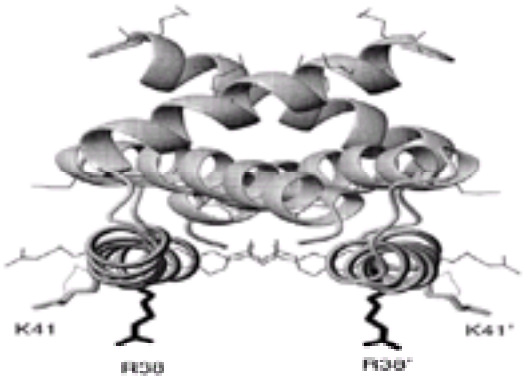

FIG. 24. The three-dimensional structure of the RNA-binding domain of the NS_{1A} protein. The four basic amino acids (R38, R38', K41, K41'), which are required for, or strongly enhance, RNA-binding are shown. All the other solvent-exposed basic amino acids are shown in stick diagram format. (Redrawn from data in refs. 42 and 357, with permission.)

It has been proposed that helix 2 and helix 2', which are antiparallel and next to each other in the dimer conformation, constitute the interaction face between the NS_{1A} RNA-binding domain and its RNA targets (42). This puts the NS_{1A} protein in the small group of proteins that bind to their specific RNA targets through one or more a-helices rather than by b-sheets. The dimeric six-helical NS_{1A} RNA-binding domain almost certainly does not bind in the major groove of a dsRNA target. Rather, at least one basic amino acid (arginine 38, arginine 38'), in each of the antiparallel helices 2 and 2' (see Fig. 24), probably contacts the negatively charged phosphate backbone of dsRNA. Consequently, the dimer structure serves to position arginine 38 on helix 2 so that it is a specific distance (16.5 Å) from the corresponding arginine

38' on helix 2'. This distance is close to that (17 Å) found between the antiparallel phosphodiester backbones surrounding the minor groove of dsRNA. Presumably, the NS_{1A} RNA-binding domain recognizes a comparable type of dsRNA conformation when it binds to all its specific RNA targets.

The second functional domain, which is located in the C-terminal half of the molecule, is not required for RNA binding but is required for the inhibition of the nuclear export of poly(A)-containing mRNAs (275). Although mutagenesis originally identified the amino acid sequence from 134 to 161 as the effector domain (275), it is likely that the effector domain extends from amino acid 74 (at the end of the RNA-binding domain) to amino acid 237, the carboxyl-terminal amino acid. This domain was presumed to be an effector domain that interacts with host nuclear proteins to inhibit nuclear RNA export (see later). On the basis of current information, it can be concluded that all naturally occurring influenza A viruses encode an NS_{1A} protein that contains an effector domain. At one time, it was thought that one naturally occurring influenza virus, A/Turkey/Oregon/71, encoded an NS_{1A} protein lacking the C-terminal sequence containing the effector domain (235). It has since been established, however, that naturally occurring A/Turkey/Oregon/71 virus encodes a full-length NS_{1A} protein, indicating that the previously characterized virus isolate was probably generated during multiple passages in the laboratory (331).

The NS_{1A} Protein Interferes with the Cellular Machinery that Produces the 3' Ends of Cellular mRNAs

The effector domain of the NS_{1A} protein interacts functionally with two essential proteins of the mammalian pre-mRNA 3' end processing machinery: the human 30-kd subunit of the cleavage and polyadenylation specificity factor (CPSF) (228); and poly(A)-binding protein II (PABII) (41). Many of the functions of these two cellular proteins have been established (Fig. 25). The CPSF factor binds to the AAUAAA poly(A) signal located about 15 to 30 nucleotides upstream of the cleavage site in pre-mRNAs and is required for both cleavage and polyadenylation of pre-mRNAs (350). The 30-kd subunit is one of the two subunits of CPSF that has been implicated in the specific binding to the AAUAAA polyadenylation signal (88,149). In contrast, the PABII protein functions after 3' cleavage of the cellular pre-mRNA, and is required for the processive elongation of poly(A) chains catalyzed by the cellular poly(A) polymerase (reviewed in 350). In the absence of PABII, poly(A) polymerase adds only short poly(A) tails to the 3' cleaved pre-mRNA.

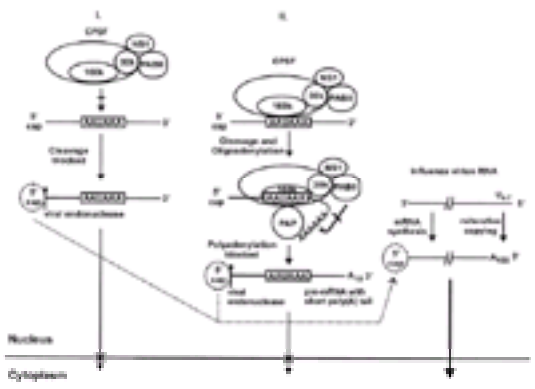

FIG. 25. Proposed two-pronged mechanism by which the NS_1 protein of influenza A virus inhibits the cellular 3' end processing system in infected cells. *Pathway I:* The binding of the NS_1 protein (and PABII) to the 30-kd subunit of cleavage and polyadenylation specificity factor (CPSF) blocks the binding of CPSF to the AAUAAA sequence of some cellular pre-mRNA molecules, thereby blocking 3' cleavage of these pre-mRNAs. The uncleaved pre-mRNAs remain in the nucleus. *Pathway II:* CPSF binds to the AAUAAA sequence of other cellular pre-mRNA molecules, despite the binding of the NS_1 protein and PABII to the 30-kd CPSF subunit. A short poly(A) sequence is then added to these cleaved pre-mRNAs by PAP in a CPSF-dependent reaction. Subsequent elongation of the short poly(A) sequence is blocked by the binding of the NS_1 protein to PABII, resulting in the nuclear accumulation of cleaved pre-mRNAs containing short poly(A) tails. In both pathways, an individual NS_{1A} protein forms a complex with both PABII and the 30-kd subunit of CPSF. In this complex, the two cellular 3'-processing proteins, 30-kd CPSF and PABII, also bind directly to each other. The presence of PABII in the 3'-processing complexes that are formed before 3' cleavage probably results from the binding of PABII to the NS_{1A} protein because PABII has not been found in 3' cleavage complexes formed *in vitro* in the absence of the NS_{1A} protein. Both species of the cellular pre-mRNAs that are sequestered in the nucleus are cleaved by the virion cap-dependent endonuclease to produce the primers required for viral mRNA synthesis. The 3'-terminal poly(A) sequence on viral mRNAs is produced by the viral transcriptase, which reiteratively copies a stretch of 4 to 7 U in the virion RNA templates. The poly(A)-containing viral mRNAs are exported from the nucleus. (Redrawn from refs. 41 and 228, with permission).

Binding of the influenza virus NS_{1A} protein through its effector domain to the 30-kd CPSF subunit dramatically inhibits CPSF function and hence inhibits the 3' end cleavage and polyadenylation of the cellular pre-mRNAs that are synthesized after infection (see Fig. 25, pathway I) (228). Indeed, influenza viruses that contain ts mutations in the NS_{1A} protein coding sequence inhibit 3' cleavage of cellular pre-mRNAs at the permissive, but not at the nonpermissive, temperature (313). Nonetheless, 3' cleavage of some cellular pre-mRNAs still occurs in virus-infected cells, followed by the addition of short poly(A) tails catalyzed by the cellular poly(A) polymerase (see Fig. 25, pathway II) (41). The subsequent processive elongation of these short poly(A) tails does not occur because the NS_{1A} protein inhibits the function of the cellular PABII protein (41).

Both the cellular pre-mRNAs that do not undergo cleavage and those that contain short (about 12 nucleotides) poly(A) tails accumulate in the nucleus of infected cell. The newly synthesized cellular pre-mRNAs that are trapped in the nucleus are almost completely degraded (144). This efficient nuclear degradation probably occurs because the viral

cap-dependent endonuclease removes the 5' terminal cap of the cellular pre-mRNAs and mRNAs (163), thereby facilitating degradation by cellular 5'-3' exoribonucleases in the nucleus. Consequently, little or no cellular mRNAs that are synthesized after infection should survive, and little or no proteins encoded by such cellular mRNAs should be synthesized in influenza A virus–infected cells.

In contrast to cellular pre-mRNAs, the nuclear export of viral mRNAs in infected cells should not be hindered by the NS_{1A} protein because the poly(A) tails of viral mRNAs are produced by the viral transcriptase and not by the cellular 3' end processing machinery (203,273,286).

The NS_{1A} Protein Inhibits the Splicing of Pre-mRNAs

By using transfection experiments, it was established that the NS_{1A} protein inhibits the splicing of cellular pre-mRNAs *in vivo* (82,201) and that purified recombinant NS_{1A} protein inhibits pre-mRNA splicing *in vitro,* catalyzed by nuclear extracts from uninfected cells (201,279). Splicing inhibition *in vitro* is mediated by the binding of the NS_{1A} protein to a specific stem-bulge in U6 snRNA (279), an snRNA that plays a central role in the splicing most of the cellular pre-mRNAs (307). In contrast, splicing inhibition *in vivo* requires the effector domain as well as the RNA-binding domain of the NS_{1A} protein (201).

However, it has not yet been conclusively established that the NS_{1A} protein inhibits the splicing of cellular pre-mRNAs in virus-infected cells. Any such inhibition is obscured by the rapid degradation of cellular pre-mRNAs that occurs in the nucleus of infected cells (143,163). The only evidence for the NS_{1A} protein-mediated inhibition of cellular pre-mRNA splicing in infected cells is that the NS_{1A} protein synthesized during virus infection is specifically associated with U6 snRNA molecules (202). Several important questions about the presumed inhibition of the splicing of cellular pre-mRNAs in virus-infected cells have not yet been addressed. Thus, it is not known how the NS_{1A} protein-mediated inhibition of pre-mRNA splicing would benefit virus gene expression and how the splicing of the viral M_1 and NS_1 mRNAs by the cellular splicing machinery could take place in the face of an overall inhibition of pre-mRNA splicing.

The NS_{1A} Protein Inhibits the Cellular Interferon Response

The several hundred cellular proteins that are induced by IFN-a/b constitute one of the initial host defenses against virus infection (62,327). Reverse genetics experiments have established that the NS_{1A} protein plays a crucial role in protecting influenza A virus against the cellular IFN response: influenza A viruses that lack the NS_{1A} gene replicate only when the cellular IFN response is defective (84).

One IFN-induced pathway involves PKR, and as discussed previously, the RNA-binding domain of the NS_{1A} protein, by binding to dsRNA molecules, inhibits the activation of PKR *in vitro* (101,102,202). Evidence that the NS_{1A} protein carries out this function in influenza virus–infected cells was obtained using mutant viruses that contain ts mutations in the NS_{1A} protein coding sequence (102).

IFN-induced pre-mRNAs are synthesized after infection and consequently should be subjected to the effector domain-mediated inhibition of nuclear export, followed by nuclear degradation (41,143,228,313). As a result, few or no IFN-induced mRNAs should survive, and few or no IFN-induced proteins should be synthesized in influenza A virus–infected cells. Consistent with such a role of the effector domain, laboratory-generated viruses that lack deletions of the effector domain fail to protect the virus against IFN (70). Only in Vero cells, which are defective in IFN production, do these mutant viruses grow as well as wild-type virus in tissue culture. The efficiency of replication of these mutant viruses in MDCK cells, which produce IFN, is inversely correlated with the length of the effector domain of the encoded NS_{1A} protein, and these viruses are attenuated in wild-type mice that produce IFN.

A Latent Nuclear Export Signal in the Effector Domain of the NS_{1A} Protein

An amino acid sequence in the effector domain of the NS_{1A} protein (amino acids 134 to 147) has the same spacing of hydrophobic residues (leucines) as other proven NES sequences (reviewed in 91). When this short NS_{1A} sequence is linked to a heterologous protein, it functions as an NES; that is, it transports the heterologous protein from the nucleus to the cytoplasm (198).

In uninfected cells that are transfected with the NS_{1A} gene, however, the NES of the NS_{1A} protein does not function. In contrast, in influenza virus–infected cells, the NES of a fraction of the wild-type NS_{1A} protein molecules is activated, and a substantial amount of the NS_{1A} protein is found in the cytoplasm. The mechanism by which the NES of the NS_{1A} protein is activated in infected cells has not yet been established. In addition, the functions of the NS_{1A} protein molecules that are exported to the cytoplasm of virus-infected cells have not been identified. Several possibilities have been suggested. For example, the binding of dsRNA by the NS_{1A} protein to inhibit the activation of the PKR kinase, a cytoplasmic enzyme, could occur in the cytoplasm (102,202). Furthermore, as discussed previously, NS_{1A} protein molecules in the cytoplasm may also play other roles in the translation of viral mRNAs.

Comparison of the NS_{1A} Protein with the Influenza B Virus NS_1 Protein (NS_{1B} Protein)

The NS_{1A} and NS_{1B} proteins share little sequence homology, and NS_{1B} proteins are usually larger than NS_{1A} proteins (26). For example, the NS_{1B} protein encoded by B/Lee/40 virus is 281 amino acids long, whereas the NS_{1A} protein encoded by A/Udorn/72 is only 237 amino acids long. However, the NS_{1B} protein binds to the same specific RNA targets as the NS_{1A} protein (356). In addition, as is the case with the NS_{1A} protein, an N-terminal fragment of the NS_{1B} protein

possesses all the RNA-binding and dimerization activities of the full-length protein and is largely a-helical (356). The NS_{1B} fragment is 93 amino acids long, and is thus about 20 amino acids longer than the functional N-terminal fragment of the NS_{1A} protein. A reasonable alignment between the two N-terminal fragments that perfectly aligns helix 2 and 2' can be made (357). Thus, influenza B viruses probably encodes an NS_{1B} proteins with a N-terminal, six-helical RNA-binding domain similar to that of the NS_{1A} protein.

In contrast to the RNA-binding and dimerization domain, the effector domain of the NS_{1A} protein is not conserved in the NS_{1B} protein (356). Thus, unlike the NS_{1A} protein, the NS_{1B} protein does not inhibit either the nuclear export of cellular mRNAs or the splicing of cellular pre-mRNAs (356). Consequently, these effector domain functions are not needed for the propagation of influenza B viruses in nature, and the function of the large C-terminal region of NS_{1B} proteins is not known. All naturally occurring influenza B viruses encode an NS_{1B} protein with such a large C-terminal region (235). This fundamental difference between NS_{1A} and NS_{1B} proteins probably contributes to the different biologic properties of influenza A and B viruses.

Viral Assembly and Release

Intracellular Transport of the Integral Membrane Proteins

The influenza virus integral membrane proteins HA, HEF, NA, M_2, and NB are synthesized on membrane-bound ribosomes and are translocated across the membrane of the ER in a signal recognition particle (SRP)-dependent manner (71,130). For HA, the N-terminal signal sequence is cleaved in the ER by signal peptidase: NA, M_2, and NB do not contain cleavable signal sequences. N-linked carbohydrate chains are transferred to HA, NA, NB, and CM2 (M_2 is not glycosylated) *en bloc* from a dolicyl lipid carrier, and trimming of terminal glucose residues from mannose-rich oligosaccharides occurs in the ER. The HA and NA have been used as prototypes from which much of what we know about the process of folding and oligomerization of an integral membrane protein has been learned. For HA, a large body of data indicates that there is a step-wise conformational maturation of the protein with independent folding of specific domains in the HA monomer, followed by trimerization and the completion of folding to the pH neutral form of HA (reviewed in 66). Once correctly folded and assembled, proteins are transported out of the ER to the Golgi apparatus. There, oligosaccharide chains may be further processed to the complex form. For influenza virus A/Aichi/68 HA, five carbohydrate chains are in the complex form, and two are in the high mannose form (359). HA and NA lack terminal sialic acid on their complex carbohydrate chains in influenza virus–infected cells, presumably because of the action of the viral NA (8,156). Palmitoylation of the three C-terminal proximal cysteine residues of HA (two in the cytoplasmic tail and one in the presumed TM domain) and palmitoylation of the M_2 protein cytoplasmic tail residue 50 (119,333,346) are thought to occur in the cis-Golgi complex. In HAs containing a furin cleavage site, cleavage activation occurs in the TGN (330).

In polarized epithelial cells, influenza viruses assemble and bud at the apical surface of cells (287,290), and it has been shown that HA (influenza A virus), HEF, NA (influenza A virus), M_2, and CM2, when expressed alone from cDNAs in polarized cells, are transported to the apical surface (128,140,291,398). Thus, apical transport is an intrinsic property of these proteins.

The last step in intracellular transport is the expression of the proteins at the plasma membrane. Although HA appears to be diffusely distributed over the surface, M_2, NA, and the influenza C virus HEF glycoprotein appear to cluster in patches (53,54,112,128,140,185,395,396). At the present time, the significance of this cell surface distribution is not known.

Role of M_2 Ion Channel Activity on Maturation of Hemagglutinin in the trans-Golgi Network

Amantadine has a second late effect during the replication of avian influenza virus A/chicken/Germany/34 (H7N1) fowl plague virus (FPV) Rostock. A premature conformational change occurs in its HA in the TGN during the transport of HA to the cell surface (95,96,332; (reviewed in 179). This form of HA is indistinguishable from the low-pH–induced form of HA. Several experiments indicate that the M_2 ion channel activity also functions in the TGN and associated transport vesicles, where it regulates intracompartmental pH and as a result keeps the pH above the threshold at which the FPV Rostock HA conformational change occurs (238,297,332,339; reviewed in 104,179). Consequently, in the presence of amantadine, the low-pH–induced conformational change occurs, and the resulting extrusion of the fusion peptide at the wrong time and in the wrong subcellular compartment results in the aggregation of HA molecules; hence, budding is greatly reduced (292). However, it is clear that the avian influenza virus FPV Rostock, even for an influenza virus with an HA that is cleaved intracellularly, is an exceptional case in requiring a functional M_2 protein ion channel activity in the TGN. Other viruses that also contain an H7 HA do not share such a requirement because their pH of transition to the low-pH–induced form is lower (96).

The Budding Process

Influenza viruses can be observed to bud from the plasma membrane of infected cells morphologically (reviewed in 51) (see Fig. 2). Electron microscopic observations suggest that the precursor to the envelope of a budding virion is a patch of cell membrane containing viral envelope proteins (reviewed in 51). Host cell membrane proteins appear to be excluded from virions. In addition, among virus-encoded proteins, there must be a positive selection or a rejection process. The ratio of M_2 to HA at the plasma membrane is about 1:4, whereas in the virus, it is 1:25 (185,395).

Interactions between the cytoplasmic tails of the viral integral membrane proteins and the internal proteins of the virion likely provide the necessary molecular information for formation of the budding particle. The 10- to 11-residue HA C-terminal cytoplasmic tail and the six residues constituting the predicted NA cytoplasmic tail are highly conserved among the HA and NA subtypes (47,233). Given the mutation rate of the influenza virus RNA genome, this sequence conservation suggests an important function for the HA and NA cytoplasmic tails. To elucidate such a function, reverse

genetics procedures were used to generate influenza viruses that lack either the cytoplasmic tail of HA (136,138) or the cytoplasmic tail of NA (86,217) or both cytoplasmic tails (137). Based on observation of properties of these mutant viruses, a model was proposed in which, for the normal budding of influenza virus, the requirements of the HA and NA cytoplasmic tail interactions with an internal component of the virion (most likely the M_1 protein) are so crucial for normal budding that these two cytoplasmic tail interactions are redundant (137). When both cytoplasmic tails are eliminated, the virions possessed greatly altered morphology (137).

The M_1 and M_2 proteins may also form crucial interactions during virus assembly and budding. It has been found that a monoclonal antibody (14C2) with specificity for the M_2 ectodomain restricts the size of plaque growth of a variety of influenza A virus strains (395). This M_2 antibody reduces the level of cell surface expression of M_2 and reduces the level of influenza virus particle formation in a single cycle of infection (129). Furthermore, this M_2 antibody also reduces the level of filamentous particle formation (285). When variant viruses resistant to the antibody were isolated, they were found to have compensating changes in the cytoplasmic tail of M_2 as well as in the N-terminal domain of the M_1 protein (394). These variant viruses resistant to the antibody retain the filamentous particle phenotype (285). Thus, the evidence suggests important roles for the putative M_1 and M_2 interactions in virus assembly.

The positive selection or exclusion process for inclusion of viral integral membrane proteins into virus particles may be affected by the organization of the lipids in the plasma membrane. It was long thought that the lipids of the plasma membrane functioned mainly as a solvent for membrane proteins (the fluid mosaic model) (315). However, more recently, this view has been refined to include lateral organization resulting from preferential packaging of sphingolipids and cholesterol into moving “platforms,” or “rafts,” in which specific membrane proteins become incorporated (29,314). Rafts can incorporate specific proteins, including many, but not all, glycophosphatidylinositol-anchored proteins and N-terminally myristoylated and palmitoylated cytoplasmic proteins (216; reviewed in 314). Rafts also incorporate some integral membrane proteins. HA and NA enter cholesterol-sphingomyelin–rich raft domains, and it is becoming increasing clear that the rafts are the site of assembly of budding virions at the plasma membrane (300,398). The M_1 protein also associates with these rafts, but this association is decreased in cells infected with viruses lacking both the HA and NA cytoplasmic tails (398). In contrast, the M_2 ion channel protein is largely excluded from rafts (398), thereby providing an explanation for the low amount of M_2 protein in virions as compared with HA (185,395). However, some M_2 is included into virions, and for the positive inclusion of M_2 into virions, it has been suggested that the extracellular domain of M_2 is required (250).

The mechanism by which the bud pinches off from the plasma membrane is not known. For retroviruses, there is a role for monoubiquitination of Gag in the budding process (255), and it is known that monoubiquitination of some receptor protein promotes their internalization and down-regulation (115). Thus, for retroviruses, budding involves cellular machinery, and this is also likely to be the case for influenza virus. To release fully formed influenza virions from the cell surface, the action of the viral NA is thought to be needed because in the absence of NA activity, sialic acid present on the carbohydrate chains of HA and cell surface molecules causes the virus to aggregate to itself and the cell surface through the HA sialic acid receptor–binding pocket (248).

Packaging a Segmented Genome

Production of an infectious influenza virus particle requires incorporation of at least one copy of the eight genomic segments. Nevertheless, random packaging cannot be distinguished from a selective mechanism for inclusion of a full complement of genomic RNAs. A random packaging mechanism in which any eight RNA segments of the genome are incorporated into virions would generate a maximum of 1 infectious particle for every 400 assembled ($8!/8^8$), a number within the range of noninfectious to infectious particles found in virion preparations. If 12 segments can be randomly packaged, 10% of virions would contain one copy of each of the eight segments (77).

A selective mechanism for incorporation of one copy of each RNA segment exists for the three segments of dsRNA of phage f6. The positive strand of each segment is packaged before synthesis of the complementary negative strands within particles. The particle-to-plaque forming unit ratio is close to 1, indicating that essentially all particles contain a complete complement of genome segments. Such precise packaging appears to be due to the serial (sequential) dependence of packaging of the positive-stranded RNA segments with the smallest segment entering first, followed by the medium dsRNA segment and then the largest dsRNA segment (277).

For influenza virus, particles containing more than eight RNA segments (77) and less than eight RNA segments (208) have been obtained consistent with random packaging. However, the specific interference with packaging of wild-type RNA segment 1, but of no other genome segment, by an internally deleted defective RNA segment 1, argues strongly for a specific mechanism of packaging, at least for RNA segment 1 (69,237).

GENETICS OF INFLUENZA VIRUSES

RNA Segment Reassortment

Influenza type A, B, and C viruses can form reassortants *in vivo* between members of the homotypic virus type but not between types. The emergence of new pandemic strains of influenza A virus usually results from such a reassortment. The consequence of this reassortment is the appearance of a new virus subtype containing a novel HA or NA that is immunologically distinct from those of the previous circulating strain. In the 20th century, there was the appearance of “Spanish” influenza in 1918 and 1919, with an HA related to those of swine viruses or H1 subtype viruses. Viruses of this subtype circulated until 1957, when viruses of the H2N2 subtype (Asian strains) were isolated. The H2 subtype HA has little or no cross-reactivity with the H1 HA. In addition to containing an H2 HA, the Asian strains had a new NA (N2). For 11 years, the H2N2 strains of influenza virus spread and changed until the next pandemic in 1968 with the introduction of a new H3 subtype (Hong Kong strains). In 1976, an H1N1 virus reemerged, and in 1997 and 1998, in Hong Kong, a

virulent avian H5 virus crossed the species barrier from birds to humans (see Chapter 47). The extensive changes in the HA or NA that lead to new subtypes of human influenza viruses are known as *antigenic shifts* (reviewed in 152 and 366) (see Chapter 47). These drastic antigenic changes come about from the reassortment of previously circulating human viruses and influenza viruses of animal origin. There is a great deal of evidence for the reassortment of RNA segments between human and animal viruses *in vivo* (365) and among human viruses in nature (392). It has been established that the A/Hong Kong/68 H3N2 virus contains the NA and all genes encoding internal proteins, except that for PB1, from an Asian (H2N2) strain; the genes for HA and PB1 are thought to be derived from a strain that is closely related to Eurasian avian viruses and A/equine/Miami/63 (H3N8 viruses) (145).

Theoretically, it might be expected that *in vivo,* the eight RNA segments of influenza A virus could give rise to 256 possible reassortants. However, a random segregation does not occur because certain viral proteins apparently need their matched strain-specific cognate protein. Nowhere is this more clearly demonstrated than with the requirement of the A/chicken/Germany/34 (H7N1) fowl plague virus Rostock HA (encoded by RNA segment 4), which always cosegregates with its cognate M_2 protein (encoded by RNA segment 7) (95,96).

RNA Mutations

Minor changes in antigenic character of influenza viruses occur as a result of the accumulation of amino acid changes due to mutation; of principal importance are changes in HA and NA. This process is known as *antigenic drift* and occurs with influenza A, B, and C viruses (reviewed in 152 and 366) (see Chapter 47). However, influenza A viruses show a high number of substitutions accumulating in a sequential pattern with time, whereas influenza C viruses isolated decades apart show much lesser degrees of variability (reviewed in 322). The mutation rate for the H3 HA (HA_1 domain) has been estimated to be 6.7×10^{-3} substitutions per site per year. The observation that the nucleotide substitutions in HA were found predominantly in HA_1 suggests that many substitutions may be selected for by the immune pressure (322 and references therein).

Many studies have been performed to analyze the rate of mutation of RNA viruses in tissue culture. Recent calculations, which take into consideration many artifacts of earlier studies, indicate the influenza virus mutation rate at 1.5×10^{-5} mutations per nucleotide per infectious cycle (253). However, although the influenza virus mutation rate is high compared with mammalian DNA genomes (10^{-8} to 10^{-11} per incorporated nucleotide), the mutation rate of influenza A virus is not markedly different from that of other RNA viruses (reviewed in 322).

RNA Recombination

RNA recombination is the joining of two separate RNA chains by crossing-over or copy-choice mechanisms. Historically for influenza virus, the term *RNA recombination* has been used to mean RNA segment reassortment. Unlike the situation with the positive-stranded RNA viruses, the *Coronaviridae* and *Picornaviridae* (see Chapter 23 and Chapter 35), in which RNA recombination occurs at high frequency, until recently, recombination had not been measured for influenza viruses. However, natural examples of RNA recombination have been found when HAs were identified that contain at the HA_1/HA_2 cleavage site either an insertion of 54 nucleotides derived from host 28S ribosomal RNA (151,242) or 60 nucleotides derived from the NP gene (241). In addition, using molecular genetic techniques (see later), RNA recombination within an RNA segment has been shown to occur (12).

Molecularly Engineered Genetics (Reverse Genetics)

The study of viruses and their interactions with host cells and organisms has benefited greatly from the ability to engineer specific mutations into viral genomes, a technique known as *reverse genetics* (368). The negative-stranded RNA viruses present a difficult problem because the virion RNA is assembled with an active transcriptase complex for the genome to initiate replication.

The finding that it was possible to isolate an active polymerase complex from influenza virus RNP cores by using CsCl-glycerol gradient centrifugation (121) made it possible to transcribe *in vitro* short synthetic RNA molecules containing the influenza virus 5'- and 3'-terminal nucleotide sequences (254). It was then shown that an artificial gene construct containing the 5'- and 3'-terminal nucleotide sequences flanking a chloramphenicol acetyltransferase (CAT) reporter gene could be replicated *in vivo* in cells infected with a “helper” virus. The artificial CAT gene was replicated and packaged into virions, and it could be passaged several times in cells (204). These important experiments made it possible to introduce mutations into the influenza virus genome (75). This technology was later improved by finding that the efficiency of isolating a virus containing a foreign gene is enhanced if the transcription of the synthetic RNA is performed in the presence of the influenza virus RNA polymerase complex (76) (Fig. 26). The application of a strong selection pressure against the helper virus is needed to isolate progeny virus containing the plasmid DNA-derived RNA segment, and for this reason, the method has been used mainly for analysis of the surface proteins of the virus, because of strong antibody-dependent selection procedures. Several important discoveries pertaining to individual influenza virus proteins, as well as demonstrating the use of influenza virus to serve as a viral expression vector, have been obtained by application of this reverse genetics technology (7,12,85,195,197,222,245,249,261,280,326,401; reviewed in 231 and 256).

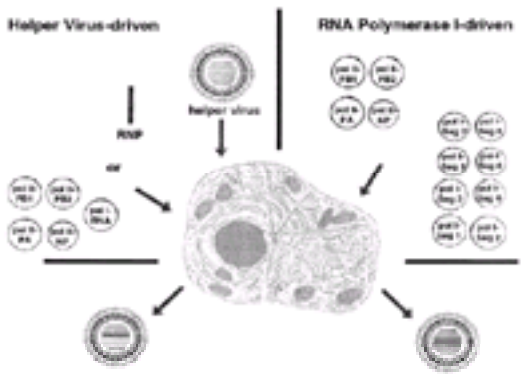

FIG. 26. Influenza virus reverse genetics. The initial replacement of individual RNA segments of influenza virus involved either the *in vitro* reconstitution of vRNPs or *in vivo* assembly of vRNPs after transfection of a cell with plasmids that use pol II promoters driving the expression of the PA, PB1, PB2, and NP proteins, and pol I promoters and terminators controlling viral genome synthesis. Influenza virus rescue entirely from plasmid DNA involves the transfection of plasmids encoding each of the eight RNA segments (under control of the pol I promoter and terminator), four of the proteins that make up the polymerase complex (under control of the pol II promoter) and is aided by, but does not require, the other five viral structural proteins. (Redrawn from ref. 257, with permission.)

Recently, two very similar systems have been established in which helper influenza virus is not needed, making it possible to manipulate every gene in the influenza virus genome (see Fig. 26) (80,232,264). In one system, the host cell is conscripted into making the vRNPs using specific properties of the cellular DNA-dependent RNA polymerase I (pol I) promoter and transcription terminator sequences. The essence of the system is that pol I transcription and termination signals permit the production of artificial influenza virus RNA segments with the same 5'- and 3'-termini as authentic vRNAs. Eight plasmids encoding each of the influenza virus genomic RNA segments under the control of the the pol I promoter and terminator are transfected into cells together with four plasmids encoding the polymerase complex proteins and NP cDNAs under control of an RNA polymerase type II (pol II) promoter (232). In the other system a pol I promoter and aribozyme are used (80,264).

MEANS OF CONTROLLING INFLUENZA VIRUS

Influenza virus causes widespread human disease. In a typical year, influenza virus afflicts 10% -20% of the U.S. population, causing up to 40,000 deaths. During pandemics, a much greater loss of life occurs. The 1918 pandemic was the worse of those pandemic: at least 20 million people died worldwide, many of whom were young adults in the prime of life (56). The reason for the high pathogenicity of this particular virus strain has not yet been ascertained (361). The potential for the reemergence of a highly pathogenic influenza virus strain is exemplified by the sudden appearance of a lethal virus in Hong Kong in 1997, which killed 6 of the 18 infected individuals (46). This virus was transmitted from birds to humans, contrary to the long-held dogma that such a transmission was not possible because the viral receptors on avian cells differ from those on human cells. The spread of infection was controlled because the entire live bird market population in Hong Kong was sacrificed and because the virus did not develop the ability to spread from humans to humans. Usually, influenza virus is readily transmitted from humans to humans by aerosol. For these and other reasons, influenza virus is now considered a dangerous threat as a reemerging viral disease (240).

A detailed description of the means of controlling future influenza virus epidemics is beyond the scope of this chapter. Many reviews of this subject have been published elsewhere (see 35 and 55). Here, we outline a few salient features of the currently employed means of control.

The primary means of controlling influenza virus epidemics at the present time is vaccination (55). The vaccine, which is made up of formaldehyde-fixed virus (killed) or surface glycoproteins (split), has to be reformulated each year because, as discussed previously in this chapter, the viral HA, the protein that elicits the primary neutralizing immune response, usually undergoes changes that render the previous year's vaccine ineffective against the new strain. Each year, the new vaccine takes about 6 months to produce, which is clearly too long to control a fast-moving epidemic. In addition, the 1997 Hong Kong virus demonstrated another difficulty, namely, that it could not be grown in embryonated eggs because it was so pathogenic that it killed the embryos before high levels of virus were produced (338).

In contrast to vaccines, antivirals can be rapidly employed to combat an epidemic, and the efficacy of antiviral therapy against influenza virus has been greatly enhanced because the virus can now be detected at an early time of infection using rapid diagnostic tests (55). Several approaches have been employed to identify compounds that specifically inhibit influenza virus replication. The antiviral drug amantadine (rimantadine) (Fig. 27) exemplifies a compound that was identified by a mass screening empirical approach. As discussed previously, amantadine only inhibits influenza A virus because its target site of action is the M_2 ion channel protein. These drugs have other limitations: they are effective against some, but not all, strains of influenza A viruses; virus mutants that are resistant to these drugs rapidly emerge; and these drugs cause undesirable side effects (e.g., anxiety, lightheadedness, seizures) (55,381).

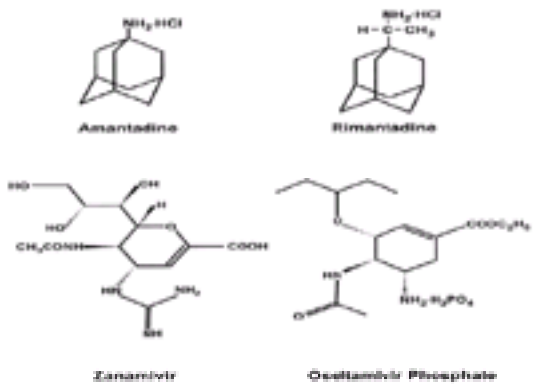

FIG. 27. Influenza virus antiviral compounds. The structures of amantadine, rimantadine (Flumadine), zamanivir (Relenza), and oseltamivir phosphate (Tamiflu) are shown.

Another approach, rational drug design, has been used to devise inhibitors of NA. As discussed previously, the sialic acid–binding site on NA was identified as a large pocket on the surface of each of the four subunits (49). The pocket is lined by amino acids that are invariant in all influenza A and B viruses that have been characterized. The crystal structure indicated that there should be an empty cavity in this pocket when sialic acid is in the pocket, which led to the prediction that substitution of the 4-hydroxyl group of sialic acid with an amino or guanidinyl group would increase the binding interaction of the resulting compound (349). X-ray crystallography confirmed this prediction. Two compounds (4-amino or 4-guanidino 2-deoxy-2,3-didehydro-D- *N*-acetylneuraminic acid) were synthesized, and they were found to be extremely effective inhibitors of NA of both influenza A and B viruses, and these compounds were orders of magnitude less active against an array of nonviral neuraminidases. These compounds, particularly the 4-guanidino derivative (Zanamivir or Relenza; see Fig. 27), inhibit influenza virus plaque formation and virus replication in ferrets (349). This drug has to be administered by nasal spray, and similar rational drug design resulted in another NA inhibitor that can be administered orally, GS4104 (Oseltamivir or Tamiflu) (336; see Fig. 27). Viruses resistant to these NA inhibitors have occurred infrequently *in vitro,* and many appear to map to HA (17,336). However, in the first year of their use (the 1999 to 2000 winter), these two new drugs were not as effective as had been hoped: they shortened the length of influenza virus symptoms by only about 1 day and did not decrease serious complications of influenza virus infections (e.g., pneumonia, hospitalization) (381). Research directed at developing more effective antiviral drugs against influenza virus is continuing.

CHAPTER 47 Orthomyxoviruses

Peter F. Wright and Robert G. Webster

HISTORY

The highly contagious, acute respiratory illness known as influenza appears to have afflicted humans since ancient times. The sudden appearances of respiratory disease that persist for a few weeks and equally suddenly disappear are sufficiently characteristic to permit identification of a number of major epidemics in the distant past. One such epidemic was recorded by Hippocrates in 412 B.C., and numerous episodes were described in the Middle Ages. Historical data from 1500 until 1800 collected by Webster (518) and Hirsch (219) and reviewed by Potter (405) permit us to establish that features included (a) epidemics occurring relatively frequently but at irregular intervals; (b) epidemics varying in severity but usually causing mortality in the elderly; and (c) some epidemics, such as those in 1781 and 1830, appearing to spread across Russia from Asia. There are similarities with this historical picture and our current knowledge of the epidemiology of influenza—recent epidemics have appeared first in China and usually have had the highest mortality in the elderly.

Although influenza has killed untold millions throughout the centuries, the pandemic of 1918 to 1919 was particularly severe. Not only did Spanish influenza, as it was called, kill between 20 and 40 million people worldwide, it also altered the course of history (89). General Erich F.N. Von Ludenddorff, Chief of Staff of the Imperial German Army, blamed the failure of the Marne Offensive not on the influx of fresh American troops, but rather on the diminished strength of the German Army, which he attributed at least in part to influenza. All the armies in Europe were hit hard by this outbreak; in fact, 80% of the U.S. Army's war deaths were due to influenza.

The severity of the pandemic of 1918 to 1919 greatly accelerated the search for the causative agent of influenza. In the

late 1920s, Richard E. Shope (456) showed that swine influenza could be transmitted with filtered mucus, suggesting that the causative agent was a virus. In 1933, a virus was isolated from humans by Wilson Smith, Sir Christopher Andrewes, and Sir Patrick Laidlaw of the National Institute for Medical Research in London, England (466).

Recent retrospective seroepidemiologic analysis, also known as seroarcheology, suggests that the influenza epidemic in humans in 1889 and 1890 was caused by a virus antigenically similar to more contemporary Asian strains (H2N2) (Fig. 1) (345). The epidemic of 1900 may have been caused by a virus with a hemagglutinin similar to the H3N2 pandemic virus of 1968, A/Hong Kong-like strain, but with a neuraminidase like that of the A/Equine/Miami/1/63 strain. An influenza virus (H1N1) similar to those in swine is believed to have caused the catastrophic pandemic in 1918 to 1919 (89). The seroepidemiologic information is supported by sequence analysis of influenza RNA from lung tissue of humans who died at the peak of the pandemic (415,488).

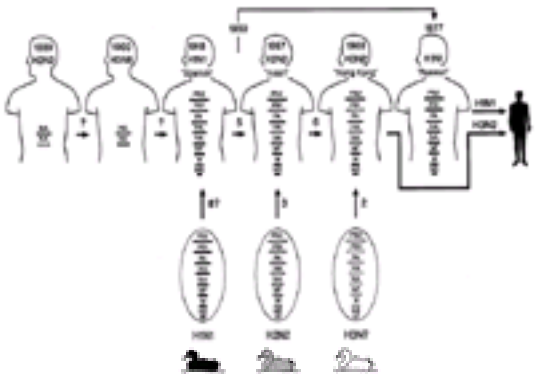

FIG. 1. Postulated evolution of the influenza A viruses currently circulating in humans. Seroarcheology suggests that H2N2 and H3N8 influenza viruses circulated in humans in 1889 and 1900, respectively. Phylogenetic evidence suggests that an influenza virus possessing eight gene segments from avian influenza reservoirs was transmitted to humans and pigs before 1918 and replaced the 1900 strain. This virus was probably carried from North America to Europe by American troops and caused the catastrophic Spanish influenza pandemic of 1918. In 1957 the Asian pandemic virus acquired three genes (PB1, HA, and NA) from the avian influenza gene pool in wild ducks by genetic reassortment and kept five other genes from the circulating human strain (257). After the Asian strain appeared, the H1N1 strains disappeared from humans. In 1968 the Hong Kong pandemic virus acquired two genes (PB1 and HA) from the duck reservoir by reassortment and kept six genes from the virus circulating in humans. After the appearance of the Hong Kong strain, the H2N2 Asian strains were no longer detectable in humans. In 1977 the Russian H1N1 influenza virus that had circulated in humans in 1950 reappeared and spread in children and young adults. This virus probably escaped from a laboratory and has continued to cocirculate with the H3N2 influenza viruses in the human population.

Since 1933, major antigenic shifts have occurred: in 1957 when the H2N2 subtype (Asian influenza) replaced the H1N1 subtype; in 1968 when the Hong Kong (H3N2) virus appeared; and in 1977 when the H1N1 virus reappeared. In 1997 the direct transmission of avian H5N1 influenza viruses to humans (see section on Evolutionary Pathways), with death of six of the 18 infected humans, provided evidence for the role of avian influenza viruses in the emergence of human strains (98,555).

NOMENCLATURE

Influenza viruses belong to the *Orthomyxoviridae* family of RNA viruses and is constituted of four genera: Influenza A virus, Influenza B virus, Influenza C virus, and Thogovirus. Influenza A viruses are subdivided into subtypes, and the current nomenclature system (534) includes the host of origin, geographic location of first isolation, strain number, and year of isolation (Table 1). The antigenic description of the hemagglutinin (HA) and neuraminidase (NA) is given parenthetically [e.g., A/Swine/Iowa/15/30 (H1N1)]. By convention, the host of origin of human strains is not included [e.g., A/Puerto Rico/8/34 (H1N1)]. There are 15 HA and nine NA subtypes; the subtypes differ by 30% or more in amino acid sequence homology (429). No new subtypes have been isolated since 1983, suggesting that there are a finite number of distinct influenza A viruses circulating in aquatic birds.

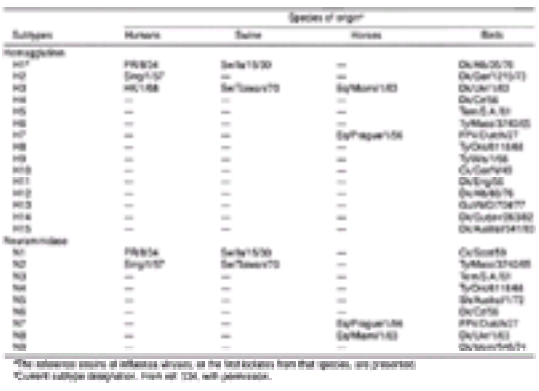

TABLE 1. *Hemagglutinin and neuramindase subtypes of influenza A viruses isolated from humans, lower mammals, and birds*

PROPAGATION

Influenza viruses can be grown in embryonated hens' eggs or in a number of primary tissue-culture systems (for technical details, see 389). Influenza virus was first grown in embryonated eggs (54). Cultivation of influenza viruses in eggs is still the system of choice for vaccine production and for the generation of large quantities of virus used in laboratory studies. Currently, tissue-culture systems [primary monkey kidney and Madin–Darby canine kidney (MDCK) cells] are generally used for the primary isolation of influenza viruses from humans (493). Many, but not all, strains of human influenza A viruses, and most avian influenza viruses, can be isolated directly in the allantoic cavity of embryonated eggs. Some human influenza A and B viruses must first be isolated in the amniotic cavity and subsequently adapted to growth in the allantoic cavity of the chicken embryo. Virus replication in these systems is detected by the ability of an aliquot of culture fluid to agglutinate erythrocytes, suggesting the presence of progeny. On initial passage in eggs, some influenza viruses agglutinate guinea-pig erythrocytes to higher titers than chicken erythrocytes, but on continued passage, the viruses usually agglutinate the latter to higher titers.

Influenza viruses will replicate, cause cytopathology, and produce plaques in a number of primary cell cultures including monkey kidney, calf kidney, hamster kidney, chicken kidney, and primary human respiratory epithelium. However, few cell systems other than primary kidney cells are suitable for plaque formation by influenza viruses unless trypsin is present to activate the HA molecule.

Exceptional viruses produce plaques in chicken embryo fibroblasts without trypsin. Alternative tissue-culture systems used for studies on influenza virus include primary organ cultures (502) and the allantois-on-shell system (133); African green monkey kidney (Vero) cells will support the replication of many influenza A and B viruses (169).

MORPHOLOGY AND NATURE OF THE GENOME

The structure of influenza viruses of types A and B is similar, whereas influenza C reveals a different pattern of surface projections. When examined by electron microscopy, negatively stained preparations of viruses derived from infected eggs or tissue-culture fluids reveal irregularly shaped spherical particles approximately 120 nm in diameter (Fig. 2). In contrast, most influenza virus isolates from humans and other species, after a single passage in culture, show a much greater shape variation, including the presence of greatly elongated forms (70,71). Morphologic examination of primary influenza virus isolates from avian species before passage in culture systems revealed that some strains are predominantly spherical, whereas others are extremely heterogeneous in size with long, filamentous, and bizarrely shaped particles (521). The morphologic characteristics of influenza viruses are a genetic trait (268), but spherical morphology appears to be dominant in passage in chicken embryos or tissue-culture systems. The M gene seems to be a major determinant of this morphologic difference, although the HA and NP genes also may contribute (462).

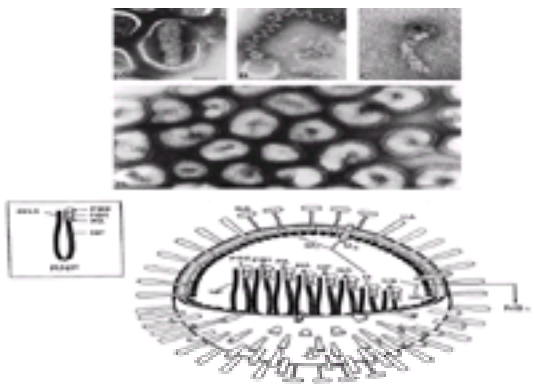

FIG. 2. Structure of influenza virus. Electron micrographs **(top)** and diagram **(bottom)** of influenza virus. **A–C:** The structure of the internal components; **(D)** the external view. A substantial fraction (up to 50%) of influenza virions contain large helical internal components **(A, B)**, which may contain individual ribonucleoprotein (RNP) segments **(C)** linked together. The individual RNPs each contain a binding site for the viral polymerase, as seen by the immunogold labeling of the end of the RNP segment **(C)**. The external view of the virions **(D)** illustrates the pleomorphic appearance and the surface spikes. Bar in all figures equals 50 nm. Courtesy of G. Murti, St. Jude Children's Research Hospital, Memphis, Tennessee. The diagram illustrates the main structural features of the virion. The surface of the particle contains three kinds of spike proteins: the hemagglutinin (HA), neuraminidase (NA), and matrix (M2) protein embedded in a lipid bilayer derived from the host cell and covers the matrix (M1) protein that surrounds the viral core. The ribonucleoprotein complex making up the core consists of at least one of each of the eight single-stranded RNA segments associated with the nucleoprotein (NP) and the three polymerase proteins (PB2, PB1, PA). RNA segments have base pairing between their 3' and 5' ends forming a panhandle. Their organization and the role of NS2 in the virion remain unresolved.

The most striking feature of influenza A and B virions is a layer of spikes projecting radially outward over the surface (357). These surface spikes on influenza A viruses are of two distinct types, corresponding to the HA and NA. The M2 surface component of the virus is present in small numbers and is not found in influenza B strains. Influenza C viruses possess only one type of surface spike, with both HA and esterase activity. On influenza A and B viruses, the HA spike seen by electron microscopy appears rod-shaped, and the NA spike is mushroom-shaped. These differences are seldom, if ever, apparent on intact particles but are revealed after isolation of the proteins after detergent disruption of the virion envelope (549). The HA and NA glycoproteins are attached by short sequences of hydrophobic amino acids to a lipid envelope derived from the plasma membrane of the host cell. Within the lipid envelope lies the matrix protein (M1), which is believed to be structural in function and plays a role in ribonucleoprotein (RNP) nuclear export. Inside the matrix shell are eight single-stranded RNA molecules of negative sense (i.e., the virion RNA is complementary to the messenger

RNA) associated with the nucleocapsid protein (NP) and three large proteins (PB1, PB2, and PA) responsible for RNA replication and transcription. The two virus-coded nonstructural proteins (NS1 and NS2) are found in infected cells.

The organization of the eight single-stranded RNA segments within the virion is still poorly understood. Biochemical and biologic studies support the idea that each RNA segment exists as a distinct ribonucleoprotein complex (82,388), whereas electron microscopic studies have shown that the internal component released from a disrupted influenza virion is a single large helix (8). Genomic RNAs of influenza virus are held in a circular conformation in virions and in infected cells in a terminal panhandle form that might play an important role in replication (229). Up to 50% of virions partially disrupted with Triton X-100 revealed large helical structures (see Fig. 2) (356). These helices also were detectable in spontaneously lysed virions and in thin sections of fixed particles. It is possible that the helices represent the native organization of RNP and that multiple RNPs arise from the degradation of helices. Whether particles with helices are infectious remains to be determined, as does the question as to whether there is a mechanism by which the eight individual RNA segments are packaged or whether this is a random process.

Influenza C virus has only seven RNA segments and contains only one surface glycoprotein (410). Tick-borne viruses (Dhori and Thogoto) are structurally similar to orthomyxoviruses and have six or seven RNA segments. Although the single envelope protein of Dhori virus does not share significant sequence homology with orthomyxoviruses, segments 5 and 6, which presumably code for the nucleoprotein and matrix proteins, respectively, share conserved amino acid sequences with influenza A, B, and C viruses (296,401). These viruses have not yet been given a taxonomic classification. Further information on the nature of the genomes in *Orthomyxoviridae* can be found in the accompanying chapter (see Chapter 46).

EPIDEMIOLOGY AND PATHOGENESIS IN NONHUMAN LOWER ANIMALS AND BIRDS

Influenza A viruses infect swine, horses, seals, and a large variety of birds as well as humans (112). Influenza B viruses infect humans and have been isolated from seals (382). Influenza C virus infects humans, dogs, and swine. Phylogenetic studies of influenza A viruses have revealed species-specific lineages of viral genes and have demonstrated that the prevalence of interspecies transmission depends on the animal species. It also has been revealed that aquatic birds are the source of all influenza viruses in other species, as illustrated in Fig. 3.

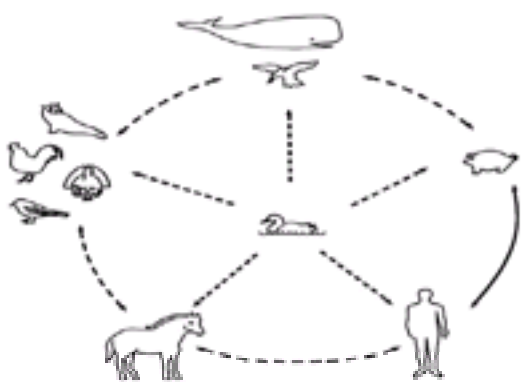

FIG. 3. The reservoir of influenza A viruses. The working hypothesis is that wild aquatic birds are the primordial reservoir of all influenza viruses for avian and mammalian species. Transmission of influenza has been demonstrated between pigs and humans (*solid lines*). There is extensive evidence for transmission between wild ducks and other species, and the five different host groups are based on phylogenetic analysis of the nucleoproteins of a large number of different influenza viruses.

Naturally Occurring Infections

Influenza in Birds

Representatives of each of the known subtypes of influenza A viruses have been isolated from aquatic birds (217). These viruses have been isolated worldwide from both domestic and wild species. The largest number of viruses have been isolated from feral water birds including ducks, geese, terns, shearwaters, and gulls, as well as from a wide range of domestic avian species such as turkeys, chickens, quail, pheasants, geese, and ducks, and less frequently from passerine birds such as starlings (365) and budgerigars (112). The disease signs associated with influenza A virus infections in avian species vary considerably with the strain of virus and species of bird. Infection with most strains of influenza virus are completely asymptomatic. However, a few strains produce systemic infection accompanied by central nervous system (CNS) involvement, with death occurring within 1 week. The viruses that belong in this last category are members of the H5 and H7 subtypes such as A/FPV/Dutch/27 (H7N7) and A/Tern/South Africa/1/61 (H5N3). The most serious problems associated with other influenza A subtypes (H1 through H15) are in turkeys, in which they cause chronic respiratory illnesses. For example, economic losses in a 2-year period in Minnesota exceeded $5 million. Infection in turkeys is thought to be caused by virus strains that are periodically introduced from migrating ducks. Influenza occurs much less frequently in domestic chickens, perhaps because they are housed indoors. However, in 1997, an H5N1 influenza virus gained access to chicken farms in Hong Kong, caused high mortality, and spread to poultry markets and to humans (see later).

In ducks, the majority of avian strains of influenza virus replicate in the lungs and in cells lining the intestinal tract (528). The viruses gain access by passage through the digestive tract of the duck, despite the low pH of the gizzard, and are shed in high concentration in the feces. Influenza A viruses of each of the major subtypes that infect humans (H1N1, H2N2, H3N2) also will replicate in ducks; however, after intranasal administration, these viruses replicate only in the

upper respiratory tract to a limited extent and not in the intestinal tract. Some human strains will replicate to a limited extent in the cloaca if administered rectally.

Studies on wild ducks in Canada from 1975 to 1999 have shown that (a) a high percentage (up to 20%) of juvenile birds are infected with influenza virus when the birds congregate before migration; (b) none of the birds show any symptoms of infection; and (c) many subtypes of influenza virus are enzootic (218). Influenza A viruses have been isolated from water samples collected from lakes in Canada at the time when wild ducks were marshalling before migration. Fecal samples collected from the shores of these lakes also revealed influenza A viruses. The high concentration of duck influenza viruses in fecal material and the isolation of influenza A viruses from lake water offer a logical mechanism for the transmission of avian influenza viruses among feral ducks and to domestic avian and mammalian species. The available information supports the continuous circulation of influenza in migrating waterfowl, with a lower incidence of virus in birds in their overwintering sites in the subtropics.

The avirulent nature of avian influenza infection in ducks may be the result of virus adaptation to this host over many centuries, creating a reservoir that ensures perpetuation of the virus. This speculation strongly suggests that ducks occupy a unique and very important position in the natural history of influenza viruses. Influenza viruses of avian origin have been implicated in outbreaks of influenza in mammals such as seals (523), whales (213), pigs (446), and horses (347), as well as in domestic poultry, especially turkeys.

Influenza in Swine

Swine are susceptible to infection with several different variants of the H1N1 and H3N2 subtypes of influenza A viruses. These include the H1N1 viruses of classic swine influenza, the H1N1 viruses antigenically similar to viruses isolated from avian sources, as well as the H1N1 viruses similar to strains from humans. The H3N2 variants of human influenza viruses also replicate in swine, and reassortants between human swine and avian H1N1 and H3N2 viruses have been detected in pigs (448). Other subtypes isolated from swine include H1N7 and H9N2 (45,393a) but have not established stable lineages.

Influenza in swine was first observed in the United States during the catastrophic 1918 to 1919 human influenza pandemic. The disease signs in pigs, as in humans, are characterized by nasal discharge, coughing, fever, labored breathing, and conjunctivitis (456). The isolation of swine influenza virus [A/swine/Iowa/15/30 (H1N1)] by Shope and retrospective serologic studies on humans indicated that the swine virus was antigenically similar to the type A influenza virus responsible for the human pandemic (345). Analysis of human lung samples from the 1918 Spanish influenza pandemic period by Taubenberger's group (488) established the HA sequence of three 1918 viruses and confirmed the relationship to classic swine influenza virus (415). Since then, swine influenza virus has remained in the swine population, circulating year-round, and responsible for one of the most prevalent respiratory diseases in pigs in North America.

In 1976, swine influenza virus (H1N1) was isolated from military recruits at Fort Dix, one of whom died of pneumonia (164). Antigenically and genetically indistinguishable isolates were subsequently obtained from a man and a pig on the same farm in Wisconsin (214). These studies confirmed the earlier serologic and virus isolation studies that implicated swine viruses in human disease (443). Serologic studies on slaughterhouse workers indicated that transmission of swine influenza viruses to humans occurs quite frequently (up to 20% of workers in 1977 had antibodies to swine influenza virus), but in the recent past, none of these incidents has resulted in an epidemic of disease in humans. However, swine virus occasionally is transmitted to humans and causes respiratory illness (91) and occasionally is lethal (432).

Influenza A viruses of the H3N2 subtype were first isolated from swine in Taiwan by Kundin (278) during an outbreak in humans. Since then, human H3N2 variants have been detected in pigs, usually in serologic studies, for the disease signs are generally mild. In Italy the A/Port Chalmers/1/73 (H3N2) virus established a stable lineage in pigs (64,65), and variants and reassortants containing avian H1N1-like genomes continue to circulate (62). In 1998 two new H3N2 reassortant influenza viruses emerged in American pigs (557). One reassortant [A/swine/Texas/4199-298 (H3N2)] contained the HA, NA, and PB1 genes from 1995 human H3N2 influenza viruses, the NP, M, and NS gene segments from classic swine influenza virus, and the PB2 and PA genes from avian sources. The second reassortant contained the HA, NA, and PB1 gene segments from human H3N2 virus and the remaining genes from classic swine influenza virus. Both reassortants caused respiratory disease and abortion in pigs; serologic surveillance indicates that the first of these [e.g., A/Swine/Texas/4199-298 (H3N2)] has become widespread in pigs in the U.S.

In 1979 an avian H1N1 influenza virus was transmitted to pigs in Europe and established a stable lineage that continues to circulate in pigs throughout Europe (448). H1N2 reassortants containing HA genes related to human H1N1 strains have been detected in pigs in Europe and Japan (44,481), each with different internal genes. Thus reassortant influenza viruses between H1N1 and H3N2 influenza viruses from pigs, humans, and avians are increasingly being detected, and some of these reassortants have been transmitted to and caused typical influenza in children (72). These observations lend support to the hypothesis that pigs may serve as an intermediate host facilitating interspecies transmission and serve as a “mixing vessel” for generation of reassortant viruses (448). The possession of receptors in pigs for both avian (*N*-acetylneuraminic acid, a 2,3 galactose) and human (*N*-acetylneuraminic acid, a 2,6 galactose) influenza viruses (232) again supports this contention. The direct transfer of H5N1 avian influenza viruses to humans in Hong Kong (98) indicates that pigs are not always involved in interspecies transmission but may be involved in adaptation that permits human-to-human transfer. Although the role of pigs in the emergence of human influenza virus is not fully resolved, the available evidence indicates that continued surveillance is important for both human and swine influenza preparedness.

Influenza in Horses

Although influenza virus was not isolated from horses until 1956, there are records indicating that influenza virus probably infected horses centuries ago (49). Two different subtypes of influenza A viruses infect and cause disease in horses, A/Equine/Prague/1/56 (H7N7) and A/Equine/Miami/1/63 (H3N8) (347). The former is commonly known as

equine-1, and the latter, as equine-2. Both viruses produce similar disease signs in horses, but equine-2 infections are usually more severe. The signs of disease include a dry hacking cough, fever, loss of appetite, muscular soreness, and tracheobronchitis. Secondary bacterial pneumonia almost always accompanies equine influenza. The recommendation to horse owners is that all equines recovering from influenza must be rested for 3 weeks after infection (49), or permanent disability can occur. A high incidence of inflammation of the heart muscle (interstitial myocarditis) has been recorded in horses during and after A/Equine/Miami/1/63 (H3N8) (equine-2) infections (155). International transport of horses to competitive events and breeding occurs globally, and the replication of viruses without disease signs in vaccinated horses now plays a part in international virus transmission (347).

Formalin-inactivated vaccines are available, but these vaccines in horses induce immunity that lasts only 3 months (50). The available evidence indicates that the short-lived immunity is a property of the immune response of horses rather than low vaccine potency or genetic drift (346). Antigenic drift is not extensive and thus is probably not the major factor in short-lived immunity to influenza viruses in horses (25,347). Since 1987, equine-2 influenza viruses have evolved into two lineages; isolates from Europe, Mongolia, and China belong to the “Eurasian family,” and those from the U.S. and Argentina to the “American family” (92).

Equine-1 influenza viruses have not been isolated from most countries since 1980, and the possibility has been considered that they are extinct or nearly so (519). However, unconfirmed reports of equine-1 from India and Egypt (231,460) raise the possibility that isolated pockets may still exist. Additionally, antibodies to equine-1 influenza virus have been detected sporadically in horses, either from vaccination or from subclinical infections. In 1989 a new H3N8 influenza virus appeared in horses in Northern China; it derived all of its gene segments from an avian influenza virus (183). This virus initially caused severe respiratory disease, with 20% mortality, but it is unknown whether this variant has established a stable lineage in horses. It is noteworthy that avian influenza viruses are replication competent in equine tracheas without producing disease signs (347), but to date only the H3N8 and H7N7 subtypes have been established in horses.

Influenza in Seals, Whales, and Mink

In 1979 to 1980, approximately 20% of the harbor seal (*Phoca vitulina*) population of the northeast coast of the U.S. died of a severe respiratory infection with consolidation of the lungs typical of primary viral pneumonia (153). Influenza virus particles were found in high concentrations in the lungs and brains of the dead seals. Antigenic and genetic analysis (523) established that this virus derived all its genes from avian influenza viruses and was associated with severe disease in mammals. Biologically, the virus behaved more like a mammalian strain of influenza, replicating to high titers in ferrets, cats, and pigs. In humans, the replication of A/Seal/Massachusetts/1/80 (H7N7) influenza virus is confined to the eyes and causes conjunctivitis. Infected persons recovered without complications, but antibodies to the virus were not detectable in hemagglutination inhibition tests (522), which has since been shown to reflect the inadequacy of this test in the detection of antibodies to avian influenza viruses in mammals (252). In squirrel monkeys, the seal influenza virus replicates in the lungs and nasopharynx after intratracheal administration and in the conjunctiva after administration to the eye (350). In this study, one monkey died of pneumonia, and the seal influenza virus was recovered from the spleen, liver, muscles, and lung, indicating that the virus has the capability for systemic spread in primates. Influenza viruses have subsequently been isolated from seals found dead on the New England coast of the U.S., including H4N5 in 1983, H4N6 in 1991, and H3N2 in 1992 (215).

Influenza A viruses (H13N2 and H13N9) have been isolated from the lungs and hilar nodes of one stranded pilot whale. The relationship between influenza virus infection and stranding remains unknown. Genetic analysis of the H13N9 whale virus has shown that the virus was introduced from birds (213). Influenza A viruses (H1N3) also have been isolated from the lungs and a liver of whales (Balaenopteridae) in the South Pacific (303).

Influenza viruses have been isolated from mink, which together with ferrets, belong to the genus *Mustela* and are naturally susceptible to influenza viruses. These viruses, which were of avian origin (H10N4), caused systemic infection and disease in the mink and spread to contacts (274). Collectively, these findings demonstrate that interspecies transmission of influenza A viruses occurs relatively frequently, mainly from aquatic birds to mammalian species. The epidemics tend to be self-limiting, and the newly introduced viruses are not maintained in animal species such as seals, whales, and mink.

Experimental Infections

Influenza in Mice

Mice are not naturally infected with influenza viruses but can be experimentally infected with both influenza A or B viruses. Newly isolated human influenza A viruses cause an inapparent infection of the upper and lower respiratory tract, where they may replicate to high titer depending on the strain. When large inocula (i.e., titer greater than 1,000 HA units) of non–mouse-adapted influenza viruses are administered, mice develop a toxic pneumonitis even in the absence of significant virus replication (17). Mice are an ideal animal model to study pathogenesis and the immune response to influenza viruses, and the availability of mice with targeted gene disruptions (103) is providing new insights into the molecular basis of virus–host interactions. Thus mice with a targeted defect in the STAT1 gene that are unable to respond to type 1 or type 2 interferons (IFNs) are 100 times more sensitive to lethal infections with A/WSN/33 (H1N1) (151). The clearance of influenza virus by $CD4^+$ T cells is inefficient in the absence of B cells (495). It is becoming apparent that whereas antibody responses are critical for protection from influenza, the various components of the immune response act together to provide optimal protection (419). Mutations in the HA, NP, M, or NS gene segments each can contribute to pneumovirulence of mouse-adapted viruses (43). Histopathologic findings in infected murine pulmonary tissues are similar to the pathologic changes during human infection described elsewhere in this chapter (210). Neonatal mice are more susceptible to lethal pneumonia than are adult animals (81).

The ability of influenza virus to replicate in the CNS of mice has been studied in detail. In adult mice, the intracerebral

administration of non–mouse-adapted human virus initiates an abortive infection of ependymal cells, and a noninflammatory hydrocephalus can result from destruction of ependymal cells (238). In neonatal mice, several cycles of replication can occur with nonneurotropic strains (145). The avian H5N1 influenza viruses that are transmitted to humans also are neurotropic in mice (149). The neurotropic A/WSN/33 (H1N1) virus was isolated by serial passage of the WS strain of H1N1 virus in the brains of mice (477). This virus undergoes multiple cycles of replication in the brains of adult and neonatal animals and causes fatal encephalitis (145). The loss of a glycosylation site at residue 130 of the N1 neuraminidase is required for the neurovirulence phenotype (293). It has been proposed that the binding of plasminogen by the neuraminidase of A/WSN/33 (H1N1) leads to plasmin cleavage of the HA and high pathogenicity (168).

Most strains of mice are susceptible to infection with influenza A viruses. However, the A2G strain of mice is resistant to the neurotropic, hepatotropic, and pneumotropic influenza virus variants (192). The resistant A2G mice carry a dominant allele that specifies an influenza virus–specific increase in sensitivity to IFN (192). The NS1 gene of influenza virus can modulate the induction of IFN and affect the pathogenicity of the virus (151).

Influenza in Ferrets

Human influenza A virus was first isolated in ferrets. They develop a febrile rhinitis after inoculation with throat washings obtained from a symptomatic person (466). Ferrets have proven to be a very permissive host for all influenza A and B viruses. Pathology in the ferret is largely confined to the nasal mucosa, in which the influenza antigen–containing ciliated epithelial cells desquamate and are replaced by antigen-negative cuboidal epithelial cells (465). Infection of the lower respiratory tract can occasionally be demonstrated, and the pathologic changes of bronchitis and pneumonia that occur are similar to those seen in mice and humans (465).

Ferrets have been used extensively to study various aspects of influenza virus biology, largely because they are the only small animal that regularly develops febrile illness when infected with naturally occurring influenza A viruses. Ferrets are used to produce postinfection antisera for the study of antigenic shift in the World Health Organization centers. These animals have been useful in studying the development of immunity to influenza virus infection (16,129,404). The level of attenuation of various strains of virus has been assessed in ferrets (465) and in ferret tracheal organ explant cultures (341).

Influenza in Primates

Influenza A virus can infect many species of Old and New World primates including chimpanzees; gibbons; baboons; and owl, squirrel, cebus, rhesus, African green, patas, cynomolgus, and cercopithecus monkeys (3255, 354). Gibbons, baboons, and chimpanzees can be naturally infected with epidemic human influenza A viruses; the gibbon and baboon develop illness (237). Illness has been observed in squirrel, cebus, cynomolgus, and rhesus monkeys experimentally infected with influenza A virus, but the development of illness requires intratracheal inoculation of virus (55,173). Three human influenza A viruses known to be virulent in humans produce illness in squirrel monkeys, making it possible to evaluate the genetic determinants of virulence of influenza A viruses for primates in this species (351).

EVOLUTIONARY PATHWAYS OF INFLUENZA VIRUSES

Studies on the ecology of influenza viruses have led to the hypothesis that all mammalian influenza viruses are derived from avian influenza reservoirs (520). Support for this theory comes from phylogenetic analyses of nucleic acid sequences of influenza A viruses from a variety of hosts, geographic regions, and virus subtypes.

A surprising discovery from phylogenetic analyses of amino acid changes (Fig. 4) was that avian influenza viruses, unlike mammalian strains, show low evolutionary rates (166). In fact, influenza viruses in wild aquatic birds appear to be in evolutionary stasis, with no evidence of net evolution over the past 60 years. Nucleotide changes have continued to occur at a similar rate in avian and mammalian influenza viruses, but these changes no longer result in amino acid changes in the avian viruses, whereas all eight mammalian influenza gene segments continue to accumulate changes in amino acids. The high level of genetic conservation suggests that avian influenza viruses in their natural reservoirs are approaching or have reached an adaptive optimum, wherein nucleotide changes provide no selective advantage. It also means that the source of genes for pandemic influenza viruses exists phenotypically unchanged in the aquatic bird reservoir.

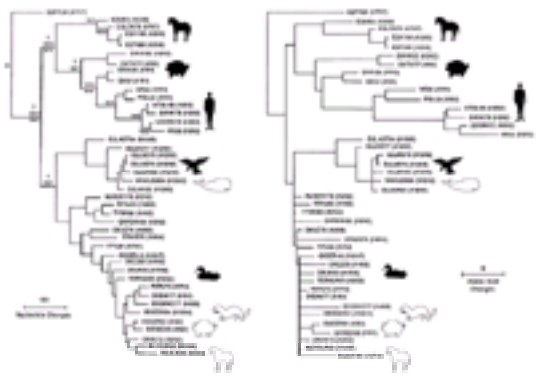

FIG. 4. Phylogenetic trees for 41 influenza A virus NP genes rooted to influenza B virus NP (B/Lee/40). **Left:** Nucleotide tree. Horizontal distance is proportional to the minimal number of nucleotide differences to join nodes and NP sequences. *Vertical lines*, Spacing branches and labels. Animal symbols (*black*) denote the five host-specific lineages. Animal symbols (*white*) denote viruses in that lineage that have been transmitted to other hosts. **Right:** Amino acid tree. A table of abbreviations for virus isolates shown in these trees may be found in Gorman et al. (166)

Phylogenetic analyses of the NP gene show that avian influenza viruses have evolved into five host-specific lineages (see Fig. 4): an ancient equine lineage, which has not been isolated in more than 20 years; a recent equine lineage; a lineage in gulls; one in swine; and one in humans. The human and classic swine viruses have a genetic sister-group relationship, which shows that they evolved from a common origin. It appears that the ancestor of the human and classic swine virus was an intact avian virus that, like the influenza virus currently circulating in pigs in Europe, derived all of its eight genes from avian sources (520). Studies of the NP and other genes in avian species reveal separate sublineages of influenza in Eurasia and the Americas. Studies on the 1918 influenza genome by Taubenberger's group (415) suggested that the precursor of the 1918 pandemic may have circulated in mammals before being transmitted to humans or alternatively may have been derived from a contemporary avian strain.

Influenza A viruses in humans usually evolve along a single-branch lineage, leading to the hypothesis that these viruses evolve by clonal reconstitution after widespread extinction (52). However, detailed analysis shows that some human influenza sublineages can cocirculate for a limited period (86,93), which causes added difficulties in the selection of vaccine strains. In contrast, the B and C viruses exhibit multiple-lineage evolution, which indicates the presence of cocirculating strains within the human population (551). The pattern of epidemiology and evolution of the B and C viruses suggests that they are at or approaching an evolutionary equilibrium with their human hosts, whereas the A viruses of humans are not and are prevented from it by perturbations arising from reassortment of human virus genomes with those from avian viruses.

Overall, the most important implication of phylogenetic studies is that the ancestral viruses that caused Spanish influenza in 1918, as well as the viruses that provided gene segments for the Asian/1957 and Hong Kong/1968 pandemics, are still circulating in wild birds, with few or no mutational changes.

MOLECULAR DETERMINANTS OF HOST RANGE AND PATHOGENESIS

The available evidence indicates that host range and pathogenesis are polygenic traits. Phylogenetic analysis of NP gene segments has established that there are five host-specific lineages and suggests the putative role of NP as one determinant of host range (148). Thus when the NP gene of FPV was replaced by the same gene segment of a human strain [A/Hong Kong/1/68 (H3N2)], the reassortants failed to replicate in chickens or chicken cells but replicated in MDCK cells (449). Similarly, if a human influenza virus NP gene was replaced by an avian counterpart, the reassortants were attenuated in monkeys (490). It has been proposed that the NP is a major determinant of host specificity (447) and that host-specific phosphorylation patterns of NP can affect the replication of influenza viruses (272). The other internal genes of influenza A viruses (PB1, PB2, PA, M1, M2, NS1, and NS2) also may play roles in host discrimination. The involvement of polymerase gene products as determinants of host range/pathogenicity has been demonstrated in a number of studies (9,26,449,450 and 451), and NS gene products have been implicated (151,498).

The HA plays a central role in the pathogenicity of avian influenza viruses (see review, 471). Infection with certain avian influenza viruses possessing the H5 or H7 HA is associated with high mortality in starlings and domestic poultry (365). The HA of these viruses is readily cleaved in tissue culture and does not require an exogenous protease for plaque formation. The virulent H5 and H7 viruses differ from the HAs of other influenza A subtypes in that their HAs possess multiple basic amino acids at the carboxyl terminus of HA_1 (Table 2). This permits cellular proteases that recognize multiple basic amino acids to cleave the HA and to render the virus infectious and capable of spread *in vitro* and *in vivo.* The number of basic amino acids may vary from four to six residues, and cleavability is influenced by the presence of an adjacent oligosaccharide side chain on the HA molecule (see Table 2). The proposed sequence requirement for HA cleavage by endogenous proteases, when carbohydrate is nearby, is X-X-R-X-R/K-R (X, nonbasic residues); otherwise, it is R/K-X-R/K-R (225,380,508). The cleavage enzyme for the HA with multiple basic amino acids appears to be located in the trans-Golgi apparatus, to be calcium dependent, and to have an acidic pH optimum (512).

Table modified from ref. 471, with permission.

A, Absence of a series of basic amino acids, typical of nonpathogenic avian influenza viruses found in aquatic birds in nature; B, presence of a carbohydrate residue in the vicinity of the HA_1-HA_2 cleavage site, blocking activating enzymes (from ref. 257, with permission); C, mutations resulting in loss of carbohydrate residue (from refs. 257 and 380, with permission); D, increases in the length of amino acid sequence at the cleavage site sequence (from refs. 225 and 380, with permission).

TABLE 2. *The cleavage site on the HA is a determinant of pathogenicity*

Two groups of proteases appear responsible for HA cleavage *in vivo.* One includes enzymes able to cleave avirulent as well as virulent HAs, such as plasmin, blood-clotting factor X-like protease, tryptase Clara, and bacterial proteases (273). Of these, tryptase Clara is of particular interest in that it is a product of specialized respiratory epithelial cells and has been isolated from rat lungs and shown to activate avirulent HA cleavage (266) The second group comprises proteases that cleave only virulent-type HAs with multiple basic residues at the cleavage site and include the subtilisin-related endoprotease furin and PC6 (225, 474). Based on the fact that a large number of pathogenic viruses of both H5 and H7 subtypes contain direct repeats that give rise to basic residue insertions of various lengths, and RNA secondary structure predictions, a mechanism for the generation of cleavage site insertion mutants, was proposed (394). It was postulated

that during RNA synthesis from the positive-sense template, the polymerase encounters a region of stable secondary structure at the coding sequence for the cleavage site, which can cause it to stutter.

The receptor specificity of influenza virus HAs depends on the host species from which they evolved. Human H3 viruses bind almost exclusively to sialyloligosaccharides terminated by SAa2,6 galactose, whereas avian and equine H3 viruses preferentially bind SAa2,3 glactose (427). This difference in specificity is tightly associated with the presence, in the structure of the HA receptor-binding site, of Leu-226 in human H3 viruses instead of Gln-226 in avian or equine viruses. H1 viruses isolated from humans after 1977, swine H1 viruses, and human H2 viruses are also preferentially SAa2,6 galactose specific.

The amino acids identified as constituting the heart of the HA receptor-binding site [Tyr-98, Trp-153, His-183, Glu-190, Leu-194, and Gln (Leu)-226] (529) are essentially invariant features of the HA of influenza A viruses. Immediately adjacent, Ser-227 is highly characteristic of duck viruses of all subtypes as well as of human/swine H3 viruses, whereas Ala/Gly-227 is present in the HA of some other mammalian viruses. Gly-228 covaries with Gln-226; as it is conserved in all duck and mammalian viruses except in human/swine H3 HA, which have Leu-226-Ser-227-Ser-228. Substitution of Gln-226-Ser-227-Gly-228 into a human H3 virus permitted virus replication in ducks, whereas substitution of Gln-226-Ser-227-Ser-228 did not (358).

The propagation of influenza viruses in different host cells including chicken embryos or MDCK cells can result in selection of variants with different receptor-binding specificities (146,423). Thus influenza virus grown in chicken embryos selects variants that preferentially bind to SAa2,3 galactose, which can affect the efficiency of vaccines (10,255). Optimally, human vaccines should be grown in cell substrates that favor SAa2,6 galactose–containing influenza viruses, but this would mean changes in vaccine preparation, which conventionally uses the chicken embryo.

There is evidence for a role of influenza virus NA in host-range discrimination and pathogenicity. Recent studies (168) have demonstrated that the A/WSN/33 (H1N1) neuraminidase has the ability to bind plasminogen and that this activity is dependent on the absence of carbohydrate and the presence of a lysine residue at the C-terminus of the NA (293). By concentrating the plasmin precursor at the surface of viral or infected-cell membranes, HA is readily available for cleavage after the generation of activated plasmin. The relevance of this form of cleavage activation of the HA to explain the pathogenicity of human influenza viruses is an interesting possibility, but it remains to be demonstrated whether this mechanism is generally applicable.

Thus pathogenicity and host range are very complex phenomena that can involve a multitude of interrelated determinants, including the properties of individual viral components, the interaction of such components with one another and with elements of the host cell, and immunologic and environmental factors.

INFLUENZA VIRUS GENETICS

Mutational Frequency

The following is a brief description of the genetics of the influenza A viruses, and the reader is referred to other reviews that cover the subject in greater depth (268,445,482).

The mutation frequency for influenza A virus HA and NA genes for any single nucleotide appears to be about $10^{-5.5}$ per replication (527). This rate is similar to that observed for the genes coding for the surface glycoproteins of a paramyxovirus and a rhabdovirus (402). This indicates that the rapid evolution of influenza virus strains in nature cannot be explained by a mutation rate higher than that of viruses that do not undergo rapid antigenic drift. The mutation rate of influenza A virus is nonetheless higher than that observed for bacterial DNA, suggesting that the RNA polymerases of influenza and other animal RNA viruses are less faithful than are DNA polymerases and are not able to correct errors by a proofreading mechanism. Thus although influenza A viruses do not differ in mutation rate from other RNA viruses, mutation occurs often enough to provide an ample source for the selection of naturally occurring variants.

Genetic Reassortment

Exchange of genetic markers between two influenza A viruses was first observed in 1949 during experiments in which an exchange of the HA serotype and neurotropism occurred between two viruses differing in these traits during mixed infection in mouse brain (56). Even before the segmented nature of the influenza A viruses became clearly defined by biochemical techniques, the nature of the genetic interaction between influenza A viruses suggested that influenza virus genes segregated independently (57). It was shown in 1951 that influenza viruses could undergo multiplicity reactivation (206); an influenza A virus whose infectivity had been inactivated by ultraviolet light produced infectious virus when a cell adsorbed two or more irradiated viruses. The first evidence that the gene exchange occurs with high frequency was obtained in 1952 when it was found that reassortant virus composed 27% of the progeny from a cross between two different influenza A viruses (58).

High frequency of reassortment is characteristic of influenza A, B, and C viruses, and the frequency of reassortment at any given locus can be as high as that expected for independently segregating genes [i.e., 50% (491)]. However, exchange of genes between influenza type A, B, or C viruses has not been observed (482). Thus the process of genetic interaction between influenza viruses differs from classic recombination in which breakage, exchange of DNA, and ligation occur. Instead, the exchange of RNA segments between two viruses (Fig. 5) occurs by the process of genetic reassortment in a manner analogous to the exchange of parental chromosomes during meiosis.

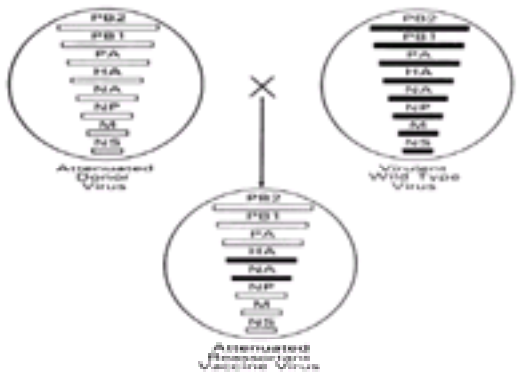

FIG. 5. Production of live attenuated viruses by genetic reassortment between two influenza A viruses by transfer of genes from an attenuated donor virus to a virulent wild-type virus. The attenuated reassortant live vaccine virus contains the genes that code for the hemagglutinin and neuraminidase from the virulent wild-type virus and the genes that confer attenuation from the attenuated donor virus.

With the development of conditional lethal temperature-sensitive (ts) mutants of influenza A virus, the process of gene exchange between influenza A viruses was studied in greater depth. Eight different reassortment groups are defined using ts mutants (307). If there is random reassortment of RNA segments, then linkage between segments should not occur, and this is indeed the case. It has been calculated that if the process were indeed random and the virus packaged any eight segments, then only one in 416 virus particles would receive a full complement of eight different genes (361). However, careful determination of the particle-to-infectivity ratios of four different preparations of influenza A or B virus indicated that one in 10 particles were infectious (107). Hirst (220,221) found that cells yielding reassortant viruses exceeded the expected number of cells doubly infected (calculated from multiplicity of infection, based on plaque formation) by a factor of 30 to 60 and concluded that non–plaque-forming particles are the principal source of viruses that exchange genes during mixed infection. Thus non–plaque-forming, presumably noninfectious virus can enter cells and participate in genetic interactions leading to replication of a full complement of influenza virus genes. Hirst (220) further suggested that because of significant variation in size of individual virions, the amount of RNA per particle could vary and that it could be unevenly distributed such that not every virion received a full complement of eight RNA segments; some particles might contain more than one genome equivalent. The infectivity-to-particle ratio of one to 10 could thus be explained by the packaging of more than eight segments per virion in a substantial number of virions. Alternatively, an unidentified mechanism could exist for precise selection of the full complement of eight segments. The resolution of this question remains an important goal in influenza virus genetic research.

Recombination

Classic recombination in which an influenza RNA segment contains genetic material from two different parental viruses is rare among influenza viruses (428). The gene coding for the NP protein of an influenza A virus was shown to have been produced by intracistronic recombination between the two parental NP genes (428). The viral RNA segment was a mosaic structure with sequences derived from segments 1 and 3. This RNA could have been produced by jumping of the polymerase from one segment to another, rather than by classic recombination (130). An influenza A virus HA gene was shown to contain an insertion of 54 nucleotides, which correspond to a region of host cell 28S ribosomal RNA (265). This occurred presumably by a mechanism of polymerase jumping, and the insertion, which encoded eight amino acids adjacent to the HA_1–HA_2 cleavage site, increased the pathogenicity of the virus for chicken embryos (265).

Complementation

When a cell is infected with two viruses that have defective functions at different loci, complementation can occur between the viruses; the function defective in one virus is provided by the coinfecting virus, and vice versa. After this occurs, infectious reassortant viruses that receive a full complement of eight nondefective genes are replicated. The first step in multiplicity reactivation and cross-reactivation is complementation, which is then followed by reassortment. Complementation between influenza A viruses has been most extensively evaluated between ts mutants under conditions in which mixed infection is carried out at the restrictive temperature (i.e., a temperature at which the ts viruses are unable to replicate). The ts mutants are arranged in complementation groups defined by the ability of two ts viruses to produce infectious virus during coinfection at restrictive temperature. The number of complementation groups so defined exceeds the number of RNA segments of influenza virus, and this finding suggests that intrasegmental complementation has occurred (203,311). Intrasegmental complementation occurs with each of the RNA segments except those coding for the M and HA proteins. Four complementation groups have been identified for RNA segment 8 (NS), which codes for two proteins (455). Thus for the NS ts mutants, it is possible that both intra- and intercistronic complementation occur. Three complementation groups exist for the NP gene, and this represents intracistronic complementation, because the NP gene is monocistronic. It is likely that intracistronic complementation occurs by the formation of a multimeric protein consisting of two defective subunits that are able to correct the defect present in each other. The resulting multimeric protein can function effectively at restrictive temperature and thus has the wild-type phenotype.

Heterozygosis

Heterozygotes are viruses that contain RNA derived from two parents at one or more loci. The suggestion offered previously that some influenza A viruses transiently contain more than eight RNA segments suggests that heterozygote formation might be a common feature of influenza A viruses. Methodologic difficulties make it almost impossible to assess the frequency of transient heterozygotes that form after mixed infection. However, a stable, partial heterozygote has been observed (451). It was suggested that the presence of a recombinant NP gene was functionally related to

heterozygosis (428).

Phenotypic Mixing and Transcapsidation

Infection of cells with two antigenically distinct influenza A viruses gives rise to progeny virus particles that contain HA from both parents (222,223). Such particles are inhibited in hemagglutination-inhibition (HAI) and neutralization assays by antiserum directed against either parent, and are referred to as phenotypically mixed particles. Phenotypically mixed particles can represent up to 84% of all virus progeny (220). Phenotypic mixing occurs between two different influenza A viruses (222), between influenza A and B viruses (167), and between influenza A and heterologous viruses such as Newcastle disease virus and vesicular stomatitis virus (VSV) (170).

Transcapsidation is a process by which the genome of one virus is carried in the coat of another virus. In dual infection of cells with influenza A virus and VSV, virus that contains the VSV genome in an influenza A virus coat composes about 1% of the progeny (433). Trancapsidation occurs between influenza A and B viruses such that 20% of progeny virus displaying only the HA of type B virus possess an HA gene derived from the type A virus (492). The influenza A HA can encapsidate a retroviral genome and extend the host range of the retrovirus (108).

Dominance

Certain influenza strains, including cold-adapted live, attenuated vaccine candidates, have been shown to interfere with the growth of other strains on coinfection (532). This dominance appears to be mediated by the M protein (533). This observation has potential implications for the use of live, attenuated vaccines in the face of an influenza outbreak.

Suppressor Reassortants and Suppressor Mutants

The product of one RNA segment can alter (i.e., suppress) the phenotype specified by a different RNA segment (158,452). In one instance, the ts phenotype specified by the PB2 gene was suppressed by the development of a mutation in the PA gene (494); this is referred to as extragenic suppressor mutation. In extragenic suppressor mutations that modify the ts phenotype of FPV mutants with a ts lesion in the PB2 or PB1 gene, the locus of the suppressor mutation is not known (452). The genetic mechanisms of reversion, extragenic suppressor mutation, and intragenic suppressor mutation were each able to correct a ts mutation in the HA gene (343).

Reverse Genetics

A major advance in the ability to manipulate the genome of influenza viruses occurred when Palese et al. (118,302) established the reverse genetic system, which permits the generation of influenza viruses containing genes derived from cloned cDNA. A further major advance occurred when Kawaoka et al. (366) demonstrated the generation of influenza A viruses entirely from cloned cDNAs with high efficiency. These advances permit complete manipulation of all genes of influenza viruses, and are considered in detail in the accompanying Chapter 46.

EPIDEMIOLOGY IN HUMANS

The influenza viruses are unique among the respiratory tract viruses in that they undergo significant antigenic variation. Both of the surface antigens of the influenza A viruses undergo two types of antigenic variation: antigenic drift and antigenic shift. Antigenic drift involves minor antigenic changes in the HA and NA, whereas shift involves major antigenic changes in these molecules resulting from replacement of the gene segment.

Nature of Antigenic Drift

Antigenic Composition of HA

HA is the major surface antigen of influenza viruses and with the neuraminadases defines the subtype-specific serotype of the virus. The HA from H3 human influenza viruses has been crystallized, and the three-dimensional structure has been determined (see Chapter 46). Five antigenic domains (A to E) have been defined on the HA_1 by comparative sequence analysis (Fig. 6) (413,535). Site A is centered around a protruding loop of residues 140 to 146. Residues 138, 139, 147, and 148 are conserved, thus preserving the structural foundation of the site. Site B, at the extreme membrane distal end of the molecule, is centered on a loop of residues 155 to 160, as well as the a-helix of residues 188 to 198 situated at the edge of the receptor-binding site. Site C is situated at the base of the globular domain in the antiparallel strands of HA_1. Site D is situated near the trimeric interface of the globular domains of HA_1 on the top of the molecule. Site E is near the bottom of the globular distal domain between sites C and A. Antigenic mapping with mouse monoclonal antibodies and sequence analysis of escape mutants confirm the number and location of the antigenic sites in H3 and H1 influenza viruses (156,527). Crystallographic studies of escape mutants have confirmed that antibodies bind to those regions of the molecule where amino acid substitutions permitting escape from neutralization have been found (276).

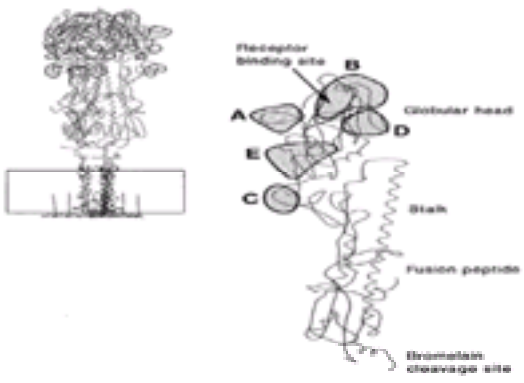

FIG. 6. The hemagglutinin of H3 influenza A virus, showing the location of the five antigenic areas on the globular head of the monomeric and trimeric molecules (535,539). In the HA spike, site *D* is buried and may not be involved in antibody binding. The fusion peptide is also buried in the intact molecule and is exposed only after a conformational change at low pH. The trans-membrane domain of the molecule (**box**) is a hypothetical model illustrating an a-helix, cytoplasmic tails, and palmitic acids.

Drift of HA

After the appearance of a new subtype, antigenic differences between isolates can be detected within a few years by using ferret antisera for analysis (Table 3). Analysis with monoclonal antibodies indicates that minor antigenic heterogeneity is detectable among different influenza virus isolates at any time (383,461,473,524). Antigenic drift occurs by accumulation of a series of point mutations resulting in amino acid substitutions in antigenic sites A to E at the membrane distal region of the HA. These substitutions prevent binding of antibodies induced by the previous infection, and the virus can infect the host. In influenza A viruses of humans and other mammals, antibodies play a role in selection of mutants, whereas in influenza A viruses in avian species and in influenza B and C viruses, antibody selection does not appear to play an important role in emergence of drift variants (4).

TABLE 3. *Antigenic drift of H3N2 viruses between 1968 and 1997 as demonstrated by their cross-reactivity in hemagglutination-inhibition tests*

Antigenic drift can be mimicked in the laboratory by growth of influenza viruses in the presence of monoclonal antibodies to a single antigenic site (e.g., to site A). However, it is not possible to select antigenic variants with mixtures of monoclonal antibodies to different antigenic sites (e.g., to sites A, B, C). The frequency of selection of variants by monoclonal antibodies to a single site *in vitro* is 10^5 (527,553); with a mixture of monoclonal antibodies to two different antigenic sites, the frequency would be 10^{10}. How then does selection of drift variants occur in humans who have polyclonal responses and a mixture of antibodies to each antigenic site? Analyses of postinfection human sera indicate a limited antibody repertoire (516), and studies on animal sera demonstrate that some are essentially monoclonal (101). The reactivity of human sera with monoclonal antibody escape mutants (362) suggests that the selection of variants may be sequential, involving several different humans.

Antigenic Composition of NA

The NA is the second most abundant spike protein on influenza virus, and with the HA, determines serotype specificity. The NA spikes are clustered in patches on the virion surface and are important in virus release from infected cells (357) (for additional information on structure and function see Chapter 46). The majority of the nine subtypes of influenza type A and influenza B NA have been crystallized (489), and the three-dimensional structures have been elucidated and are similar. The antigenic structure of the NA has been determined by comparison of amino acid sequences of naturally occurring variants and by analysis with monoclonal antibodies. At least two antigenic sites on the upper surface of the influenza NA encircle the sialic acid–binding activity and there is probably another on the bottom of the head (Fig. 7) (5). The detailed structure of one of these epitopes on N9 NA was established by crystallization of the Fab fragment of monoclonal antibody (NC41) and comprises five peptide loops located at the rim of the enzyme active site (501). A second epitope has been characterized with monoclonal antibodies on N8 NA and is located at the interface of two adjacent monomers in the tetrameric NA, involving at least two peptide loops on each monomer (residues 150 and 199 on one subunit and at 367, 399, 400 on the other subunit) (437). Antibodies to this epitope react with the NA only after the tetrameric molecule is formed.

FIG. 7. The neuraminidase of influenza A virus, showing the location of the antigenic sites. Schematic diagram of the four identical subunits of N8 neuraminidase viewed from above. The enzyme active center is shown (*asterisk*) surrounded by antigenic sites (*B*). Amino acid substitutions found in different escape mutants are plotted to illustrate that some antibodies combine with individual monomers, whereas others bridge two monomers. The best characterized epitope is NC-41 (*D*), comprising five peptide loops on each monomer adjacent to the enzyme active site (501). Another epitope located at the interface of adjacent monomers (*A, C*) involves at least two peptide loops in each monomer (437). Note that some peptide loops are involved in both epitopes (e.g., loop containing residue 367). N8 diagram courtesy of G. Taylor, University of St. Andrews, Scotland.

The interaction of antibodies with NA has been elucidated for monoclonal antibodies NC10 and NC41 in combination with N9 NA (308). The epitopes recognized by these monoclonal antibodies overlap. The surface areas on NA buried by interaction with the NC10 and NC41 antibodies are 716 $Å^2$ and 899 $Å^2$, respectively, and the buried surface areas contributed by the residues common to both epitopes are 594 $Å^2$ (83% of total) and 686 $Å^2$ (77% of total), respectively. The NC10 binding site is somewhat farther from the NA active site, consistent with observations that NC41 antibody can inhibit enzyme activity on trisaccharide substrates, but NC10 has inhibitory activity only against macromolecular substrates. Thus two different antibodies can combine with portions of the same epitope and show different biologic activities.

Other epitopes on the NA are at distant sites from the enzyme active center, o not include antibodies that select escape mutants, and remain to be fully characterized. One of these appears to be on the bottom of the head; it is difficult to imagine how antibody could gain access to this site on the virion unless the NA head is presented sideways on the virion.

Drift in NA

Antigenic drift also occurs in the NA of influenza viruses (90,390) and has been correlated with differences in amino acid sequences (80). The mechanism of antigenic drift in the NA of human influenza viruses is believed to be the same as for the HA. The process can be mimicked with monoclonal antibodies *in vitro,* and the frequency of selection of variants is approximately 10^5 (525).

Nature of Antigenic Shift

Since the first human influenza virus was isolated in 1933, antigenic shifts in type A influenza viruses have occurred in 1957, when the H2N2 subtype (Asian influenza) replaced the H1N1 subtype; in 1968, when the Hong Kong (H3N2) virus appeared, replacing H2N2; and in 1977, when the H1N1 virus reappeared (see Fig. 1). Each of these major antigenic shifts has several characteristics in common: (a) their appearance was sudden; (b) they first occurred in China; (c) they were antigenically distinct from the influenza viruses then circulating in humans; and (d) they were confined to the H1, H2, and H3 subtypes.

On the basis of phylogenetic evidence, a likely explanation for the appearance of new pandemic strains in humans is that they are derived from avian influenza viruses, either after reassortment with the currently circulating human strain or by direct transfer. There is ample evidence for genetic reassortment between human and animal influenza A viruses *in vivo* (520), and genetic reassortment also has been detected among human viruses (87). Genetic and biochemical studies have concluded that the 1957 and 1968 strains arose by genetic reassortment. As described earlier, the 1957 Asian H2N2 strain obtained its HA, NA, and PB1 genes from an avian virus and the remaining five genes from the preceding human H1N1 strain (257,450).

A new pandemic strain that emerged in Hong Kong in 1968 contained the H3 HA and PB1 genes from an avian donor (126,257) and the N2 NA and five other genes from the H2N2 strain circulating in early 1968. The HA of the human Hong Kong/68 strain differed by only seven amino acids from hypothetical Asian avian H3 strains (25), providing the strongest evidence yet that the Hong Kong virus originated by reassortment between an avian influenza virus present in Asia and the circulating human strain.

The second way that new pandemic viruses could occur in the human population would be if an avian or mammalian strain were transmitted to humans. The transmission of H5N1 and H9N2 influenza viruses to humans in Hong Kong establishes that this can occur (see later section, Transmission of Avian Influenza Viruses to Humans). Phylogenetic evidence favors this mechanism for the appearance of the Spanish influenza virus in 1918. The periodic transmission of swine influenza viruses to humans that presumably occurred at Fort Dix and the isolation of virtually identical viruses from pigs and humans (432) leave no doubt that such transmissions occur in nature and may be more frequent than originally thought. Most of these transmissions are dead-end transmissions, in that the viruses have little or no capacity to be transmitted secondarily to human contacts and initiate an epidemic. However, the disastrous pandemic virus of

1918 to 1919 did possess this property.

A third explanation for the origin of pandemic viruses is that virus that caused an epidemic many years previously remained hidden and unchanged in some place since that time. The appearance of Russian influenza (H1N1) provided support for this concept. This virus appeared in Anshan, northern China, in May of 1977 and subsequently spread to the rest of the world; it is identical in all genes to the virus that caused a human influenza epidemic in 1950 (360). Where was this virus for 27 years? The possible explanations include preservation in a frozen state, preservation in an animal reservoir, or retention in an integrated, as yet undetected form in the genetic material of a human or lower animal. The animal-reservoir option is unlikely, for the accumulation of mutations would have continued. There is no evidence for integration of influenza genetic material into the host genome, leaving the most likely explanation that in 1977, the H1N1 virus was reintroduced to humans from a frozen source.

From this discussion, it is apparent that there are multiple ways in which pandemic influenza viruses can arise, and each has probably played a role in the evolution of the influenza viruses currently circulating in humans. The primordial source of all influenza virus genes is from the aquatic bird reservoir, and many mutations and reassortments occur during adaptation to the human host.

Transmission of Avian Influenza Viruses to Humans

Although serologic studies (457,555) and the isolation of H7N7 influenza viruses from the eyes of humans with conjunctivitis (279,522) support the notion that avian influenza viruses could be transmitted to humans, it was the transmission of H5N1 influenza viruses to humans in 1997 that confirmed the direct transmission of avian influenza to humans apparently without an intermediate host. The avian H5N1 influenza virus that was transmitted to poultry and humans in 1997 caused high mortality in both species, killing 70% to 100% of chickens and six of 18 humans (73,98,478,479,555) and is unusual in having a large proportion of amino acid changes in all gene products except in the surface genes (558). It was therefore proposed that this H5N1 influenza virus might be a reassortant possessing the HA from A/goose/Guandang/1/96 (H5N1) (550) and the other gene segments from H6N1 or H9N2 viruses (Fig. 8) (177,224).

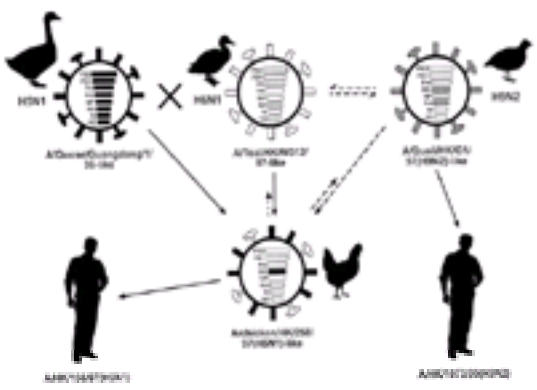

FIG. 8. The emergence of avian H5N1 and H9N2 influenza viruses that were transmitted to humans in Hong Kong. The avian H5N1 and H9N2 influenza viruses that were transmitted to humans in 1997 and 1999 contained the same six genes composing their replicative complex. The source of these six genes is from either a duck virus [A/teal/HK/W312/97(H6N1)-like] or a quail virus [A/quail/HK/G1/97(H9N2)-like] (177,224). The donor of the hemagglutinin in the A/HK/156/97(H5N1)-like viruses that killed six of 18 infected persons was probably a goose virus [A/goose/Guangdong/1/96/(H5N1)] (550). The H9N2 virus that was transmitted to two children in Hong Kong was identical in all gene segments to A/quail/HK/G1/97 (H9N2).

Surveillance studies in the live poultry markets in Hong Kong in December of 1997 revealed the presence of nearly identical highly pathogenic H5N1 virus in 20% of birds and in the majority of live poultry markets tested. In addition, H9N2 influenza virus was present in approximately 5% of birds. Two antigenically and genetically distinguishable variants of H5N1 were circulating among avians and humans (29,458,478). There was no correlation between lethality in humans and one or other of the variants. Both H5N1 variants were highly pathogenic in chickens, causing generalized systemic infection and, like the viruses from the index case, possessed a polybasic amino acid insertion at the cleavage site of the HA. They also contained a shortened stalk of the NA. It has been proposed that NA stalk deletions are a characteristic of pathogenic H5 and H7 viruses (312).

The majority of human and chicken H5N1 influenza viruses were highly pathogenic in mice, requiring no adaptation and spread after intranasal infection to the brain. A subgroup of the human and avian H5N1 viruses were nonpathogenic in mice (149,253,458). The slaughter of approximately 1.6 million poultry in Hong Kong on December 29 and 30, 1997, stopped the spread of H5N1 influenza viruses to humans. The failure of H5N1 to be transmitted from human to human, and the slaughter of poultry a matter of days before the human A/Sydney/05/95 (H3N2) strain began circulating in humans in Hong Kong probably prevented the generation of reassortants.

The H9N2 detected in the live poultry market in 1997 were genetically heterogenous with three serologically and genetically distinguishable groups (177). These H9N2 viruses were by definition not pathogenic in chickens in laboratory studies (they did not possess polybasic amino acids at the cleavage site of the HA and did not kill six of eight chickens after intravenous injection), but in the field, they caused respiratory problems, a decrease in egg production, and one isolate killed up to 80% of chickens. In 1998 through 1999, H9N2 influenza viruses was transmitted to humans and pigs. The initial report of five human cases in southern China (184) was confirmed by the isolation of H9N2 viruses from two children in March 1999 in Hong Kong (297). The children had typical influenza and recovered; the isolates were genetically similar to H9N2 isolates from quail [A/quail/Hong Kong/G1/97 (H9N2)] (see Fig. 8). The viruses isolated from

apparently healthy pigs during surveillance in the slaughterhouse in Hong Kong belonged to the H9N2 virus from ducks [A/duck/Hong Kong/Y280/97 (N9N2)]. Further characterization of the H9N2 viruses revealed that the human isolates from Hong Kong and the quail isolates (A/quail/Hong Kong/G1/97) shared the replicative gene complex (PB2, PB1, PA, NP, M, NS) with the H5N1-like viruses from chickens and humans in Hong Kong in 1997 (177), whereas the pig isolates contained the genome similar to A/duck/Hong Kong/Y280/98 (N9N2). Thus avian influenza viruses can be transmitted directly to humans and cause disease, but additional mutations and/or reassortant events are probably required to permit efficient human-to-human spread.

Maintenance of Influenza A Virus in Human Populations

There is no evidence of persistent or latent infection with human influenza viruses. The virus is maintained in humans by direct person-to-person spread during acute infection. Isolated communities become infected by the introduction of virus by an infected individual, often resulting in an explosive localized epidemic. Subsequent epidemics in such isolated communities are initiated by reintroduction of virus (46). Influenza virus activity can be detected in a large city during each month of the year, although each subsequent epidemic is likely from exogenous introduction of virus, as typified by the circulation of a limited number of strains globally each year (137,243,271,374,395). The minimal population size necessary to sustain influenza virus transmission during nonepidemic periods is unknown. On a global scale, influenza viruses are isolated from humans during most months of the year somewhere in the world (374). In the U.S., influenza virus epidemics generally occur during January through April, with occasional epidemics in December or May (374). One biologic property of the virus that could contribute to this seasonal distribution is the ability of influenza A viruses to survive in aerosol under the condition of low relative humidity that exists indoors during the winter months (204,439).

Transmission of Influenza Between Humans

Epidemiologic observations indicate that influenza A virus is most effectively spread from person to person by the aerosol route (319,339). It is probable that most influenza A virus infections are transmitted by droplets formed during coughing or sneezing. A high proportion of particles generated during a sneeze or cough are less than 2 μm in diameter; particles of this size are preferentially deposited in the lower airways of the lung (275). Infection of volunteers can best be achieved by aerosol administration of virus (6,109). The human infectious dose 50 (HID_{50}) of influenza A wild-type virus administered intranasally by drops is 127 to 320 tissue culture infectious dose 50s ($TCID_{50}$) (84,85), and that of virus delivered by an aerosol is 0.6 to 3 $TCID_{50}$ (6).

Preschool and school-age children are major vectors in transmission of influenza A viruses in the community (136,189,335,336). After introduction of the Asian influenza A virus (H2N2) in 1957 and the Hong Kong virus (H3N2) in 1968, epidemics occurred soon after school opened in September and October (242,374). Clearly, crowding that occurs in schools favors the rapid spread of virus by aerosol transmission of virus (69). The incubation period for influenza viruses is about 3 days for influenza A virus and 4 days for influenza B viruses (139).

The virus, host, and environmental factors that limit the size of an influenza virus epidemic have not been clearly delineated. One indicator that epidemics might occur the next winter is isolation of a virus with an altered hemagglutinin in the late spring during a miniepidemic (herald wave) (338). Such herald waves can precede both influenza A and B epidemics.

The immunologic status of the population as reflected in seroprevalence of antibody influences the size of an epidemic and which age is affected. This was seen in 1957, when a pandemic was caused by an H2N2 virus to which the vast majority of the population was fully susceptible (i.e., they had not had previous experience with influenza A viruses bearing a related HA or NA) (Fig. 9). During 1968, the first year of spread of the Hong Kong (H3N2) virus, excess mortality was about one half that caused by the H2N2 virus during its first year of prevalence. This dampening of the first H3N2 epidemic may have been a consequence of partial immunity induced by prior infection with H2N2 viruses that possessed a related NA antigen. Furthermore, the size of epidemics occurring during interpandemic periods are always smaller than those occurring during the introduction of a new virus subtype, although their cumulative mortality may exceed that of the rarer pandemics.

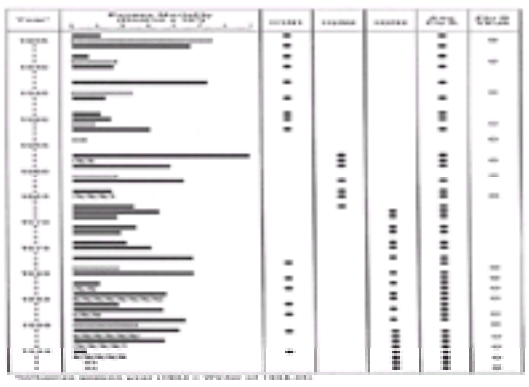

FIG. 9. Excess mortality caused by influenza A and B viruses (1934–1998). *1935*, Winter of 1934 through 1935. The excess mortality figures that are depicted use two sets of data with slightly different methods for their calculation (374,459). ■, Excess mortality predominantly caused by influenza A virus; ■, excess mortality caused by influenza B virus; ▨, excess mortality occurring during a year of mixed circulation of influenza A and B viruses.

There is no regular periodicity in the occurrence of epidemics (see Fig. 9), indicating that the appearance of an epidemic in any given year represents a subtle interplay between intrinsic properties of the virus, the extent of antigenic drift of the

virus, and the waning immunity in the population (93). During 9 of the 22 years of circulation of H1N1 virus from 1934 to 1956, there were epidemics associated with excess mortality. During years when H2N2 or H3N2 viruses were the sole influenza A viruses circulating, excess mortality occurred in 64% and 80% of years, respectively.

The temporal curves of individual influenza virus epidemics are similar. Seeding of a community with virus is followed by a relatively sharp, single peak of virus activity, as indicated by school and industrial absenteeism and, slightly later, excess mortality (374). Exceptions to this pattern were observed in 1918 and 1957, in which introduction of a pandemic virus was followed by two waves of epidemic activity within 1 year (242,374,514).

Morbidity

Influenza viruses have a major impact on morbidity, with increases in hospitalizations and visits to health care providers. With large databases, the morbidity has recently been defined in children (367), in women of all ages with high-risk conditions (368), and in pregnant women (369). In the elderly, who remain the group at highest risk, the impact of influenza has been shown to extend beyond influenza and pneumonia illnesses to all acute and chronic respiratory conditions and to congestive heart failure (371). Hospitalization due to influenza A virus infection averaged over 8 years (1970 to 1978, which did not include a pandemic year) were 1 per 2,900 for the 1- to 44-year-old age group, 1 per 1,100 for the 45- to 64-year-old age group, and 1 per 270 for those older than 65 years (18,20). High rates of hospitalization also are observed in children younger than 5 years, with the highest rates in children being in those younger than 1 year (396). The observation that 14% to 16% of children seeking medical care for febrile respiratory illness are infected by influenza virus indicates influenza's contribution to outpatient morbidity (163,548).

The major factor that diminishes morbidity after exposure to influenza A virus is the level of preexisting immunity from past exposure, through vaccination or natural infection, to viruses bearing related surface glycoproteins. The more severe illness seen in naive individuals explains the high morbidity seen in infants and young children undergoing first infection (396) and the high morbidity seen in all age groups after the introduction of new pandemic viruses such as in 1918 (H1N1), 1957 (H2N2), and 1968 (H3N2) (242).

Another factor that appears to contribute independently to morbidity is age at the time of infection. Regardless of the level of antibody to the HA, infections in young adults are more often asymptomatic than are those in children (102,136,160,335). In the elderly, influenza poses special risks of debilitating illness (19). It is important to emphasize that infection rates and attack rates reflect the delicate interplay between immunity in the population and the relative virulence of the virus and can thus vary greatly after introduction of an influenza virus into a population (69,136,160,243,418). Immunity to influenza viruses is incomplete, and morbidity can occur after reinfection with the same or with a drift strain (96,97,136,141,142,467). However, the morbidity after reinfection is usually less than that after first infection (96,97,160,467). Significant morbidity and mortality with influenza A viruses can occur during nosocomial spread of infection (152,186).

The economic impact of influenza A virus infection is considerable (256). The estimated total cost (direct and indirect) of each of three different epidemics varied from $1 to 3 billion depending on the size of the epidemic (256).

Mortality

Influenza virus is uniquely important among respiratory viruses as a cause of excess mortality. During the period from 1934 to 1990, influenza B virus was associated with excess mortality in 16 (26%) of 63 years examined, whereas excess mortality associated with influenza A virus was seen in 38 (60%) of 63 years (see Fig. 9). A recent article has created a severity index for judging the impact of influenza epidemics (459). The authors found that epidemics associated with the circulation of influenza A H3N2 viruses have higher mortality than do those seen with H1N1 or B strains. Their estimate of the total mortality attributable to influenza in the U.S. for the 20-year period from 1972 to 1992 was 426,000 deaths, but in some years, influenza B infections can be a serious problem (e.g., 1990).

Although morbidity with influenza A virus is concentrated in people younger than 20 years, the highest rates of excess mortality occur in persons older than 65 years (22,94,117,469). However, excess mortality is seen in all ages (94). During the 1918 epidemic, the excess mortality rate was extremely high in young adults, as well as in those older than 65 years, but this pattern has not been seen since (374). Various underlying medical conditions place an individual at high risk for serious consequences of influenza virus infections. These conditions include cardiovascular disease, pulmonary disease, metabolic disease, neoplastic disease, and pregnancy (20,21,171,369). The highest risk for pneumonia is seen in those older than 65 years who have both a cardiovascular and pulmonary condition (22). Mortality due to influenza is not confined to the bedridden, because up to 50% of all deaths occurred in people who were chronically ill but medically stable and functioning independently (19). The average yearly rate of death due to influenza A virus infection is 1 per 2,200 adults 65 years or older (7). For a pandemic year (1957 to 1958) in which the excess mortality totaled 70,000 persons, 1 in 300 of adults older than 65 years died of influenza infection. Although excess mortality is highest during the first year of circulation of a new subtype, cumulative interpandemic mortality significantly exceeds that caused during the first year (374,459).

Strain Differences in Virulence

Although there has been remarkable similarity in the clinical manifestation of influenza A viruses belonging to different subtypes (95,109,476), some differences between virus strains are suggested by their epidemic behavior (271,514,547). In a prospective long-term study of urban children, H3N2 viruses were more frequently associated with croup than were H2N2 strains (271). The H1N1 virus that caused the 1918 epidemic was associated with very high mortality in young adults, an age group that was not at high risk for mortality in subsequent H1N1, H2N2, or H3N2 epidemics (512). Host, viral, and/or environmental factors that contributed to this unusual pattern have not been identified. Furthermore, encephalitis lethargica is epidemiologically associated only with the H1N1 viruses in 1918 and years immediately thereafter (412). In comparison to H3N2 viruses, H1N1 viruses, when reintroduced in 1977, caused relatively mild illness

in most but not all investigational outbreaks in susceptible children and young adults (141,159,400,547).

PATHOGENESIS IN HUMANS

Pattern of Virus Shedding

Influenza virus replicates throughout the respiratory tract, with virus being recoverable from the upper and lower tracts of people naturally or experimentally infected with virus. The pattern of virus replication in six adult volunteers administered an influenza A/HK/68-like H3N2 virus, in relation to the onset of clinical symptoms, IFN response, and serum and nasal wash antibody responses, is presented in Fig. 10) (420). Virus replication peaks at about 48 hours after inoculation and declines somewhat slowly thereafter, with little shedding after days 6 to 8. Peak virus titers in symptomatic volunteers range from $10^{3.0}$ to $10^{7.0}$ $TCID_{50}$/mL of nasopharyngeal wash (349), with a positive correlation between the amount of virus shedding and the severity of the clinical response. Individuals who shed less than $10^{3.0}$ $TCID_{50}$/mL are either asymptomatic or have only minor upper respiratory tract symptoms. Even after infectious virus can no longer be recovered, viral antigen can be detected for several days in cells and secretions of infected individuals (33,113,487). In children naturally infected with influenza viruses, virus is most frequently recovered 1 to 2 days after the onset of symptoms and can be found for up to 13 days thereafter (143). The peak titer is achieved on the first day of illness and averages $10^{4.0}$ $TCID_{50}$/mL of nasal wash (188).

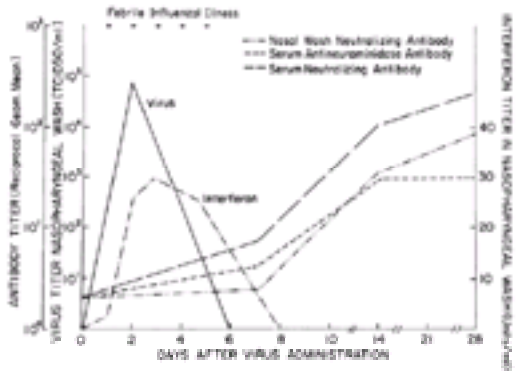

FIG. 10. Six seronegative volunteers received $10^{4.0}$ $TCID_{50}$ of wild-type A/Bethesda/1015/68 virus intranasally on day 0. From ref. 149, with permission.

Pathology

Influenza A virus induces pathologic changes throughout the respiratory tract, but the most significant pathology is present in the lower respiratory tract (207,208,209 and 210,513). During bronchoscopy of persons with uncomplicated influenza infections, acute diffuse inflammation of the larynx, trachea, and bronchi were observed with mucosal inflammation and edema. Light-microscopic studies of infected cells revealed that the columnar ciliated cells become vacuolated, edematous, and lose cilia before being desquamated. Within 1 day after the onset of symptoms, desquamation of the ciliated and mucus-producing epithelial cells down to a one-cell-thick basal layer is observed; in other areas, the thickened and hyalinized basement membrane is exposed. Submucosal edema and hyperemia occur with an infiltration by neutrophils and mononuclear cells (310). Viral antigen is present predominantly in epithelial cells and mononuclear cells, but is infrequently found in the basal cell layer (344). In a more severe primary viral pneumonia, there is an interstitial pneumonitis with marked hyperemia and broadening of the alveolar walls, with a predominantly mononuclear leukocyte infiltration and capillary dilation and thrombosis. The alveolar walls become denuded of epithelium; intraalveolar edema and exudate are present; hyaline membranes cover alveolar walls; and intraalveolar hemorrhage occurs. Influenza virus–specific antigen is present in type 1 and 2 alveolar epithelial cells, as well as in intraalveolar macrophages (344). Necrotizing changes may occur with rupture of walls of alveoli and bronchioles. Influenza virus has been obtained from lungs at autopsy in titers of $10^{2.0}$ to $10^{5.7}$ 50% egg infectious doses per gram of tissue (300).

At a cellular level, influenza virus shuts off cell protein synthesis and induces apoptosis as an additional means of cell destruction (216). From the third to fifth day after onset of illness, mitoses appear in the basal cell layer, and regeneration of the epithelium begins. During this time, reparative and destructive processes may be present simultaneously. Complete resolution of the epithelial necrosis probably takes up to a month, because pulmonary-function abnormalities persist beyond the period of symptomatic recovery from the acute phase (190).

Immune Response to Infection

Innate Immune Response

Human influenza viruses replicate exclusively in superficial cells of the respiratory tract. They are released from the apical surface of the cell, which may limit more systemic spread but facilitate accumulation of virus in the lumen of the respiratory tract for transmission to the next susceptible host (37). The apical release of virus raises not yet explored questions of how antigen recognition and modulation of infection by antibody may occur. The extremely short incubation period between infection and clinical illness implies that innate immunity or preformed cognate recognition components are important.

The respiratory tract has a series of protective mechanisms against influenza infection, including the mucin layer, ciliary

action, and protease inhibitors that may prevent effective cell entry and virus uncoating. Once the epithelial cell is infected, proinflammatory cytokines, notably interleukin-6 (IL-6) and IFN-a, are induced and released from these cells. These cytokines reach their peak by day 2 after experimental infection (199). These two cytokines correspond in their release with the highest clinical symptom score, mucus production, fever, and viral load. Other cytokines either appeared later [IL-8 and tumor necrosis factor-a (TNF-a), or did not increase IL-b, IL-2, or TGF-b in the respiratory secretions or serum. The importance of IFN in regulation of influenza replication is suggested by the observation that the NS-1 protein is an IFN antagonist. Deletion of NS-1 leads to increased induction of IFN and a virus that is highly attenuated, except in a mouse with an interruption in the IFN-induction pathway (151). It is generally believed that IFN contributes to recovery from infection, and the early cytokine pattern directs the immune response toward a Th1 pattern (150).

A transient increase in natural killer cell activity occurs after influenza infection (121,292).

Cognate Immune Response

Humoral Immunity

In 80% of naturally acquired human infections, a serum antibody response can be documented (136). After primary infection, HA-specific antibodies of IgG, IgA, and IgM isotypes are detected, whereas in the secondary response, IgG and IgA antibodies predominate (47,349). B cells producing influenza virus–specific IgG, IgA, and IgM antibodies are present in the peripheral blood of normal individuals and of individuals undergoing infection with an influenza A virus (59,552). Serum antibody plays a role in resistance to or recovery from influenza illness in humans. A protective effect of transplacentally acquired antibody has been inferred from the observation that a significant direct correlation exists between age at the time of symptomatic influenza A virus infection in infants and level of maternally transmitted antibody measured in cord serum (408).

During infection of humans with influenza A virus, antibodies to the HA, NA, NP, and M proteins are produced (88,403). Antibodies to the HA and NA glycoproteins are associated with resistance to infection and/or illness in humans and in laboratory animals, whereas antibodies to the internal M1 and NP proteins are not (12). Passively transferred monoclonal antibody to the M2 protein is protective in mice, and M2 antibodies develop in humans infected with influenza A viruses (36,499). A universal influenza A vaccine has been proposed based on the extracellular domain of the M2 protein (364). Studies of vaccinia recombinant viruses expressing each of 10 gene products of the influenza A virus clearly identified the HA and NA glycoproteins as primary protective antigens, and the primary mediators of the resistance to virus challenge induced by these glycoproteins were antibodies (123). Because of the importance of antibodies to the surface glycoproteins in resistance to infection, only the antibody response to these proteins is discussed further. The reader is referred to four reviews that have considered immunity to influenza virus infection in detail (12,85,349,403).

The level of serum antibody to the HA and NA correlates with resistance to illness and with restriction of the influenza virus replication in the respiratory tract of humans (76,352). This has been shown after experimental infection with influenza virus (76) or after natural infection (85). HA antibodies can prevent infection by neutralizing the infectivity of the virus (509), whereas NA antibodies mediate their antiviral effect primarily after infection has been initiated by restricting spread of virus within the respiratory tract of the host (453).

It was previously thought that $CD8^+$ T cells were solely responsible for clearance of virus during primary infection or during reinfection. However, it has been demonstrated that passively transferred antibodies can clear an influenza A virus infection in the absence of B or T cells in the host (442).

Although immunity mediated by infection can be long lived, reinfection with antigenetically closely related influenza A viruses occurs, indicating that immunity against this highly infectious virus induced by a single infection can be incomplete (141,142,467). Two mechanisms have been identified that can contribute to this incomplete immunity. First, there is a gradual diminution in the total amount of serum (IgG), local IgA antibodies, or antibody-secreting cells within the first year after the first infection (239,240,545). Second, after infection with a new influenza virus subtype, antibodies are generated that react with only a limited number of antigenic sites on the HA glycoprotein, whereas after several infections, antibodies are generated that have a broad range of specificities (516). Consistent with this is the greater degree of resistance to infection with antigenic drift strains in humans previously infected twice with prototype virus than in those with only one previous infection (97).

Cellular Immunity

The role of cellular immunity in clearance of influenza virus has been well defined in the murine model but less well in humans (251). There are two subsets of effector lymphocytes in humans. The first subset consists of cells that mediate cytoxicity that is restricted by class I histocompatibility antigens and has the $CD8^+$ phenotype. These cytotoxic lymphocytes (CTLs) appear in the blood of infected or vaccinated individuals on days 6 to 14 and disappear by day 21 (122). Most studies have examined memory CTLs, which are detected *in vitro* by stimulation of peripheral blood lymphocytes with antigen. These CTLs exhibit a cross-reactive pattern of virus specificity (i.e., they lyse target cells infected with influenza A viruses belonging to any subtype, but not target cells infected with influenza B virus) (553). However, a more specific subpopulation of CTLs lyses only cells infected with homologous virus. Human class I–restricted CTLs recognize either glycoprotein HA or nonglycoprotein antigens (M, NP, PB2), which can account for their subtype-specific and cross-reactive specificities, respectively (134,553). Depending on human leukocyte antigen (HLA) haplotype, individuals can differ considerably in the antigens that their CTLs can recognize (321). The memory CTLs characterized after infection or vaccination of humans have the cross-reactive pattern of cytotoxicity (120,122). Passively transferred class I–restricted CTLs mediate recovery from influenza pneumonia in mice (553). The prechallenge level of memory CTLs did not correlate with susceptibility to infection or illness after experimental administration of wild-type virus, but it correlated with accelerated clearance of virus from the respiratory tract of humans (321).

The other class of CTLs is restricted by histocompatibility class II antigens and has the $CD4^+$ phenotype (248,472) and

thus belong to the T-helper class of T cells. The $CD4^+$ T cells have two functional properties. First, they are helper T cells, providing help both to B cells for antibody production and to class I–restricted CTLs for their proliferation (281,282,553). It is interesting to note that the helper T cells specific for M or NP antigen can provide help to B cells secreting HA antibody (282,283,441), and in this manner, can augment the antibody response to protective antigens. Second, the $CD4^+$ T cells can have cytolytic activity, with a range of antigen specificities similar to those of class I–restricted CTLs (553). Little further is known of the role of these T cells in immunity in humans or of the kinetics of their responses after infection or vaccination.

$CD4^+$ and $CD8^+$ T cells both can contribute to immunity to influenza A virus infection. The important role of $CD4^+$ T cells in immunity to influenza virus infection has been defined from studies in $CD8^+$ T cell–deficient animals, which can clear influenza A virus by a $CD4^+$ T cell–dependent mechanism (28,116,295). Passively transferred influenza virus specific $CD4^+$ T-cell clones are not able by themselves to clear an ongoing influenza virus infection, but require functional B cells to accomplish this clearance (442). Thus the primary antiviral activity of the $CD4^+$ T cell is to provide help to B cells to produce antiviral antibodies. Because $CD4^+$ T cells recognize many epitopes on influenza viral proteins, a large number of T cells are available to provide such help (66).

$CD8^+$ T cells also are able to mediate clearance of influenza A virus infection in $CD4^+$ T cell–deficient animals (115,295). The $CD8^+$ T cells not only clear infectious virus from experimentally infected animals, but also clear influenza virus RNA from lung tissue. Thus the immune system is functionally redundant in its ability to clear influenza A virus infections. Animals deficient in both $CD4^+$ and $CD8^+$ T cells succumb to infection, indicating that nonspecific mediators of immunity are not sufficient in the absence of T cells to restrict influenza A virus infection significantly (116,295). Although passively transferred $CD8^+$ T cells that have been activated *in vitro* with influenza virus antigen can modify infection with influenza A virus, it remains problematic to induce protective $CD8^+$ T cells by immunization (287,475). The mechanisms by which influenza A virus $CD8^+$ T-cell clones clear influenza A virus infections, be it by cytolysis or antiviral cytokine secretion, remains unknown. The number of $CD8^+$ T-cell epitopes on viral proteins is much more restricted than the number of B-cell or $CD4^+$ T-cell epitopes (30). Cytolysis of influenza virus–infected cells also can be mediated by antibody plus complement, and antibody-armed lymphocytes (195,409,434).

Lymphproliferation is another measurement of a cellular response to influenza. Lymphocytes responsive to influenza antigens have been isolated from the blood and lower respiratory tract secretions of influenza virus–infected humans, but only the former have been studied extensively (244,553). Lymphocyte blastogenic responses to influenza antigens in humans increase after influenza A virus infection, beginning between the third and sixth day after infection (104), and return to baseline levels by day 28. Influenza antigen-specific cutaneous reactivity or *in vitro* blastogenesis in humans correlates weakly with susceptibility to infection with influenza A viruses (234).

Influenza A virus infection can depress skin test reactivity to common antigens used to assess cutaneous delayed hypersensitivity (38,246,414). In addition, depression of the peripheral blood lymphocyte blastogenic responses to mitogenic and antigenic stimulation (104,246,292) is seen during the acute stage of infection and early convalescence. Despite this transient depression of delayed hypersensitivity and blastogenic responses to noninfluenzal antigens or mitogens, influenza virus–specific cellular responses develop (106,122). The mechanisms underlying the depression in the function of lymphocytes in influenza indicated earlier have not been defined, but influenza A virus can abortively infect human lymphocytes *in vitro* (48) and possibly *in vivo* (537).

Mucosal Antibody Response

Francis (140) was the first to detect neutralizing activity to influenza virus in nasal secretions, and subsequently, resistance to experimental influenza A virus infection in the mouse was found to be mediated primarily by antibody present in bronchial secretions (128). The neutralizing antibody in nasal secretions of humans is primarily of the immunoglobulin A (IgA) isotype (11) and is locally produced (431). Antibody to both the HA and NA can be detected in local secretions, but the former is easier to detect and thus has been studied more frequently (85). Furthermore, IgA antibodies, which are the primary mediators of resistance to influenza A virus infection in the upper respiratory tract, can act intracellularly to inhibit replication of virus and likely actively participate in clearance of infectious virus from the epithelial cells of the respiratory tract (314,315,416,417).

During primary viral infection, IgA, IgG, and IgM hemagglutinin-specific enzyme-linked immunosorbent assay (ELISA) antibodies appear in nasal washes, with IgA and IgM antibodies detected more frequently than IgG antibody (349,353). Most of the HA-specific IgA and IgM antibodies are actively secreted locally, whereas local secretion could be demonstrated only infrequently for IgG antibody. Individuals with a local IgA response also had a serum IgA response. Local IgA antibody stimulated by natural infection is detectable for 3 to 5 months after infection, and there is local IgA memory for influenza antigen (349,545). After secondary infection, local antibody is also primarily of the IgA isotype. Again, those individuals with a local IgA response also have a serum IgA response, and the magnitude of the serum IgA HA antibody response correlates with that of the local response. Nasal wash IgG appears to be predominantly a transudate from serum, with a serum-to-nasal wash concentration gradient of 350:1 (353).

The presence of local IgA antibody induced by infection with an attenuated virus correlated with resistance of volunteers to infection and illness after challenge with a virulent wild-type virus (239). Challenge of children with an attenuated live vaccine showed similar findings (40). Resistance to experimental wild-type infection also correlated with the level of local HA antibody present at the time of virus administration, with IgG and IgA each contributing to resistance (76).

Effect of Infection on Bacterial Flora and Phagocytic Cell Function

Influenza A virus infection does not generally significantly alter the normal bacterial flora (39,102); however, several exceptions have been noted. In patients with chronic bronchitis, influenza A virus infection was followed by an increased incidence of colonization with *Streptococcus pneumoniae* (463). During an outbreak of meningococcal and influenza A

virus infections, influenza virus infection was found to be significantly associated with infection or carriage of *Neisseria meningitidis* (554). Furthermore, pharyngeal cells from experimentally infected volunteers demonstrated an increased adherence for pathogenic bacteria during acute disease (124).

Infection of human polymorphonuclear (PMN) and mononuclear (MN) leukocytes with influenza A virus *in vitro* depresses the ability of these cells to respond to a chemotactic stimulus (1,63). During influenza A virus infection in humans, PMN and MN leukocytes obtained from peripheral blood also exhibit depressed chemotaxis *in vitro* (1). Phagocytosis has generally not been affected by infection of PMN or MN leukocytes *in vitro,* but infection does decrease bactericidal capacity of the phagocytic cells (1). Similar findings have been reported in experimental animals, although not by all investigators (377,438). Influenza A virus infection of macrophages *in vitro* can inhibit their ability to help or augment the proliferative response of lymphocytes to mitogens (422). Perhaps these virus-related alterations in phagocytic cell function act in concert with the destruction of the ciliated epithelium to set the stage for the secondary bacterial infections that can occur during influenza virus infections of humans.

CLINICAL FEATURES IN HUMANS

Adults

Infection with influenza A viruses results in a spectrum of clinical responses ranging from an asymptomatic infection to a primary viral pneumonia that rapidly progresses to a fatal outcome. Reviews of the signs and symptoms of illnesses due to different strains of influenza A virus have been published (102,109,476). The typical uncomplicated influenza syndrome is a tracheobronchitis with the additional involvement of small airways (513). The incubation period can be as short as 24 hours or up to 4 or 5 days, depending in part on the dose of virus and the immune status of the host.

The onset of illness is usually abrupt, with the occurrence of headache, chills, and dry cough, which is rapidly followed by high fever, significant myalgias, malaise, and anorexia. Substernal tightness and soreness can accompany the cough. The most prominent sign of infection is fever that often peaks within 24 hours to as high as 41°C, but more commonly is in the 38°C to 40°C range. The fever usually begins to decline on the second or third day of illness and is usually gone by the sixth day; the median duration is 3 days (109). The elderly can have high fever, lassitude, and confusion without respiratory signs.

Other than fever, the physical findings in influenza are usually minimal, although patients can appear quite toxic. Nasal obstruction, rhinorrhea, and sneezing often occur, and pharyngeal inflammation without exudate is common. Conjunctival inflammation and excessive tearing may occur. Influenza A virus usually does not cause purulent conjunctivitis, but has been recovered from the conjunctiva of a person with conjunctivitis who was infected with a virus of seal origin (522). Viral antigen is detectable in conjunctival cells and secretions (487). Small cervical nodes can be felt in a minority of cases. Chest radiograph and auscultatory findings are usually normal, although occasionally patchy rales and rhonchi are heard.

As the fever is declining, the respiratory signs and symptoms such as rhinorrhea and coughing may become more intense. The cough frequently changes from a dry, hacking nature to one that is productive of small amounts of sputum that are usually mucoid but can be purulent. After the fever and upper respiratory tract symptoms resolve, cough and weakness can persist for 1 to 2 additional weeks. Illness is more frequent and more severe in cigarette smokers (249). It is important to emphasize that influenza virus can also give rise to asymptomatic infection, as well as to lesser illnesses such as rhinitis and/or pharyngitis.

Tracheobronchial clearance of radiolabeled particles is depressed during acute influenza virus infections but returns to normal levels about 1 month later (61). Clearly, the loss of the mucociliary blanket is a factor in the predisposition to secondary bacterial pneumonia seen after influenza infection. Although air flow in large airways is usually unaltered in uncomplicated influenza, there is a transient increase in bronchial reactivity to chemical and particulate stimuli during natural infection (503). Small peripheral airways are often affected in uncomplicated influenza A virus infections (190). This small-airway abnormality can persist after symptomatic illness has subsided. Alterations in pulmonary gas exchange, with a depression of the diffusing capacity of carbon monoxide and an increase in the alveolar–arterial oxygen tension gradient, also are seen (226). Although significant abnormalities in large and small airways can be demonstrated during acute infection and early convalescence, uncomplicated influenza appears to cause little permanent damage in the lung, even in patients with chronic obstructive lung disease (288,464).

Children

The clinical manifestations of influenza in children are similar to those seen in adults, but there are some distinct differences between these two age groups.

First, children have higher fever, and febrile convulsions can occur (163,407,546,548). At least 14% of fevers associated with respiratory tract symptoms that result in a visit to a pediatrician are caused by influenza viruses (163,548).

Otitis media, croup, pneumonia, and myositis are more frequent in children (205,271). Influenza A and B virus infections increase the risk of developing otitis media as well as the risk of recurrence of middle ear disease in children (205). In approximately 12% of naturally infected seronegative children, otitis media develops (548). From 24% to 33% of children hospitalized with influenza A virus infection have otitis media (384). Control measures that are effective in preventing influenza virus infection or illness decrease the incidence of otitis media in children. Although less well documented, bacterial sinusitis may follow acute influenza.

Studies in children in an urban setting have shown that influenza A viruses are important causes of laryngeotracheobronchitis (croup) (271). In the H2N2 era, influenza A virus infection was associated with 8% of all croup requiring hospitalization, and in the H3N2 era, with 24% of all such croup. Croup occurred predominantly in children

younger than 1 year. Influenza-associated croup can be especially severe and occasionally requires intubation (42,51).

It is important to emphasize that influenza A and B viruses are a significant cause of serious lower respiratory tract disease in children (42,162,163,271,298,363,381). In a prospective study of 121 susceptible (seronegative) young children seen in a clinic during an H3N2 virus outbreak in 1974, five of 60 infected infants had clinical and radiographic evidence of pneumonia (546). In addition, influenza A virus infection has been shown to exacerbate asthma (277,330,399).

In children, myositis is usually localized to the gastrocnemius and soleus muscles and is characterized by pain on walking. It has its onset as respiratory illness wanes; the muscles are tender and swollen; serum levels of muscle enzymes are elevated; the course is usually benign and reversible; and light-microscopic changes of muscle necrosis and an inflammatory cell infiltrate occur (100,325,329). Children (especially those younger than 3 years) have a higher incidence of gastrointestinal manifestations such as vomiting and abdominal pain (102). Infection of neonates can present as unexplained fever (322) and can be life-threatening (24,322).

Differential Diagnosis

The respiratory tract manifestations of influenza virus infections are not specific and can be seen during infection with other viral respiratory tract pathogens, including respiratory syncytial virus, parainfluenza viruses, coronaviruses, adenoviruses, rhinoviruses, and *Mycoplasma pneumoniae* (271). Because the severe forms of viral pneumonia are extremely rare with other respiratory viruses in adults, it is reasonable to assume that during an epidemic of influenza A virus in the community, diffuse interstitial viral pneumonia in an adult is likely to be due to influenza virus. The recent documentation that another wintertime virus, respiratory syncytial virus, can cause equally severe illness in the elderly makes even this assumption tenuous (125). The protean manifestations of influenza A virus demand that influenza virus be considered in the differential diagnosis of fever in neonates and of myositis, febrile convulsions, and encephalopathies occurring in the general population during influenza epidemics. The diagnosis can be established only by recovery of virus, by demonstration of the presence of viral antigen or viral genetic material in clinical specimens, or by detection of an increase in specific antibody titer in serum or nasal secretions (74,85a,440,515).

Lower Respiratory Tract Complications

Three distinct syndromes of severe pneumonia can follow influenza infection in children or adults. Complications are most common in the elderly (301).

Primary Viral Pneumonia

Primary influenza virus pneumonia was first described in 1959 (300,310) in fatal cases caused by the 1957 Asian influenza A virus (H2N2), although retrospectively, it had been observed during previous influenza A epidemics (165,344). Primary viral pneumonia occurs predominantly in individuals at high risk for the complications of influenza virus infection (i.e., the elderly or patients with cardiopulmonary disease), but 25% of the cases are in normal individuals and an additional 13% in pregnant women. The typical case of primary viral pneumonia develops abruptly after the onset of influenza illness. It progresses within 6 to 24 hours to a severe pneumonia with rapid respiration rate (30 to 60 respirations per minute), tachycardia (greater than 120 beats/min), cyanosis (in 80% of patients), high fever (average of 39°C), and hypotension. The illness may rapidly progress to hypoxemia and death in 1 to 4 days; the presence of frothy hemoptysis, tachypnea, and cyanosis portends a fatal outcome. Auscultatory findings include bilateral crepitant inspiratory rales. Examination by radiograph reveals mottled densities in two or more lobes and diffuse symmetrical interstitial infiltrates or areas of consolidation; cavitation or pleural effusion suggests bacterial superinfection. Electrocardiographic abnormalities occur, but are not those consistent with myocarditis. Pathologic findings in the trachea and bronchi are similar to those previously described during acute uncomplicated disease, but bronchiolitis also is present. Significantly, pathologic findings are present in the alveoli (210,310). The clinical, laboratory, and physiologic findings in primary viral pneumonia are not specific. The erythrocyte sedimentation rate is usually normal; a leukocytosis with band forms is seen in a little fewer than half the cases; and the partial pressure of arterial oxygen is depressed, often markedly.

In nonfatal cases, initial improvement occurs from 5 to 16 days after onset of pneumonia, with resolution of radiographic changes taking up to 4 months (541). Survivors can develop diffuse interstitial fibrosis with a decrease in diffusion capacity of carbon dioxide and a decrease in arterial oxygen tension (285,398,541). Influenza B virus can cause severe disease but has not been reported to be associated with fatal primary viral pneumonia in normal individuals (131,500).

Combined Viral–Bacterial Pneumonia

A combined viral–bacterial pneumonia is approximately 3 times more common han primary viral pneumonia. The bacteria most commonly involved are *Streptococcus pneumoniae, Staphylococcus aureus,* and *Hemophilus influenzae,* although other microorganisms can play a role (35,154,300,310,397,454). Clinically, this syndrome may be indistinguishable from primary viral pneumonia, except that the symptoms of pneumonia appear somewhat later after onset of influenza symptoms, and chest radiographs taken early in the course of pneumonia are more apt to reveal the presence of pleural effusion. Virus has been recovered from the lungs (in a titer of $10^{2.0}$ $TCID_{50}$/g) and from pleural fluid (310,313). The erythrocyte sedimentation rate is elevated more frequently than in primary viral pneumonia. Because there is no effective distinction between the two syndromes, the diagnosis depends solely on the demonstration of bacteria in the sputum, in fluid obtained at bronchoscopy, or in the pleural fluid. The case fatality rate for combined viral–bacterial pneumonia is about 10% to 12% (35,300,397). However, coinfection with influenza and *S. aureus* has a higher fatality rate of up to 42% (425).

There are strains of *S. aureus* that secrete proteases capable of activating the infectivity of influenza virus by proteolytic cleavage of the HA. These strains play a synergistic role in experimental pneumonia in mice (485,486). Such

protease-secreting bacterial strains could well be an added pathogenic factor in combined viral–bacterial pneumonias in humans.

Influenza Infection Followed by a Bacterial Pneumonia

In this syndrome, an individual has a typical influenzal illness and is beginning to improve, but then develops shaking chills, pleuritic chest pain, and an increase in cough productive of bloody or purulent sputum (300). Cyanosis and a marked increase in respiratory rate are less common than with a primary viral pneumonia. Examination by radiograph reveals local areas of lung consolidation but not diffuse pneumonia. Often influenza A virus is not recovered from the upper or lower respiratory tract, leukocytosis is common, and the erythrocyte sedimentation rate is elevated. This is generally a milder form of pneumonia, although a case fatality rate of about 7% has been described (300).

Extrapulmonary Manifestations of Influenza

Viremia

Viremia is unusual in influenza virus infection (267,332). Virus has been isolated from the blood in low quantity (present only in undiluted blood specimens) from a patient in the fourth day of influenza illness (359). In experimental or natural infection, virus has been recovered from the blood during the 1- to 3-day incubation period but not thereafter (264,470). Virus was present in barely detectable amounts in the blood of two patients with fatal primary viral pneumonia on the sixth day after the onset of illness and was recovered at necropsy from the liver and spleen of one patient (289). In addition, the presence of viremia has been inferred because virus was present in low titer in extrapulmonary tissues such as heart, liver, spleen, kidney, adrenal glands, and meninges obtained from patients dying of pneumonia (245,421).

Myositis and Cardiac Involvement

In adults, a diffuse form of the myositis occurs with generalized pain, tenderness, and weakness of muscles, increased serum levels of muscle enzymes, myoglobinemia, and myoglobinuria (331). Fatal acute renal failure can follow this form of the disease. The pathogenesis of the myositis remains uncertain. Muscle cell necrosis with or without inflammation can occur, and although influenza virus has been recovered from muscle, the relation between the virus and the myositis remains unclear (147,263,331).

Attempts at virus recovery from the heart of patients with myocarditis associated with fatal pulmonary infection have largely been unsuccessful (132,300,310,381). Virus was recovered from the heart of a patient with fatal pneumonia, but postmortem examination revealed arteritis, not myocarditis (381). Clinical findings and cardiac-function studies in patients with severe pulmonary infection suggest that myocardial dysfunction is not a direct result of influenza A virus infection (53,300). In uncomplicated influenza A virus infection, electrocardiographic abnormalities have been observed (506). Virus has been recovered from pericardial fluid in two cases (211,542), and influenza A and B virus–associated myopericarditis has been described (3).

Reye Syndrome

Reye syndrome, which is a neurologic and metabolic disease of children and adolescents, is characterized by a rapidly progressive noninflammatory encephalopathy and fatty infiltration of the viscera, especially the liver, resulting in severe hepatic dysfunction, as indicated by elevated serum transaminase and ammonia levels. This syndrome has followed respiratory viruses, varicella virus, and gastrointestinal infections (230). Histologically there is electron-microscopic evidence of mitochondrial swelling (391). Influenza B in particular but influenza A H1N1 and H3N2 viruses as well have been identified as antecedent infections (230). The administration of therapeutic doses of salicylates appears to be a risk factor in the development of Reye syndrome (23). The incidence of Reye syndrome after influenza infection was estimated to be between 0.37 and 0.88 cases per 100,000 children younger than 18 years. The incidence was likely to have been underestimated because milder forms of Reye syndrome have been described (294). The onset of the CNS and hepatic symptoms usually begins as respiratory tract symptoms wane. The case fatality rate varies and has been estimated to be between 22% and 42% (230). The disease associated with influenza B virus occurs in children aged 0 to 18 years (median age, 11 years) and is more frequently seen in a rural than in an urban environment (230). The etiology and pathogenesis of this syndrome are unknown. Virus has been isolated from affected tissue in low titer in several instances (376,392), and the syndrome has been observed in three siblings of different HLA types (540). A syndrome similar to, but milder than, Reye syndrome was observed in India during the 1957 influenza A (H2N2) virus epidemic (247). Noninflammatory encephalitis and hepatic dysfunction occurred in association with that influenza epidemic. There has been a dramatic decrease in Reye syndrome cases in the U.S. in both varicella-associated and non–varicella-associated cases. This reduction is thought to be associated with reduced use of salicylates, which are contraindicated for use in influenza infection (23).

Central Nervous System Involvement

A wide spectrum of CNS involvement has been observed during influenza A and B virus infections in humans (31,99,110,111,201,316,317,381,407), ranging from irritability, drowsiness, boisterousness, and confusion to the more serious manifestations of psychosis, delirium, and coma. Physical signs of altered reflexes can be elicited. The pathogenesis of these CNS symptoms is unclear. Nonspecific metabolic effects such as hypoxia resulting from severe pulmonary infection contribute to the CNS signs and symptoms.

Two specific CNS syndromes have been suggested to accompany influenza infection: influenzal encephalopathy and postinfluenzal encephalitis. Encephalopathy occurs at the height of influenza illness and may progress to death (99,135,228). The cerebrospinal fluid (CSF) is usually normal, the brain at autopsy shows severe congestion, and histologic changes are minimal. Lungs of such patients show changes typical of influenza and can yield virus in high titer. The postencephalitic syndrome is extremely rare and occurs from 2 to 3 weeks after recovery from influenza. The CSF

findings indicate inflammatory changes, and recovery occurs in the majority of cases. The association of the postencephalitic syndrome with influenza virus infection is less certain because virus is not usually recovered, and initial serum specimens usually contain antibodies (135). Influenza A virus has only rarely been recovered from the brain or CSF (135,384,407), and attempts to isolate it from the CNS of individuals dying of primary viral pneumonia have been unsuccessful (300,310).

It has been suggested that the syndrome of encephalitis lethargica followed by postinfluenzal encephalitic Parkinson's disease was associated with the influenza epidemics of 1918 and the epidemics following shortly thereafter (412). The epidemics of encephalitis lethargica followed 1 year after the epidemics of influenza, and these were followed in turn by postencephalitic Parkinson's disease about one decade later (412).

Febrile convulsions leading to hospitalization occur in children with and without underlying CNS abnormalities. An increase in the incidence of the Guillain–Barré syndrome (GBS) has not been seen after influenza A or B virus epidemics.

Toxic Shock Syndrome

Toxic shock syndrome has been seen in association with influenza virus infection in humans and is believed to be the consequence of the bacterial exotoxin (TSST-1) secreted by colonizing *S. aureus* strains (83,305).

Infection During Pregnancy and Fetal Risk

Pregnant women in the second or third trimester have an increased risk of developing fatal influenza disease (300,310,369,444,468). The increased mortality is generally seen during the years after introduction of a new pandemic strain, as in 1918 and 1957 (171,444,543), although using a large data set, the impact can be appreciated in the interpandemic period (369). Virus is usually not recovered from the fetus (310). An increase in congenital anomalies and hematologic malignancies has been reported after influenza virus infection in pregnancy (13,172,185,411). However, no consistent association between specific defects or malignancies and influenza epidemics has emerged, and the virus itself has not been implicated as a cause of congenital defects (250,306,334).

Influenza Infections in Immunosuppressed Patients

Influenza viruses can infect and cause severe disease in immunocompromised individuals (299,426,531), but more often the illness that occurs resembles that seen in fully immunocompetent persons. Prolonged shedding of virus occurs in immunosuppressed persons (426,531).

Influenza B and C Virus Infections

Influenza B virus can cause the same spectrum of disease as that seen after influenza A virus infection, and severe illness can occur (15,271,544). The frequency of serious influenza B virus infections requiring hospitalization is about four-fold less than that of influenza A virus (271). Influenza B virus illness occurs in epidemic form and predominantly involves adolescents and school-age children, but adults and the elderly also can be involved (15,75,161,191,363,375,418). Myositis and gastrointestinal symptoms are more common manifestations of influenza B than of A virus infection (75,127,262,284).

Influenza C virus causes sporadic upper respiratory tract illness and is rarely associated with severe lower respiratory tract disease (140,337). By early adulthood, most individuals (96%) have antibody to influenza C virus (378). Administration of influenza C virus to volunteers induced mild coryza with some systemic symptoms (241).

PREVENTION AND CONTROL

Antivirals

Amantadine and Rimantadine

Amantadine hydrochloride and rimantadine, an analogue of amantadine, are currently licensed for prophylactic and therapeutic use against influenza A virus in humans in the U.S. Both have a tricyclic structure with an amine side group and have antiviral properties against all subtypes of influenza A virus but not against influenza B or C viruses (504). The concentration of amantadine and rimantadine that inhibits virus plaque formation ranges from 0.2 to 0.4 µg/mL for sensitive influenza A viruses and is greater than 100 µg/mL for influenza B viruses. The former level of drug is found in the blood and nasal secretions after oral administration.

The antiviral activity of amantadine and rimantadine is exerted after adsorption of virus to cells but before primary transcription (196). Resistant strains of influenza A virus can be isolated *in vitro* and *in vivo.* In experimental studies, amantadine-resistant mutants can spread to susceptible contacts and cause disease, including fatalities, indicating that acquisition of amantadine resistance is not associated with attenuation (483,526). Amantadine and rimantadine inhibit virus replication by blocking the acid-activated ion channel formed by the virion-associated M2 protein. The primary antiviral action of these compounds results from blocking the flow of H^+ ions from the acidified endosome into the interior of the virion, a process necessary for release of the transcriptionally active ribonucleoprotein complex for transport to the nucleus. In addition, a second effect of these compounds is to block maturation of the HA during transport from the endoplasmic reticulum to the plasma membrane (196).

At the recommended adult dose of amantadine or rimantadine (i.e., 200 mg orally), side effects are unusual. At dosages of 300 to 400 mg per day, significant symptoms referable to the CNS such as depression, difficulty concentrating,

nervousness, sleep disturbances, and gastrointestinal complaints occur. These effects are more frequently observed in recipients of amantadine than of rimantadine and are more evident in the elderly, in whom a reduced dose of 100 mg orally is recommended. Amantadine is cleared by the kidneys, and the dose must be adjusted with renal impairment, whereas rimantadine is metabolized by the liver. Compared with amantadine, rimantadine has the desirable properties of (a) fewer side effects, (b) one dose can be administered daily rather than two, and (c) clearance of drug is not affected by the level of renal function.

Amantadine and rimantadine are useful for prophylaxis against H1N1, H2N2, and H3N2 influenza A virus infections in adults and children. During an epidemic involving both influenza A H1N1 and H3N2 viruses, amantadine and rimantadine protected against influenza-like illness (78% and 65%, respectively), documented influenza illness (91% and 85%), and influenza infection (74% and 66%) (105). Lower efficacy rates against documented illness (70%) and infection (39%) were observed for amantadine prophylaxis during an H1N1 virus epidemic.

Amantadine or rimantadine also is useful in the therapy of illness caused by influenza H1N1, H2N2, and H3N2 viruses. Symptomatic improvement, including accelerated clearance of local symptoms and fever, occurs about 1 day earlier in treated patients, and peripheral airway dysfunction also resolves more quickly. Accelerated clearance of symptoms is seen in children infected with an H3N2 virus treated with rimantadine compared with control children receiving an antipyretic (187). Virus was cleared more rapidly in such treated individuals than in controls. Development of serum and nasal wash influenza antibodies was not inhibited by amantadine treatment.

Recommendations for prophylactic and therapeutic uses of amantadine include prophylactic use in individuals at high risk who have not been vaccinated, as well as hospital personnel who could spread infection in the hospital. Therapeutic use includes individuals with uncomplicated influenza who have a high temperature of less than 48 hours' duration. It would be helpful to know that amantadine is useful in treating primary viral pneumonia, but efficacy in this clinical setting remains to be established. Updated recommendations for use of these compounds by the Advisory Committee on Immunization Practices are published yearly (67).

Neuraminidase Inhibitors

The first NA inhibitors included DANA (2-deoxy-2,3-dihydro-*N*-acetylneuraminic acid; Neu5Ac2en) and its *N*-trifluoroacetyl analog FANA, which were effective *in vitro* but did not inhibit replication of influenza viruses in animals (324,387). After solution of the structure of the NA (79,505), DANA served as the lead compound in the rational design of drugs targeting the NA. Replacement of the 4-hydroxyl group on DANA with a guanidino group filled the unoccupied pocket in the NA active site with an inhibition constant (K_i) of 2×10^{-10} mol/L (510). The compound zanamivir or [GG-167] is a specific inhibitor of the NA of all influenza A and B viruses.

Zanamivir must be administered intranasally or inhaled for optimal effect. An additional NA inhibitor can be taken orally. This was achieved through the discovery and use of a hydrophobic pocket in the enzyme-active center that could accommodate lipophilic groups necessary to improve the inhibitor's oral biovailability (270). The oral compound oseltamivir or GS 4104 (Fig. 11) is converted to oseltamivir carboxylate or GS 4071 in the body. The resulting molecule retains the carboxylate bond of sialic acid but also makes use of a hydrophobic group. This group induces the binding cleft to form a hydrophobic pocket, which holds the drug in place through hydrophobic interactions. The carbocyclic inhibitor GS 4071 is as potent as zanamivir against the NA of both influenza A and B viruses when tested in NA inhibition assays, and it demonstrated antiviral efficacy in mice and humans when administered orally (198,326). A third compound targeting the NA and designated RWJ-270201 also is under development; preliminary reports indicate that it is effective on all subtypes of influenza A and B, is as potent as both of the NA inhibitors given earlier, and is administered orally (181).

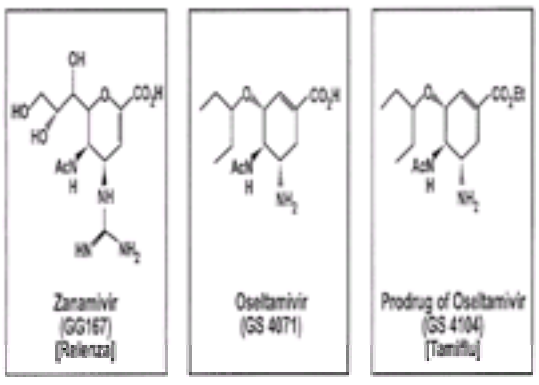

FIG. 11. Neuraminidase inhibitors. Zanamivir and oseltamivir were designed based on the structure of the enzyme active site of the neuraminidase. Zanamivir is inhaled or administered intranasally, whereas the prodrug of oseltamivir is administered orally. The prodrug oseltamivir phosphate (GS 4104) is converted predominantly by hepatic esterases to oseltamivir carboxylate (GS 4071).

Both zanamivir and oseltamivir are well tolerated in lower animal models and in humans (for reviews, see 179,182) and are efficacious for prophylaxis and treatment of influenza in humans. Both zanamivir and oseltamivir have been approved for use in humans. To determine the dose-related prophylactic activity of zanamivir in humans, it was administered intranasally 2 or 6 times daily for 5 days beginning 4 hours before inoculation of the virus. For all zanamivir recipients, prophylaxis was 96% effective against viral shedding, 82% effective against infection, and 95% effective in preventing febrile illness ($p < .001$), reduced peak viral titers by 2.0 log $TCID_{50}$/mL ($p < .001$), and reduced the median duration of

viral shedding by 3 days ($p < .001$) and the frequency of febrile illness by 85% ($p < .01$).

The efficacy of zanamivir against acute influenza was shown in double-blind placebo-controlled field trials. For all infected patients, the median time to alleviation of all major influenza symptoms (i.e., headache, myalgia, cough, and sore throat) was 4 days compared with 5 days for the placebo group (200). When treatment was started within 30 hours after infection, the treated group recovered 2 days earlier, and if treatment was started less than 30 hours after infection, the alleviation of symptoms was up to 4 days. Thus early diagnosis and treatment are necessary. Similar efficacy has recently been shown for oseltamivir (197). Recommendations for the use of each compound have recently been published by the Centers for Disease Control and Prevention (CDC) (68). Oseltamvir is currently recommended for those as young as 1 year.

Resistant variants to the NA inhibitors have been selected under drug pressure *in vitro* but only with difficulty and at a much lower frequency than amantadine (78,178,181,318). The emergence of resistance is first detected by appearance of mutations around the receptor-binding site of the HA, which compensates for reduced NA activity by lowering the affinity of binding to receptors. The second step in emergence of resistant mutants is selection of variants with mutations in the inhibitor binding site of the NA. The most common substitution with zanamivir occurs at residue 119, where Glu was typically replaced by Gly and less frequently by Asp or Ala. Less frequently substitutions occur at residues 292. Glu 119 is conserved among all influenza viruses and is one of the “framework” residues, which do not directly participate in substrate catalysis but stabilize the enzyme structure. The interaction of Glu at residue 119 and 227 with the 4-guanidinium moiety of zanamivir provides the high potency and selectivity of the inhibitor, and changes at residue 119 weaken the interaction between the mutated NA and the drug (77).

Characterization of these mutants reveals that the functional integrity of their NA activity is impaired (77,181,318). They have reduced NA activity, are heat labile, and have a narrower range of pH optima. Thus zanamivir-resistant mutants that contain structural changes in their NA and HA may not succeed in nature.

There is no evidence of selection of zanamivir-resistant mutants during clinical trials. Typical zanamivir treatment in humans (5 days) is likely to be too brief for development of resistance. However, prolonged treatment and immunocompromised status may create conditions conducive to the selection of drug-resistant mutants. A zanamivir-resistant mutant that emerged after treatment of an immunocompromised child was reported (180). The HA of the influenza B virus present in the patient's endotracheal tube aspirate after 1 week of treatment with zanamivir had reduced affinity for the *N*-acetylneuraminic acid 2,6-galactose-receptor determinant present on human tracheal epithelium. After 2 weeks of treatment, the isolated mutant had acquired an additional substitution in the NA-active site. Future large-scale studies are needed to determine whether resistant mutants can be detected after *in vivo* use in humans. Now that zanamivir and oseltamivir have been approved for use in humans, it is important to monitor for the emergence of resistance to these inhibitors under field conditions.

Other Antivirals Against Influenza

Ribavirin

Ribavirin, which is a synthetic nucleoside analogue that has antiviral activity against influenza A and B viruses in tissue culture and mice, currently does not have a defined role in the prevention of or therapy for influenza infections in humans (504). The antiviral activity is exerted after adsorption, penetration, and uncoating have taken place and can be reversed by adding an excess of guanosine or xanthosine to the tissue-culture medium. The *in vitro* inhibitory activity of ribavirin for influenza A and B viruses is 3 to 6 µg/mL, which is considerably higher than the peak levels achieved in serum after a single dose of 400 mg. Orally administered ribavirin has an inconsistent prophylactic or therapeutic effect, whereas aerosol administration has a detectable therapeutic effect.

Interferon

Interferon and IFN inducers induce resistance to influenza infection in mice (60,157,484). In humans the administration of exogenous IFN or an IFN inducer before experimental or natural challenge with a virulent influenza virus fails to reduce the level of illness or the quantity of virus shed (212,327). Studies with recombinant IFN-a2 indicate slight protection against illness and virus shedding (496).

Vaccines

Inactivated Vaccines

Vaccine Formulation

Inactivated influenza A and B virus vaccines are licensed for parenteral administration in humans. The strains to be included each year for the annual vaccination program and recommendations for use are made by the Public Health Service (PHS) (67,235,269) for an extensive discussion of these vaccines). Seed viruses for the A and B components of the vaccine are naturally occurring virus strains that replicate to high titers in the allantoic cavity of embryonated chicken eggs, the substrate used for vaccine production. Alternatively, the influenza A components may be reassortant viruses that contain internal genes from the A/PR/8/34 (H1N1) virus, which confer a high level of growth in eggs plus genes coding for surface antigens of the current influenza A virus (424).

Virus present in allantoic fluid is purified and concentrated by zonal centrifugation or column chromatography and inactivated with formalin or b-propiolactone. These purification procedures have greatly reduced the incidence of local and systemic reactions. The quantity of immunoreactive HA in each dose is standardized to contain the amount recommended by the Advisory Committee on Immunization Practices (67), which is usually 15 µg per component for adults and older children or 7.5 µg for children younger than 3 years. The quantity of NA is not standardized because this

glycoprotein is quite labile during the process of purification and storage (260,261). Each 0.5-mL dose of vaccine contains approximately 10 billion virus particles, and one egg yields one to three doses of vaccine. Vaccine also contains variable but small quantities of endotoxin, egg-derived protein, free formaldehyde, and preservative, which do not appear to contribute to the reactogenicity of the vaccines for humans. The route of immunization is intramuscular.

The vaccines currently in use are designated whole-virus (WV) vaccine or subvirion (SV) (split or purified surface antigen are alternative terms) virus vaccine. The WV vaccine contains intact, inactivated virus, whereas the SV vaccine contains purified virus disrupted with detergents that solubilize the lipid-containing viral envelope, followed by chemical inactivation of residual virus. Experimental vaccines have been prepared and evaluated in humans that contain either baculovirus-expressed HA alone (280) or purified NA alone (236). An experimental inactivated WV vaccine containing an NA antigen immunologically related to the epidemic virus and an unrelated HA appears to be less effective than conventional vaccine (379). Only inactivated vaccines containing both relevant surface antigens will be considered further.

It has recently been observed that human influenza A and B viruses isolated in the allantoic cavity of embryonated chicken eggs can have altered antigenicity and possess mutations in the HA that promote growth in eggs (370,536). Studies that have compared the efficacy of viruses egg-passaged or cell-culture grown indicate that the egg-passaged viruses are protective against cell-culture viruses grown in the predominant virus isolated from humans (194,254,432). In humans, immunization with vaccines containing an HA egg made from grown virus induces less neutralizing antibody to virus possessing the nonadapted HA than to the homologous virus (370). At present, egg-grown viruses are used in the inactivated virus vaccine.

Vaccine Reactogenicity

Reactogenicity of vaccines has been evaluated in four large-scale, placebo-controlled trials in adults and children (67). The vaccines contained a monovalent influenza A H1N1 virus or a mixture of H1N1, H3N2, and B viruses. In each instance, vaccine was standardized with respect to quantity of HA. Satisfactory serologic responses were achieved in children and adults with doses of vaccine that caused minimal clinical reactions. Reactions generally occurred within the first 24 hours and lasted for 1 to 2 days; these included systemic manifestations such as fever, malaise, myalgia, and headache, as well as local manifestations such as pain, erythema, induration, and tenderness at the site of inoculation.

In adults, the frequency of systemic reactions to monovalent or trivalent WV or SV vaccines containing from 6 to 65 µg of HA was not different from that of recipients of placebo. Only when vaccine containing 118 µg of HA was used were systemic reactions significantly greater than those in placebo recipients. Reactions were observed most frequently in vaccinees lacking detectable preexisting serum antibody. Local reactions occurred in 3% to 5% of adults and rarely caused significant morbidity. The reactogenicity of influenza B virus vaccine is similar to that of influenza A virus.

In children from ages 6 months to 18 years, a difference in reactogenicity of WV or SV vaccine was apparent. WV vaccinees exhibited significantly more systemic reactions than did SV vaccinees. Febrile reactions with occasional febrile convulsions occur in young children younger than 2 years after administration of WV vaccine containing either monovalent H3N2 or B antigen. These observations form the basis for recommending that only SV vaccine be used in children younger than 12 years. WV vaccines cause an increase in systemic reactions at doses as low as 4 µg of HA, whereas SV vaccines were acceptable at dosages as high as 40 to 60 µg. Reactions in children are less frequent after the second or booster inoculation of WV vaccine.

Local or systemic allergic reactions to vaccine components occur rarely. It is believed that the majority of these reactions are due to residual egg protein (67). High-risk patients who have egg allergies may be immunized by using a specific protocol (355).

An increase in the number of reported cases of the GBS occurred after the National Influenza Immunization Program in 1976 to 1977 (430,436). About 1 in 100,000 individuals who received the swine influenza virus vaccine developed GBS, with a relative risk in vaccinees about four- to eight-fold greater than that in unvaccinated subjects. Influenza virus vaccine produced after 1977 had not been associated with an increased risk of GBS, until a recent report implicated a low but definable excess risk (one to two cases per million vaccinees) with the 1992 to 1993 and 1993 to 1994 vaccines (286). The reason for the difference between 1977 and subsequent years is not known.

Vaccine Immunogenicity

Prior antigenic experience with an influenza A virus within the same subtype is an important determinant of the serum antibody response to SV and WV vaccines. An example occurred in 1977 when those younger than 24 years in 1977 represented a unprimed population to H1N1 viruses, which had last circulated in 1957. In contrast, most persons 25 years or older probably had one or more infections with H1N1 viruses and thus represented a primed population. A dose of either SV and WV vaccine containing 20 to 30 µg of HA induced an acceptable level of antibody in primed adults. In contrast, 2 to 3 times as much vaccine was required to induce a similar antibody response in unprimed individuals (i.e., 60 µg or more of HA). In general, increasing the dose of vaccine increases the level of antibody achieved, but there is a rather shallow dose–response curve with WV and SV vaccines in primed and unprimed individuals (342,385). Responses to individual antigens in trivalent vaccines are as great as responses to the same components administered separately. The neuraminidase-inhibiting antibody response to WV and subunit vaccines in primed and unprimed individuals followed the same patterns as the HAI antibody response (261). The serum antibody response of elderly subjects to inactivated virus vaccines is variable but is generally lower than that of younger subjects (386). The antibody response of children older than 6 months was similar to that of unprimed adults but with two doses of SV vaccine needed to achieve a satisfactory level of antibody on primary immunization of children up to age 8 years. In infants younger than 6 months, inactivated vaccines are less immunogenic than they are in older infants and children (174). The serum antibody response of the young seronegative vaccinee can be quite strain specific, which is an important property to bear in mind

when antigenically distinct viruses of the same type or subtype are cocirculating (291).

The level of antibody induced in unprimed or primed individuals given two doses of SV vaccine decreased 75% over an 8-month period. The rate of decline of antibody after SV vaccine administration is faster than that observed after infection in young children.

Parenteral administration of vaccine leads to an increase in nasal wash antibody in 25% to 50% of primed vaccinees (340). A correlation between an increase in serum and an increase in nasal wash antibody has been observed, and the nasal wash response is dose dependent (340,530).

Antibody responses in patients with renal failure or with cancer are less than those in control individuals (34,175,507). Vaccine responses in high-risk patients with pulmonary or heart disease not receiving immunosuppressive drugs do not differ from those of controls. Immunization of immunocompromised individuals can induce antibody responses dependent, in part, on the level of immunocompetence (67,119,333).

Carefully controlled studies comparing the antibody response after intradermal and parenteral administration of vaccine containing comparable amounts of HA antigen indicated that intradermal administration offers no advantage over parenteral administration (373). A systematic comparison of intranasal versus parenteral administration of vaccine in primed and unprimed individuals using a vaccine of known HA content has not been performed, but intranasal administration of inactivated vaccine induces little systemic response (41). The oral route of immunization with inactivated virus vaccine induces secretory IgA antibody but little serum antibody (511). The efficacy of oral immunization has not been compared with that of parenterally administered inactivated vaccine.

Vaccine Efficacy

Parenteral vaccination with influenza A and B viruses consistently induces resistance to illness and, to a lesser extent, infection with influenza A and B viruses (14,114,128,138,233,323,328). The resistance induced is manifested by a reduction in the frequency and severity of the illness, including otitis media in children (202). Efficacy ranges from 60% to 80%, with the higher value seen after challenge with homologous virus and the lower value after challenge with virus that has undergone antigenic drift.

Resistance to experimental or natural challenge correlates with the level of serum HAI antibody induced to the infecting strain. In those situations in which vaccine efficacy was low or not detectable, surface antigens of the epidemic virus differed significantly from those of the vaccine virus, or vaccines were of low potency and thus did not stimulate sufficient antibody to the epidemic virus. A polyvalent influenza A virus vaccine containing antigens not related to the subtype present in the epidemic virus did not induce resistance to natural challenge (342). Vaccine is effective in the elderly who are at high risk for morbidity and mortality, but the level of efficacy is often less than that seen in young adults (21,176,393,435). Vaccination protects the vaccinee, but unvaccinated individuals also can benefit if the extent of vaccination is sufficient to dampen the epidemic spread of virus in the community (335,517). The duration of immunity after vaccination has not been evaluated systematically, but the relatively rapid decline in antibody levels suggests that protective immunity is of short duration. At any rate, antigenic changes in the influenza virus predicate annual immunization with current vaccines.

Inactivated vaccines boost HLA-restricted cytotoxic T cells in adults (406), but their ability to stimulate CTLs in unprimed individuals has not been evaluated. In contrast to virus infection, inactivated vaccines stimulate a poor CTL response in unprimed mice. However, WV vaccine stimulates T cells that mediate delayed-type hypersensitivity (T_d-cells) (2). In cell-transfer studies in mice, T_d-cells have been implicated as an important mediator of cellular infiltration in the lungs; these cells also increase mortality during influenza infection of mice (290). It is important to emphasize that potentiation of influenza illness in human vaccine recipients in any way analogous to that occurring after measles or respiratory syncytial virus vaccination has not been observed. Inactivated influenza virus vaccines have a consistent record of efficacy and safety.

Although influenza vaccine is currently recommended for annual vaccination of high-risk groups, most of the studies that have demonstrated efficacy have involved populations that received one or two doses of vaccine shortly before experimental or natural challenge. In one study in a boys' boarding school, the value of annual administration of vaccine was assessed over a 7-year period from 1970 to 1976, during which time three outbreaks occurred that involved different H3N2 drift viruses (227). The protective effect of inactivated influenza A vaccines was limited to boys after they received their first vaccination. As a consequence of the ineffectiveness of revaccination, the cumulative attack rate in the three epidemics was similar in vaccinated and unvaccinated boys. This raised a question concerning the current recommendation for annual vaccination with inactivated vaccine. However, subsequent studies have confirmed that annual vaccination with inactivated virus vaccines is indeed beneficial (114).

Vaccine Recommendations

Annual vaccination is recommended for persons regardless of age who have chronic conditions, such as (a) heart disease, (b) bronchopulmonary disease, (c) renal disease, (d) diabetes or other metabolic disorders, (e) children receiving long-term aspirin therapy, and (f) women in the second or third trimester of pregnancy (67). In addition, individuals older than 65 years should be vaccinated annually. Health care providers should be vaccinated as well as others in contact with high-risk groups.

Live Virus Vaccines

Live influenza virus vaccines are currently not a licensed product, but experimental live vaccines have been developed and evaluated for their usefulness in the immunoprophylaxis of influenza illness in adults (372) and in children (27). There are two major reasons for continued interest in the use of live vaccines in humans. First, the current inactivated

vaccines are recommended primarily for those at high risk of influenza virus infection and yet do not, in those groups, provide complete protection. In contrast, live vaccines appear to have the potential to broaden the indications for influenza vaccine and hence to have an impact on the overall morbidity and perhaps spread of the disease. Second, local immunity is increasingly recognized to play a major role in resistance to most respiratory pathogens (40). Respiratory tract infection with a live attenuated vaccine has been found to be the most efficient method of stimulating such immunity. Because infection of the respiratory tract stimulates systemic as well as local immunity, and theoretically is a good way of stimulating cell-mediated immunity, all components of the host's immune response are brought into play.

As previously indicated, influenza A viruses (and to a lesser extent, influenza B viruses) are unique among viruses that infect the respiratory tract in that they undergo significant antigenic variation on virtually a yearly basis. The strategy for developing a live virus vaccine must take this property into account. It is not feasible to attenuate each new variant of influenza virus that appears in nature by multiple passages in a heterologous host(s), a method that has been successfully used to attenuate viruses that do not show antigenic variation. Therefore, a strategy is needed in which attenuation can be achieved in a single step by transfer of attenuating genes from an attenuated donor virus to each new epidemic or pandemic virulent virus (348).

Because resistance to influenza A virus is mediated by the development of an immune response to the HA and NA glycoproteins, the genes coding for these surface antigens must come from the epidemic virus, whereas the attenuating genes are derived from the attenuated parent. This scheme is possible because of the segmented nature of the influenza genome and is illustrated in Fig. 5, in which the HA and NA genes are derived from the virulent wild-type virus, and the other genes are derived from the attenuated donor virus. In this approach, it is necessary that the genes that confer attenuation not code for the HA and NA glycoproteins, as these genes must be derived from the new epidemic or pandemic virus. In the figure, the attenuated reassortant vaccine virus was intentionally shown to receive each of the six other internal genes from the attenuated donor virus because such reassortants would be expected to exhibit the same level of attenuation each time a new vaccine virus is produced. Many donor viruses have been evaluated for their ability to attenuate new epidemic influenza A viruses reproducibly, including significant work in Russia with the A/Leningrad strains (259). However, only the background for the A/Ann Arbor/6/60 (H2N2) cold-adapted (ca) donor virus developed by John Maassab is presented, because this virus shows considerable promise as a vaccine candidate (27,114,348).

The influenza A/AA/6/60 (H2N2) ca donor virus was developed by passage of the wild-type virus at progressively lower temperatures in primary chick kidney cell cultures until a mutant was identified that replicated efficiently at 25°C, a temperature restrictive for the replication of wild-type virus (304). The donor virus and reassortants derived from it have three phenotypes: (a) the temperature-sensitive (ts) phenotype (i.e., restricted replication at temperatures of 38°C to 39°C, temperatures permissive for the replication of wild-type virus); (b) the ca phenotype (i.e., efficient replication at 25°C); and (c) the attenuation (att) phenotype (i.e., restricted replication in the upper and lower respiratory tract of ferrets). New live, attenuated reassortant virus vaccines are generated by mating the ca donor virus with a virulent wild-type virus and then selecting reassortant progeny at 25°C (restrictive for replication of wild-type virus), in the presence of an H2N2 antiserum, which inhibits replication of the viruses bearing the surface antigens of the attenuated A/AA/6/60 (H2N2) ca donor virus. A large series of H1N1 and H3N2 reassortants has been evaluated in humans and found to be satisfactorily (a) infectious, (b) attenuated for seronegative children and immunologically primed adults, (c) immunogenic, and (d) genetically stable. The viruses are poorly transmissible. The attenuation manifested by ca reassortants was accompanied by markedly reduced replication of virus in the upper respiratory tract of susceptible adults compared with that of volunteers infected with wild-type virus. Similar studies in other age groups revealed that the level of replication of ca reassortant viruses is (a) greatest in seronegative infants or children because viral growth is not limited by immunity induced by prior infection with influenza viruses; (b) intermediate in children and young adults who have had prior experience with related influenza A viruses; and (c) lowest in the elderly who have been infected many times with related influenza A viruses. Despite the efficient replication of ca reassortant viruses in young, fully susceptible, seronegative pediatric subjects, the vaccinees experience few symptoms, and those that occur are confined to the upper respiratory tract. The immunogenicity of the ca reassortants parallels their level of replication. Thus the acquisition of the six transferable genes of the ca donor virus by new wild-type viruses has reproducibly attenuated these viruses for susceptible adults and children.

The genetic basis of the ts, ca, and att phenotypes of ca reassortant viruses was determined. The PB1 and PB2 genes independently specify the ts phenotype, and the PA gene specifies the ca phenotype. Each of the three polymerase genes specifies the att phenotype (480), and only seven amino acid differences between the ca and wild-type viruses that could contribute to attenuation are present in these genes.

The ca reassortant vaccines induce resistance to experimental or natural challenge with wild-type influenza A viruses in adult and pediatric subjects who have had some prior experience with influenza A viruses (114,348,372). In addition, they are highly immunogenic in seronegative subjects, and this suggests that the vaccine would be efficacious in this population (239). Recent very impressive efficacy, 93% overall, against culture-confirmed influenza A/H3N2 and B was shown in a pediatric population aged 15 to 71 months after either one or two doses of trivalent ca reassortant vaccine given as a nasal spray (27). In the elderly, coadministration of live ca virus vaccine and inactivated virus vaccine may be more efficacious than inactivated virus vaccine alone against natural infection with influenza A virus (497).

Because the populations to be immunized have such disparate experience with influenza A viruses, it is not surprising that different vaccines (i.e., live vs. inactivated virus vaccine) or different vaccine schedules would be needed for each population. The suggested use and schedule of annual immunization with ca reassortant and inactivated virus vaccines and the reasons for the choice of vaccine in the pediatric, young adult, and elderly adult populations are (a) seronegative pediatric population older than 6 months may preferentially get live vaccine because this type of vaccine has been shown to be more immunogenic in this population; (b) previously primed children and adults younger than 65 years may get either vaccine because efficacies of live and inactivated vaccines are comparable for this population, although a live virus vaccine may be better accepted because of an easier route of delivery; and (c) elderly (older than 65 years) may get live plus inactivated virus vaccine because this combination is more efficacious in this population (348,497). Additional studies are needed to support this suggested use, and licensure of the live vaccine must be achieved over the

next few years.

CHAPTER 48 *Bunyaviridae:* The Viruses and Their Replication

Connie S. Schmaljohn and Jay W. Hooper

CLASSIFICATION

The family *Bunyaviridae* was established in 1975 to encompass a large group of arthropod-borne viruses sharing morphologic, morphogenic, and antigenic properties (55). The family currently contains four genera of animal-infecting viruses (*Bunyavirus, Hantavirus, Nairovirus,* and *Phlebovirus* genera) and one genus of plant-infecting viruses (*Tospovirus* genus). Most viruses in the family were isolated from or are transmitted by arthropods, primarily mosquitoes, ticks, sand flies, or thrips. Hantaviruses are exceptions; these viruses are rodent borne and are transmitted in aerosolized rodent excreta.

Viruses in the family *Bunyaviridae* were classified historically based on their antigenic relationships. Serogroups were identified that contain viruses related by their reactivity in any serologic test. Bunyaviruses, phleboviruses, and nairoviruses were further divided into complexes of closely related members of a serogroup. Genetic characterization of newly discovered viruses has largely circumvented serologic classification methods, particularly for the hantaviruses, which are very difficult to isolate and propagate in cell cultures.

Efforts to classify viruses as species resulted in a revision in the catalogue of viruses in the family *Bunyaviridae.* The most recent report from the International Committee on the Taxonomy of Viruses lists 47 species (and four tentative species) in the *Bunyavirus* genus, 22 species in the *Hantavirus* genus, seven species in the *Nairovirus* genus, nine species in the *Phlebovirus* genus (and 16 ungrouped viruses), and eight species in the *Tospovirus* genus (and five tentative species) (169). In addition, seven groups (19 viruses) and 21 ungrouped viruses are probable members of the family, but have not been characterized molecularly or antigenically. Because classification criteria vary among the genera, as well as among virus families, it is certain that the taxonomy of the family *Bunyaviridae* will continue to evolve.

VIRION STRUCTURE

Morphology

Virions are spherical, 80 to 120 nm in diameter, and display surface glycoprotein projections of 5 to 10 nm, which are embedded in a lipid bilayered envelope approximately 5- to 7-nm thick (Fig. 1A). Electron microscopy and biochemical studies of the bunyavirus La Crosse virus suggest that there are 270 to 1,400 glycoprotein spikes per virion (76,137). The spikes are generally thought to consist of heterodimers of the viral glycoproteins, G1 and G2; however, one study suggested that homodimers make up the minimal surface unit of the phlebovirus, Uukuniemi virus (176). Studies have not been conducted to exclude the presence of homodimers for other viruses in the family. The glycoproteins interact to form surface morphologic units that vary among viruses in different genera. Viruses in the *Phlebovirus* genus (e.g., Rift Valley fever, Punta Toro, sandfly fever Sicilian, and Uukuniemi viruses) have round, closely packed morphologic units, approximately 10 to 11 nm in diameter, with central cavities approximately 5 nm in diameter (49,120,194). Negative staining of glutaraldehyde-fixed particles, as well as freeze-etching techniques, demonstrated that the surface units of Uukuniemi virus are penton-hexon clusters arranged in a T=12, P=3 icosahedral surface lattice with hexon–hexon distances estimated at 12.5 to 16 nm for stained viral particles and 17 nm for freeze-etched samples (213).

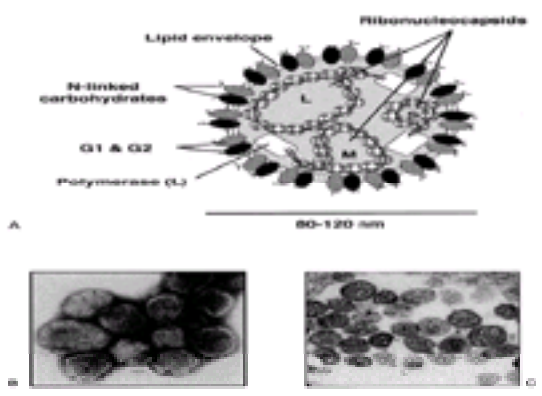

FIG. 1. Morphology of *Bunyaviridae* virions. **A:** Schematic cross section of virus. The three RNA genome segments (S, M, and L) are complexed with nucleocapsid protein to form ribonucleocapsid structures. The nucleocapsids and RNA-dependent RNA polymerase are packaged within a lipid envelope that contains the viral glycoproteins, G1 and G2. Note that there is no matrix protein. **B:** Electron micrograph of glutaraldehyde-fixed, negatively stained Hantaan virions (*Hantavirus* genus). The morphologic units on the surface form a grid-like pattern. As described in the text, viruses in other genera have varying characteristic surface structures. **C:** Thin-section electron micrograph of Puumala virus (*Hantavirus* genus). The interior of the virions has a filamentous or coiled-bead appearance, presumably due to the presence of the ribonucleocapsids. Micrographs courtesy of T. Geisbert, K. Kuhl, and J.E. White, U.S. Army Medical Research Institute of Infectious Diseases, Frederick, MD.

The surface structure of viruses in the *Hantavirus* genus (e.g., Hantaan virus) also are distinctly ordered and have a unique square grid-like appearance (see Fig. 1B) (124,221). In contrast, virions in the *Bunyavirus* genus (e.g., Anhembi, La Crosse, and Bunyamwera viruses) have surfaces covered with knob-like morphologic units with no detectable order (120,204). Similarly, no obvious order was found for the small surface structures with central cavities observed on viruses in the *Nairovirus* genus (e.g., Crimean Congo hemorrhagic fever, Qalyub, and Dugbe viruses) (17,120).

The appearance of viruses in the *Tospovirus* genus (e.g., tomato spotted wilt and impatiens necrotic spot viruses) has been likened to that of the nairoviruses (128). Other than the presence of glycoprotein projections, which are observed as a fringe on negatively stained virions, distinctive surface structure has not been noted for these viruses (98).

The interior of virions, as observed by thin-section electron microscopy, has a filamentous or coiled bead appearance, presumably due to the presence of the ribonucleocapsids (see Fig. 1C) (41,63,79).

Biochemical and Biophysical Properties

The composition and structure of virions has been inferred from biochemical and morphologic studies. An overall chemical content of 2% RNA, 58% protein, 33% lipid, and 7% carbohydrate was estimated for Uukuniemi virus (139). Sedimentation coefficients of virions range from 400 to 500 S, and their buoyant densities in sucrose are 1.16 to 1.18 g/cc, and in CsCl, 1.20 to 1.21 g/cc. Treatment with lipid solvents or nonionic detergents removes the viral envelope and results in loss of infectivity for arthropods and mammals (121,128,139). For plants, the envelope is not required for infectivity, as demonstrated in studies with tomato spotted wilt virus, for which repeated mechanical passage among plants resulted in a defective virus that was unable to produce enveloped particles but was able to infect and replicate in plant cells (170). These studies provide indirect evidence that the L polymerase protein remains associated with ribonucleocapsids and is active despite the absence of intact virions.

GENOME STRUCTURE AND ORGANIZATION

Viral Genome

Virions contain three single-stranded RNA genome segments designated large (L), medium (M), and small (S). All three gene segments of a virus have the same complementary nucleotides at their 3' and 5' termini. The terminal nucleotide sequences are highly conserved among viruses within a genus, but differ from those of viruses in other genera (Table 1). Base-pairing of the terminal nucleotides is predicted to form stable panhandle structures and noncovalently closed circular RNAs. Direct support for base-pairing comes from electron microscopy of RNA extracted from virions, in which three sizes of circular RNAs were evident (77).

Genus/Virus	Consensus S, M, L terminal nucleotides	Gene sizes (accession no.) S	M	L
Bunyavirus				
Bunyamwera	3′ UCAUCACAUG– 5′ AGUAGUGUGC–	961 (X00053)	4458 (M11852)	6875 (X14383)

TABLE 1. *Terminal nucleotide sequences of the S, M, and L genome segments of representative members of the family Bunyaviridae*

The RNA segments are complexed with N to form individual L, M, and S nucleocapsids, which appear to be helical (138). Nucleocapsids released by nonionic detergent treatment of virions often also appear as circular structures in electron micrographs, suggesting that the complementary RNAs can base-pair even when complexed with protein in an estimated ratio of 4% RNA:96% protein (137,157,165). This hypothesis is supported by data showing cross-linking of the ends of nucleocapsid-enclosed RNAs by treatment with psoralens, which are photoreactive, nucleic acid, cross-linking agents

(165).

At least one each of the L, M, and S ribonucleocapsids must be contained in a virion for infectivity; however, equal numbers of nucleocapsids may not always be packaged in mature virions, as suggested by various reports of equimolar or nonequimolar ratios of L, M, and S RNAs (16,81,207). Unequal complements of the ribonucleocapsids may contribute to the size differences of virions observed by electron microscopy (204).

In addition to ribonucleocapsids containing virion sense RNA (vRNA), certain viruses in the *Phlebovirus* and *Tospovirus* genera encapsidate small amounts of complementary sense RNA (cRNA) of their ambisense genes (i.e., S, but not M for Uukuniemi virus, and both M and S for tomato spotted wilt virus) (102,191). For the bunyavirus, La Crosse virus, S segment cRNA was detected in virions synthesized in insect cells, but not in mammalian cells (165). The significance of this finding, if any, is not known.

Coding Strategies of Viral Genes

Both similarities and noteworthy differences in the coding strategies of viruses in the family *Bunyaviridae* are known. Viruses in each genus encode all structural proteins (N, G1, G2, and L) in virus cRNA. Nonstructural proteins are encoded in the M segment cRNA of phleboviruses and bunyaviruses and in the S segment cRNA of bunyaviruses. In addition, phleboviruses encode a nonstructural protein in their S segment vRNA, and tospoviruses encode nonstructural proteins in both their M and S segment vRNAs. Therefore bunyaviruses, hantaviruses, and nairoviruses use strictly negative-sense coding strategies, but phleboviruses and tospoviruses use ambisense coding strategies (Fig. 3).

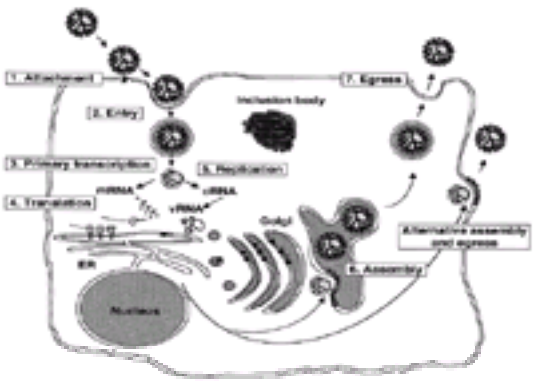

FIG. 3. Replication cycle of viruses in the family *Bunyaviridae.* Steps in the replication cycle are numbered as follows: *1*, attachment of virions to cell-surface receptors; *2*, entry via receptor-mediated endocytosis followed by membrane fusion, allowing viral ribonucleocapsids and RNA-dependent RNA polymerase access to the cytoplasm; *3*, primary transcription; *4*, translation of viral proteins; *5*, replication of vRNA via a cRNA intermediate; *6*, assembly of virions at the Golgi or plasma membrane; *7*, egress by budding into the Golgi followed by exocytosis, or budding through the plasma membrane. For several members of the family, inclusion bodies are found in the cytoplasm. *ER*, endoplasmic reticulum; *black and white boxes*, receptor; *open circles*, N; *shaded circles*, G1 and G2

S Segment Strategies

Viruses in the *Bunyavirus* genus have smaller S segments than those of viruses in other genera (Fig. 2A). Two polypeptides, N and NSs, are encoded in overlapping reading frames in cRNA (15). The presence of NSs in virus-infected cells was demonstrated for several members of the genus (46). Only one S segment mRNA species can be found in bunyavirus-infected cells (26); therefore N and NSs likely are generated by ribosomal recognition of start codons in both reading frames.

FIG. 2. Genomic structure and coding strategies of viruses in the family *Bunyaviridae.* All members of this family have a genome that consists of three single-stranded RNA segments (S, M, and L) that have either a negative-sense or ambisense coding strategy. Numbers of nucleotides for the L, M, and S segments listed below the boxes, which represent relative sizes of the gene segments and show regions encoding the viral proteins. **A:** S-segment coding strategies. Hantaviruses and nairoviruses use negative-sense coding to express a single protein, N from their virion complementary-sense RNA (cRNA). Bunyaviruses also use negative-sense coding but express two proteins, N and NSs, from overlapping open reading frames (ORFs) of cRNA. Phleboviruses and tospoviruses use ambisense coding to express two proteins, N and NSs, from separate, subgenomic mRNAs. Lines, N coding regions; solid, NSs coding regions. **B:** M segment coding strategies. Bunyaviruses, hantaviruses, nairoviruses, and phleboviruses all use negative-sense coding to express two surface glycoproteins, G1 and G2, from a single ORF of cRNA. Bunyaviruses and

phleboviruses encode an additional nonstructural protein, NSm, in the same ORF. M segment products are processed from a precursor polyprotein by cotranslational cleavage. Tospoviruses generate two subgenomic messages and use ambisense coding to express G1 and G2, from an ORF in cRNA, and NSm, from an ORF in vRNA. *Dots*, G1 and G2; *cross-hatch*, NSm coding regions; *solid*, G1 precursor region of nairoviruses. **C:** L segment. All viruses in the family use negative-sense coding to express the L protein, which is the RNA-dependent RNA polymerase, from an ORF in cRNA. Vertical dashes, L coding region.

Hantaviruses and nairoviruses encode larger nucleocapsid proteins than do viruses in other genera, but are not known to encode NSs proteins (see Fig. 2A) (117,187,217). Although some hantaviruses (e.g., Sin Nombre, Puumala, and Prospect Hill viruses) have an overlapping reading frame with N that has a coding potential of approximately 6 kd, NSs proteins have not been detected in hantavirus-infected cells (141,195,197). Only one S segment mRNA, similar in size to the coding region for N, was identified in hantavirus- or nairovirus-infected cells, indicating that transcription termination occurs shortly after the translation stop codon (81,186,216). Certain hantaviruses (e.g., Sin Nombre virus) have long 3' noncoding regions (>700 nt) containing numerous repeated sequences. These repeats may result from polymerase slippage on the vRNA template (195).

The ambisense coding strategy of the S segments of phleboviruses and tospoviruses produces N from a subgenomic mRNA that is complementary to vRNA, and NSs from a subgenomic mRNA of the same polarity as vRNA (see Fig. 2A) (37,82). Evidence that the mRNA for NSs is copied from cRNA (after genome replication) comes from time-course studies. For the phlebovirus Uukuniemi virus, N was detected at 4 to 6 hours after infection, whereas NSs did not appear until 8 hours after infection (192,205). Likewise, the mRNA for NSs of the tospovirus, tomato spotted wilt virus, was detected in infected plant cells 15 hours later than for N (196). In addition, studies with the phlebovirus, Punta Toro virus, demonstrated that protein synthesis inhibitors arrest production of NSs mRNA, but not N mRNA (84). These results suggest that protein synthesis must occur before the NSs mRNA can be made. The requirement for protein synthesis is probably related to the need for an adequate supply of newly formed N to encapsidate nascent cRNA, which in turn is then available as a transcription template for NSs mRNA (see transcription section later).

M Segment Strategies

The M segment encodes the two envelope glycoproteins, G1 and G2, in a single open reading frame (ORF) of cRNA. Some viruses encode NSm proteins, and others do not. Except for the tospoviruses, which use an ambisense strategy to generate NSm from a subgenomic mRNA, a single mRNA, nearly equivalent in size to the cRNA ORF, has been detected in virus-infected cells (30,86,118,186). The G1 and G2 gene order varies between genera and even among viruses of a single genus; however, these discrepancies are due to nomenclature anomalies rather than to functional differences. That is, the G1 and G2 designations refer to the electrophoretic migration of the envelope proteins, with G1 being the more slowly migrating band on an sodium dodecylsulfate (SDS)-polyacrylamide gel.

Bunyaviruses have a cRNA M segment gene order of 5'-G2-NSm-G1-3' (see Fig. 2B) (53). The synthesis of NSm in bunyavirus-infected cells was confirmed by immune-precipitation with antisera to viruses or to synthetic peptides representing amino acids predicted from the NSm coding region (53,56,134).

Hantaviruses have a M segment cRNA gene order of 5'-G1-G2-3' (188). Immune-precipitation with antisera to peptides representing predicted G1 or G2 amino acids showed that the carboxyl terminus of G1 extends to within 17 amino acids of the signal sequence for G2 and that the carboxyl terminus of G2 extends to the end of the ORF (188). Consequently, with the possible exception of a very short intergenic region, no coding information for a NSm polypeptide is available.

A gene order of 5'-G2-G1-3' was determined for the nairovirus, Dugbe virus, by expression of portions of the genes with recombinant baculoviruses and by amino-terminal sequence analysis of authentic G1 (116). These studies indicated that the amino terminus of G1 was about 50 amino acids downstream of the nearest predicted signal sequence. Consequently, it was postulated that G1 arises by proteolytic processing of a precursor protein (116). Further studies are needed to confirm this finding and to determine if additional nonstructural proteins are encoded in the nairovirus M segment.

The M segment gene order and the coding strategy varies among viruses in the *Phlebovirus* genus. The tick-borne phleboviruses (e.g., Uukuniemi virus) encode only G1 and G2 proteins (178) in cRNA, whereas the mosquito- and sandfly-vectored phleboviruses also have coding information for a NSm protein. For Rift Valley fever virus, the cRNA gene order is 5'-NSm-G2-G1-3' (32). The gene order for Punta Toro virus is 5'-NSm-G1-G2-3', but the reversed order has no significance, as indicated at the beginning of this section. The NSm protein of Rift Valley fever virus, but not that of Punta Toro virus, could be detected in virus-infected cells (83,93).

Like the S segments, the M segments of tospoviruses use an ambisense coding strategy. The cRNA has a gene order of 5'-G2-G1-3', and the vRNA encodes NSm (108). There are separate, subgenomic messages for the G1–G2 precursor and for NSm (101,108). NSm is readily detected in infected plants and is the only M segment nonstructural protein in the *Bunyaviridae* family to have a defined role (i.e., it is a movement protein, as discussed later).

L Segment Strategies

A conventional negative-sense coding strategy was found for all L segments of viruses in the family *Bunyaviridae.* For each L segment described thus far, there are fewer than 200 nucleotides of total noncoding information, and there is no evidence for additional coding regions in either the cRNA or vRNA (36,47,130,131,183,210).

STAGES OF REPLICATION

The principal stages of the replication process for viruses in the *Bunyaviridae* are illustrated in Fig. 3 and are summarized.

1. Attachment, mediated by an interaction of viral proteins and host receptors.
2. Entry and uncoating, by endocytosis of virions and fusion of viral membranes with endosomal membranes.
3. Primary transcription of viral-complementary mRNA species from genome templates using host cell–derived primers, and the virion-associated polymerase.
4. Translation of primary L and S segment mRNAs by free ribosomes, translation of M segment mRNAs by membrane-bound ribosomes, and primary glycosylation of nascent envelope proteins.
5. Synthesis and encapsidation of viral-complementary RNA to serve as templates for genomic RNA or, in some cases, for subgenomic mRNA.
6. Genome replication.
7. Secondary transcription of mRNA from newly synthesized genomes and of ambisense mRNAs from cRNA.
8. Continued translation and RNA replication.
9. Morphogenesis, including accumulation of G1 and G2 in the Golgi, terminal glycosylation, and acquisition of modified host membranes, generally by budding into the Golgi cisternae.
10. Fusion of cytoplasmic vesicles with the plasma membrane and release of mature virions.

Attachment and Entry

Viral Attachment Proteins and Cellular Receptors

The mechanisms by which members of the family *Bunyaviridae* gain access to the host cell's cytoplasm appear similar to those reported for many other enveloped viruses. The first step involves an interaction between cell-surface receptors and viral attachment proteins, G1 and/or G2. The functions of G1 and G2 during attachment and entry may vary among the genera. For the bunyavirus, LaCrosse virus, it was suggested that G1 might be used for attachment to mammalian cells, whereas G2 might be used for attachment to mosquito cells (113). However, studies involving proteolytic digestion of virions or incubation of virions with glycoprotein-specific antibodies implicated G1 as the attachment protein for mammalian cells, mosquito cells, and mosquitoes (67,71,75,96,148,201). For viruses in other genera, little is known concerning the use of G1 or G2 for attachment. The presence of neutralizing and hemagglutination-inhibiting sites on both the G1 and G2 proteins of the phleboviruses, Rift Valley fever (94), and Punta Toro (159) viruses, and on those of the hantavirus Hantaan virus (9,35), suggest that both proteins may be involved in attachment, either directly or because of conformational requirements.

Host-cell receptors have not been identified for most viruses in the family; however, b $_3$ integrins, which are surface proteins found on endothelial cells and platelets, were found to facilitate cellular entry of some pathogenic hantaviruses (59,60). Evidence for this comes from studies in which cells were rendered resistant to hantavirus infection by pretreating them with vitronectin, the physiologic ligand of b $_3$ integrins, or with b$_3$ integrin–specific antibodies. Consistent with these findings, stably transformed CHO cells expressing b$_3$ integrins supported hantavirus infections, whereas normal CHO cells did not. A nonpathogenic hantavirus, Prospect Hill virus, was found to use b $_1$ integrins rather than b$_3$ integrins, suggesting a role for viral receptors in determining virulence (60). Whether integrins are involved in virion attachment, or a postattachment entry event, has not been determined.

Entry of the Viral Genome into the Host Cytoplasm

Shortly after attachment, viruses in the *Phlebovirus* and *Nairovirus* genera were observed in phagocytic vacuoles (49,181). This finding suggests a mode of viral entry similar to that first described for alphaviruses in which the virus is endocytosed in coated vesicles (119). Acidification of the endosomes is thought to promote a conformational change in G1 and/or G2 that facilitates fusion of the viral and cell membranes, allowing the viral genome and polymerase access to the cytoplasm. Consistent with this, treating cells with ammonium chloride to prevent acidification of endosomes inhibited infection by the bunyavirus, California encephalitis virus, or the phlebovirus, Uukuniemi virus (74,176). Additional indirect support for membrane fusion as a mode of entry came from experiments demonstrating the ability of viruses in the family to mediate syncytia formation at low pH (10,64,65 and 66,86).

Whether one or both of the envelope proteins are necessary for viral entry has not been defined for most members of the family. For bunyaviruses, several lines of evidence indicate that G1 is involved not only in viral attachment to cells, but also has a role in membrane fusion. Protease sensitivity assays, detergent partitioning experiments, and antibody-binding studies, suggest that G1 undergoes a conformational change at pH conditions in which fusion is observed (65,74,147). In addition, a mutant of La Crosse virus, generated by passage in the presence of a monoclonal antibody to G1, displayed a reduced capacity to undergo pH-dependent conformational changes at low pH, and to cause cell-to-cell fusion (65). G1 alone, however, when expressed from recombinant vaccinia viruses, could not cause cell–cell fusion, suggesting that an association of the two glycoproteins is probably needed for membrane fusion (23,86).

Primary Transcription

Transcription Initiation

After uncoating of viral genomes, primary transcription of negative-sense vRNA to mRNA is initiated by interaction of the virion-associated polymerase (L) and the three viral RNA templates (18,167). Only ribonucleocapsids, not free RNA, can serve as transcription templates, as demonstrated in studies with expressed phlebovirus and bunyavirus L and N proteins. In these studies, transcription depended on the presence of both proteins and was unaffected by the presence

of other viral proteins (43,112).

Like influenza viruses, viruses in the family *Bunyaviridae* prime mRNA synthesis with capped oligonucleotides that are scavenged from host mRNAs. Unlike influenza viruses, which take primers from newly synthesized mRNAs in the host cell's nucleus (85), members of the *Bunyaviridae* family use primers cleaved from cytoplasmic host-cell mRNAs. A result of this mode of mRNA transcription is the presence of 5' terminal extensions of approximately 10 to 20 heterogeneous nucleotides that are not found in vRNA (14). Studies using anti-cap antibodies to immunoselect mRNAs (73) provided direct proof for the presence of caps on the scavenged primers and substantiated earlier, indirect findings that showed stimulation of La Crosse virus transcription by methylated cap analogs such as m ^{7}GpppAm, or naturally capped RNAs (144). Further evidence for capped extensions of mRNAs was provided by a study with the tospovirus, tomato spotted wilt virus, in which plants were coinfected with the tospovirus and with a positive-strand RNA virus (alfalfa mosaic virus). The tospovirus acquired 5' mRNA extensions with nucleotide sequences that matched those of the other virus. Presumably, these extensions retained the cap structures normally found on the positive-strand RNA viral messages (42). Cleavage of the capped primers is accomplished by endonucleolytic activity associated with virions (144). The endonuclease activity was demonstrated to localize to the L protein of Bunyamwera virus in studies in which vaccinia virus–expressed L was shown to transcribe mRNAs with heterogeneous extensions analogous to those found on authentic viral mRNAs (90).

For several viruses in the family, there appears to be a nucleotide or nucleotide motif preference for endonuclease cleavage. That is, although heterogeneous in sequence, the 5'-terminal extensions often have a preponderance of specific mono-, di-, or trinucleotides at the –1 to –3 positions with respect to the 5' terminus of their mRNAs. These preferences vary among the genera, and sometimes among viruses within a genus. For example, in one study, almost all cDNA clones of the S mRNA of the bunyavirus, Germiston virus, displayed U or G at the –1 position (19). In contrast, the bunyavirus, snowshoe hare virus, was found most commonly to have A as the 3'-terminal nucleotide of the S mRNA extensions (52). For phleboviruses, C was detected most often at the –1 position of the M mRNA of Rift Valley fever virus and also at the –1 position of the N and NSs mRNAs of Uukuniemi virus (30,193). For the hantaviruses, Hantaan and Sin Nombre viruses, the preferred –1 nucleotide was G (38,81), and for the nairovirus, Dugbe virus, C was most common (91). Examination of terminal nucleotides of 20 clones of N mRNAs of tomato spotted wilt virus revealed no base preference at the endonucleolytic cleavage site (209); however, a preference for A was observed in studies in which oligonucleotides were acquired from messages of another plant virus (42). A selective preference for an entire primer sequence was observed with La Crosse virus in persistently infected mosquitoes. In both embryonating and dormant eggs, specific, but different, 5'-extensions were observed on the majority of mRNAs (39). It was not determined whether the paucity of heterogeneous sequences related to poor availability of diverse host mRNAs, or to a preference by La Crosse virus for certain mRNAs as a source of primers.

A preferred primer sequence, or a favored nucleotide at the site of cleavage, might imply that a restricted or specific subset of host mRNAs is used for generating transcription primers, perhaps because of a need for limited base pairing with the viral genome. In one study, the 3'-terminal nucleotides of the scavenged host primers often were similar to the 5'-terminal viral nucleotides (91). It was proposed that after transcription of two or three nucleotides of the nascent mRNA, the viral polymerase might slip backward on the template before further elongation, resulting in a partial reiteration of the 5'-terminal sequence. This mechanism would explain findings with the bunyavirus, Germiston virus, which had an insertion of U or GU between the primer and viral sequences (211). Likewise, the mechanism could explain the finding that Bunyamwera virus mRNAs, which were synthesized by vaccinia virus–expressed L protein, had insertions of GU or AGU (90). Polymerase slippage also was suggested to be a possible reason for the AG insertions observed in a few mRNAs of the tospovirus, tomato spotted wilt virus (42).

An extension of this concept, termed “prime and realign,” was proposed for mRNA transcription of hantaviruses (58). According to this model, priming by host oligonucleotides with a terminal G residue would initiate transcription by aligning at the third nucleotide of the viral RNA template (C residue). After synthesis of a few oligonucleotides, the nascent RNA could realign by slipping backward two nucleotides on the repeated terminal sequences (AUCAUCAUC) (see Table 1), such that the G becomes the first nucleotide of the nontemplated 5' extensions. The frequent deletion of one or two of the triplet repeats in hantaviral mRNA supports this sort of slippage mechanism and suggests that sometimes the initial priming might start at the C residue of the third triplet in the conserved sequence rather than at the C of the second triplet (58). A prime-and-realign model also was postulated for transcription of hantaviral vRNA and cRNA, except that transcription would initiate with pppG alignment at the third nucleotide (C residue) of the template RNA. After synthesis of several nucleotides, polymerase slipping would realign the nascent RNA such that the initial priming G residue would overhang the template. It was further theorized that nucleolytic activity of the L protein might remove the overhanging G, leaving a monophosphorylated U residue at the nascent 5' end. The presence of the monophosphorylated U on Hantaan virus RNA was experimentally demonstrated (58).

Indirect evidence suggesting that a prime-and-realign method of initiation is used by phleboviruses was obtained by using a reconstituted transcription system to study the polymerase recognition sequence at the 3' termini of the ambisense S segment RNA of Rift Valley fever virus. In those studies, mutational analysis of the terminal nucleotides revealed that the first 13 nucleotides are required for polymerase recognition, but that one of the two terminal dinucleotides (UGUG) could be removed without deleterious effects on transcription (161). These data also suggested that realignment is not a prerequisite for transcription initiation.

Host Factors

Beyond the need for host-derived primers for initiating mRNA synthesis, little is known about the role that host factors might play in viral replication. Although transcriptional host factors have not been identified, they cannot presently be excluded. Whereas inhibitors of host-cell protein synthesis, such as cycloheximide and puromycin, have been found to have no effect on primary transcription in other negative-strand RNA virus families (e.g., *Orthomyxoviridae, Rhabdoviridae,* and *Paramyxoviridae*), conflicting data exist on their effects on viruses in the *Bunyaviridae* family. Early reports indicated that the bunyaviruses, Bunyamwera and Akabane viruses, were sensitive to cycloheximide (1) and that either no or greatly reduced amounts of S mRNA could be detected in La Crosse bunyavirus–infected cell cultures treated with cycloheximide or puromycin (145,162). In addition, La Crosse virion–associated polymerase produced only

incomplete transcripts *in vitro* unless rabbit reticulocyte lysates were added to provide a coupled transcription–translation system. In the coupled system, drugs that inhibit protein synthesis also inhibited full-length mRNA synthesis and resulted in the reappearance of the incomplete transcripts (13,163). This led to a hypothesis that translation of the nascent bunyavirus S mRNA is required to prevent premature termination of primary transcription products and that the nascent chain may be interacting with its template to cause premature termination. Such a translation requirement was postulated to be similar to that observed in certain bacterial systems, whereby ribosomes prevent RNA–RNA interaction and thus premature termination (163).

For the bunyavirus, Germiston virus, although S segment mRNA was inhibited in cell culture by either anisomycin or cycloheximide, full-length S transcripts could be obtained in an *in vitro* transcription system without added translational capabilities (61). Further studies, however, revealed that these full-length transcripts were obtained only under conditions of increased temperature, and that premature termination products were obtained under more usual transcription conditions. Adding of reticulocyte lysate improved transcription significantly and restored the ability for full-length transcription to occur (211).

The mechanism of the inhibition of transcription by proteinase inhibitors was more clearly defined for Germiston virus, in that adding the translation inhibitors cycloheximide, puromycin, or anisomycin, but not edeine, inhibited transcription. Because edeine inhibits translation by preventing the 40S and 60S ribosomal subunits from complexing, but still allows the 40S subunit to scan the transcript, the need for ongoing protein synthesis was postulated to be at the level of ribosome scanning, and to be independent of the need for actual translation (211). These data are consistent with an earlier hypothesis that scanning ribosomes prevent premature termination by preventing base-pairing between the template RNA and the transcript, which would cause the polymerase to halt and terminate prematurely. This theory is based on the finding that if inosine was substituted for guanosine in the *in vitro* transcription reaction, thus destabilizing base pairing, less premature termination was observed (13).

Results conflicting with these findings were obtained with the bunyavirus, snowshoe hare virus, in that strand-specific cDNA probes were able to detect full-length S segment mRNA (but not vRNA) readily in the presence of puromycin or cycloheximide (52). These results suggest that primary transcription depends neither on ongoing host protein synthesis nor on ribosomal scanning. A similar finding was obtained with La Crosse virus transcription in mosquito cells, in that translation inhibitors had no effect on transcription, suggesting that host-cell factors may influence the ability of the viral polymerase to function in the presence of such inhibitors (166). At present, it is unclear whether the variations reported in transcriptional requirements for viruses in this genus are due to differences in their transcriptional properties or to differences in the sensitivities of methods used.

Transcription Termination

Differences between vRNA and mRNA are found, not only at their 5'-termini but also at their 3'-termini. For gene segments with simple negative-sense coding, mRNAs are truncated at the 3'-termini by approximately 100 nucleotides as compared with cRNA (19,20,30,52,145,146,158,164). Potential transcription-termination sites have been proposed for the S segments of the bunyaviruses La Crosse (145) and snowshoe hare viruses (51,52) at or near the genomic sequence, 3'-G/CUUUUU, which is similar to other negative-strand RNA viral transcription termination–polyadenylation signals (72,174). U-rich regions also were observed at putative transcription-termination sites for the M and S segments of the bunyavirus Germiston virus (3'-AUGUUUUUGUU and 3'-GGGGUUUGUU, respectively) (19) and the M mRNA of hantaviruses (81). Despite these findings, there is little evidence to suggest that the mRNAs of viruses in the family *Bunyaviridae* are polyadenylated (146,158,205). Moreover, transcription-termination sites without the homopolymeric U5 or U6 tract have been proposed for numerous gene segments of viruses in the family. For example, a C-rich motif was proposed as the site of termination for the S mRNA of Sin Nombre virus (CCCACCC) (81), and purine-rich regions have been suggested as termination sites for the S and M segment mRNAs of snowshoe hare virus (5'-GGUGGGGGGUGGGG and 5'-GGUGGGGGGUGGGG, respectively), (51) and the M segments of the phleboviruses Rift Valley fever and Punta Toro viruses (5'-UGGGGUGGUGGGGU and 5'-GGUGAGAGUGUAGAAAG, respectively) (30). If these sequences are involved in transcription termination, the mechanism by which they are recognized will require further study.

Interestingly, the polymerase protein of Bunyamwera virus, expressed with a recombinant vaccinia virus, was able to transcribe virion-derived nucleocapsids, and some of the S transcripts terminated at the authentic transcription-termination site, but most did not (90). These results suggest that an additional factor(s), of either viral or cellular origin, may be required for consistent transcription termination. Likewise, in studies with the bunyavirus, Germiston virus, transcription termination was abolished if the drug edeine was included in reaction mixtures. Two suggested mechanisms to explain these findings were proposed. One possibility is that transcription termination involves an interaction between the transcriptase and a newly synthesized viral protein, such as NSs. This could not be a familial characteristic, however, because hantaviruses and nairoviruses do not encode NSs proteins. A second possibility is that the abnormal presence of scanning 40S ribosomes might mask the transcription-termination site (90,211).

The mechanism of transcription termination of the ambisense genes of phleboviruses and tospoviruses may differ from negative-sense genes, and is likely to involve RNA secondary structure. The transcription-termination sites for both the N and NSs mRNAs of Punta Toro virus were mapped by hybridizing a series of synthetic oligonucleotides corresponding to vRNA or cRNA to the messages. The results indicated that the 3' termini of both mRNAs are within 40 nucleotides of one another (50). Computer analysis of the intergenic region and the sequences encoding the 3' termini of the messages revealed a long, inverted complementary sequence that could potentially form a hairpin structure.

Similar stable hairpin structures are predicted to occur in the intergenic regions of the S and M segments of tospoviruses (37,104,108). For the S segment of the phlebovirus Uukuniemi virus, although there is a noncoding region of 70 nucleotides between the N and NSs genes, hybridization studies demonstrated that the 3' ends of the subgenomic messages overlap one another by about 100 nucleotides. Thus the 3' end of the NSs mRNA extends into the coding region of N, and the 3' end of the N mRNA terminates just before the coding sequences for N. A short palindromic sequence in the intergenic region (including the 3' ends of each mRNA) was predicted to allow formation of an A/U-rich

hairpin structure (193). Similar (but shorter), energetically favored structures have been identified in intergenic regions of the S segments of the arenaviruses, Pichinde and lymphocytic choriomeningitis viruses, which also use ambisense coding (175). For the *Bunyaviridae,* such structures could affect transcription termination only if they can form while the genome is complexed with N, and there is no direct evidence that this occurs.

In addition to secondary structure, particular sequences or motifs also may play a role in transcription termination of ambisense mRNAs. Comparing the S-segment sequences of several phleboviruses revealed the presence of G-rich regions and similar sequence motifs in the intergenic regions of Rift Valley fever, Toscana and sandfly fever Sicilian viruses, but not for Punta Toro or Uukuniemi viruses (62). Currently, there is no conclusive evidence that either of these mechanisms (i.e., secondary structure or gene sequence) is important for transcription termination with viruses in this family.

Genome Replication

For negative-strand viruses, the change from primary transcription to replication requires a switch from mRNA synthesis to synthesis of full-length cRNA templates and then vRNA. For viruses in the family *Bunyaviridae,* the polymerase protein, acting either alone or in concert with undefined viral or cellular factors, must first function as a cap-dependent endonuclease to generate a primer for transcription of a nonencapsidated, subgenomic mRNA. At some point, the polymerase must switch to a process of independently initiating transcription at the precise 3' end of the template to produce a full-length transcript. The processes involved in making that switch from primary transcription to genome replication have not been defined completely for any member of the family. Presumably, some viral or host factor is required to signal a suppression of the transcription-termination signal responsible for generation of truncated mRNA. There is no question that genome replication and subsequent secondary transcription are prevented by translational inhibitors such as cycloheximide. These results indicate that continuous protein synthesis is required for replication of the genome. Although not proven, it is likely that synthesis of N is required for genome replication, as described for other negative-strand RNA viruses such as the rhabdovirus, vesicular stomatitis virus, and the paramyxovirus, Sendai virus (see Chapter 38 and Chapter 41). For these viruses, encapsidation by N seems to serve as an antitermination signal, thus allowing full-length genome synthesis. It was suggested that the vesicular stomatitis virus NS protein also is involved and acts to control the availability of N (78). A similar mechanism appears plausible for viruses in the family *Bunyaviridae,* whereby N would function to regulate replication and might be tempered by the presence of nonstructural proteins, where they exist. A model for genome transcription and replication based on information presented earlier, and modified slightly from that proposed by Simons (190), is presented in Fig. 4.

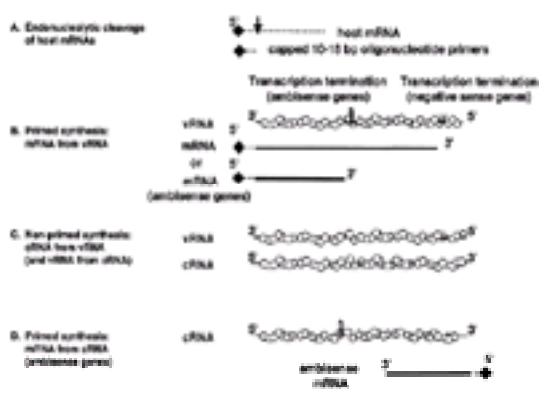

FIG. 4. Transcription and replication of RNA (*Bunyaviridae* family viruses). **A:** Transcription of viral mRNA is preceded by endonucleolytic cleavage of host mRNA caps and adjacent oligonucleotides (*solid diamond*) by viral polymerase (cap snatching). **B:** The capped oligonucleotides prime transcription of viral mRNA from the virion-encapsidated RNAs (vRNAs). Negative-sense genes are copied to yield mRNAs nearly as long as the vRNA template. Ambisense genes (S segments of phleboviruses and tospoviruses, and M segments of tospoviruses) are copied to yield mRNAs complementary to the 3' portion of the vRNA template. A hairpin structure (*hairpin shape*) is believed to be involved in transcription termination of ambisense genes. An undefined transcription termination signal (*V*) is found near the 5' end of the vRNA template for negative-sense gene segments. **C:** Replication involves primer-independent synthesis of complementary RNA (cRNA) from vRNA templates followed by primer-independent synthesis of progeny vRNA from cRNA templates. **D:** For viruses that use ambisense coding strategies to express nonstructural proteins (NSs of phleboviruses and tospoviruses and NSm of tospoviruses), the cRNA also serves as template for mRNA synthesis. As in primary transcription, capped, host-derived oligonucleotides prime synthesis of the ambisense mRNAs, and transcription termination occurs at a predicted hairpin structure.

Translation and Processing of Viral Proteins

Viral polypeptides are synthesized shortly after infection, with S and L mRNAs translated on free ribosomes, and M mRNAs translated on membrane-bound ribosomes. Expression products vary among the genera, and even within a genus.

S Segment Products: N and NSs

The N proteins of viruses in the family range in size from approximately 19 kd for bunyaviruses to 54 kd for hantaviruses and nairoviruses (see Fig. 2A). Posttranslational modifications to N have not been described. Few studies have characterized interactions of N and viral RNA. Biochemical analysis of RNA binding by N of Hantaan virus suggested that specific recognition of vRNA by N occurs in the terminal, noncoding regions of vRNA (189). For Hantaan and Puumala viruses, it was suggested that the carboxyl-terminal portion of N is needed for nucleic acid binding (68). In contrast, both

amino-terminal and carboxyl-terminal portions of N of the tospovirus, tomato spotted wilt virus, were postulated to bind to RNA (172).

In addition to N, viruses in the *Bunyavirus, Phlebovirus*, and *Tospovirus* genera produce NSs proteins. Sizes of NSs range from 10 kd for bunyaviruses to more than 50 kd for tospoviruses (see Fig. 2A). The NSs protein of the phlebovirus Rift Valley fever virus is phosphorylated and accumulates in the nuclei of infected cells, where it forms fibrillar structures (200). The major phosphorylation sites of the Rift Valley fever virus NSs were mapped to serine residues located near the carboxyl terminus of the protein (100). Expression studies revealed that fibrils could form in the absence of other viral proteins; however, if the carboxyl-terminal region of NSs was removed, NSs was still transported to nuclei, but did not coalesce into fibrils (224). Similar fibrillar structures of NSs were observed for some strains of tomato spotted wilt virus, but the structures appeared only in the cytoplasm. For other strains of tomato spotted wilt virus, NSs was found to be distributed throughout the cytoplasm but did not form discernible structures (103). The NSs protein of the phlebovirus Uukuniemi virus was also found to be distributed throughout the cytoplasm. This protein was not phosphorylated but did associate specifically with the 40S ribosomal subunit (192). The significance of this association, if any, was not determined.

The characteristics and functions of NSs are not well defined, and there is no evidence that NSs proteins serve the same function for viruses in different genera. Comparing the deduced amino acid sequences of NSs for five different phleboviruses revealed homologies of only 17% to 30% (62). However, comparison of the NSs gene sequences for a number of strains of a single phlebovirus, Rift Valley fever virus, showed that certain areas were highly conserved (182). These data suggest that there may be a strong evolutionary pressure to maintain distinct portions of the NSs for individual viruses, but that the remainder of the protein can diverge without affecting the function of NSs.

For phleboviruses and tospoviruses, it is unlikely that NSs is involved in early stages of replication because their ambisense mRNAs are produced only after vRNA has been copied to cRNA; therefore, NSs appears later in infection than the structural proteins. Consequently, it is likely that NSs is involved in late stages of replication, in morphogenesis, or in the spread of newly formed viruses. Consistent with this, a mutant of the phlebovirus Rift Valley fever virus, with an in-frame deletion of about 70% of the coding information for NSs, was found to replicate in Vero and mosquito cells, but not in human lung diploid cells. In addition, the deleted virus was avirulent in mice and hamsters, as compared with wild-type virus (132). These data suggest a role for the phlebovirus NSs in host range and perhaps in virus dissemination. Similarly, disruption of the coding sequences of NSs in a genetically engineered Bunyamwera virus resulted in a mutant virus that produced smaller plaques, displayed reduced shutoff of host-cell protein synthesis, and showed poorer cell-to-cell spread as compared with wild-type virus (22). The mechanism resulting in these effects remains to be determined.

M Segment Products: G1, G2, and NSm

The viral envelope glycoproteins, G1 and G2, are translated from a single mRNA complementary to vRNA. The polyprotein precursor of G1 and G2 is not seen in infected cells, and has been observed only by *in vitro* translation of RNA transcripts in the absence of microsomal membranes (178,202,205). For most viruses, both G1 and G2 are preceded by signal sequences; therefore, cleavage of the polyprotein precursor is likely mediated by host signalase (54). The nairovirus, Dugbe virus, differs in that there is no signal sequence immediately preceding G1 (the second polypeptide encoded in the ORF); therefore, this protein may be processed from a precursor (116). All M segment polyproteins display variable numbers of predicted transmembrane regions, and a hydrophobic sequence at the carboxyl terminus, indicative of a membrane anchor region. Thus the M segment translation products of viruses in the family *Bunyaviridae* are typical class 1 membrane proteins, with the amino terminus exposed on the surface of the virion and the carboxyl terminus anchored in the membrane.

M segment gene products have a cysteine content of approximately 4% to 7% (32,83,101,108,110,116,188). For related viruses, the positions of the cysteine residues in the polyprotein are highly conserved, suggesting that extensive disulfide-bridge formation may occur and that the positions may be crucial for determining correct polypeptide folding. The secondary structure of the proteins also is involved in immunogenicity, as indicated by the finding that neutralizing or protective epitopes are often nonlinear (11,215).

The nonstructural protein, NSm, produced by phleboviruses and bunyaviruses, is translated from the same mRNA as G1 and G2, whereas that of tospoviruses comes from an ambisense mRNA. There is no known functional equivalence of NSm proteins of viruses in different genera. Hantaviruses and nairoviruses produce no known M segment products except for G1 and G2 (116,188). However, because nairovirus-infected cells display several viral polypeptides of unknown origin (25,116,219), it is possible that additional precursor–product relationships may still be uncovered. In contrast, some viruses in the *Phlebovirus* and *Bunyavirus* genera produce NSm from the same M segment mRNA as G1 and G2. The NSm protein of bunyaviruses is encoded between the G1 and G2 proteins (53,134). Its hydropathy profile suggests that it is a membrane-bound protein, and expression studies demonstrated that it localizes to the Golgi along with G1 and G2 (134). Although a function for this protein has not been identified, it was suggested that it might be involved in facilitating virion assembly in the Golgi (134).

For the phlebovirus, Rift Valley fever virus, a NSm of approximately 14 kd is cleaved from the amino terminus of the polyprotein translation product. Sequence studies revealed five in-frame translation-initiation codons upstream of the amino-terminus of G2. Mutational analysis of those codons indicated that the first four can be used efficiently to translate G2 and G1. NSm was found to originate from the second ATG, and a 78-kd polypeptide, representing uncleaved NSm and G2, was translated from the first ATG (92,203). Pulse-chase experiments revealed no precursor–product relationship between the 78- and 14-kd proteins; thus it appears that use of the first and second ATGs, respectively, is what dictates generation of these proteins (31). Both the 14-kd NSm and the 78-kd polypeptide are found in abundance in Rift Valley fever virus–infected cells, (32,92,202), suggesting that they might play a role in replication or morphogenesis.

An even larger NSm (~30 kd) is cleaved from the amino terminus of the M segment polyprotein of the phlebovirus, Punta

Toro virus. *In vitro* expression studies indicated that both envelope glycoproteins could be produced in the absence of the NSm coding region (123), but other studies to evaluate the use of the 13 potential translation-initiation codons present in the NSm coding information have not been reported. No homology between the NSm proteins of Punta Toro and Rift Valley fever viruses was apparent (83).

In contrast to Punta Toro and Rift Valley fever phleboviruses, the tick-borne phlebovirus, Uukuniemi virus, does not produce an NSm. The first (and only) initiation codon preceding sequences of the envelope glycoproteins is located 17 amino acids upstream of the amino terminus of G1 (178); hence the G1 protein of Uukuniemi virus appears to be analogous to the 78-kd NSm–G2 fusion product produced by Rift Valley fever virus (although there is no obvious sequence homology of these predicted products). Until a function can be assigned to NSm, it is impossible to determine whether Uukuniemi virus replicates in the absence of such a function or accomplishes whatever function is required without removal of a portion of the amino terminus of G1.

Unlike all other viruses in the family, the NSm protein of tospoviruses is translated from an ambisense mRNA (101). It is also the only NSm protein in the family to have an assigned function. By subcellular fractionation of infected plants, or in thin-section immunoelectron microscopy studies, the NSm of tomato spotted wilt virus was found to be present in cell wall–containing fractions or associated with aggregates of nucleocapsids and with the plasmodesmata (101). Expression of the NSm protein in plant cells or insect cells revealed that the protein first appeared near the cell surface and later as tubular structures protruding from the cell surface. In infected leaf tissues, the tubules were observed only in the plasmodesmata (198). These data were interpreted to indicate that the tospovirus NSm protein is involved in cell-to-cell movement of the nonenveloped ribonucleocapsid structures across the cell walls in infected plants.

All G1 and G2 proteins examined to date possess asparagine-linked oligosaccharides. Two broad classes of asparagine-linked oligosaccharides, complex or high-mannose (simple), generally are found on mature glycoproteins (reviewed in 111). Often both types are attached to the same polypeptide chain. As described for the hemagglutinin protein of influenza virus, as well as other glycoproteins (reviewed in 99,105), for oligosaccharides to evolve from the high-mannose type to the complex type, they are normally transported through the Golgi, where mannose residues are trimmed and terminal residues added. Examination of the oligosaccharides attached to the G1 and G2 proteins of Uukuniemi virus in infected cells revealed that G2 has mostly high-mannose glycans, whereas G1 contains both complex and a novel intermediate-type oligosaccharide (152). Similar results were obtained with the bunyaviruses Inkoo and La Crosse viruses (115,152), whereas the glycoproteins of Hantaan virus were found to be mostly of the high-mannose type (8,180,185). These findings indicate that the proteins are incompletely processed through the Golgi. This is likely related to retention of G1 and G2 in the Golgi, where assembly and release occur.

Between four and nine potential glycosylation sites were identified in the deduced amino acid sequences of the G1 and G2 proteins of viruses in the family (32,53,70,83,101,108,110,178,188). The number of sites actually used in mature virion proteins has not been defined for all viruses; however, G2 of the phlebovirus Rift Valley fever virus was demonstrated to be glycosylated at its single available site and at least three of four possible G1 sites (92). Examination of glycosylated tryptic oligopeptides of the envelope glycoproteins of several bunyaviruses suggested that all three potential glycosylation sites on G2 are used and at least one of two sites on G1 (214). The single glycosylation site available in the G2 protein of Hantaan virus is used, and this site is conserved among numerous other hantaviruses (7,185). Potential N-linked sites also were identified in the NSm proteins of phleboviruses and tospoviruses, and at least for Rift Valley fever virus, are used to some extent (31,92). The NSm of Bunyamwera was found not to be glycosylated (110).

L Segment Product: L Polymerase Protein

The L proteins of viruses in the family *Bunyaviridae* range in size from about 237 kd for phleboviruses to 459 kd for nairoviruses (see Fig. 2C). This huge difference in protein sizes might reflect varying functional activities of the enzymes, but as yet, there are no data to support this. There are no known processing or posttranslational modifications to the L proteins (208). Comparing the deduced amino acid sequence of the L proteins of viruses in the family *Bunyaviridae* revealed several conserved motifs commonly associated with RNA polymerases (69,131,160,173). In addition, two novel regions, found at the amino terminus of the L protein of the phlebovirus Rift Valley fever virus, were shown to be conserved only in the polymerases of viruses in the *Bunyaviridae* and *Arenaviridae* families (131).

The function of the L protein as the viral polymerase was confirmed by using L protein expressed from vaccinia virus recombinants to transcribe authentic bunyavirus ribonucleocapsid templates (89). Endonuclease activity also was demonstrated, *in vitro,* with expressed Bunyamwera virus L protein, providing evidence that the L protein is responsible for generating the capped primers needed for transcription (90)

Transport of Viral Proteins, Assembly, and Release

One of the earliest notable features found to distinguish members of the family *Bunyaviridae* from other negative-strand RNA viruses was that virions are formed intracellularly by a budding process at smooth-surface vesicles in the Golgi (Fig. 5A) (16,114,133,212). The plant-infecting members of the family, the tospoviruses, also appear to assemble in the Golgi; however, it was suggested that instead of budding, there is a coalescence of Golgi membranes around the ribonucleocapsids (95). Although most members of the family examined have been found to mature in the Golgi, budding at membranes other than those associated with the Golgi also has been reported for some viruses. The hantaviruses, Sin Nombre and Black Creek Canal viruses, were shown to bud preferentially from the plasma membrane of infected cells (63,168). Similarly, the phlebovirus, Rift Valley fever virus, was found to bud from the plasma membrane as well as in the Golgi of primary rat hepatocytes (3). Because Rift Valley fever virus is a hepatotropic virus and can cause liver necrosis and death in animals, these results raise questions of possible differences in morphogenesis in target versus nontarget cell types that might affect pathogenesis and/or immune defense. The reason(s) for maturation of viruses in the family *Bunyaviridae* in the Golgi complex as opposed to the more usual mode of viral morphogenesis (budding at the plasma membrane) are not known completely; however, important clues have been obtained by studying the viral proteins'

transport to and retention in the Golgi.

Golgi Targeting and Retention

Expression of M gene segments of representative phleboviruses, hantaviruses, and bunyaviruses demonstrated that G1 and G2 are targeted to the Golgi in the absence of other viral components (29,123,134,151,180,218). When expressed individually, the first glycoprotein of the M segment ORF (i.e., encoded in the 5' portion of the M segment) was able to exit the endoplasmic reticulum (ER), but the second glycoprotein remained in the ER (23,107,122,125,150,177). These data indicate that the signal for Golgi transport resides in the first protein encoded in the M segment ORF and that dimerization of G1 and G2 in the ER is necessary for efficient transport of the downstream product.

The Golgi complex actually consists of several subcompartments, including the cis-, medial, and trans-Golgi (reviewed in 126). The exact location in the Golgi where the viral glycoproteins accumulate has not been conclusively determined. By using the fungal antibacterial reagent, brefeldin A, which inhibits transport of proteins out of the ER and causes a redistribution of the Golgi component to the ER, the glycoproteins of the phlebovirus Punta Toro virus were found to be localized in the cis/medial Golgi membranes (27). Similar redistribution of G1 and G2 from the Golgi to the ER were observed after brefeldin A treatment of cells infected with vaccinia virus recombinants expressing the M segment of Bunyamwera virus (134). Immunohistochemical and electron-microscopy studies of Uukuniemi virus demonstrated that budding may begin as early as pre-Golgi intermediate compartment and that virus budding continues in the Golgi stack (88). Similar studies are needed to determine if localization is the same for viruses in other genera.

The mechanism by which G1 and G2 are arrested in the Golgi is not completely known. To map the Golgi targeting and retention signal(s) of phleboviruses, a series of deleted and chimeric genes were constructed and their expression products examined for Golgi targeting and retention. The cytoplasmic tail of the first glycoprotein encoded in the M cRNA was found to contain the targeting signal (4,5,122). For Uukuniemi virus, the minimal transport signal was a 30-amino-acid peptide within the cytoplasmic tail (5). Similar expression studies with M2 segment constructs of Hantaan virus also demonstrated that the cytoplasmic tail of the upstream glycoprotein was needed for exit of the proteins from the ER. Although G2 did not have a targeting signal, results suggested that it might contribute to retention in the Golgi (6).

The NSm proteins are not known to play a role in transport or Golgi retention. For representative phleboviruses and bunyaviruses, expression of G1 and G2 in the absence of NSm had no effect on their transport to the Golgi (23,107,123,134,218). However, when the entire M segments were expressed, NSm colocalized to the Golgi with G1 and G2, suggesting an interaction of these proteins before their exit from the ER.

Kinetics of Transport

Examination of the types and amounts of oligosaccharides attached to viral proteins has been used to assess transit of the proteins through the Golgi compartments. For example, shortly after primary glycosylation of nascent proteins at the ER, oligosaccharides are susceptible to cleavage by endoglycosidase H (endo-H), an enzyme that cleaves only high-mannose residues. Later, after removal of glucose residues at the rough ER, migration of the glycoproteins to the smooth ER and Golgi, trimming of residues, and attachment of peripheral sugars, the oligosaccharides are no longer susceptible to endo-H cleavage. This acquired resistance to endo-H therefore generally indicates that the proteins have been processed through the Golgi. The time required to convert between endo-H susceptibility and resistance correlates with the time needed for protein transport from the ER to the Golgi.

For the phlebovirus, Punta Toro virus, heterodimerization occurred between newly synthesized G1 and G2 within 3 minutes after protein synthesis, and the dimers were found to be linked by disulfide bonds. The dimeric G1/G2 proteins were observed both during transport and after accumulation in the Golgi complex (27). For another phlebovirus, Uukuniemi virus, it was found that the transport of G1 and G2 from their site of synthesis on the rough ER through the Golgi occurred at an estimated 2 to 3 times slower rate than that of most viral membrane glycoproteins destined to be transported to the plasma membrane (57). That is, endo-H resistance was achieved at 45 and 90 to 150 minutes for G1 and G2 of Uukuniemi virus (106), compared with 15 to 20 minutes for the hemagglutinin protein of influenza virus or the G protein of vesicular stomatitis virus (33,40,199). The finding that Uukuniemi virus G1 and G2 have different transport

kinetics (i.e., G1 is incorporated into virions 20 minutes faster than G2) suggests that the dimers may arise from different precursor proteins, possibly because faster-folding G1 can not dimerize with slower-folding G2 until G2 has reached its correct conformation (223). In this same study, the G1 and G2 proteins of Uukuniemi virus were found to exit the ER quickly, but did not enter the Golgi for 15 to 20 minutes. The investigators interpreted these findings as indicating that the G1 and G2 proteins may dimerize in an intermediate compartment between the ER and Golgi (223).

Assembly and Release

Unlike most other negative-strand RNA viruses, members of the *Bunyaviridae* do not have a matrix (M) protein to link the integral viral envelope proteins and their nucleocapsids and to act as the nucleating step for assembly. The absence of M protein suggests a direct interaction between the ribonucleocapsids, which accumulate on the cytoplasmic side of vesicular membranes, and viral envelope proteins, which are displayed on the luminal side. Electron microscopy of cells infected with the phleboviruses, Punta Toro or Karimbad viruses, revealed that ribonucleocapsids and spike structures (i.e., viral envelope glycoproteins) were present only in regions of Golgi membranes where budding appeared to be occurring, and not on adjacent areas of the same membrane, suggesting a transmembranal interaction of N with G1 or G2 (194).

The signal directing the ribonucleocapsids to the budding compartment is not known. Excess ribonucleocapsids of hantaviruses (see Fig. 5B and Fig. 5C) tospoviruses, and nairoviruses were found to accumulate in large cytoplasmic inclusions, suggesting that only ribonucleocapsids that interact with the envelope proteins are transported to the Golgi (17,63,80,97,129,206). It is likely that the transmembrane domains of G1 or G2 that are exposed on the cytoplasmic face of the membrane are involved in this interaction. Candidate transmembrane regions have been predicted from hydropathic characteristics of derived amino acid sequences representing the envelope proteins of all members of the *Bunyaviridae* examined to date. Direct examination of the phlebovirus, Karimabad virus, by enzymatic digestion of exposed proteins embedded in intracellular membranes, demonstrated that approximately 12% of G1 and/or G2 was exposed on the cytoplasmic face of membranes in infected cells and was accessible to digestion. A large protease-resistant fragment was identified, which was presumably sequestered in the membrane in a manner that rendered it safe from enzymatic digestion (194). These enzyme-resistant fragments may therefore represent transmembrane regions of proteins, which could provide the interaction between ribonucleocapsids and the cellular membranes required for envelopment. For Uukuniemi virus, the cytoplasmic tail of G1, which is at least 70 residues long, may be a logical candidate for interaction with the nucleocapsids (156,178). Similar cytoplasmic tails also are predicted for other members of the family.

After budding into the Golgi cisternae, virions apparently are transported to the cell surface within vesicles analogous to those in the secretory pathway. The release of virus from infected cells presumably occurs when the virus-containing vesicles fuse with the cellular plasma membrane (i.e., by normal exocytosis). Numerous viruses in the family have been observed late in infection within vesicles or in the process of exocytosis by electron microscopy (41,181,194). In polarized cells, the phleboviruses, Rift Valley fever and Punta Toro viruses, were found to be released primarily from the basolateral surface, whereas the hantavirus, Black Creek Canal virus, was released from the apical surface (3,28,168). Such polarized release of viruses might be important for disseminating virus during natural infection to produce a systemic disease (28).

The assembly and release of tospoviruses may differ from those processes of other viruses in the family. A model was proposed in which Golgi membranes with integral viral envelope proteins wrap around ribonucleocapsids. These particles may then fuse with each other or with ER membranes to release single enveloped particles into the cisternae (95). Mature virions accumulated within the ER cisternae likely remain there until ingested by thrips. Release of tospoviruses from insect cells probably occurs via secretory exocytosis similar to that of animal-infecting members of the family (222).

EFFECTS OF VIRAL REPLICATION ON HOST CELLS

The cytopathic effects observed in cultured cells infected with members of the family *Bunyaviridae* vary widely, depending on both the virus and the type of host cell studied. Viruses in all genera except the *Hantavirus* genus are capable of alternately replicating in vertebrates (or plants for tospoviruses) and arthropods and generally are cytolytic for their vertebrate/plant hosts but cause little or no cytopathogenicity in their invertebrate hosts (12,87,114,222). Some viruses display a very narrow host range, especially for arthropod vectors. Although the reason for this has not been defined completely, studies on La Crosse variant and revertant viruses suggested that the specificity was related to G1, probably at the level of viral attachment to susceptible cells (201). In natural infections of mammals, viruses are often targeted to a particular organ or cell type. For example, bunyaviruses such as La Crosse virus appear to be neurotropic (142); the phlebovirus, Rift Valley fever virus, is primarily hepatotropic (2,3,44,153,154); and the hantavirus, Hantaan virus, persists in rodent lungs (109). It will be interesting to determine whether this targeting is due solely to host-cell receptors or to other factors such as differences in effects on host-cell metabolism in targeted cell types versus the unnatural situation in cultured vertebrate cell lines.

Effects on Host-Cell Metabolism

In vertebrate cells, bunyaviruses and some phleboviruses were found to cause a reduction in host-cell protein synthesis, which became more prominent as the infection progressed. For example, by 5 hours after infection, Bunyamwera virus–infected cells showed reduced levels of host protein synthesis, and by 7 hours, there was almost no synthesis (149). Similar results were obtained in La Crosse virus–infected cells (115). Rift Valley fever virus–infected cells displayed reduced host protein synthesis, which gradually became more pronounced from 4 to 20 hours after infection (140). In contrast, a reduction in host protein synthesis did not occur, even late in infection, with another phlebovirus, Uukuniemi virus, or with the nairovirus Dugbe virus (25,155,205), both of which are transmitted by ticks rather than mosquitoes. Host protein synthesis was slightly inhibited, however, in a *Xenopus laevis* (frog) cell line infected with the tick-borne nairovirus, Clo Mor, or the phlebovirus, St. Abb's head (220). Hantaviruses not only cause no detectable

reduction in host macromolecular synthesis (45,184), but they also routinely establish persistent, noncytolytic infections in susceptible mammalian host cells, a finding consistent with their nonpathogenic persistence in their natural rodent hosts (109).

The mechanism of host protein shutoff has not been determined; however, recent studies with Bunyamwera virus derived from cDNA indicated that mutations introduced into the NSs coding region drastically reduced the shutoff of host protein synthesis (21,22). Whether this is a direct consequence of eliminating NSs or a secondary effect remains to be determined. It is noteworthy that some of the viruses that do not shut off host protein synthesis do not produce an NSs protein (e.g., hantaviruses and nairoviruses) and/or do not produce NSm proteins (e.g., Uukuniemi and hantaviruses).

The arthropod-borne members of the family, like most other arboviruses, cause little detectable cytopathology in mosquito cell cultures, and viral persistence is readily established (24,48,135,136,179). Unlike cultured vertebrate cells, mosquito cells infected with the bunyavirus, Marituba virus, displayed no reduction in host macromolecular synthesis; thus viral infection apparently does not drastically interfere with normal cellular processes (24). One suggested reason for this is that, in arthropod cells, excess viral proteins do not accumulate in the cells but rather are more efficiently processed into mature virions (135). Another possibility is that viral transcriptase may be less active in arthropod cells than in mammalian cells and that the endonuclease activity of the polymerase (which is used to acquire transcriptional primers) is detrimental to host-cell messages. A reduced level of activity of the viral transcriptase would, therefore, produce less damage to host-cell messages and consequently to protein synthesis (179).

Persistence, both in insect and mammalian cells, can be mediated by defective interfering (DI) viruses. Conventional DI particles, which displayed deletions only in L, were described for Bunyamwera virus. The defect in L was found to be a single internal deletion, amounting to 72% to 77% of the L RNA segment (143). Defective L RNA segments and resultant DI particles also were reported for the bunyavirus, Germiston virus (34), and for the tospovirus, tomato spotted wilt virus (170,171). The tospovirus deletions, which were generated by repeated high-multiplicity passage, amounted to 60% to 80% of the L segment (171). Interestingly, the L deletions identified both in the tomato spotted wilt and Bunyamwera DI particles were in-frame, thus allowing translation of truncated L polypeptides (143,171). The significance of this finding is not known, but conservation of the terminal sequences and the observed encapsidation of these shortened L segments suggest that they may retain all signals necessary for replication, transcription, and translation, and might be able to interfere at several steps in the replication process.

Persistent infections of viruses in the family have also been described that do not involve typical DI particles. For Bunyamwera virus, temperature sensitive and plaque morphology mutants were recovered from persistent infections of mosquito cells (48,135). These carrier cultures were found to be resistant to superinfection with homologous virus. In addition, virus released from the cultures inhibited infection of normal mosquito cells by standard virus (48). No evidence for deleted RNAs was obtained; thus classic DI particles were apparently not involved (48,179). For the hantavirus, Seoul virus, persistence in mammalian cell cultures was found to be related to short deletions in the conserved terminal regions of the gene segments, particularly the 5' end of the L segment (127). It will be interesting to determine if similar deletions occur in rodents persistently infected with hantaviruses.

CONCLUSION

The family *Bunyaviridae,* a large and widely diverse group of viruses, is divided into five genera based on molecular properties and serologic relationships among its members. Viruses in different genera display common morphologic, biochemical, and genetic attributes, yet have unique replicative properties. All viruses have three-segmented, single-stranded RNA genomes and encode their N, G1/G2, and L proteins in the S, M, and L genome segments, respectively. Viruses in this family generally display an unusual Golgi-associated morphogenesis and usually acquire their envelopes by budding into intracytoplasmic vacuoles. Recent advances in the molecular biology of viruses, including the development of *in vitro* replication systems and infectious clones, should allow rapid progress in furthering our understanding of these viruses. Among the unresolved questions to be answered are the following: Can the polymerase carry out all of the replication functions by itself, or are cellular factors involved? What dictates the switch in polymerase function from primer-dependent mRNA synthesis to primer-independent cRNA synthesis? What are the functions of the nonstructural proteins encoded in the S and M segments of some viruses? What are the protein–protein and protein–nucleic acid interactions? How do virions assemble to include a full complement of the genome segments? What factors permit viral persistence? It is likely that the answers to these questions will differ for the many diverse viruses in this family.

CHAPTER 49 Bunyaviruses

Stuart T. Nichol

Bunyamwera virus was originally isolated from *Aedes* species mosquitoes in Uganda during a yellow fever study in 1943 (253). This seemingly insignificant event would open the door to the discovery and characterization of a large new family of viruses, the *Bunyaviridae.* After the isolation of Bunyamwera virus, several additional arboviruses were discovered that clearly did not fit in the classic arbovirus group A and B antigenic groups (which later formed the *Alphavirus* and *Flavivirus* genera of the *Togaviridae,* respectively) and were assigned to what became known as group C (39,59). During the next decade, further virus discovery and detailed serologic characterization led to refinement of the virus groupings and formation of closely related groups, including the Bunyamwera, California, group C, and Simbu serogroups. These serologic studies, together with biochemical and morphologic analyses (194), led to the concept of a Bunyamwera "supergroup" consisting of these groups of closely related viruses that could be linked by weak but repeatable serologic cross-reactions. Eventually, the family *Bunyaviridae* was defined, which now contains more than 350 viruses with worldwide distribution and which includes several important human, livestock, and plant pathogens.

Electron microscopic thin-section studies have shown these viruses to have similar morphologies, forming generally spherical particles 80 to 120 nm in diameter (Fig. 1), although oval or more elongated forms can also been seen, particularly with the hantaviruses. The viruses share a common genetic organization of three predominantly negative-stranded RNA segments (S, M, and L). Based on antigenic, genetic, and ecological relatedness, they are organized into five genera: *Bunyavirus, Hantavirus, Phlebovirus, Nairovirus,* and *Tospovirus.* A listing of the most notable members of each genus is shown in Table 1. Most of these viruses, with the exception of the hantaviruses, are primarily maintained in nature by replication in arthropod hosts with alternating amplification cycles in vertebrate species. The arthropod vector varies with different viruses, and although mosquitoes are most frequently used, phlebotomine sandflies, culicoid flies, ticks, and thrips are also common vectors. Transovarial and venereal transmission have been demonstrated for several of these viruses in their arthropod hosts. These viruses are generally noncytopathic in arthropod cells but can cause reduction in host macromolecular synthesis and cytopathic effect (CPE) in susceptible vertebrate cells. In contrast, hantaviruses are found in specific rodent reservoir species in nature and are generally noncytopathic in susceptible vertebrate cells. The geographic range and natural history features of the vertebrate or arthropod hosts play an important role in determining the regional or global virus distribution and disease epidemiology.

BUNYAVIRUS GENUS

The *Bunyavirus* genus now contains more than 150 viruses that are found throughout the world with the exception of Australia. Almost all of these viruses are transmitted by mosquitoes and have amplification cycles in a variety of vertebrate hosts.

History

After the original isolation of bunyamwera virus from *Aedes* species mosquitoes in Uganda in the 1940s, the virus was found to be distributed throughout much of sub-Saharan Africa and associated with cases of febrile illness (100,143,253,278). Over several decades, many additional distinct bunyamwera serogroup viruses were detected in mosquitoes in the Americas, several of which were associated with disease in humans or livestock. For example, Cache Valley virus, which was isolated from mosquitoes trapped in Utah in 1956, is now known to be distributed throughout much of the United States and possibly elsewhere in the Americas (33,117).

The California serogroup viruses are found throughout a broad range of ecological zones ranging from the tropics (e.g., Guaroa and Lumbo viruses) to temperate and arctic zones (e.g., Inkoo and snowshoe hare viruses). Most of these viruses are vectored by mosquitoes of the *Aedes* genus. The type member, California encephalitis virus, was isolated in California in 1941 during now classic studies involving processing of large numbers of mosquito pools for virus isolation attempts by inoculations into suckling mouse brains. The virus was shown to be associated with three cases of encephalitis in California (108). Another member of the serogroup, La Crosse virus, was isolated from the brain of a child who died of encephalitis in La Crosse, Wisconsin in 1960 (281). It was found to be antigenically related to, but distinct from, California encephalitis virus and has been shown to be a significant cause of arboviral encephalitis in the United States. Snowshoe hare virus was originally isolated from a snowshoe hare captured in Montana in 1959 and is now known to be distributed throughout Alaska, Canada, and the northern United States (104). This virus is considered a variety of La Crosse virus and has been shown to be infrequently associated with febrile central nervous system (CNS) disease in children and adults. Jamestown Canyon virus was isolated from a pool of *Culiseta inornata* mosquitoes captured in Colorado in 1961 (104). This virus (including the closely related Jerry Slough variety) is now thought to be second only to La Crosse virus as a cause of arboviral encephalitis in the United States.

A large number of group C viruses were isolated during the 1950s and early 1960s, predominantly in South and Central America (248). Many have been shown to be associated with acute febrile illness in humans. Several Simbu serogroup viruses were also isolated at this time from throughout the world, including Oropouche virus in Trinidad in 1955 and Akabane virus in Japan 1959 (5,128). Akabane virus is an important cause of fetal malformations in cattle in Australia, Japan, Korea, and Israel and is also present in Africa (128). Oropouche virus has caused several major epidemics of febrile illness in Brazil (219).

Infectious Agents

The classic method for isolation of bunyaviruses is either intracranial inoculation of suckling mice or infection of susceptible cell lines such as Vero cells. Thin-section electron micrographs show that the viruses of the *Bunyavirus*

genus have a typical overall morphology with predominantly spherical or ovoid particles of about 68 to 110 nm in diameter with surface fringe projections of about 7 nm. However, negative-staining studies show *Bunyavirus* genus viruses to have a distinctive surface structure consisting of small knoblike morphologic units but no distinct organization pattern (173) (Fig. 2).

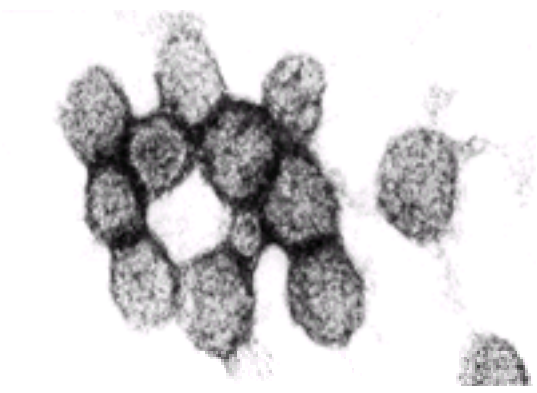

FIG. 2. Electron micrograph negative-stain image of La Crosse virus (genus *Bunyavirus*) (135,000× magnification). (Courtesy of Mary Lane Martin and Helen L. Regnery.)

Pathogenesis and Pathology

Human infections with California encephalitis, La Crosse, or Jamestown Canyon viruses are initiated by bite of a virus-infected mosquito. The course of the infection has been extensively modeled in mice (129,133,209). Similar to the human infection, the outcome of the infection in mice is dependent on the age of the animal and strain of virus used, with subcutaneous challenge of newborn mice most closely mimicking the natural human infection. Virus initially spreads from the site of inoculation into the skeletal muscle, which is the major site of replication. The virus spreads to the plasma, presumably through the lymphatic channels, delivering the virus to skeletal and cardiac muscle where further rounds of replication occur. The resulting plasma viremia spreads the virus (possibly through vascular endothelial cells) to the CNS, where the virus replicates in neurons and glial cells causing considerable neuronal necrosis. Death occurs 3 or 4 days after infection.

The lesions observed in the brains of fatal La Crosse encephalitis cases differ from those in infected suckling mice. In humans, and to a large extent in adult mice infected intracranially, one sees cerebral edema, perivascular cuffing, glial nodules, mild leptomeningitis, and occasional areas of focal necrosis which are typical of acute severe viral encephalitis. Lesions are mostly in the cerebral cortex, with some in the brain stem (134).

Infection of natural vertebrate amplifying hosts of these viruses, such as adult chipmunks (La Crosse virus) or snowshoe hares (snowshoe hare virus), results in inapparent infections and viremias sufficient to infect mosquitoes (242). *Aedes triseriatus* mosquitoes are the principal vector of La Crosse virus, and their experimental infection with California encephalitis serogroup viruses has been studied in detail (18,274,280,295). Virus ingested through a viremic blood meal infects the epithelial layer surrounding the mosquito midgut. Replication of the virus results in release of virus across the basal lamina into the hemocele, allowing transport of the virus to tissues throughout the body. Virus infection of mosquitoes other than the principal vector species usually results in poor penetration of the virus across this midgut barrier. Experimental infections using reassortant viruses have shown that virus M genomic segment (encoding the glycoproteins and NSm protein) is an important component in the correct match between virus and host mosquito, which allows efficient transit across the midgut barrier (18). Once across the barrier, virus replication occurs in a wide variety of tissues, including the ovaries and salivary glands (274). Release of virus from the salivary glands allows virus transmission from the female mosquito to the vertebrate host during feeding. Mosquitoes begin to be infectious about 1 or 2 weeks after ingestion of virus, an interval referred to as the *extrinsic incubation period.*

The infection of the ovaries is thought to be crucial to virus maintenance in mosquito populations in that this results in transovarial transmission of the virus from the female to the offspring, allowing the virus to overwinter in infected eggs (295). Male mosquitoes play no role in the vertical transovarial transmission of virus nor in the horizontal transmission through amplifying vertebrate hosts because they do not take a blood meal. However, virus is detected in the gonads of transovarially infected males and can result in venereal transmission of the virus horizontally within the mosquito population (280). This combination of transmission mechanisms allows efficient maintenance of the La Crosse virus in *A. triseriatus* populations. Similar processes are thought to function in host mosquito infections with other California serogroup viruses (285), and the work done with these viruses and their arthropod hosts often serves as a model for understanding virus maintenance and transmission mechanisms in other family *Bunyaviridae* viruses.

The Simbu serogroup virus, Akabane virus, is an important cause of disease in livestock, causing epizootics of abortions and congenital defects in cattle, sheep, and goats (110). Experimental infections of pregnant cattle or ewes with Akabane have been shown to produce viremia, followed by virus replication in the placenta and fetal tissues, and resulting in congenital defects such as microencephaly and hydrocephalus (110,153,208). Similarly, experimental infection of pregnant hamsters results in death of the fetus (4).

Epidemiology and Ecology

California Serogroup Viruses

La Crosse virus is the most significant of the California encephalitis serogroup viruses in terms of causing human disease

in the United States. The primary vector is the forest-dwelling, tree-hole breeding mosquito, *A. triseriatus.* This vector is found throughout the northern Midwest and northeastern United States. La Crosse virus is maintained in these mosquitoes by transovarial transmission, which allows overwintering of the virus in mosquito eggs (297). During the summer months, squirrels, chipmunks, foxes, and woodchucks become viremic following La Crosse virus infection and are important amplifying hosts (279,312). Most La Crosse encephalitis cases occur in the summer and early fall months when risk of bite from infected female mosquitoes is highest. Most cases are in the Mississippi and Ohio river basins, with more than 90% of cases occurring in Wisconsin, Minnesota, Iowa, Indiana, Ohio, and Illinois (31,135). During the 1980s, several cases were also reported in West Virginia and Georgia (249). Cases have now been reported from 28 states, and an incidence in endemic areas is about 20 to 30 per 100,000, exceeding that of bacterial meningitis (175). Cases are usually seen in residents in proximity to hardwood forests or in people entering forested areas for recreation (111). The breeding of *A. triseriatus* in discarded tires and other artificial containers has brought the vector into more urban settings (182).

Jamestown Canyon virus (including the closely related Jerry Slough variety) is also an important cause of arboviral encephalitis in the United States. The virus is vectored by *C. inornata* mosquitoes and several *Aedes* species mosquitoes and is broadly distributed across much of North America. Vertical transmission of the virus has been demonstrated in several *Aedes* species mosquitoes (109). White-tailed deer are the most likely vertebrate amplifying host. Unlike La Crosse virus, which mainly causes encephalitis in children, Jamestown Canyon virus appears to cause disease predominantly in adults. Together, the California encephalitis serogroup viruses are responsible for about 60 to 130 reported cases of encephalitis per year, although there is likely considerable underreporting of the disease.

Bunyamwera Serogroup Viruses

Bunyamwera virus is present throughout much of sub-Saharan Africa and appears to be an important cause of acute febrile illness in humans. The virus has been isolated from humans in Uganda, Nigeria, and South Africa (100,143,278). More recently, a reassortant of Bunyamwera virus has been isolated from hemorrhagic fever patients in Somalia and Kenya (S.T. Nichol and colleagues, unpublished observations). In addition, human antibodies reactive with Bunyamwera virus have been detected in most of sub-Saharan Africa, with high prevalence (up to 82%) recorded in some locations (253). Isolation of the virus from several *Aedes* species mosquitoes has implicated them as the primary vector (143,144,253). Antibodies reactive with Bunyamwera virus have been detected in domestic animals, nonhuman primates, rodents, and birds, and viremias capable of supporting mosquito transmission have been recorded in experimentally infected rodents, bats, and primates (253,301). However, the role of a potential vertebrate amplifying host is currently unclear.

Several additional Bunyamwera serogroup viruses are present in the Americas and are infrequently reported to cause acute febrile illness in humans. Cache Valley virus is found throughout the United States, Canada, and Mexico and has most frequently been isolated from *C. inornata* mosquitoes. The virus often infects sheep and possibly all ruminants, and infections have been associated with embryonic and fetal death, stillbirths, and multiple congenital malformations in sheep (80,174). More recently, the virus was the cause of a fatal encephalitis in a human (241). It remains unclear whether Cache Valley and serologically closely related viruses may play a role in syndromes of congenital malformations and embryonic losses in humans in North America (34).

Simbu Serogroup Viruses

Simbu serogroup viruses are global in distribution and are principally vectored by biting midges of the genus *Culicoides.* Since the original isolation of Oropouche virus from a febrile patient in Trinidad in the 1950s, the medical importance of the virus, particularly in the Amazon basin regions of northern Brazil and Peru, has become increasingly evident (219). The virus has been shown to be associated with several large epidemics of febrile disease, with attack rates as high as 83% (219,229). Most of these outbreaks were in relatively urban areas, leading to the suggestion that there is likely separate urban and sylvatic cycles (71,227). High antibody prevalence in populations in endemic areas suggest that human infection can be quite common in such areas (15,229,296).

The principal urban vector in Brazil appears to be the tiny biting midge, *Culicoides paraensis* (216,227). Isolates have also been made from mosquitoes such as *Culex pipiens quinquefasciatus,* but its vector competence is poor (71,116). The *C. paraensis* midges breed in rotting vegetative matter, and seasonal populations can become high in agricultural areas where buildup of debris, such as banana tree stalks or cacao husks, may occur (218). These midges feed predominantly in the early evening hours and are quite anthropophilic. Infected humans develop viremias sufficiently high to transmit virus to uninfected midges and appear capable of serving as the vertebrate amplifying host during urban epidemics (218). Serologic data also suggest that primates, sloths, or even birds may be potential hosts in the sylvatic cycle. Recent phylogenetic studies indicate that distinct Oropouche virus lineages are present in different geographic areas, with lineage I viruses including the prototype strain from Trinidad and most of the Brazilian strains, with lineage II containing six Peruvian strains isolated between 1992 and 1998 and two strains from western Brazil isolated in 1991, and with lineage III containing viruses isolated in Panama during 1989 (234).

Akabane virus is widely distributed throughout Australasia (Australia, Japan, Korea, Taiwan), the Middle East (occasionally extending as far north as Turkey), and sub-Saharan Africa (2,64,183,271,299). The virus is an important cause of disease in livestock with periodic outbreaks of abortions, stillbirths, and congenital malformations being recorded in cattle, sheep, and goats in Australia, Japan, Korea, Israel, and Turkey. It is currently unclear why no disease outbreaks have been observed in Africa, despite the widespread presence of the virus (2).

The virus is vectored by midges of the genus *Culicoides,* and although *C. brevitarsis* is the primary vector in Australia (195,260), different species are important in Asia and the Middle East (3,131,151). These midges have short flight ranges, but wind dispersal is thought to play a role in movement of infected *Culicoides* over substantial distances, occasionally resulting in disease epizootics in areas where the disease is not enzootic (20,24,195,239,240).

Clinical Features

The California serogroup viruses, La Crosse, Jamestown Canyon, and the prototype California encephalitis virus, all cause a similar encephalitic disease in humans (230). Indeed, because of serologic cross-reactivity, many of the early disease descriptions of California encephalitis cases were likely due to Jamestown Canyon or La Crosse viruses rather than California encephalitis virus, which is now known to be less common (36,70,259). The major difference between the viruses is in age dependence of the spectrum of clinical disease observed, in that La Crosse virus infections tend to be more severe in children, whereas Jamestown Canyon virus infection is more severe in adults. The spectrum of disease ranges from inapparent or mild febrile disease through to fatal encephalitis (57,175,281).

The incubation period is about 3 to 7 days. Most affected patients report sudden onset of fever, followed by stiff neck, lethargy, headache, and nausea and vomiting, and symptoms usually end within 7 days. About half of patients exhibit seizures, and up to 30% develop coma and exhibit a longer disease course. About 65% of patients have meningitis on presentation, with both mononuclear and polymorphonuclear cells present in cerebrospinal fluid. Despite mild neurologic symptoms often being present at the time of patient discharge, surprisingly little residua is found. The most important sequela is epilepsy, which is observed in about 10% to 15% of children, almost always patients who had seizures during the acute phase of illness. In addition, about 2% of patients have persistent paresis (56,57,103,107,175).

Several thousand cases of acute febrile illness can occur during Oropouche virus epidemics observed throughout the Amazon basin regions of Brazil and Peru. Humans acquire the infection by bite from infected midges. The incubation period is about 4 to 8 days, followed by sudden onset of fever, with arthralgia, myalgia, severe headache, chills, photophobia, and prostration. Occasionally, rash, meningitis, or meningismus is seen (217). Most of the symptoms resolve within 3 to 5 days, although the myalgia may last 1 or 2 weeks. Viremias are detectable in most patients 2 to 3 days after onset of illness. Rather unusually, about half of patients exhibit recurrence of some disease symptoms 1 to 10 days after initial recovery (291). Oropouche virus is also suspected to be infectious by aerosol based on reported laboratory infections (219).

Diagnosis

A wide variety of serologic assays have been used in the diagnosis of infections with viruses of the genus *Bunyavirus,* including complement fixation (CF), hemagglutination inhibition (HI), neutralization (NT), immunoglobulin M (IgM) capture enzyme-linked immunosorbent assay (ELISA), and reverse transcriptase–polymerase chain reaction (RT-PCR) (32,46,73,105,150,241). Diagnosis of California serogroup virus infections relies on serologic methods because virus is generally absent from blood or secretions during the phase of CNS disease. The HI test is considerably more sensitive for these viruses than CF, but NT assay or RT-PCR is needed for confirmation and subtype identification. The IgM capture ELISA works well for diagnosis of most infections by viruses of the genus *Bunyavirus* but has not been widely applied to date (73,127,241). Virus isolation attempts complement serologic and genetic assays, and isolation is best achieved by intracranial inoculation of suckling mice or by infection of susceptible cells, such as Vero cells.

Prevention and Control

Prevention and control are difficult for the mosquito-borne California and bunyamwera serogroup viruses because of the widespread presence of the mosquito vector hosts and relatively sporadic nature of the associated human or livestock diseases. Broad application of insecticides as carried out in earlier decades is no longer ecologically acceptable. Relative to human disease, use of fine mesh netting and personal protectants containing diethyltoluamide (DEET) are highly recommended in areas where people are at high risk of being bitten by virus-infected mosquitoes.

Similar vector control challenges exist for the Simbu serogroup viruses vectored by *Culicoides* species midges. With Oropouche virus disease in Brazil and Peru, avoiding the buildup of rotting organic debris, such as banana tree stalks and cacao husks, in agricultural areas may help curtail population levels of *C. paraensis* and reduce the risk of seasonal epidemics (218). Avoiding exposure (treated netting, DEET repellents) to these midges during their early evening feeding hours is also recommended. Similar protective measures are recommended for Akabane virus. In addition, a successful formalin-inactivated Akabane virus vaccine has been developed in Japan using virus-infected hamster lung cell cultures (152), and a similar product is planned in Australia. With knowledge of the distribution and seasonality of Akabane disease outbreaks, vaccination of at-risk animals before pregnancy is feasible.

PHLEBOVIRUS GENUS

The viruses of the genus *Phlebovirus* are present throughout the world, with the exception of Australia, and are more diverse in terms of arthropod vector than those of the other arthropod-borne genera. Most virus members are associated with phlebotomine sandflies, hence the genus name *Phlebovirus* (see Table 1). However, there are prominent exceptions, such Rift Valley fever (RVF) virus, a medically and agriculturally important virus in Africa, which is primarily associated with *Aedes* species mosquitoes. In addition, Uukuniemi virus, which has been used in a number of laboratory studies, is associated with the tick *Ixodes ricinus.*

History

RVF virus was first isolated in 1930 by Daubney and colleagues from an infected newborn lamb, as part of investigation of a large epizootic of disease causing abortion and high mortality in sheep (66). Large RVF epizootics in various areas of sub-Saharan Africa have been noted since that time, and clinically compatible outbreaks have been retrospectively identified as far back as 1912 (78). It was several decades later before serologic and molecular similarities to phlebotomine fever viruses were noted. Sandfly fever Sicilian and Naples viruses were first isolated from American troops with febrile illness in the Palermo region of Sicily, Italy in 1943 and Naples, Italy in 1944, respectively, by inoculation of acute-phase sera into human volunteers and passage in newborn mice (231,232). Outbreaks of compatible

human illness in the Mediterranean region date back to the time of the Napoleonic Wars, and association of the disease with sandflies was suggested as early as 1905 (112).

Infectious Agents

The classic general method for isolation of phleboviruses is either intracranial inoculation of suckling mice or infection of a susceptible cell line, such as Vero, LLC-MK2, or BHK-21 cells. Sandfly fever Sicilian and Naples viruses usually cause CPE in susceptible cells, but often blind intracranial passage is necessary before a lethal infection of the suckling mice is achieved (232,233). RVF viruses are generally cytopathic, grow well in a wide range of tissue culture cells, and result in fatal infection of mice after intracranial challenge. Thin-section electron micrographs show viruses of the *Phlebovirus* genus to have a typical overall morphology with predominantly spherical or ovoid particles of about 90 to 100 nm in diameter with surface fringe projections of about 6 to 7.5 nm. These viruses are distinct when viewed by negative staining, with sharply defined surface structures of small round morphologic units about 9.5 nm in diameter with a visible central hole (173) (Fig. 3).

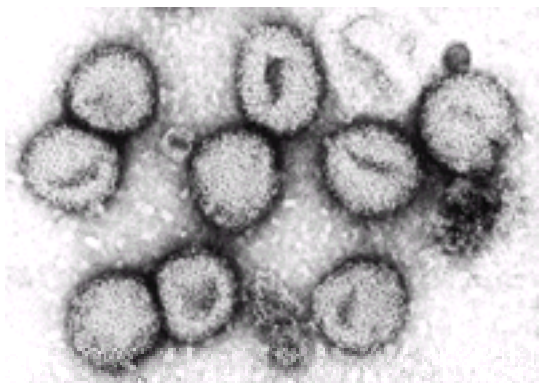

FIG. 3. Electron micrograph negative-stain image of Uukuniemi virus (genus *Phlebovirus*) (135,000× magnification). (Courtesy of Mary Lane Martin and Helen L. Regnery.)

Pathogenesis and Pathology

Several excellent reviews of RVF pathogenesis and disease exist (66,75,270). RVF virus infections of livestock are often recognized by the onset of abortion “storms,” which sweep through livestock producing areas, with simultaneous acute febrile disease in humans. Most human infections with RVF virus result in a relatively mild febrile illness. The incubation period is about 2 to 6 days and is followed by abrupt onset of fever, chills, and general malaise. Susceptibility of livestock to RVF infection varies considerably, depending on a variety of factors, including livestock species and age and strain of virus. Based on data from experimental infections and analogy with other arbovirus infections, the general pattern of infection likely follows the course that, after inoculation of virus by mosquito bite, virus is transported by lymphatic drainage to the regional lymph node where local replication takes place. Virus spills over into the circulation, causing the primary viremia and spread of the virus to the major organs. Replication in the lymph nodes, spleen, liver, adrenals, and lung and kidney tissues results in high viremias; in severe cases, hepatic necrosis is prominent, and necrotic foci can be observed in the brains of cases exhibiting the less frequent encephalitic form of the disease (6,187,286). RVF virus replication in cells is highly cytotoxic, suggesting that most cellular destruction in acute illness is likely due to direct virus killing of host cells.

Pathologic features of the disease in livestock varies considerably. Leukopenia is frequently seen during the first 3 or 4 days of infection when fever and viremia are usually at their highest. Altered serum enzyme levels (e.g., aspartate aminotransferase and sorbitol dehydrogenases) indicative of hepatocyte destruction are often seen during the acute phase. Leukocytosis often occurs in the early phase of recovery. Thrombocytopenia and fibrin thrombi in several organs suggest that disseminated intravascular coagulopathy (DIC) may be a feature of severe disease in livestock, as is seen in hemorrhagic infections in humans (62,268).

Infection of pregnant animals frequently results in abortion of the fetus. Abortions early in the course of infection are probably the result of the high fever associated with the acute phase of illness; later abortions are more commonly the result of direct infection of the fetus with resulting hepatic necrosis (270). No clear correlation between RVF infection and abortion has been seen in human infections (179).

Epidemiology and Ecology

The geographic distribution of sandfly fever Sicilian and Naples viruses closely follows that of their sandfly host, *Phlebotomus papatasii* (102,238,273). This distribution extends from the Mediterranean basin throughout the Middle East and Arabian peninsula, north up into areas around the Caucus mountains, and as far east as Pakistan and India. Sandflies are most numerous in the warmer months, are found at ground level, and feed in the early evenings. Unfortunately, their small size allows them to pass through untreated mosquito netting.

A related phlebovirus, Toscana virus, is hosted by *P. perniciocus* and is found in central Italy, Cyprus, Portugal, and Spain. Relatively high (20% to 25%) antibody prevalence rates suggest that human infections with Toscana virus are widespread and frequent in endemic areas (23,81). In addition, many acute lymphocytic meningitis and meningoencephalitis cases, particularly those in children, occurring in the summer months are attributable to Toscana infection (21,22,81,180,202). These viruses replicate in their sandfly hosts, and virus transstadial and transovarial transmission have been demonstrated (16,58,275,277). Sexual transmission of Toscana virus among sandflies has also

been shown (276). The relatively low efficiency of transovarial transmission demonstrated in experimental infections suggests that vertebrate amplifying hosts are required to maintain these viruses in endemic areas. However, such wildlife hosts have not yet been identified. Data showing that viremic humans can infect *P. papatasii*, together with attack rates as high as 75%, and records of urban outbreaks of sandfly fever suggest that humans can on occasion serve as the amplifying vertebrate host (106,232).

The ecology and epidemiology of RVF is complex and poorly understood. The geographic distribution of RVF covers much of Africa, from Senegal to Madagascar and from Egypt to South Africa, with most reported epizootics in livestock being reported in East and Southern Africa (270). Beginning in fall 2000, the presence of RVF in the Arabian peninsula was confirmed for the first time, with large epizootics identified in Saudia Arabia and Yeman (T.G. Ksiazek and colleagues, unpublished observations). Mosquitoes have long been known to play an important role in RVF epizootics, with epizootics frequently occurring at times of unusually high precipitation (167). More recent data have indicated that floodwater *Aedes* species mosquitoes of the subgenera *Aedimorphus* and *Neomelaniconion* are likely the principal vectors. The ecology of RVF has been best studied in Kenya, Zimbabwe, and South Africa. In these regions, damboes or vleis, which are shallow depressions up to several hundred meters across near streams and fed by ground water, are thought to play a central role (264). These damboes flood at times of unusually heavy rainfall, which triggers a population explosion in floodwater *Aedes* species mosquitoes.

Isolation of RVF virus from unfed male and female *Aedes mcintoshi* mosquitoes hatched at a dambo in the endemic area of Kenya during an interepidemic period demonstrated the maintenance of the virus between epidemics and the transovarial transmission of the virus in such mosquitoes (166). *A. mcintoshi* is thought to be the principal maintenance vector in Kenya and Zimbabwe (270). The biology of these mosquitoes is such that they are among the earliest mosquitoes to hatch from eggs after flooding. If the eggs contain virus (by transovarial transmission), infected mosquitoes hatch and feed on nearby livestock, potentially initiating a local epizootic. Viremic livestock act as amplifying hosts, transmitting the virus to other floodwater *Aedes* species mosquitoes as well as to other species of mosquitoes, including culicines and anophelines, promoting further amplification and spread of the virus. When such a cycle is initiated at damboes throughout a livestock-producing area, it can give rise to a regional, relatively synchronous eruption of RVF activity with associated abortion storms such as those observed in livestock at various intervals in East and Southern Africa (212,264). Although such a scenario is an attractive explanation of the dynamics of RVF epizootics, more data are necessary to confirm it.

Hemorrhagic fever cases in humans are usually seen 1 or 2 weeks after the appearance of abortions and disease in livestock. Cases are usually among farmers and others living in close proximity to livestock. Humans likely acquire infection through a bite from infected mosquitoes when vector densities are very high. However, contact transmission appears to be most important with RVF. People involved in the birth or abortion of livestock, butchering of animals, or abattoir workers are at high risk of infection during epizootics (1,44,306). RVF virus is also highly infectious by aerosol, having resulted in many infections of laboratory personnel working with the virus (91,255). The relative contribution of infectious aerosols or fomites to transmission is unclear. Although less than 1% of human infections result in severe disease (hemorrhagic fever, encephalitis, retinitis), this can add up to a substantial number of cases given the large scale of some epizootics. For instance, an estimated 27,500 RVF infections occurred during the recent 1997 and 1998 RVF outbreak in the Garissa district of Kenya (308), and about 200,000 human cases with 600 deaths were estimated to have occurred during the RVF outbreak in Egypt in 1977 and 1978 (154,177).

In contrast to the long history of periodic RVF epizootics in East and Southern Africa, the relatively recent large RVF outbreaks in Egypt in 1977 and 1978 and in West Africa in Mauritania and Senegal in 1987 are quite different situations (317). In Egypt, retrospective studies showed that RVF had not been enzootic before 1977 (178). Virus activity disappeared after 1981, only to be reintroduced in 1993 (10). These data suggest that although mosquitoes capable of acting as epizootic vectors (e.g., *Culex* species) exist in Egypt, mosquitoes capable of RVF transovarial transmission are probably lacking. It is thought that RVF was most likely introduced into Egypt from enzootic areas in Sudan (177,212).

The 1977 outbreak of RVF near the Senegal river was the first confirmed outbreak in West Africa. This is thought to have been precipitated by dams built on the river, which caused flooding and increased mosquito populations. Unlike in Egypt, antibody surveys in West Africa suggested that RVF was present earlier than 1977, and activity continues in various areas of the region. Similar to the situation in East and Southern Africa, flood water *Aedes* species mosquitoes (of the subgenus *Aedimorphus* in West Africa, as opposed to the subgenus *Neomelaniconion* in East Africa) are likely the enzootic vector (89,317), and continuing epizootics may be linked to unusual increases in precipitation (282).

Clinical Features

Human infection with sandfly fever virus results in an acute febrile illness with rapid onset. The incubation period lasts 2 to 6 days, followed by fever and general malaise, often accompanied by headache, photophobia, and back and joint pain (17,232). The disease is self-limiting, lasting 2 to 4 days, before rapid and complete recovery.

Experimental RVF infection of new-born lambs and kids suggest that the incubation period is usually 24 to 36 hours, but it can be as short as 12 hours (75,76 and 77). Fever, which is often biphasic, is accompanied by listlessness, lack of appetite, abdominal pain, increased respiration rate, and lack of movement. Mortality rates of greater than 90% can be seen in animals less than 1 or 2 weeks of age, with animals rarely surviving more than 24 to 36 hours after onset of illness. Older lambs and kids and adult sheep and goats are often less susceptible to RVF infection, with disease ranging from peracute to inapparent infection. Most older animals develop a febrile acute illness similar to the disease seen in 1- to 2-week-old animals, but with morality rates ranging from 5% to 60%, and a longer incubation period, ranging from 1 to 6 days. High and prolonged viremias, widespread tissue damage, vasculitis, and hepatic necrosis are seen in the more severe cases. Abortions in pregnant animals are frequently observed, with rates varying from 40% to 100%.

Human infections rarely lead to severe illness, with most infections resulting in a self-limiting influenza-like illness. About 0.5% of infections, however, lead to severe hemorrhagic fever. In such cases, it is likely that the reduction of the

antithrombotic function of the endothelial cells initiates intravascular coagulation and extensive necrosis of hepatocytes and other infected cells. The release of procoagulants into the circulation, together with the extensive liver damage that severely impairs synthesis of coagulation factors and removal of circulating activated coagulation factors are likely important factors resulting in DIC in the hemorrhagic fever cases (210,214).

In less than 0.5% of human RVF infections, retinal vasculitis or encephalitis can be observed 1 to 4 weeks after recovery from the acute illness. Encephalitis begins with headache, meningismus, and confusion. Often, fever reappears, and symptoms of severe cases include hallucinations, stupor, coma, and death. Focal necrosis is seen in the brain, which likely involves direct cell destruction by the virus. In addition, the onset of encephalitis after viremia has ceased and after RVF-specific antibodies are readily detectable suggests there may be an immunopathologic component to these late complications (213). Indeed, polymorphonuclear and mononuclear cell infiltration associated with necrotic lesions implicates delayed hypersensitivity or cytotoxic T cells (213).

Diagnosis

Sandfly fever should be suspected when patients present with a classic “3-day fever” in areas where phlebotomine sandflies are numerous (81,231,232 and 233). Similarly, Toscana infection should be suspected in patients from rural or semirural areas where phlebotomine sandflies are present, who are suffering from acute CNS disease during the summer months (23,202). Diagnostic confirmation using acute or early convalescent-phase samples is readily achieved by virus isolation by intracranial inoculation of suckling mouse or susceptible tissue culture cells or by IgM capture ELISA.

Differential clinical diagnosis of RVF varies depending on the region in question. The disease should be suspected in RVF endemic regions, following abnormally high precipitation, increased rates of abortion in livestock, and appearance of acute influenza-like illness in individuals in close contact with potentially infected livestock (e.g., farmers, veterinarians, abattoir workers). Virologic diagnosis is usually quite simple given the high viremias present throughout the acute phase of illness and the ease of growth of the virus when inoculated intracranially into suckling mice, or in a wide variety of susceptible tissue culture cells (270). Serologic testing is also straightforward, particularly if paired sera (one taken acutely and the other 1 or 2 weeks later) are available. IgM and IgG ELISA tests using inactivated RVF virus–infected cell lysates or slurries have proved particularly useful in outbreak investigations (189,308).

Prevention and Control

The sandfly hosts of sandfly fever Naples and Sicilian and Toscana viruses have short flight range, and locomotion is often by hopping, making localized use of insecticide sprays particularly effective near residences. The use of repellants and treated bed nets and screens is also recommended in such areas.

Immunization of livestock remains the most effective way to prevent RVF epizootics and human cases. Several vaccines exist. Live attenuated viruses based on the mouse neuroadapted Smithburn RVF strain are used in Kenya and South Africa (37,254). Formalin-inactivated wild-type viruses have also been used in Egypt and South Africa (82). The modified live Smithburn vaccine has good efficacy in sheep (but not cattle), with a single dose inducing lasting immunity in sheep 6 to 7 days after vaccination (61). However, it appears to be only partially attenuated, causing abortions or teratology in some pregnant animals (11). The formalin-inactivated vaccines are safer but are expensive and induce only short-lived immunity in sheep and cattle. The main livestock vaccination problem is the long periods between epizootics and their irregular appearance, which makes it difficult to convince livestock owners to vaccinate on a regular basis. Recent advances in the use of satellite imagery and surface ocean temperatures to predict regions at higher than usual risk of RVF activity may allow the timely vaccination of animals before potential epizootics (167).

In an African setting, humans are probably best protected by vaccination of livestock to prevent amplification of virus, thus limiting human exposure and epizootic potential. Formalin-inactivated RVF vaccines have been developed for immunization of laboratory and field workers at risk of exposure (176,223) but are unlikely to be used on a larger scale, given their limited commercial potential. New-generation live attenuated RVF vaccine strains (MP-12 and clone 13) are also currently under consideration (188,193,235). RVF virus is highly infectious by aerosol, as shown by numerous infections of laboratory personnel (91,255). Workers at risk of exposure wear protective clothing to avoid contact with potentially infectious materials and aerosols. The antiviral drug ribavirin may be of some benefit in the treatment of sandfly fevers and RVF, although human efficacy data are still lacking (63,211,298).

NAIROVIRUS GENUS

The nairoviruses are almost exclusively tick-borne viruses, although a few isolations have been made from culicoides flies and mosquitoes (see Table 1). Several serogroups exist, but the most important ones are the Crimean-Congo hemorrhagic fever group (CCHF), which includes CCHF and Hazara viruses, and the Nairobi sheep disease (NSD) group, which includes NSD and Dugbe viruses (see Table 1).

History

The *Nairovirus* genus was named after NSD virus, which was originally isolated in Nairobi, Kenya in 1910 by inoculation of sheep with the blood of sheep with acute gastroenteritis (185). The virus is now known to be present throughout various parts of Africa, and possibly India. CCHF was first recognized in the Crimean peninsula in the mid-1940s, when a large outbreak of severe hemorrhagic fever among agricultural workers was identified. The outbreak included more than 200 cases and a case fatality of about 10% (54). Similar disease cases were later reported throughout the European and central Asian republics of the former Soviet Union, Romania, and Bulgaria. However, the virus was first isolated from a patient with a 1-day fever in Kisangani, Democratic Republic of Congo, in 1956 (250,307). It was some years before the connection was established, but subsequent serologic studies and virus isolations from Asia and Europe revealed that the viruses from the different outbreaks and geographic regions were essentially the same virus, which then became

named CCHF virus (40,55).

Infectious Agents

The classic method for isolation of CCHF viruses has been by intracranial or intraperitoneal (i.p.) inoculation of patient acute-phase blood samples or ground tick pools into newborn mice. Isolation in tissue culture cells is generally less sensitive but provides a faster result in terms of diagnosis (244). Susceptible tissue culture cells include LLC-MK2, Vero, and BHK-21 cells, and SW-13 cells are particularly useful for plaque assay (298). Maximal virus yields (up to 10^7 to 10^8 plaque-forming units per milliliter) are obtained 4 to 7 days after inoculation. The virus frequently produces little CPE and often results in a noncytopathic persistent infection of the cells. Initial isolations of NSD virus were by subcutaneous or intravenous inoculations into sheep. More routinely, similar methods to those used for CCHF have been used, namely intracranial or i.p. inoculation of newborn mice. NSD virus will also grow in a wide variety of tissue culture cells with production of large cytoplasmic inclusions. Thin-section electron micrographs show viruses of the *Nairovirus* genus to have an overall morphology typical of other viruses of the family *Bunyaviridae,* forming predominantly spherical particles about 90 nm in diameter with an indistinct surface fringe of about 7 nm. These viruses, however, are quite distinct when viewed by negative staining, possessing very small morphologic surface units with no central hole (unlike the phleboviruses) (173).

The genome of these viruses consists of three negative-stranded RNA segments, S, M and L, encoding the N nucleocapsid, G1 and G2 glycoproteins, and L polymerase, respectively (171,172; M.D. Parker and colleagues), with the N, G1, and G2 representing the major antigens. Animals susceptible to experimental infection with CCHF virus include newborn mice, newborn white rats and cotton rats, guinea pigs, rabbits, rhesus monkeys, sheep, donkeys, and calves. Mice, sheep, and goats can be experimentally infected with NSD virus.

Pathogenesis and Pathology

Vertebrate Hosts

CCHF and NSD viruses are maintained in nature predominantly in their respective tick hosts. Although the viruses can persist in the ticks through the various life stages (transstadial transmission) and can be passed to the offspring (transovarial transmission), vertebrates are needed to provide blood meals for the ticks, and they can become infected and develop viremias capable of supporting virus transmission to uninfected ticks (69,98,165,168,246). In this manner, vertebrates may play an important amplifying role in the virus natural cycle. In the case of CCHF, a variety of livestock (sheep, goats, cattle, ostriches), large wild herbivores, hares, and hedgehogs may become infected, resulting in an inapparent or subclinical disease (118,245,247,267). Sheep and goats are implicated as being important vertebrate hosts of NSD virus and infection often results in severe disease (67). These animals are presumably subcutaneously infected when bitten by infected ticks. In experimental CCHF virus infections, such as may occur in sheep and ostriches, a viremia develops 1 to 4 and 3 to 9 days after infection, respectively, with maximal titers of about 10^3 to 10^4 mouse intracerebral median lethal dose (LD^{50}) per milliliter (99,266). Virus can be detected in the visceral organs, such as the spleen, liver, and kidneys, up to 5 to 10 days after infection, and CCHF-specific antibody responses are detectable about 7 to 10 days after infection.

In experimental NSD virus infections of sheep, goats, and suckling mice, virus replicates to high titers in the lung, liver, spleen, and other organs of the reticuloendothelial system (192). Vascular endothelium appears to be the primary cell target. Virus replication in the endothelial cells results in edema and necrosis of the capillary walls of the mucosal surfaces of the intestine, gallbladder, and female genital tract, leading to congestion, hemorrhage, and catarrhal inflammation.

Human Infections

In contrast to the inapparent infection characteristic of CCHF infection of other vertebrate hosts, human infections often result in severe hemorrhagic fevers. On introduction of the virus, there is likely local replication followed by blood- and lymph-borne spread of the virus to the major organs, including liver, where high levels of replication take place (30,265,267). Congestion, edema, and focal hemorrhage and necrosis are seen in most organs. DIC is evident early, with thrombocytopenia, elevated prothrombin ratio, and activated partial thromboplastin time present during the first few days of illness, and likely plays a central role in disease progression. Little is known regarding host cell receptor use or factors influencing virus virulence. Both IgM and IgG antibodies are usually detectable about 7 days after onset of illness and are detectable in all survivors by day 9 (243). Antibody responses are rarely detectable in fatal cases.

NSD virus has been isolated from sick patients in Uganda, and the identical or closely related Ganjam virus from febrile patients in India, but their importance in terms of human disease is unclear.

Epidemiology and Ecology

The epidemiology of CCHF reflects the complex ecology and geographic distribution of the ixodid tick hosts of the virus, particularly those of the genus *Hyalomma* (118,267,269). Although CCHF has been isolated from about 30 different tick species, evidence is lacking for many of these as to whether they truly represent vectors or merely reflect the isolation of virus from engorged ticks that have fed on a viremic vertebrate host. Only some ticks of three genera, *Hyalomma, Dermacentor,* and *Rhipicephalus,* have actually been shown to be capable of transstadial transmission of CCHF after feeding on a viremic host, that is, passing the virus through the various stages of the life cycle, from larva to nymph to adult. Transovarial transmission of CCHF has also been shown to occur with some of the tick species in these genera. Moreover, the overall global pattern of geographic distribution of CCHF cases corresponds most closely with the distribution of *Hyalomma* ticks, suggesting their principal role as vector.

There is evidence that CCHF virus is present throughout much of sub-Saharan Africa (from Egypt to South Africa, and

from Senegal to Madagascar), Bulgaria, former Yugoslavia, northern Greece, European Russia, the Arabian peninsula, Iraq, Pakistan, the former Soviet Union (particularly the former Central Asian republics), and Xinjiang province of Northwest China.

Different tick species or subspecies are likely the principal vector in different regions. For instance, *Hyaloma marginatum marginatum* is thought to be an important vector for the virus in Bulgaria, Greece, and European Russia. This is a two-host tick; the larva and nymphs develop on birds or small mammals such as hares and hedgehogs, but the adults feed on large vertebrates such as livestock or occasionally humans. Amplifying viremias occur in the hares and hedgehogs and also in livestock such as sheep and goats, likely making them an important component of the virus natural life cycle. Although some species of ground-feeding birds are susceptible to CCHF infection, several are not, but these may play an important role in providing virus-infected immature ticks with a blood meal and in their dispersal over local and large distances (118,315,316). In contrast, *H. marginatum rufipes* and *H. marginatum turanicum* are two of the more important vectors in West and Southern Africa (35,269); *H. anatolicum anatolicum* in the former Central Asian Soviet Republics and *H. asiaticum* in China (310). However, other ticks may play significant roles. Each tick species has different host preferences, which are reflected in the local epidemiology of the disease.

Most human infections are acquired by bite from infected ticks, contact with infected ticks during their removal from animals or human body, or contact with blood or tissues of infected livestock. As one would expect, most cases are among humans living or working in close contact with livestock (sheep, goats, cattle, or ostriches) in endemic areas, including shepherds, ranchers, and abattoir workers. Nosocomial outbreaks have also been reported in several regions, with infection of medical personnel after treatment of or surgery on a patient with unsuspected CCHF.

The distribution of NSD virus mirrors the distribution of the principal tick host, *Rhipicephalus appendiculatus.* The virus is present throughout much of Africa; from as far north as Ethiopia and Somalia, extending through much of East and Central Africa, to as far south as the Mozambique coastal plain (68,79). The distribution likely extends through parts of the Middle East and into India, based on the detection of the identical or closely related Ganjam virus from *Haemaphysalis intermedia* ticks (65).

Clinical Features

The incubation period for CCHF infections is commonly 3 to 7 days but varies depending on type of exposure (265). Symptoms usually appear abruptly and can include severe headache, dizziness, nausea, fever, neck and abdominal pain, and chills. Overall myalgia and malaise occurs, and hepatomegaly may be seen. Hemorrhage frequently appears by 3 to 6 days after onset of illness, with a petechial rash observable on the trunk and limbs. Patients are often apathetic or obtunded by this stage, with delirium or coma occurring in the more severe cases. Blood may be seen in the urine, and bleeding from the nose, gums, vagina, and other mucosal surfaces or needle puncture sites may occur about 5 days after onset. The case fatality is about 30%, with most deaths occurring 5 to 14 days after onset of illness (269).

Diagnosis

The clinical differential diagnosis of CCHF varies in the different regions where the disease is known to occur and can be difficult in the early stages. In general, the disease can be suspected in patients presenting with a rapid onset of severe influenza-like symptoms and known exposure to tick bite or contact with blood or tissues of potentially infected livestock or humans. The early stages can be confused with sandfly fevers in regions where the diseases overlap; and leptospirosis, Omsk hemorrhagic fever, other viral hemorrhagic fevers (yellow fever, hemorrhagic fever with renal syndrome [HFRS], Ebola), tick typhus, and mycotoxicoses can appear similar in the more advanced hemorrhagic phase of the illness. Clinical values can be helpful in diagnosis, with leukopenia and thrombocytopenia both frequently being present early in the disease (265,289).

Laboratory diagnosis of CCHF is ideally done by virus isolation or antigen-detection ELISA from patient acute-phase sera (28,139,228,304). Virus and antigen are usually detectable up to 1 to 2 weeks after onset of illness. For CCHF isolation, intracranial or i.p. inoculation of patient acute-phase blood samples into newborn mice is probably most sensitive, although quicker results can be obtained by inoculation into susceptible tissue culture cells, such as LLC-MK2, Vero, and BHK-21 cells, followed by fluorescent antibody (FA) staining (244). Fatal cases rarely show significant antibody responses; however, in those destined to survive, IgM and IgG antibodies are frequently detectable after about 1 week of illness. RT-PCR analysis has proved a useful complement to serodiagnosis (29,228).

Prevention and Control

The best means of prevention is to minimize exposure to the virus. Treatment of clothing with pyrethroid preparations that repel and even kill ticks is highly recommended for those likely to come in contact with CCHF-infected ticks, such as slaughterhouse workers, sheep shearers, veterinarians, and others involved with livestock. Also, habits that avoid virus-contaminated blood or tissues contacting the skin should be practiced, including wearing of gloves and avoiding crushing ticks with fingers. Medical personnel should practice standard barrier-nursing techniques during care of suspected CCHF patients. Formalin-inactivated vaccines have been prepared from virus-infected suckling mouse brains and used in Bulgaria and other parts of Eastern Europe and the former Soviet Union, but their efficacy is unclear (284,292).

Treatment of patients is by means of supportive and replacement therapy with blood products. Administration of immune plasma has been tried on numerous occasions, but its usefulness remains unclear (163,290). Based on the susceptibility of the virus in experimental tissue culture and mouse infections to the antiviral drug ribavirin (283,298), several CCHF cases have been treated with ribavirin, with encouraging results (88).

HANTAVIRUS GENUS

History

The discovery of hantaviruses traces back to 1951 to 1953 when United Nations troops were deployed during the border conflict between North and South Korea. More than 3,000 cases of an acute febrile illness were seen among the troops, about one third of which exhibited hemorrhagic manifestations, and an overall mortality of 5% to 10% was seen (74,158,252). The disease was initially termed *Korean hemorrhagic fever* but is now referred to as HFRS. A typical case would exhibit influenza-like symptoms for about 1 week, followed quickly by a hypotensive phase marked by thrombocytopenia, often with petechial hemorrhage, and shock in about 10% to 15% of patients. Fatalities were primarily due to renal failure. A similar disease (epidemic hemorrhagic fever) had been recognized many years earlier in northeastern China (157) and had also been described in eastern former Soviet Union (41). Despite considerable efforts, it took about 25 years until the field mouse, *Apodemus agrarius,* was identified as the rodent reservoir, and the virus was eventually isolated. At that time, all identified viruses of the family *Bunyaviridae* were known to be arthropod-borne viruses. Thus, it was a big surprise when this rodent-borne virus was shown to share characteristics of viruses of the family *Bunyaviridae.* The virus was named *Hantaan virus* after the Hantaan river close to the location of some of the initial Korean cases and became the prototype of the *Hantavirus* genus (157). During the course of the early studies in Korea, it became clear that HFRS cases were also occurring in urban areas. Years of investigation finally demonstrated that the urban cases in Korea, China, and Japan were associated with infection with Seoul virus, which is hosted by the rats *Rattus norvegicus* and *R. rattus* (156,157,256,263). The common rat is now global in its distribution, and study of rats from a number of port cities throughout the world showed that Seoul virus–infected rats are present throughout the world (156).

For more than 50 years, a similar, but generally milder, disease termed *nephropathia epidemica* was described in various parts of Scandinavia (203). After the isolation of Hantaan virus, the virus was shown to react with sera from convalescent-phase patients with nephropathia epidemica (203). This led to the discovery of Puumala virus as the cause of this form of HFRS and the bank vole, *Clethrionomys glareolus,* as the virus host. Additional hantaviruses were identified as researchers realized that many different murid rodents carried their own specific hantaviruses (Table 2). Notable discoveries included the finding of Thottapalayam virus in India in tree shrews (*Suncus murinus*), the only insectivore implicated as a hantavirus host. Prospect Hill virus was the first hantavirus shown to be associated with a rodent species indigenous to the Americas, namely the meadow vole, *Microtus pennsylvanicus.* However, Prospect Hill virus is not know to be associated with human disease. Later, Dobrava virus was shown to be the cause of severe HFRS (similar to that seen with Hantaan virus) in the Balkan region and was found to be associated with *Apodemus flavicollis* (14).

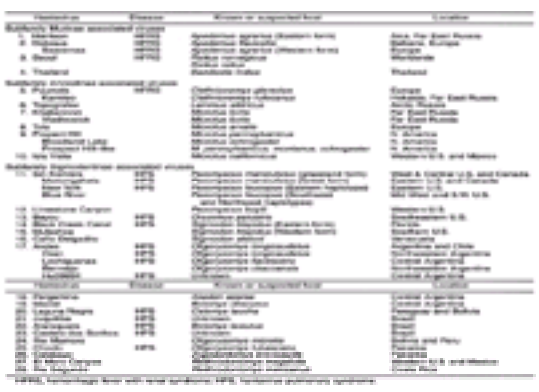

TABLE 2. *Hantaviruses and their their murid hosts*

The most recent major event in the history of hantaviruses was the discovery of hantavirus pulmonary syndrome (HPS) in the southwestern United States in 1993 (201). A cluster of cases identified in the Four Corners region (meeting point of New Mexico, Arizona, Colorado and Utah) presented with an influenza-like illness with fever, headache, muscle aches, and chills; disease rapidly progressed to a more severe respiratory disease with bilateral pulmonary infiltrates, respiratory failure, shock, and death occurring about 2 to 10 days after onset of illness in almost 50% of the cases (138). Within a couple of weeks of the initial outbreak, a newly identified virus, Sin Nombre virus, was shown to be the cause of HPS, and rodent reservoir was shown to be the common deer mouse, *Peromyscus maniculatus* (52,201). Within the next several years, HPS was shown to occur throughout the Americas from Canada to Patagonia and was found to be caused by least 10 different hantaviruses, each associated with different rodent species (see Table 2). During the study of the hantaviruses associated with HPS and HFRS, many additional hantaviruses not know to be associated with human illness were discovered in a wide variety of rodent hosts (see Table 2).

Infectious Agents

Virtually all of the hantaviruses have been difficult to isolate and propagate in tissue culture cells. Vero cells (monkey kidney), particularly the E6 clone, are thought to be most susceptible and are the usual cell of choice for work with hantaviruses. The viruses generally grow slowly, taking 5 to 14 days to produce maximal yields of progeny virus. Growth of these viruses usually results in little, if any, CPE. Electron microscopic studies of thin sections show the hantavirus particles to have a morphology fairly typical of members of the *Bunyaviridae* family, forming predominantly spherical or ovoid particles 80 to 120 nm in diameter. Elongated particles averaging about 170 nm in length have also been observed, which is atypical of other *Bunyaviridae* family viruses (173). Viruses of the Hantavirus genus are the most distinct of any of the genera when viewed by negative staining, which reveals surface structures in an unusual square gridlike pattern with each morphologic unit being about 8 nm in diameter (Fig. 4).

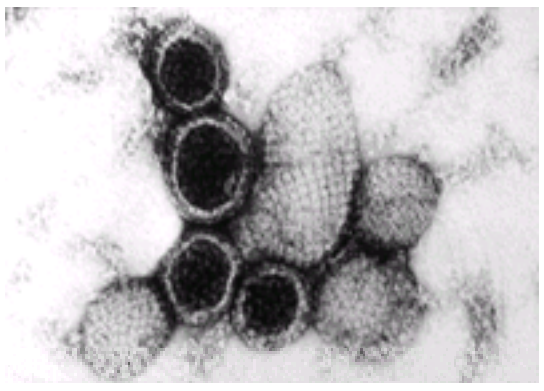

FIG. 4. Electron micrograph negative-stain image of Hantaan virus (genus *Hantavirus*) (135,000× magnification). (Courtesy of Mary Lane Martin and Helen L. Regnery.)

Three major virus antigens are present in infected cells: the virus nucleocapsid (N) protein and glycoproteins GP1 and GP2 (see Chapter 48 for more detailed description). The immunofluorescence staining of infected cells using anti-N antibody shows characteristic punctate staining throughout the cytoplasm. Glycoprotein-specific antibodies tend to show a perinuclear staining pattern typical of proteins accumulating in the Golgi compartment (258). Typical of viruses in the family *Bunyaviridae,* hantavirus glycoproteins are thought to accumulate in the Golgi as a first step in the maturation and assembly of mature virions in the Golgi complex. No accurate disease model exists for HFRS or HPS; however, hantaviruses have been shown to grow in a number of experimentally infected animals, including laboratory mice, rabbits, and nonhuman primates.

Pathogenesis and Pathology

Rodents

The hallmark of a hantavirus infection of a natural rodent reservoir species is the absence of overt disease symptoms and the establishment of a prolonged persistent infection that may last several months or years (19,92,160,161,200,311). Virus is horizontally transmitted among rodents, and infection is thought to be primarily by scratching and biting, although infectious aerosols may also play a role. These conclusions are based on studies examining the prevalence of hantavirus-specific antibodies in rodent host populations, which frequently show a greater number of scars of seropositive individuals relative to seronegative rodents, and often highest seropositive rates are seen in older males (96). Results from experimental infections of host rodents indicate that initial local virus replication leads to viremia, which peaks about 2 weeks after infection and results in dissemination of the virus throughout body (92,125,160,161,200,311) (Fig. 5). Hantaviruses appear to target primarily endothelial cells, with highest concentrations of virus antigen being observed in the lungs and kidneys (199). Hantaviruses are largely noncytopathic, with no virus-induced cell death observable in infected animals. Virus is shed in urine and feces and probably in the saliva too, based on the observation of considerable virus replication in the salivary glands. The reduction and eventual clearance of the viremia correlates with the induction of hantavirus-specific antibodies, which first become detectable about 14 days after infection, peak about 50 days after infection, and remain detectable for the life of the rodent. Despite the presence of serum neutralizing antibodies, the virus persists and is shed for several months after infection, although peak shedding occurs about 2 to 10 weeks after infection (126,161) (see Fig. 5). No overt disease symptoms are observed in naturally or experimentally infected rodent hosts.

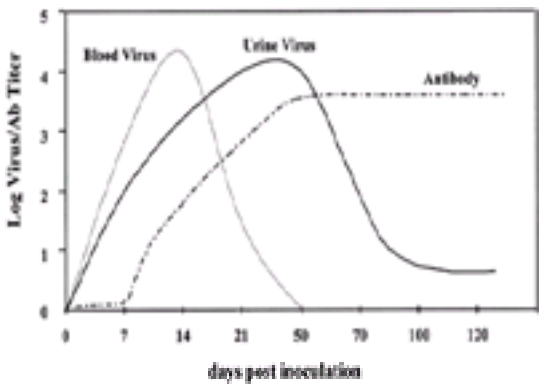

FIG. 5. Dynamics of a typical hantavirus infection of its primary reservoir rodent host. (Modified from ref. 200, with permission.)

Humans

In stark contrast to the asymptomatic hantavirus infection of primary rodent reservoir species, human infections frequently result in disease, with HFRS or HPS resulting depending on the hantavirus type. Hantaviruses are transmitted from the infected rodent reservoir to humans by inhalation of infectious aerosols produced from the rodent excreta. The early events in the human infection are poorly understood. Virus entry into cells is thought to be mediated by cell surface integrins, with pathogenic hantaviruses, such as Sin Nombre, New York, and Hantaan, using b $_3$-integrins, whereas so-called nonpathogenic hantaviruses, such as Prospect Hill and Tula viruses, use b $_1$-integrins (93,94). In the absence of

data regarding human infection with nonpathogenic hantaviruses, it is difficult to verify whether cell receptor usage does indeed correlate with virulence of the viruses in humans. Absence of reported disease with such viruses may merely reflect less human contact with these viruses owing to elements of the rodent host ecology. For instance, deer mice (*Peromyscus maniculatus*), which host Sin Nombre virus, are described as the most abundant small mammal in North America (38). They are generalists, being found throughout a wide variety of ecological zones, and are frequently found in peridomestic settings, bringing them into close and repeated contact with humans living in rural areas. These features may provide the best explanation of why most HPS cases in North America are associated with Sin Nombre virus infection. Studies of hantavirus infection of polarized cells, such as those done with Black Creek Canal virus, show that hantavirus entry into the host cell is predominantly through the apical cell surface (224). Such studies also show that most release of virus is occurring at the apical surface, in contrast to most other family *Bunyaviridae* viruses studied.

The incubation period before onset of illness lasts about 7 to 21 days. As in the rodent infections, no CPE is evident in hantavirus-infected human cells. Hantavirus-specific antibodies and T cells are detectable at the time of onset of disease symptoms, consistent with immune-modulated changes, rather than virus-induced cell death being responsible for the disease symptoms (85,148). Virus RNA is usually detectable in patient blood during the early stages of disease. At the time of death, virus antigens are detectable in endothelial cell layers throughout the body, but predominantly in lung endothelial cells in the case of HPS, or kidney endothelial cells in the case of HFRS (124,313). Acute tubulointerstitial nephritis can be seen in kidney biopsies from HFRS patients. Mild to massive proteinuria, hematuria, and a rise in the serum creatinine level are typical. The exact mechanism of kidney failure in HFRS patients is unclear. Mild to moderate interstitial infiltration of lymphocytes, plasma cells, monocyte-macrophages, and polymorphonuclear leukocytes (mainly eosinophilic granulocytes and neutrophils) can be seen in kidney biopsy specimens from Puumala virus–associated HFRS patients (272). Also, an increased expression of the cytokines tumor necrosis factor-a, transforming growth factor-b, and platelet-derived growth factor has been observed at the same sites, mainly in the peritubular area of the distal nephron. Expression of endothelial adhesion molecules CD54 (intercellular adhesion molecule-1), CD106 (vascular cell adhesion molecule-1), VCAM, and CD31 (platelet endothelial cell adhesion molecule-1) PECAM can also been seen at the same locations. Similarly, high numbers of cytokine-producing cells can be seen in the lungs (but not the kidneys and livers) of patients with fatal HPS, suggesting that local cytokine production may play an important role in pulmonary edema and high case-fatality (about 50%) seen in HPS, although the exact alteration in pulmonary endothelial cells leading to capillary leakage is still unclear (186). Although hantaviruses infect a number of laboratory animals, including mice, hamsters, and nonhuman primates, no good model of the human disease has been described. Severity of illness in humans appears to correlate with HLA type, at least in the case of Puumala virus–associated HFRS (196,197). Severe disease was shown to be associated with the HLA-B8 DRB1*0301 haplotype, whereas the HLA-B27 allele was underrepresented in hospitalized cases and those that possessed the allele had benign overall clinical course and mild renal involvement. Severity of HPS disease has also been suggested to be linked to HLA-B*35 (F.T. Koster, unpublished data).

Epidemiology and Ecology

The geographic distribution of hantaviruses and epidemiologic patterns observed for HFRS and HPS reflects the distribution and natural history features of the hantavirus-infected rodent hosts of these viruses (Fig. 6; see Table 2). This is because hantavirus infection of the rodent primary reservoir species produces a persistent infection with prolonged shedding of the virus, whereas infection of humans results in an acute infection with relatively quick clearance of virus and recovery in survivors. Epidemiologic data accumulated since the 1950s for a variety of hantaviruses, including HPS-associated hantaviruses, suggest that human-to-human virus transmission does not occur, and virtually all human infections are acquired by exposure to infected rodent excreta, with the one exception of an Andes virus–associated HPS outbreak in Patagonia, Argentina (see later).

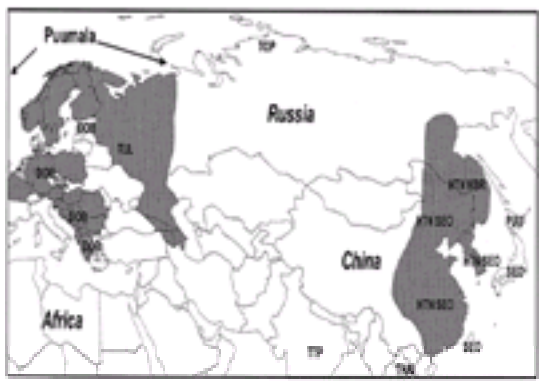

FIG. 6. Approximate distribution of hantaviruses and hemorrhagic fever with renal syndrome (HFRS) in the Old World. HTN, Hantaan; SEO, Seoul; PUU, Puumala; THAI, Thailand; TTP, Thottapalayam; KBR, Khabarovsk; TOP, Topografov; DOB, Dobrava; VLD, Vladivostok.

Hantaan virus is found in various parts of eastern China and Korea and Far Eastern Russia and is present in *Apodemus agrarius mantchuricus,* a mouse that is common in agricultural fields (51). Adults in rural areas (e.g., farmers, forest workers, or troops stationed in the field) are the most at risk for infection, and HFRS cases are seen to peak in the fall. This likely reflects a mixture of factors, including increased abundance of virus-infected mice in the fall, coinciding with increased human activity in the fields associated with harvest of crops, and movement of rodents into the houses as winter approaches (155). Most cases are 20 to 50 years in age, and cases in children younger than 10 years of age are uncommon (49,157). A greater number of male than female cases are seen, consistent with predominant exposure being in the fields rather than in the homes. Hantaan-related HFRS is probably most important in China, where about 100,000 cases are reported each year. On the order of 300 to 900 HFRS cases are estimated to occur in Korea each year, and

about the same number of cases are thought to occur in Far Eastern Russia on an annual basis.

Seoul virus is associated with the domestic rats *Rattus norvegicus* and *R. rattus* (159,263) and has a worldwide distribution owing to the relatively recent global spread of rats to port cities and beyond through international shipping (156). Seoul is the only hantavirus known to cause disease in urban areas because the other hantaviruses are associated with rodents that are predominantly rural in their distribution. Surprisingly, Seoul virus–related HFRS cases appear to be rare outside of China and Korea and institutions housing laboratory rat colonies, the exact reason for which is unclear. Seoul virus–related HFRS cases in general tend to be more moderate than those associated with Hantaan virus, although mortality rates still range to about 1% to 5%. Although most cases are in cities, Seoul virus–related HFRS cases are also seen in some rural areas in China. The seasonality of Seoul virus–related outbreaks are different to Hantaan-related HFRS, with most cases occurring in spring and early summer as opposed to fall and early winter (50). The annual number of cases is unknown; figures for Seoul virus– and Hantaan-related HFRS are often not separated. However, Chinese reports suggest that Seoul virus–related HFRS in urban areas of several provinces has been on the increase since its discovery in 1981 (47,256). A genetically related virus, Thailand virus, is found in *Bandicota indica* rodents in Thailand but is not known to cause human disease.

Dobrava virus has more recently been shown to be the cause of severe HFRS (similar to that seen with Hantaan virus) in the Balkans and perhaps elsewhere in southern Europe (9,13,206). The primary rodent reservoir is *Apodemus flavicollis,* which is widely abundant in this region. However, a distinct lineage of Dobrava virus can be found in *Apodemus agrarius agrarius* (a subspecies distinct from that which carries Hantaan virus in Asia), which is of greater abundance in more northern areas (12,51,198). Although *A. flavicollis* do not frequent houses and other man-made structures, they will often enter campsites where food may be present. Most cases of Dobrava-related HFRS occur in rural areas, involving men with occupations such as shepherds, woodcutters, or military personnel who work or sleep in open areas where these rodents may be abundant. Unlike Hantaan-associated HFRS, most Dobrava-associated HFRS cases occur in the late spring and summer months when activity in the rural areas is greatest. Epidemics of disease are seen at times when rodent populations are high and have been observed in recent years when military conflict in parts of the Balkan region have resulted in substantial numbers of troops or civilians living in open country (170). Average years see perhaps a couple of hundred HFRS cases occurring in the region, although not all are associated with Dobrava virus infection (see later discussion of Puumala virus). Seroprevalence rates can be high in some rural areas; for example, antibody positivity rates of up to 14% were seen in mountainous areas of northern and western Greece (8).

Nephropathia epidemica, generally the mildest form of HFRS associated with Puumala virus, is found throughout Scandinavia and Europe west of the Ural mountains. The virus is hosted by the bank vole, *Clethrionomys glareolus.* Puumala virus–associated HFRS is the most common form in Europe. In Sweden and Finland, the number of cases in rural residents usually peaks in November and January, although cases in urban residents appear to peak in August, which likely correlates with vacationing in summer cabins in rural areas. A male-to-female case ratio of about 2:1 is seen, and the disease is rare in children (27). Local epidemics usually reflect increased local bank vole densities, which tend to cycle with a 3- to 4-year periodicity. About 30% of Puumala virus infections result in reported disease, based on data from areas of Finland with high surveillance for disease (27). Also, antibody prevalence rates of up to 20% can be seen in known endemic areas in northern Sweden (120). In recent years, there has been an increased awareness of Puumala virus–associated HFRS in other areas of Europe. For instance, a large outbreak (60 cases) was recorded in southern Belgium in 1993, which mirrored an increase in the local bank vole population (60). Hantavirus disease in Belgium, northeastern France, and Germany mainly occurs in fall and spring, and extent of activity reflects the alterations in the size and structure of bank vole communities (215). Large Puumala virus–associated HFRS outbreaks are periodically recorded in several areas of European Russia, particularly Udmurtia and Bashkortostan. A genetically distinct Puumala-like virus has also been identified in *Clethrionomys rufocanus* voles in Far Eastern Russia and on Hokkaido Island, Japan but is not known to be associated with human disease (136). Several additional hantaviruses are known to be associated with other subfamily Arvicolinae rodents but are not known to cause human disease. Topografov virus is present in lemmings in Arctic regions of Russia, and at least five different hantaviruses are associated with various Old World and New World rodents of the *Microtus* genus (see Table 2).

Since the discovery of Sin Nombre virus and HPS in 1993, there has been an enormous expansion in the number of hantaviruses known to be associated with the New World subfamily Sigmodontinae rodents (see Table 2). In terms of the United States and Canada, by far the most important virus is Sin Nombre virus because it is responsible for most of the HPS cases identified in North America (184). Sin Nombre virus is present in deer mice (*P. maniculatus,* grasslands form) throughout western and central United States and Canada (184). The initial 1993 cluster of HPS cases occurred in the Four Corners region, and most subsequent cases have been identified in the southwestern United States. However, HPS cases have now been identified in 30 states and four provinces of Canada, and Sin Nombre virus–infected deer mice have been detected throughout most of its range, which stretches from the Yukon to Mexico and from California to the Appalachian mountains in the eastern United States and Canada (181,184). As of spring 2001, about 280 cases of HPS cases have been identified across the United States, with most cases occurring in the western region. Thirty-five cases have been confirmed in western Canada in the provinces of British Columbia, Alberta, Manitoba, and Saskatchewan. Survey of more than 9,000 sera from the U.S. general population found that about 0.2% of individuals had hantavirus-specific antibodies, indicating that hantavirus infection of humans in the United States is relatively rare (T.G. Ksiazek, personal communication). Even survey of 2,500 individuals in risk groups, such as those with occupations that would bring them in close contact with rural rodents, found hantavirus-specific antibodies in only about 0.5% of those sampled (L.R. Armstrong and associates, unpublished observations) (294,314), suggesting that infection of humans with Sin Nombre virus is rare. It appears that clusters of cases are generally associated with local increases in infected deer mice populations. The initial 1993 outbreak, which led to the discovery of the disease, was associated with unusually high deer mice populations that had risen to about 10 times normal levels owing to a prolonged El Niño effect, which produced conditions favorable for deer mice reproduction and survival in the Four Corners region (207). The peak of HPS cases occurs in late spring or early summer, and about equal ratios of males and females are affected (138). Clinical disease in children is rare. Retrospective studies suggest the disease had gone unrecognized since at least 1959 (90).

Several other hantaviruses are capable of causing HPS in the United States. The forest form of deer mice (*P.*

maniculatus nubiterrae), which are found predominantly throughout the Appalachian mountain range extending from Georgia to eastern Canada, harbor a genetically distinct Sin Nombre–like virus referred to as *Monongahela virus* (184,257). This virus has been associated with two or three HPS cases in the eastern United States. The white-footed mouse, *P. leucopus* (eastern haplotype), hosts another Sin Nombre–like virus, named *New York virus.* This virus has been responsible for at least two HPS cases in the northeastern United States (115,121). A different hantavirus, Blue River virus, is present in *P. leucopus* (western haplotypes) in the central and western U.S., but this virus is not known to be associated with human disease (191). Mitochondrial DNA (mtDNA) analysis of the different rodent hosts shows that each of these rodent hosts are genetically distinct (191) (S.P. Morzunov and S.T. Nichol, unpublished data). This is in keeping with the general pattern for hantaviruses, whereby each specific hantavirus is hosted by a single different species or subspecies of rodent, and each specific rodent species or subspecies serves as the primary reservoir for only a single specific hantavirus (200,220).

Other sigmodontine genera harbor HPS-associated hantaviruses in the U.S. Black Creek Canal virus was associated with a single HPS case in southern Florida and is hosted by the cotton rat, *Sigmodon hispidus* (eastern form) (225). The genetically distinct western form of *S. hispidus,* hosts a genetically distinct hantavirus, Muleshoe virus (226). Bayou virus was discovered in 1994 associated with a fatal HPS case in Louisiana (190). Subsequently, the virus was shown to be hosted by the rice rat *Oligoryzomys palustris,* to be present throughout the range of the rodent (147), and to be associated with a nonfatal HPS case in Texas (113). Although the HPS associated with Black Creek Canal and Bayou viruses is still predominantly a pulmonary disease, there does appear to be more renal involvement than seen in classic Sin Nombre virus–associated HPS (113,137,140).

The confirmation of an HPS case in Brazil in late 1993 marked the beginning of a wave of discovery of HPS cases and associated hantaviruses throughout South and Central America (see Table 2). Over 300 HPS cases have been identified in various parts of Argentina (website, http://www.healthig.com/hantavirus/hanta14.html), 90 in Chile (website, http://disap.minsal/epidmiologia/hantas/informedia.html), 40 in Paraguay, 26 in Brazil, 15 in Uruguay, and 12 in Panama. Notable outbreaks included the identification of 17 cases in the western Chaco region of Paraguay in 1995 to 1996 (132,305) and 20 cases in Patagonia, Argentina in 1996 (300). This unusual HPS outbreak in Patagonia was shown to be caused by a distinct hantavirus, Andes virus, hosted by *Oligoryzomys longicaudatus* (169). Similar to all the other studied hantavirus diseases, transmission of HPS-associated hantaviruses appears to be overwhelmingly from infected rodent to humans by inhalation of infectious aerosols. However, epidemiologic investigation of the Andes virus–associated HPS outbreak in Patagonia clearly demonstrated human-to-human transmission between a patient and her physician, and circumstantial evidence suggested several additional human-to-human virus transmissions during this particular outbreak (205,300). This does not appear to be a common property of Andes virus because no health care workers became infected in the course of handling Andes virus–associated HPS cases in a subsequent large HPS outbreak in Chile (45).

The finding of high prevalence of hantavirus-specific antibodies in the general population in some areas of South and Central America differs considerably from the epidemiologic picture seen in North America, where seropositivity rates of 0.2% of less are seen. For example, high rates of hantavirus-specific antibodies have been seen on surveillance of general populations in regions of Paraguay (40%), Salta province in Argentina (17%), and Los Santos province in Panama (13%) (87,293,305). These data suggest more frequent exposure of people to hantaviruses in these areas and more inapparent or subclinical infections than seen with North American hantavirus infections.

Phylogenetic analysis of hantaviruses and their rodent reservoirs have indicated that their evolutionary trees overlap with only a few exceptions (Fig. 7), suggesting that these viruses have coevolved with their rodent hosts over 20 to 30 million years (200,201,220). These data show that although HPS and many hantaviruses are only recently discovered, they are actually ancient.

FIG. 7. Hantavirus phylogenetic trees. Maximum parsimony phylogenetic trees based on the nucleotide sequences of the hantavirus entire S or M genome segments. Bootstrap values in excess of 50% are shown adjacent to internal nodes. HTN, Hantaan; DOB, Dobrava; SEO, Seoul; THAI, Thailand; PUU, Puumala; TOP, Topografov; KBR, Khabarovsk; TUL, Tula; PH, Prospect Hill; ISLA, Isla Vista; MULE, Muleshoe; BCC, Black Creek Canal; Bay, Bayou; LEC, Lechiguanas; ORN, Oran; RIOM, Rio Mamore; LN, Laguna Negra; SN, Sin Nombre; NY, New York; MON, Monongahela; BR, Blue River; ELMC, El Moro Canyon; RIOS, Rio Segundo. All sequences are available in GenBank, except those for Thottapalayam virus, which was kindly provided by Connie Schmaljohn. (Modified from ref. 200, with permission).

Clinical Features

After infection with Hantaan or Dobrava virus, there is a typical 2- to 3-week incubation phase followed by the sudden onset of influenza-like symptoms. The febrile phase lasts 3 to 5 days with high fever, headache, malaise, chills, and prostration. Flushing of the face and neck and conjunctival and pharyngeal injection (indicating capillary dilation) are

frequently observed. Increased capillary permeability is likely responsible for the retroperitoneal edema and lower back pain often described. The febrile phase is followed by a hypotensive phase lasting several hours to days characterized by marked thrombocytopenia and often petechial hemorrhage. Many patients exhibit low-grade DIC, and about 10% to 15% of patients show some degree of shock around this time. Usually, shock improves in 12 to 48 hours, and blood pressure returns to normal or the patient becomes hypertensive. Oliguria may occur, and historically, renal failure contributes to about half of the deaths (74,251,252). Recovering patients then go through a phase of diuresis, which may last several months. Obviously, not all patients go through all the stages described, with some of the more severe cases rapidly progressing through to death in a few days, whereas other, milder cases skip some phases of the disease or exhibit very mild symptoms and are not recognizable as HFRS. However, this tends to be the most severe form of HFRS, with a 5% to 15% mortality rate.

Seoul virus–associated HFRS tends to be milder, with a mortality rate of 1% or 2%. In general, the disease course resembles that observed with milder Hantaan and Dobrava virus–associated cases, although more prominent liver involvement often occurs (141). Puumala virus–associated HFRS (often referred to as nephropathia epidemica), is the mildest form of the disease, with a mortality rate of less than 1%. The phases of the illness are generally less pronounced, and symptoms are milder, with hypotension rather than shock, petechiae instead of more frank hemorrhage, and relatively mild renal involvement. There is some suggestion that cases in central Europe and Russia are more severe than those seen in Scandinavia. In contrast to HPS (see later), pulmonary edema is not a common on presentation of HFRS cases and, when seen, is not an initial symptom but is usually the result of overhydration of the patient.

Since the discovery of HPS in 1993, a considerable amount of data have accumulated on the clinical presentation of the disease, particularly for Sin Nombre virus–associated HPS, which is the most common form seen in North America (72,138). Similar to HFRS, in HPS, there is also a 2- to 3-week incubation period before rapid onset of an influenza-like illness. The febrile phase lasts about 4 days and includes fever, myalgia, malaise, and headache; gastrointestinal symptoms are also often observed at this early stage. Patients often present for medical attention with the onset of pulmonary edema, dyspnea, and hypoxemia. These features, together with the hemoconcentration that is frequently observed, are presumably linked to the hantavirus infection of the microvascular endothelial cells surrounding the lungs, which leads to increased permeability and fluid leakage into the lungs. Bilateral pulmonary infiltrates are often visible on chest radiographs. Deterioration of patient condition is often rapid, with death occurring in almost half of cases within 1 to 3 days of hospital admission. Clinical laboratory tests frequently reveal thrombocytopenia and prolonged partial thromboplastin time. Hypotension and shock can be prominent at this stage. Recovery of surviving patients is often remarkably quick, with rapid resolution of the lung lesion and shock within 3 to 6 days. Very similar clinical pictures are seen with HPS cases associated with other viruses found in rodents of the subfamily Sigmodontinae. HPS cases have also been associated with Sin Nombre virus–related Monongahela and New York viruses; Bayou virus; Black Creek Canal virus; Andes and related viruses Oran, Lechiguanas, and Hu39694; and Laguna Negra, Juquitiba, Araraquara, and Castelo dos Sonhos viruses. The clinical picture seen in HPS cases associated with Black Creek Canal and Bayou viruses differs slightly in that more renal involvement and elevated serum creatine phosphokinase are observed. Renal failure also appeared to be common with Oran virus–associated HPS in northern Argentina (164). Flushing, petechiae, and frank hemorrhage were seen in some HPS patients infected with Andes virus in Argentina and Chile, respectively (7).

Diagnosis

Clinical differential diagnosis of HFRS and HPS cases can be difficult because of the nonspecific early symptoms in both types of cases. In areas of China, Korea, Far Eastern Russia, Europe, and Scandinavia, where HFRS is known to occur, a febrile patient presenting with thrombocytopenia and renal symptoms should be questioned about potential rodent exposure and tested for evidence of hantavirus infection. The early signs of severe HFRS can be easily confused with those of leptospirosis, typhus, pyelonephritis, poststreptococcal glomerulonephritis, an acute abdominal emergency, or other hemorrhagic fevers. Mild HFRS can be confused with hepatitis A, mild leptospirosis, streptococcal pharyngitis, influenza, or nonsteroid antiinflammatory toxicity.

In the Americas, the early stages of HPS are extremely difficult to recognize, being easily confused with influenza. However, fever and myalgia and a history of potential rural rodent exposure, together with the appearance of shortness of breath and findings of thrombocytopenia, leukocytosis with left shift (higher ratio of immature-to-mature neutrophils), and atypical lymphocytes, would be strongly suggestive of HPS (204).

In keeping with the perception that both HFRS and HPS are immune-modulated diseases, virus antibodies are invariably detectable in patient sera near the time of onset of illness. Laboratory analysis of the presence of virus-specific antibodies has historically included indirect fluorescent antibody (IFA) testing. This has good sensitivity and hantavirus cross-reactivity, and use of a representative virus from each of the main rodent subfamilies harboring hantaviruses (i.e., Murinae, Arvicolinae, and Sigmodontinae) identifies infections caused by virtually all hantaviruses. However, false-positive results are not uncommon owing to rheumatoid factor problems and overall nonspecific “stickiness” of some patient sera. Some of these difficulties can be controlled for by the inclusion of appropriate negative antigens to detect and remove the effects of problem sera. Although of some utility for acute diagnosis, the inherent nonspecific background and subjectivity problems make the IFA test unsuitable for serologic survey studies. Acute diagnosis is best achieved by IgM capture ELISA using hantavirus-infected cell slurry as antigen and incorporating an uninfected cell slurry control (148). Recombinant nucleocapsid proteins with appropriate negative-control protein fractions have also proved useful as antigens in this assay format (83,86,101). Such assays have been shown to be highly sensitivity, rapid, and inexpensive. Considerable cross-reactivity among related hantaviruses is seen, such that inclusion of a limited number of representative virus antigens (e.g., Sin Nombre, Puumala, and Hantaan viruses) allows detection of virtually all acute hantavirus infections. The disadvantage of the cross-reactivity of the assay is the inability to identify precisely the virus based on a positive result. Western blot assays using recombinant nucleocapsid proteins or glycoproteins have also been effectively used for acute diagnosis, particularly with New World hantaviruses, and can provide some additional insights into virus identity (114,130).

Virus isolation attempts from acute clinical specimens are almost always negative. The exact reason for difficulty of

isolation of hantaviruses is unknown but is likely related to the presence of a strong immune response at the time of onset of illness, including serum neutralizing antibodies. Demonstration of the lack of amino acid substitutions during the isolation of Sin Nombre virus from infected lung material would suggest that virus adaptation to growth in tissue culture is not a major element in the difficulty of isolation of these viruses (53). Given the frequent difficulty in obtaining infectious virus, RT-PCR assay has been used effectively to complement immunodiagnostic assays and allow detailed genetic comparison of the hantaviruses (169,201,206,237). Given the potential for false-positive results because of cross-contamination, RT-PCR is not recommended as the sole means of hantavirus diagnosis.

Prevention and Control

The primary means of prevention is the reduction of rodent exposure. Effective measures include rodent-proofing of homes, correct storage of food, airing of seasonally closed cabins, and disinfection and removal of trapped rodents and rodent droppings (42,43,95). The lack of nosocomial transmission or person-to-person transmission reported for virtually all hantavirus outbreaks suggests that spread to medical personnel or contacts is usually not a concern. The one exception was the limited person-to-person spread seen during an Andes virus–associated HPS outbreak in Patagonia, Argentina in 1996 (205,300).

Several different inactivated virus vaccines for Hantaan and Seoul viruses have been used in Asia (reviewed in 119). These include virus-infected rodent brain–derived antigens inactivated with formalin or b-propiolactone (162,309). Although such products would not be suitable for use outside the region, good efficacy has been reported (119). Several monovalent and bivalent Hantaan and Seoul tissue culture–derived inactivated vaccines have also been produced in China (119), some of which may have high efficacy (48). In addition, a number of recombinant DNA approaches to vaccine development have been investigated (recombinant baculovirus, vaccinia, or Sindbis virus produced hantavirus proteins, naked DNA, and so forth), some of which show promise in experimental systems (119).

The sensitivity of Hantaan virus to the inhibitory effects of the antiviral drug ribavirin on virus replication in tissue culture or in animal models (123) has promoted clinical trials both with HFRS patients and HPS patients, with positive results reported in the case of HFRS (122).

TOSPOVIRUS GENUS

The tospoviruses are plant viruses that are transmitted propagatively by thrips (303). At least eight different species of thrips are reported to transmit these viruses, five in the genus *Frankliniella* and three in the genus *Thrips.* Several of these viruses are now recognized as being of significant agricultural importance (222). An excellent recent review of the tospoviruses is available on line (http://www.spg.wau.nl/viro/research/tospo.html).

The history of the tospoviruses goes back to 1915, with the recognition of spotted wilt of tomatoes in Australia (25), and then the subsequent isolation in 1930 of tomato spotted wilt virus (TSWV) (236), from which the genus gained its name (146). By the late 1940s, TSWV infections were greatly reduced in the United States and Western Europe owing to pesticide use controlling the onion thrips, *Thrips tabaci,* which was likely the primary vector at that time. The geographic spread during the 1960s and 1970s of the Western flower thrips, *Frankliniella occidentalis,* another efficient vector of TSWV, led to a rapid expansion of the virus (26,149,288). The virus is now known to be global in distribution, and is found throughout agricultural areas in warmer climate zones, and is prevalent in greenhouse cultivations in more temperate areas. In contrast to the other genus members, TSWV has an unusually wide host range, with more than 925 plant species, including 82 botanical families, reported to be susceptible to infection. These include several important crops, such as peanuts, peppers, tobacco, potatoes, peas, tomatoes, celery, lettuce, and ornamental flowers, with crop losses amounting to more than $1 billion dollars (97). In addition to TSWV, there are 12 other recognized tospovirus species (84).

In infected plant cells, several types of aggregates of virus proteins are observed, and mature virus particles accumulate in the endoplasmic reticulum (142). Although the spread of virus from plant to plant is by ingestion of the cell contents by thrips, acquisition of a virus envelope membrane containing the virus glycoproteins is still thought to be important for virus transmission by thrips. However, once inside the plant, complete virus maturation may be less critical because movement from cell to cell likely involves virus nucleocapsid movement through plasmodesmata cytoplasmic channels (146,262). In addition, to the structural proteins, nucleocapsid (N), glycoproteins (G1 and G2), and RNA polymerase (L), the tripartite genome of these viruses encode two nonstructural proteins, one from the S genome segment, NSs, and one from the M segment, NSm (145). The NSs protein accumulates in the salivary gland of infected thrips, suggesting a role in virus transmission (303). The NSm protein associates with virus nucleocapsids and localizes to plasmodesmata, where it forms tubular structures thought to be involved in virus cell-to-cell movement (146,262).

In contrast to the other arthropod-borne members of the *Bunyaviridae,* adults of the vector thrips do not acquire the virus, only larvae becoming infected when feeding on virus-infected plants (287). TSWV has been shown to be transstadially transmitted through molting, pupation, and emergence to the adult stage, and both larvae and adults can transmit the virus to plants (302). Unlike many of the other arthropod-borne bunyaviruses, there is no evidence of transovarial transmission for any of the tospoviruses. This presumably reflects the widespread and year-round replication of thrips in most climates, and the enormous number of susceptible plants, making vertical transmission of the virus in the vector thrips of lesser importance.

Control of tospovirus infections in a field setting is difficult owing to problems in eliminating thrips and the fact that many weed species surrounding cultivated fields serve as virus reservoirs. Several breeding programs have attempted to increase natural host resistence of plants to tospovirus infection, but with little success to date (261). Attempts to create genetically engineered host plant resistance are showing promising results (221,222).

CHAPTER 50 *Arenaviridae:* The Viruses and Their Replication

Michael J. Buchmeier, Michael D. Bowen, and Clarence J. Peters

HISTORY

Arenaviruses cause chronic infections of rodents indigenous to Europe, Africa, the Americas, and perhaps other continents. These asymptomatically infected animals move freely in their natural habitat and may invade human habitation; when man comes in contact with excreted viruses, disease may result. Arenavirus infections of humans are common and in some cases severe. The mechanisms that have evolved to ensure chronic infection and intergenerational survival of the virus in rodents are complex, and their elucidation over the last 60 years has led to a deeper understanding of immunology and immunopathology.

The first arenavirus isolated was lymphocytic choriomeningitis virus (LCMV), discovered in 1933 during the study of samples from a St. Louis encephalitis epidemic (14). It was soon found to be a cause of aseptic meningitis (255) and to be identical to an agent that chronically infected mouse colonies (294). This launched a series of studies that showed LCMV to be a common human pathogen and a fascinating virus with many lessons for viral immunologists (50,51,260).

By the 1960s, several other viruses had been discovered and found to share common morphology (229,230), serology (262), biochemical features (159), and a natural history that depended on chronic infection of rodent hosts, leading to the recognition of the *Arenaviridae* family after the sandy (Latin, *arenosus*) appearance of the ribosomes often seen in thin sections of virions (261). Some of these viruses caused severe hemorrhagic fever (Table 1), whereas others were apparently not pathogenic for or rarely infected humans (Table 2). After the isolation of Tacaribe virus in 1956 (87), new arenaviruses continued to be discovered in the Americas on the average of one every 3 years, including three lethal new viruses, Guanarito (266), Sabia in 1990 (188), and Whitewater Arroyo in 1996 (see Fig. 2) (54,104).

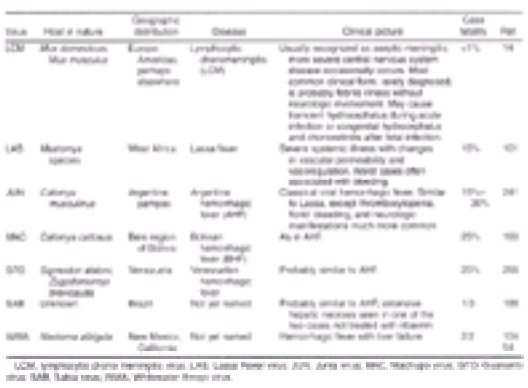

TABLE 1. *Arenaviruses that are known to be human pathogens*

Virus	Host in nature	Geographic distribution	Comments	Year isolated	Ref.
TAC	Unknown	Trinidad	Originally isolated from Artibeus bats in 1958–59; not found in subsequent attempts; bats may be reservoir	1958	57
ANA	*Oryzomys gaeldi*, *Neacomys guianae*	Brazil	Apparently has two rodent reservoirs	1964	250
PAR	*Oryzomys buccinatus*?	Paraguay	Reservoir not well established	1965	309
TAM	*Sigmodon hispidus*	United States	Antibodies detected in a few humans without disease	1963, 1965	56
PIC	*Oryzomys albigularis*	Colombia	Several asymptomatic laboratory infections	1967	292
LAT	*Calomys callosus*	Bolivia	Thought to be nonpathogenic for man	1965	311
FLE	*Oryzomys* spp?	Brazil	Two laboratory infections with disease	1975	251
OLI	*Bolomys obscurus*	Argentina	Found during field studies of Junin virus; still under evaluation	1969	210
IPPY	*Arvicanthus* spp.	Central African Republic	Proved to be an arenavirus in 1985; see Mopeia (MOP)	1970	84
MOP	*Mastomys natalensis*	Mozambique, Zimbabwe	One of several non-Lassa arenaviruses from *Mastomys* species in Africa	1977	321, 133
MOB	*Praomys*	Central African Republic	See Mopeia (MOP)	1983	110

TAC, Tacaribe virus; ANA, Amapari virus; PAR, Pirital virus; TAM, Tamiami virus; PIC, Pichinde virus; LAT, Latino virus; FLE, Flexal virus; OLI, Oliveros virus; IPPY, Ippy; MOP, Mopeia virus; MOB, Mobala virus.

TABLE 2. *Arenaviruses not known to be significant human pathogens*

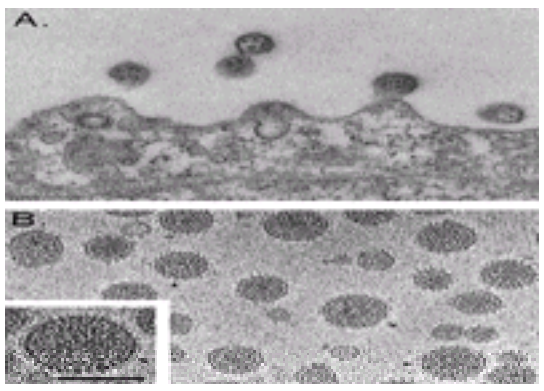

FIG. 2. Electron microscopy of lymphocytic choriomeningitis (LCM) virus. **A:** Thin section showing virions budding from infected BHK-21 cells. Glycoprotein spikes are evident (*arrows*) studding the viral envelope. Bar indicates 100 nm. (From J. W. Burns, R. Milligan, and M. J. Buchmeier, unpublished data.)

THE INFECTIOUS AGENT

Virion Structure

All arenaviruses are enveloped and have a bi-segmented RNA with a unique ambisense genomic organization (reviewed in ref. 283). Virions exhibit a pleomorphic morphology when examined by cryoelectron microscopy, ranging in size from 62 to more than 200 nM in diameter (Fig. 2). The surface of the virion envelope is studded with glycoprotein projections that consist of tetrameric complexes of the viral glycoproteins GP1 and GP2 (53). Internal nucleocapsids of another arenavirus, Tacaribe virus, have been shown to consist of two size classes of coiled circular filaments (238). Young and Howard (322a) investigated the structure of these RNAs and demonstrated that each segment is capable of forming twisted circular fibers of 20 nM, similar to the electron-dense particles observed within virons.

FIG. 1. Location of American arenaviruses with their natural host and approximate date of isolation. (Courtesy of Dr. S. Nichol, Centers for Disease Control.)

Genomic Organization

The genome of arenaviruses consists of two single-stranded RNA segments designated S (small) and L (large). In virions, the molar ratio of S to L RNAs is roughly 2:1. The complete S RNA sequence has been determined for eight arenaviruses and ranges from 3,366 to 3,535 nucleotides. The complete L RNA sequence has been determined for Tacaribe, LCM, and Lassa viruses and ranges from 7,102 to 7,279 nucleotides. The 3' terminal sequences of the S and L RNA segments are identical at 17 of the last 19 nucleotides (for S it is 5'...GCCUAGGAUCCACUGUGCG $_{OH}$3', and for L it is 5'...GCCUAGGAUCCUCGGUGCG$_{OH}$3'), and they are conserved among the arenaviruses (18,40,85,268,269). The 5'

terminus of each segment contains a tri- or diphosphate group and lacks a cap structure. The 5'-terminal 19 or 20 nucleotides at the beginning of each genomic RNA are imperfectly complementary with each corresponding 3' end. The 3' and 5' termini are thought to base-pair and form panhandle structures, which would account for the circular appearance of nucleocapsids when viewed by electron microscopy. An additional G residue, which would not participate in base-pairing with a corresponding 3'-terminal base, has been detected on the 5' end of some S genomic RNAs (40,116). In these cases, the panhandle structures would not contain flush ends, for there would be a single G overhang on the 5' side.

The S RNA segment contains two genes that encode three final gene products—the nucleoprotein (NP or N) and the envelope glycoproteins GP1 and GP2 (also termed GP-1 and GP-2, or G1 and G2). GP1 and GP2 are first expressed as a precursor protein, GPC (or GP-C), which is cleaved posttranslationally (49). The L RNA segment contains two genes that encode two gene products, the viral polymerase (L protein) and the Z protein, a small protein of undetermined function (142,268,270). On both segments, the genes are arranged in an ambisense orientation (Fig. 3) (141,270). The NP and polymerase genes reside at the 3' end of the S and L RNA segments, respectively, and are encoded in the conventional negative sense—that is, they are expressed through transcription of genome-complementary mRNAs. The genes located at the 5' end of the S and L RNA segments, GPC and Z, respectively, are encoded in mRNA sense but there is no evidence that they are translated directly from genomic RNA. These genes are expressed instead through transcription of genomic-sense mRNAs from antigenomes, full-length complementary copies of genomic RNAs that function as replicative intermediates. An unusual feature of arenavirus genomic RNAs is found in the intergenic regions that separate the two genes on each segment. The intergenic regions, which range from 59 to 217 nucleotides in length, are predicted to form one to three energetically stable, G-C–rich, stem-loop (hairpin) structures in both the genomic and antigenomic sense (Fig. 3) (19,141,316). The potential function of these stem-loop structures and the mechanisms of gene expression will be described in greater detail in the section, Viral Entry, Transcription, and Replication.

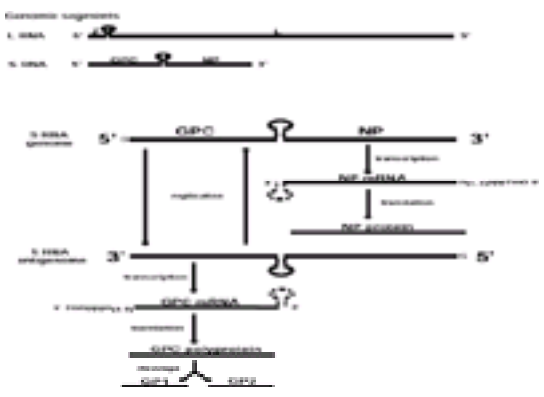

FIG. 3. Schematic diagram showing coding strategy for the L and S RNAs of the arenaviruses. Stem-loop structures indicate noncoding regions of each genomic segment. The lower portion of the diagram summarizes the transcription and replication events for the S genomic segment. As a consequence of this arrangement, the GPC and Z open reading frames can be transcribed only after initiation of replication of viral genomic RNA. Nontemplated nucleotides and a “cap” are shown at the 5' ends of N and GPC mRNAs. (Modified from ref. 283, with permission.)

Arenavirus Proteins

The NP is the major structural protein of arenavirions, with a molecular size of 60 to 68 kd. In Pichinde virus, a New World arenavirus isolated in Columbia, the NP represents 70% of the labeled virion proteins, and 1,530 molecules of NP are present in each virion. The NP is the major protein component of nucleocapsids and associates with virion RNA in the form of beadlike structures. NP can become phosphorylated in the later stages of acute infection, and this form increases in abundance during persistent infections *in vitro* (45,283). In infected cells, full-length NP is localized exclusively in the cell cytoplasm, but a 28-kd degradation fragment of NP accumulates in the nucleus of Pichinde-infected cells.

The GPC is a 70- to 80-kd polyprotein that is posttranslationally cleaved. A 58-amino-acid signal peptide is cleaved from the amino terminus before GPC is transported from the endoplasmic reticulum. Cleavage of GP1 and GP2 occurs in the secretory pathway between the medial and trans-Golgi network and requires prior glycosylation. GP1 derives from the amino-terminal portion of the GPC, and cleavage from GP2 occurs at or near a dibasic (arginine–arginine) motif that is conserved in all arenaviruses except Tacaribe virus. Equimolar amounts of the two glycoproteins are found in virions. GP1 (MW 40 to 46 kd) is the peripheral membrane glycoprotein with four to seven potential N-linked glycosylation sites (40,116). Because GP1 runs as a heterogeneous species on sodium dodecyl sulfate–polyacrylamide gel electrophoresis, it is speculated that not all potential glycosylation sites are used at the same time. GP1 molecules assemble into homotetrameric complexes that are held together by disulfide bonds. GP2 (MW, 35 kd) is the integral membrane glycoprotein, containing one to four potential N-linked glycosylation sites and a membrane-spanning domain. The carboxyl terminus of GP2 contains highly charged + or – residues and is thought to interact with NP in the cytosol, as evidenced by cross-linking studies. GP2 molecules, which are predicted to assume a coiled-coil conformation because of the presence of heptad-repeat sequences in the amino-terminal half of the molecule, assemble into homotetramers and form the stalk portion of the glycoprotein spike. GP2 homotetramers bind through ionic interactions with GP1 homotetramers, which comprise the globular head of glycoprotein spikes. GP2 is the viral fusion protein.

The arenavirus L protein has a reported molecular size of 180 to 250 kd (117,191). Motifs that are common to all RNA-dependent RNA polymerases and the polymerases of segmented negative-strand RNA viruses, as well as two regions found only in the polymerases of arenaviruses and bunyaviruses, are conserved in arenavirus L proteins. The L

protein is presumably a component of nucleocapsids, as polymerase activity has been associated with these structures.

The smallest protein encoded by the arenaviral genome is the Z protein (also called p11), which has a molecular size of 11 kd. The Z protein contains a RING-finger motif and binds zinc. It has been suggested that the Z protein is a structural protein and a component of nucleocapsids. Z protein has been detected in the cytoplasm and nucleus of LCMV-infected cells. Immunodepletion of Z protein in Tacaribe virus–infected cell extracts strongly inhibits synthesis of genomic RNA and NP mRNA, but a requirement of Z protein for transcription was seen only during the early stages of infection.

Viral Entry, Transcription, and Replication

The GP1 portion of the glycoprotein spike is responsible for initial binding to cellular receptor proteins, and antibodies directed to epitopes on GP1 can neutralize viral infectivity. GP1 binds to a 120- to 140-kd cellular glycoprotein identified as alpha-dystroglycan (57). Other arenaviruses (i.e., Lassa, Mobala, Oliveros) also bind to this glycoprotein, but Guanarito virus does not, suggesting that more than one cellular protein serves as a receptor for arenaviruses.

After attachment to cellular receptors, arenavirions are taken into the cell in large, smooth-walled endocytic vesicles that do not appear to be clathrin coated. Viral nucleocapsids are delivered into the cell cytoplasm by pH-dependent fusion of virion and endosomal membranes in response to acidification of the endosome (38,83). At acidic pH, GP1 dissociates from GP2, thus exposing the putative GP2 fusion peptide (83).

Once nucleocapsids are delivered into the cytoplasm, replication is initiated by transcription of subgenomic, genome-complementary NP and L mRNAs by the viral L protein, an RNA-dependent RNA polymerase (see Fig. 3). The mRNAs of arenaviruses are capped and contain typically four to five additional heterogeneous nucleotides at the 5' end, resembling the mRNAs of influenza viruses and bunyaviruses except that there are fewer extra bases in the mRNAs of arenaviruses. Thus it has been inferred that the arenaviral L protein uses capped primers “snatched” from cellular mRNAs by a methylated cap-dependent endonuclease domain of the polymerase, to prime transcription in a manner analogous to that described for the influenza virus polymerase complex, but this has yet to be demonstrated directly. Treatment of arenavirus-infected cells with the transcriptional inhibitor actinomycin D will reduce or inhibit viral replication in a dosage-dependent manner, presumably because the drug reduces the pool of cellular mRNAs available for “cap-snatching” by the L protein. The 3' ends of arenavirus mRNAs are not polyadenylated, and the precise structure of the 3' ends of mRNAs is somewhat unresolved. The intergenic region of the Tacaribe virus S RNA is predicted to fold into two stem-loop structures in both genomic (GPC gene) and antigenomic (NP gene) orientation. S1 nuclease mapping of NP and GPC mRNA species mapped the 3' ends of mRNAs to three or four bases located on the distal side of the stem, near the base, in the hairpin closest to each respective gene, and the ends of the mRNAs are not overlapping. The intergenic region of the Tacaribe virus L RNA is predicted to fold into a single stem-loop structure. In this case, the 3' ends of the L and Z protein mRNAs mapped to four or six bases located on the distal side of the hairpin stem. The 3' end of the L mRNA contains the complement of the 3' end of the Z mRNA, and vice versa. Determination of the 3' ends of LCMV NP and GPC mRNAs using an intramolecular circularization technique found that the 3' ends of the GPC mRNA corresponded to those described for Tacaribe virus. The NP mRNAs, however, terminated at many sites in the stem structure, on both the proximal and the distal sides of the hairpin (209). Stem-loop structures in the intergenic region of arenaviruses are thought to play a role in transcriptional termination, stabilizing the 3' end of mRNAs.

NP mRNAs can be detected as early as 2 hours after infection, and NP protein can be detected after 6 to 12 hours, depending on the multiplicity of infection. The L protein can be detected at 12 to 24 hours after infection, and its concentration increases dramatically during acute infection. NP mRNA and NP protein accumulate earlier than GPC mRNA and the GP1 and GP2 glycoproteins. NP protein accumulation either precedes replication or the two processes are contemporary. These data illustrate how the ambisense coding arrangement of the arenavirus genome temporally separates initial expression of NP and L proteins from expression of the glycoproteins and Z protein. In the presence of the protein synthesis inhibitor pactamycin, NP mRNA accumulates but replication and GPC mRNA transcription do not occur, thus demonstrating the need for *de novo* protein synthesis for RNA replication to take place.

To obtain expression of the GPC and Z proteins, a round of replication must take place in which S and L antigenomes, full-length complements to the genomic RNAs, are produced. Unlike the mRNAs, antigenomes and genomes do not contain cap structures or multiple, heterogeneous nontemplated bases at their 5' ends. The bulk of the current data suggests that genomes and antigenomes contain a single nontemplated G at their 5' terminus, although there is some evidence that this might not be a feature in LCMV genomes and antigenomes. A model has been developed to explain how the extra nontemplated G is generated. This model contends that genomic and antigenomic replication is initiated with a dinucleotide primer (pppGpC) that first base-pairs to positions 2 and 3 of the template RNA. After initiation of replication, the nascent RNA strand slips “backward” two bases to produce a single G overhang. Replication then continues until the full-length genomic or antigenomic RNA is made. The process also differs from transcription, in that the viral L protein does not terminate polymerization in the intergenic region of the template strand but rather “reads through” to produce full-length genomic and antigenomic RNAs. The transcription-to-replication switch mechanism is currently uncharacterized, but the intracellular level of Z protein may regulate this process.

After S and L antigenomes have been synthesized, they serve as templates for transcription of GPC and Z mRNAs, and as replication templates for new genomic RNAs. GPC mRNAs can be detected as early as 2 hours after infection, and the GPC polyprotein can be immunoprecipitated from infected cells by 12 hours after infection at high multiplicity of infection. The GPC is cleaved 75 to 90 minutes after translation, after the conversion of high-mannose oligosaccharide precursors to complex carbohydrates (glucosamine, fucose, galactose) and transport to the medial Golgi (52). Little is known about the kinetics of Z protein synthesis.

The assembly process of arenavirus particles is poorly characterized. Newly synthesized genomic RNAs, NP protein, and L protein are presumably assembled into nucleocapsids. For a yet-to-be-determined purpose, arenaviruses package host-cell ribosomes into virion particles. In arenavirus-infected cells, the intracytoplasmic distribution of ribosomes is altered, and inclusion bodies can be found that consist of ribosomes embedded in a matrix of virus-specific proteins.

Aggregates of electron-dense granules are found free in the cytoplasm of infected cells, as well as in juxtaposition to the plasma membrane, where patches of spikelike projections, presumably glycoproteins, are present. NP can be cross-linked to the carboxyl terminus of GP2, suggesting that interaction of these two proteins is essential for the assembly of virions at the cell membrane. Following association of electron-dense structures with the plasma membrane, budding takes place by “pinching off” of the lipid bilayer and subsequent separation of the virion and plasma membranes.

Persistent Infection and Defective Interfering Particles

Arenaviruses are known to produce persistent infections in their rodent host as well as *in vitro*. The two systems differ, however, in the fact that persistence *in vitro* is caused solely by alterations in viral gene expression and replication, whereas *in vivo* persistence is likely to be a combination of molecular biologic mechanisms and a failure of the host immune response to clear infection. The molecular mechanisms of arenaviral persistence have been investigated both in cell culture and in infected rodents. *In vitro*, most arenavirus infections progress over time from the acute phase to a persistent phase characterized by a reduction in the amount of infectious virus produced. During the acute phase of arenavirus infection *in vitro*, there is active viral replication and virus production, and usually little if any cytopathic effect (CPE). In persistent infection, cells remain infected for life, with alterations in transcription, replication, and expression of viral proteins, though it is possible that some cells may spontaneously clear arenavirus infections. There is an increase in the number of S genomic RNAs relative to the number of L genomic RNAs in cells persistently infected with LCMV (103). In both cultured cells and mice persistently infected with LCMV, there is a down-regulation of viral glycoprotein expression. In persistently infected L cells, expression of GPC, GP1, and GP2 is reduced, but a truncated GPC protein can be detected in abundance along with increased levels of NP (44). In persistent infections, full-length genomic segments and mRNAs can be detected, along with populations of heterogeneously sized, truncated RNAs that accumulate over time. The truncated RNAs detected in persistently infected cells *in vitro* tend to be less heterogeneous in size than those detected *in vivo*. Defective-interfering (DI) RNAs of arenaviruses are poorly characterized. DI RNAs from the brain tissue of mice persistently infected with LCMV have short deletions (3 to 41 bases) at the termini of both the S and L RNA genomes and antigenomes. These DI RNAs are thought to be competent for replication but not transcription and therefore are able to compete with genomes and antigenomes for viral proteins (210).

DI particles, which are able to interfere with the infectivity of standard virus, are produced during both acute and persistent arenavirus infections. Infection of L cells with LCMV at a high multiplicity of infection results in lower titers of standard virus and a higher ratio of DI to standard virus compared to an infection at a low multiplicity (183). When LCMV stocks were passed at a high multiplicity of infection in cell culture, the titer of infectious virus and DIs alternately rises and falls synchronously with each passage. This cycling effect is presumably caused by increased production of DIs during high-titer infection, which interferes with standard virus production. DIs are smaller than infectious virions (mean diameter 55 to 56 nm) and apparently lack one or both genomic RNAs. In DIs, GP1 and GP2 can be absent or nonglycosylated, and the GPC and NP often display alterations in molecular size (114,183,200). Treatment of cultured cells with DIs prior to, or up to 8 hours after, infection with standard LCMV dramatically inhibits replication of the standard virus (183,243). Concurrent intracranial injection of DIs with standard LCMV inhibits cerebellar disease in a suckling rat model. The mechanism of DI interference and its potential role in the development and maintenance of persistent infections has yet to be determined.

A DNA form of the LCMV S RNA has been detected in the spleen tissues of persistently infected mice and in persistently infected murine cell lines (174). Production of the DNA form of the LCMV S RNA was inhibited by the reverse transcriptase inhibitor zidovudine, suggesting that endogenous reverse transcriptases are responsible for this activity. The exact relevance of genomic reverse transcription to the biology of arenaviruses, and its potential roles in the maintenance of persistent infection and the immune response, remain to be elucidated.

Arenavirus Taxonomy and Relationships

The family *Arenaviridae* contains a single genus, *Arenavirus.* The 18 arenavirus species currently recognized in the genus are listed in Table 1 and Table 2 (66). Two antigenic groups within the genus, the Old World group and the New World (Tacaribe complex) group, were established using serologic assays. Epitopes shared by Old World and New World arenaviruses have been detected on NP and GP2 using monoclonal antibodies. Close antigenic relationships exist among Amapari, Junin, Latino, Machupo, and Tacaribe viruses, and among Flexal, Pichinde, Parana, and Tamiami viruses (139,271). Within the Old World arenaviruses, Ippy, Lassa, Mobala, and Mopeia share certain antigenic determinants that distinguish the African arenaviruses from LCMV virus (119,264,288,320,321).

Analysis of genetic sequence data has provided the most complete picture of arenavirus relationships. Phylogenetic analyses of the NP and/or GPC sequences separate the arenaviruses into two distinct clades corresponding to the Old World and New World groups and identified by serologic analyses (Fig. 4), and see Table 1 and Table 2). Two studies have reported clustering of Pichinde or Pichinde and Oliveros viruses with the Old World arenaviruses when glycoprotein sequences were analyzed. This observed relationship is an artifact of the method used to root the trees in phylogenetic analyses (midpoint rooting or rooting using a very distantly related outgroup). The greater sequence divergence within the New World arenaviruses compared to the Old World arenaviruses, especially in the more variable GP1 and GP2 genes, places the midpoint of inferred phylogenetic trees within the New World group, and this fact must be considered in studies of arenavirus phylogeny. Clustering of Pichinde and Oliveros within the Old World group is not observed in phylogenetic trees inferred from the more conserved NP sequences. The New World arenaviruses comprise three evolutionary lineages, designated A, B, and C (Fig. 4). Lineage A contains Flexal, Parana, Pichinde, Pirital, Tamiami, and Whitewater Arroyo viruses. Lineage B contains the four agents of arenaviral hemorrhagic fevers in the New World—Guanarito, Junin, Machupo, and Sabia, as well as Amapari and Tacaribe viruses. Latino and Oliveros viruses comprise lineage C. The observation that the four agents of South American arenaviral hemorrhagic fevers (Guanarito, Junin, Machupo, and Sabia) occupy a single lineage suggests that the highly pathogenic phenotype of these viruses may be a result of radiation from a common pathogenic ancestor. Monophyly of Junin and Machupo viruses within lineage B, both of which have rodent hosts of the genus *Calomys* (see Fig. 3 and Table 1 and Table 2), and monophyly of Flexal, Parana, and Pichinde within lineage A, three viruses with rodent hosts of the genus *Oryzomys*, provides evidence that arenaviruses are coevolving with their rodent hosts. Within the Old World arenaviruses, LCMV is most closely related to

the New World arenaviruses. Ippy virus occupies an intermediate position, whereas Mobala, Mopeia, and Lassa viruses make up two terminal groups. Considerable sequence diversity, up to 25% nucleotide and 13.5% amino acid divergence, is observed among Lassa virus strains in the NP gene (partial gene sequence), and some divergence was evident among Mopeia virus strains and among strains of LCMV. Analysis of genetic sequence data has clarified arenavirus relationships and provided insights into arenavirus evolution.

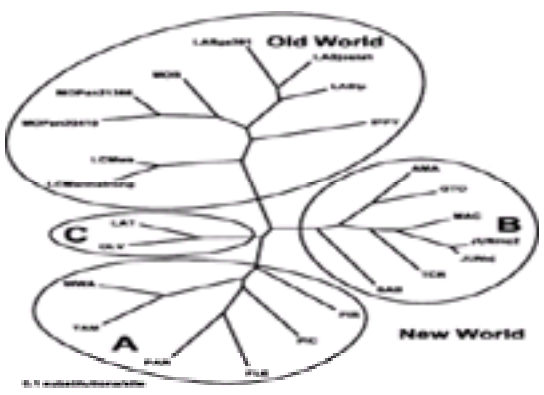

FIG. 4. Phylogenetic tree showing relationships among arenaviruses based on similarity in N gene sequences. Partial NP gene sequences were aligned using the PileUp program of the Wisconsin Package version 9.1-UNIX (Genetics Computer Group) followed by manual adjustment. The phylogenetic tree was estimated by maximum likelihood analysis performed by using PAUP version 4.0b1 [PAUP, Phylogenetic analysis using parsimony (and other methods). Sinauer Associates, Sunderland, MA]. Branch lengths are indicated by the scale bar. The Old World arenavirus group and three lineages (A, B, and C) within the New World arenavirus group are shown.

Genetics of Arenaviruses

Genetic reassortment, the association of heterologous S and L genomic RNAs within progeny virions following concurrent infection with parental virus strains, has been accomplished in the laboratory between wild-type and temperature-sensitive mutants of Pichinde virus. LCMV reassortants have been recovered after dual infections with wild-type parental strains. A Lassa-Mopeia reassortant virus that contains the L RNA of Mopeia and the S RNA of Lassa has been generated and was found to have lost the ability to kill suckling mice, a property of the Mopeia parent strain.

Diploidy, the property of having multiple genomic “alleles” packaged in the same virion, has been demonstrated for LCMV (259). Using temperature-sensitive mutants of Armstrong and WE strains of LCMV, wild-type reassortants were obtained that were diploid for the S RNA. They contained the L RNA of strain WE, and S RNAs of both strains.

Infectivity Assays and Serology

Arenaviruses are most often quantitated *in vitro* by plaque or quantal assay on Vero or L cells. CPE in cell monolayers is not typical of arenavirus-cell interactions. Plaque formation may require long incubation periods of up to 7 days for members of the Tacaribe group, but more commonly 4 to 5 days is sufficient for plaque development. Plaques may vary widely in size and appearance. For example, it has been reported that isolates of LCMV obtained from the brains of persistently infected mice are clear in appearance, whereas those from the spleens are turbid (6). Plaques obtained from a high multiplicity of inoculum or persistent infections in cell culture, both of which lead to high concentrations of DI virus, may be turbid or even exhibit a bull's eye appearance, presumably the result of alternating cycles of interfering virus production as the plaque expands (314).

In vivo LD_{50} assays for some must be used extensively to characterize arenavirus infections. Viruses that establish persistent infection in newborn mice, such as LCMV, are assayed by intracranial inoculation of 0.02 to 0.03 mL of virus dilution into adult (4- to 6-week-old) mice. Any of several inbred mouse strains may be used, but most commonly BALB/c, SWR/J, or outbred Swiss are employed. This assay is based on the fact that LCMV infection of the choroid plexus and meninges results in an acute, lethal T-cell-mediated response to viral antigens expressed in these tissues. This assay is more sensitive for LCMV strains than cell culture assays by a factor of two- to tenfold (180). As LCMV causes a persistent infection in neonatal mice, inoculation of neonates will result in a virus carrier state that might be interpreted as a negative result. Viruses in the Tacaribe complex of arenaviruses are usually lethal in newborn or suckling mice but may cause only a transient acute infection in adults. Infectivity assays for these viruses are performed in suckling mice or hamsters.

All arenaviruses are maintained in nature by persistent infection of specific species of rodent hosts, and congenital neonatal infection of the natural host usually results in lifelong infection. Persistently infected hosts may show no overt symptoms of infection, but they harbor high titers of virus and excrete infectious virus freely in their urine. Some of these characteristics may be seen in laboratory rodents. For example, hamsters infected with Pichinde virus and guinea pigs infected with LCMV may excrete virus in titers up to 10^5 plaque-forming units (pfu) per milliliter of urine. Many episodes of LCMV infection of laboratory and hospital personnel have been traced to exposure to mouse or hamster urine, contaminated cage dust, or litter, often in the absence of documented physical contact with the rodents (29,33,130,138).

A number of assays have been used to detect antibody responses to arenavirus infection. From the initial discovery of the agent in 1934 until the late 1970s, the complement fixation (CF) assay was most common. The CF assay predominantly detects nucleoprotein antigen, hence it is broadly specific (59). The CF test has largely been supplanted by indirect fluorescent antibody (IFA) and enzyme-linked immunosorbent assays (ELISA). Here again the dominant antigen is the NP. Monoclonal and polyclonal antisera against NP react across virus lines (47). Indirect

immunofluorescence assays utilizing virus-infected cells as substrate are widely used, particularly for analysis of field isolates and for work with the more dangerous pathogens (249). Antibody-positive sera usually produce granular cytoplasmic staining characteristic of intracellular nucleocapsid aggregates in arenavirus-infected cells. An identical pattern is seen when monoclonal antibodies to NP are utilized to stain infected cells (47). Antibodies to glycoprotein antigens produce a diffuse immunofluorescence staining in infected cells and also stain viral antigen on the surfaces of intact cells. The ELISA using gamma radiation–inactivated virus antigens provides greater sensitivity, more objectivity, and the capacity to accurately gauge the IgM antibody response, and it is supplanting the IFA in diagnostic and research applications. Neutralization assays are useful tools to establish relationships among closely related viruses and may be formatted as serum dilution (PRD_{50}) assays or as virus dilution log neutralization index (LNI) assays. PRD_{50} assays utilize a standardized, constant virus dilution containing 50 to 200 pfu mixed with an equal volume of diluted antiserum, incubated, and then plaqued (310). The LNI assay measures reduction of plaques from a high-titer virus pool mixed with a complement source and a single dilution (often undilute) of antibody source. Results are expressed as a $\log_{10}$ reduction of titer [$\log_{10} V/V_0$] where V_0 is the beginning titer and V is the titer after neutralization (13,147,181). This assay format also forms the basis of the neutralization kinetics assay, which, if properly applied, yields a neutralization coefficient, or K value, characteristic of a given antibody–virus interaction (139).

EXPERIMENTAL INFECTIONS OF ANIMALS

Arenaviruses readily infect mammals, and the outcome may be death, chronic infection, or immunizing acute infection. Rodents, particularly mice, guinea pigs, and hamsters, are excellent laboratory hosts for isolation; the outcome depends on virus strain, route of infection, and host genotype (244). Nonhuman primates are susceptible to many arenaviruses and may suffer serious and fatal disease with several of the human pathogens. There is little reliable information on infection of dogs, cats, livestock, or nonmammalian vertebrates, but these species are not epidemiologically implicated in transmission or as disease problems. LCMV has been reported to grow in mosquitoes, and several arenavirus isolates have been taken from arthropods, but there is no indication that these are relevant to the biology of the viruses in nature.

Pathology and Pathogenesis

Pathogenesis of arenavirus diseases is believed to involve initial replication at the site of infection in nonreservoir hosts, usually following aerosol deposition in the lung. The hilar lymph nodes, lung, and, later, other parenchymal organs are important sites of virus growth (73,168,286). Pneumonic foci are usually not present, although interstitial infiltrates and edema may occur during the course of infection. In infections by any route, the macrophage is usually identified as an early and prominent cell involved. As infection spreads, additional cell types reach equal prominence. Many epithelial structures are readily identified as containing antigen and nucleic acids. Widespread infection of the marginal zone and necrosis of lymphoid follicles of the spleen and lymph nodes are common, with the potential to blunt an effective curative immune response, and, at least in the adult LCMV-infected mouse, this is associated with cytotoxic-T-lymphocytic (CTL) destruction of critical antigen-presenting lymphoid cells (120,218,233,304). In spite of the extensive involvement of different cell types throughout the body, the pathologic changes are relatively subtle, with comparatively little frank necrosis.

The immune response to arenaviruses may be protective or deleterious or both. Cellular responses (delayed-type hypersensitivity and CTL) are readily measured and are believed to be major mechanisms in recovery and immunopathology. Antibody, although less prominently involved than in some infections, is clearly important in protection and in immune complex disease. The relative balances between protection and pathology, and between cellular and humoral responses, are determined by the virus strain and host; examples will follow.

Mouse and Other Rodent Models with LCMV

Role of T Cells in Recovery and Pathogenesis of Choriomeningitis in Mice.

Murine infection with LCMV is illustrative of the balance between immunologic protection and damage. The presence of fully functional, differentiated T cells is necessary to efficiently control the infection, but the T-cell response is also responsible for disease induction. The outcome of infection of the mouse with a given LCMV strain depends on the age and immunocompetence of the host, the route of inoculation, and the genetic background of the mouse.

Within a few days after intracranial (i.c.) inoculation of an adult mouse, LCMV replicates to high titers (>10^7 pfu/gm) in the choroid plexus and meninges, and viral antigen subsequently becomes the focus of an acute mononuclear cell infiltration driven by antigen-specific T cells (Fig. 5). During the acute infection, viral replication is limited largely to the leptomeninges and ependyma of the brain and does not penetrate into the parenchyma or involve neurons. Acutely infected mice usually succumb between 6 and 9 days after infection as a result of this T-cell-mediated acute inflammatory response; however, if the T-cell response is compromised by immunosuppression or by depletion of specific T-cell subsets, disease is prevented but viral clearance is delayed or blocked and a persistent infection ensues.

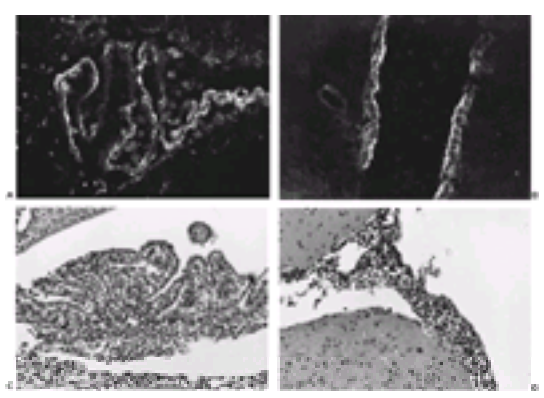

FIG. 5. Brain of a BALB/c mouse inoculated intracranially with LCMV Armstrong strain, 6 days previously. Abundant viral expression is seen in the choroid plexus (**A**) and ependymal cells lining the third ventricle (**B**) when stained by monoclonal antibody 2-11.10 that detects GP1 followed by fluorescein-labeled sheep anti-mouse IgG. Mononuclear cell infiltration is prominent in the choroid plexus (**C**) and the meninges (**D**).

The characteristic immunopathologic response following acute LCMV infection requires antigen-specific induction of CD8+ T lymphocytes that recognize LCMV antigens in the context of major histocompatibility complex (MHC) class I and are active *in vitro* in CTL assays on MHC class I–matched virus-infected target cells (325). The effector CTL can be cloned *in vitro* and used to reproduce the disease by direct central nervous system (CNS) inoculation or to mediate virus clearance from organs of acutely infected mice (55). The CD8+ cytotoxic T-cell response in LCMV infection has provided one of the most important experimental models available to immunologists for studying the nature of the signals required between cytotoxic T cells and targets to effect the lytic response (125,324). CTLs attack the infected cells and initiate dysfunction of the blood–brain barrier without any obvious morphologic correlates (9,50,306). Abnormal brain electrical activity leads to the onset of a convulsive disorder, loss of brain activity, and cardiovascular death (63). If anticonvulsants are administered, the onset of the seizure disorder is delayed by 1 to 2 days, and early morphologic signs of cell damage are seen (302). Most other arenaviruses inoculated intracranially into mice also induce this type of immunopathologic encephalitis, depending on the age of the mouse, the rapidity of growth of the virus, and the vigor of the immune response (231). Human CNS disease from LCMV is also thought to proceed by the same mechanisms as occurs in the intracranially inoculated adult mouse.

Role of Antibody in Recovery and Protection

In the immunologically naive animal, antibody plays an insignificant role in the resolution of acute LCMV infection. Evidence derived from studies of B-cell-depleted mice demonstrates no clear difference from intact controls in the development of acute choriomeningitis (61). Moreover, in studies of beta-2-microglobulin knockout mice, which lack functional CD8+ T cells, virus is not efficiently cleared (182,226). However, in certain circumstances, the importance of antibody in resistance to arenavirus infection should not be underestimated, because passive immunotherapy with neutralizing monoclonal antibodies up to 2 days after infection protects mice against lethal LCMV choriomeningitis (317). The effects of antibody were to lower virus titers in tissues including the brain and to attenuate the CD8+ T-cell response. In addition, efficient protection of offspring against chronic viremia could be passed from immune mothers by nursing, and intact IgG2a antibody was required (20). Mice protected in this manner were fully resistant to a second challenge infection given after the passive antibody had been eliminated, suggesting that the passive immunotherapy did not prevent transient infection or interfere with the memory T-cell response. Subsequent experiments have shown that antibody acts in a similar manner to protect neonatal mice against development of a persistent infection by the immunosuppressive, macrophage-tropic clone 13 ARM strain of LCMV as well (6); high doses of virus overcome antibody protection, suggesting that one effect of preexisting antibody is to restrict the replication of input virus as opposed to clearing virus-infected cells. This interpretation is further supported by the failure of passive immunotherapy in beta-2-microglobulin knockout mice, which lack functional CD8+ T lymphocytes. Following infection in these mice, virus titers are initially low or undetectable, but they rebound as the antibody is cleared (22).

In vitro neutralization of the Old World arenaviruses by antibody is usually inefficient, and significant amounts of neutralizing antibody do not appear until weeks after recovery. Even then, a constant serum dilution format (or an LNI test) with serum that has not been heated to destroy complement is needed to show neutralization (181,245). In spite of the unusual kinetics of appearance of such antibodies and their relative inefficiency, large amounts (e.g., 9 mL/kg) of convalescent serum selected for its LNI is protective or curative in both monkeys and guinea pigs infected with Lassa virus. With modern methods of preparation of therapeutic monoclonal antibodies and in the context of vaccines, these observations are significant.

With the notable exceptions of Pichinde and Latino viruses (292), Tacaribe complex arenaviruses are usually more readily neutralized, and passive antibody therapy has been used successfully in both monkeys and guinea pigs (91). When Junin virus therapy was modeled in guinea pigs, passive antibody spared the animals from disease, but, as observed in human Argentine hemorrhagic fever (AHF), there was a late neurologic syndrome associated with brain virus entry (166,169). In the guinea pig, antibody-dependent cellular cytotoxicity was thought to be important in protection because of the characteristics of *in vitro* cytotoxicity and because of the failure of $F(ab')_2$ to protect, despite being fully capable of mediating *in vitro* virus neutralization (164).

Development of the Carrier State in Mice

Inoculation of mice with LCMV, either by transplacental passage of virus from the pregnant mother to the fetus or by neonatal inoculation of virus, results in a lifelong persistent infection. The crucial difference that results in persistent infection in the neonate rather than acute, transient infection in the adult mouse is that the neonate encounters the virus prior to maturation of the cellular immune system; the neonate is unable to mount an effective antiviral CD8+ CTL response necessary to clear the infection. Persistent unresponsiveness to the virus is caused in part by the continuous presence of LCMV in the thymic environment, resulting in failure to ecognize the virus as foreign (324). Such persistently infected mice carry high levels of virus in their blood and tissues and shed virus in their urine for life (22,50,96,178,294). A consequence of persistent infection is the development of immune complex disease (48). Such mice may make a vigorous antibody response to LCMV antigens that is insufficient to clear virus, but this antibody, complexed with circulating viral antigen, lodges in the renal glomeruli and arterial walls, leading to chronic glomerulonephritis and arteritis (50). A genetic linkage was established between severity of disease, level of circulating immune complexes by C1q precipitation assay, and degree of humoral immune response to viral antigen. SWR/J animals show immune

responsiveness, immune complexes, and severe disease, whereas BALB/c are low responders with mild disease (237).

A carrier state can also be established in adult mice by immunosuppression prior to infection or by infection with macrophage-tropic immunosuppressive strains such as the clone 13 isolate. Clone 13 was derived from the spleen of a mouse persistently infected with LCMV Armstrong strain, and it has the capacity to induce a persistent infection in the adult immunocompetent mouse following intravenous inoculation. Clone 13 does not induce a CTL response in the acutely infected mouse and exhibits marked tropism for macrophage-lineage cells *in vivo* (37,202,203,273). Molecular genetic analysis of the clone 13 variant has mapped the imunosuppressive property to a single amino acid substitution (Glu to Phe) at amino acid 260 in the GP1 glycoprotein (203,267).

Macrophage tropism is not restricted to LCMV. The splenic macrophage is a primary target of infection for virulent Pichinde virus infection in MHA strain hamsters (227). Aggressive destruction of the reticuloendothelial system is a common feature of highly virulent arenavirus infections.

Termination of the LCMV Carrier State in Mice

Adoptive transfer of antigen-primed splenic T cells or cytotoxic T-cell clones is sufficient to terminate the LCMV carrier state (5,10,234). Both T-cell-subset depletion with monospecific antibody and analysis of the phenotypes of T-cell clones used in adoptive transfer experiments establish the CD8+ lymphocyte as the critical cell for virus elimination. This is further supported by the requirement for gamma interferon and for perforin, the T-lymphocyte component responsible for perforating membranes of target cells, in virus clearance.

Clearance is rapid after CTL are adoptively transferred, and initially there may be necrotic lesions and lymphoid infiltrates, presumably reflecting the cytolytic activity that is readily demonstrated *in vitro*. Different organs follow different kinetics of virus clearance; virus is cleared from the liver within 30 days, but neurons contain viral antigen for 90 days or more, and clearance of virus and antigen from the kidneys requires more than 200 days. Mechanisms of virus clearance from neurons are not well understood. As neurons lack MHC class I antigen, they are refractory to CTL lysis (161). Potential alternative clearance mechanisms include the action of cytokines and nitric oxide on persistently infected cells.

Virus-Induced Loss of Cellular Function

Although arenavirus infection is not overtly cytopathic in most tissues, evidence is mounting that the LCMV infection results in compromised function of specialized cells of the neuroendocrine system. Concentrations of the enzymes choline acetyl transferase and acetylcholine esterase are lowered in LCMV-infected neuroblastoma cells in culture (235). LCMV infection of the anterior pituitary of mice results in diminished synthesis of growth hormone without discernible cell death, but with a concomitant clinical syndrome consisting of retarded growth and hypoglycemia (236). Impairment of specialized cellular functions has been referred to as disruption of “luxury functions”—that is, functions not required for survival at the cellular level but that contribute to maintaining homeostasis of the organism. Similar observations have shown that LCMV can impair function of the insulin-producing beta cells of the pancreas and thyroid cells (173). Selective disruption of growth hormone release in a rat pituitary cell by virus infection is caused by interference with the growth hormone transactivator, GHF-1 (75). Treatment of infected cells with the antiviral agent ribavirin cures infection and restores normal growth hormone messenger-RNA levels.

Mice persistently infected with LCMV have extensive neuronal infection demonstrated by immunohistochemistry, but they have no evident lesions. These animals exhibit behavioral abnormalities, including decreased exploratory behavior when confronted with a new environment, deficits in Y-maze discrimination, and hypoactivity in locomotor testing (115,136). Low-dose scopolamine produces locomotor hyperactivity in the virus-infected group, suggesting a disruption of cholinergic function.

LCMV-Induced Ocular Disease

LCMV causes a destructive retinopathy following intracerebral inoculation into the newborn rat (224). Disorganization of the outer nuclear receptor layer is followed by loss of cells in the inner nuclear and ganglion cell layers, and finally the total disorganization and destruction of the retina. Infection is evident first in the optic nerve and inner nuclear layer, then in the pigment epithelium, and finally in all layers of the retina. Congenital retinitis occurs in offspring of LCMV-infected females and is accompanied by inflammation, macrophage infiltration, and eventual retinal detachment. In both neonatal and congenital infection, retinitis is diminished or prevented by immunosuppression, implying an immunopathologic response underlying the disease process. In the congenital model, retinitis persists in the absence of detectable viral antigen, suggesting that the retinitis can be viewed as a vertically transmitted autoimmune disease (80). Chorioretinitis and psychomotor retardation have also been reported in children with congenital LCMV infections (2,27,274).

LCMV-Induced Cerebellar Disease in Rats.

LCMV infection of 1- to 7-day-old rats interferes with normal cerebellar development (221,223). Intracerebral inoculation of LCMV (E350 strain) produces nonfatal but severe and permanent cerebellar hypoplasia and ataxia. Virus persisted for up to 4 months after infection. Evidence of an immunopathologic mechanism of disease was provided by demonstrating that antilymphocyte serum prevented cerebellar necrosis and resulted in higher brain virus titers than in control rats (222).

Ultrastructural studies of the infected rats revealed viral particles in the interstitial spaces of the apparently normal neural parenchyma at 5 days, followed by extravasation and infiltration of activated macrophages and concomitant cellular necrosis 1 to 3 weeks after infection. Several weeks after infection, an infiltration of plasma cells is accompanied by a gradual removal of viral antigen from the tissue (81). The late appearance of plasma cells in the brain tissue and concurrent disappearance of viral structures suggest that local antibody production is linked to viral clearance from

neurons.

Passive transfer of rat monoclonal antibodies to LCMV can block the cerebellar disease (22). Antibody given to the offspring as late as 48 hr after virus infection inhibits cerebellar hypoplasia. Offspring nursing on mothers who had previously received protective antibodies were also protected. Antibody substantially lowers viral titers in the brain and prevents infection of the cerebellar granular and Purkinje neurons. Cerebellar disease in the rat can also be prevented by injection of high concentrations of DI LCMV particles (102), perhaps due to homologous interference as there is no evidence of interferon activation.

Infection of the 4-day-old rat affects other sites as well. Persistent hippocampal abnormalities, consistent with a dysinhibition of gamma-aminobutyric acid (GABA)-ergic pathways in the dentate gyrus for long intervals, are observed after recovery from neonatal infection (242).

Hamster Infection

Syrian hamsters are susceptible to infection with Pichinde and LCMV. Strains of hamsters vary in susceptibility to Pichinde virus infection, with adults of the MHA strain being highly susceptible and those of the LVG strain being resistant. Peak serum virus titers in MHA animals are greater than 10^8 at 8 days after infection, and less than 10^3 in LVG animals. Cyclophosphamide immunosuppression of LVG hamsters converts them to an MHA-like susceptibility, suggesting that the differential observed is caused by a lack of effective immune response in the MHA strain. Major destructive effects of the infection in MHA animals are in liver and spleen. Primary target cells are macrophages in the marginal zone of the splenic white pulp, and Kupffer cells in the liver. Lesion sites lack mononuclear inflammatory cells, suggesting a destructive effect on the reticuloendothelium (227). Studies by Gee et al. (109) suggest that the targeting of Pichinde virus in the MHA hamster may be attributable to differences in the natural killer cell response to Pichinde virus infection.

The MHA hamster is also susceptible and the LVG hamster resistant to the WE strain of LCMV (113). Hamsters resistant to WE are susceptible to acute disease after immunosuppression. Immunosuppression does not spare susceptible hamsters, in contrast to the effects on T-cell-mediated immunopathology seen in mice intracranially inoculated with LCMV. The Armstrong strain of LCMV is not pathogenic for any hamster strain, even with sublethal irradiation or cyclophosphamide treatment (112). None of the surviving animals develop any evidence of chronic infection; viremia is cleared by 35 days and organs were free of antigen by immunofluorescence.

The disease induced in MHA hamsters by WE is characterized by a prolonged viremia, severe wasting and weight loss, and death 2 to 3 weeks after inoculation (110). There are relatively few histologically evident lesions; both hamster strains have scattered perivascular and other lymphoid infiltrates as well as lymphoid hyperplasia of spleen and lymph nodes. Fatal disease is characterized by segmental inflammatory ileal hyperplasia. Most infected cells are macrophages, and the disease, including the intestinal lesions, may be largely lymphokine mediated. Hamster strains that were genetically resistant had slightly lower viremias on day 3 and a marked decrease in viremia around day 7 to 14, concomitant with the onset of the humoral immune response measured by IFA. IFA titers were similar in both surviving and dying hamster strains. Neutralizing antibodies became detectable in all hamsters around day 21 and in surviving strains reached an LNI of 3.0 by day 35. The major distinguishing feature of the hamster strains destined to survive WE infections is the presence of foot-pad delayed-type hypersensitivity responses beginning on day 5 and reaching a maximum on day 7 (111).

Infection of outbred hamsters has also been studied with LCMV isolated from an infected transplantable tumor. The disease resembles that described in virus-contaminated hamster colonies that led to human epidemics. One third of 3-week-old hamsters died of an intestinal illness during the first month after inoculation; the remainder appeared healthy and required 1 to 3 months to clear viremia, but some were viruric for more than 6 months. Newborn hamsters fell into two groups: About one half appeared healthy but had prolonged viremia and high-titered viruria for 4 to 6 months. The other half were obviously diseased with poor weight gain, ruffled fur, blepharitis, and hunched posture. The diseased animals had much higher viremias and prolonged viruria. CF antibody responses were noted in both groups but were higher in the healthy animals. The wasted animals had histologic evidence of vasculitis and developed immune complex glomerulonephritis with renal failure. Congenital infection resulted in decreased litter size and a similar wasting disease, but it was possible to breed three generations of congenitally infected hamsters.

LCMV infection of the mouse has been the preeminent model for viral pathogenesis over the past 40 or more years. By manipulating the host age and genetic background as well as the strain of virus, the infection can be used to study mechanisms of virus clearance, virus persistence, and autoimmune disease in the mouse. Indeed, many of the fundamental concepts of modern cellular immunology have been formulated on the basis of investigation of the LCMV model. Useful models of viral pathogenesis are evident in studies of other species as well. Notably, LCMV infection of the rat may provide the most accurate paradigm for the neuropathologic consequences of congenital and neonatal infection in man, and infection of guinea pigs and monkeys has provided insight into the pathobiology of arenavirus hemorrhagic fevers.

Viral Persistence in Natural Rodent Hosts

Relatively few arenavirus experiments have been performed in the natural rodent host except with LCMV. Indeed, most studies with LCMV, however enlightening for basic immunobiology, have been designed to elucidate specific principles and apply to laboratory-selected virus strains and specific inbred mouse strains. Available data from other virus–host combinations (Table 3) show a complex pattern of infection.

Virus	Age of host at infection and subsequent viremia[a]		
	Fetal	Neonatal	Adult
LCMV, Lassa	Lifelong	Lifelong	Transient
Junin, Machupo	Fetal death	Lifelong	50% lifelong 50% transient
Guanarito	Unknown	Lifelong	>2/3 lifelong
Latino, Tamiami	Unknown	Transient	Transient

[a]Regardless of viremia, prolonged urinary virus excretion may occur and may be epidemiologically significant.
LCMV, lymphocytic choriomeningitis virus.

TABLE 3. *Duration of viremia after infection of rodent reservoirs with arenaviruses*

Lassa virus, like LCMV, induces chronic viremic infection in neonatal *Mastomys* and transient, immunizing infection in adults (228). This type of infection, which is efficiently transmitted to the fetus, would favor a maintenance cycle in which congenital, vertical transmission is the major feature. The agents of Bolivian and Argentine hemorrhagic fever can also induce chronic viremic infection in adult *Calomys* hosts, but the chronically viremic females are sterile (265,301,312). Finally, Tamiami and Latino have not induced persistent viremia in laboratory studies, although the possibility of mismatch between virus isolate and colonized host genotype might be responsible. It is also possible that maintenance strategies of these viruses result mainly in chronic viruria, with respiratory or salivary shedding (Fig. 6). For example, in spite of clearance of Tamiami virus from the blood of *Sigmodon hispidus*, and the decline in viral infectivity in organ homogenates, abundant viral antigen persisted in tissues for over a year in one study, and viruria was found for at least 28 days in another (151). The impact of these differences in host pathogenesis on the survival of the virus in wild rodent populations is clearly considerable (see Epidemiology section later) and the evolutionary significance of the different host adaptations is unknown.

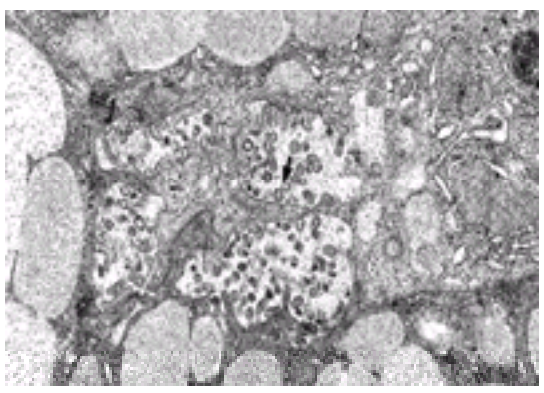

FIG. 6. Accumulation of Machupo virus (*arrow*) budding from acinar cells of the salivary gland of a virus-infected *Calomys callosus*; abundant virions in the lumen readily contaminate saliva (×22,000). (Courtesy of F. A. Murphy.)

The determinants of persistent viremia in the mature host are unknown, although a host genetic component has been identified. For example, selective breeding experiments in *Calomys callosus* identified a polygenic inheritance of the persistent viremic response following adult inoculation of Machupo virus (312). Viral genes are also important. The passage of either Machupo or Junin viruses to attenuate them for man has resulted in loss of the ability to induce chronic viremia in, and the appearance of pathogenicity for, their natural *Calomys* host.

There is a remarkable rodent species specificity seen among arenaviruses in nature. There is usually only a single major reservoir host. Amapari virus appeared to be an exception, with multiyear field observations in Brazil clearly suggesting chronic viremia and participation in maintenance for both *Oryzomys capito* and *Neacomys guianae* (251). However, closer examination of the viruses revealed that the *Orzomys* virus was indeed a different arenavirus, Cupixi, (M. D. Bowen et al., unpublished data). Similarly, initial field studies of Guanarito virus in Venezuela suggested that *Sigmodon alstoni* was the major reservoir (289), but laboratory infections of adult *Zygodontymys brevicauda* produced chronic viremia (107). This prompted a reexamination of the field situation; Guanarito virus was found to be a parasite of *Z. brevicauda* (106) and it was confirmed to be the cause of Venezuelan hemorrhagic fever (308). Viral antibodies and isolates from *Sigmodon alstoni* were related to an independent arenavirus species, Pirital virus (105).

Nonreservoir rodents may on occasion develop chronic infection and viruria, such as is seen after Machupo virus infection of hamsters or Lassa virus infection of inbred mice, but field data strongly support the concept of virus–natural host specificity (64). In the case of LCMV infection of the golden Syrian hamster, it does seem that under colony conditions virus infection can be maintained in the breeding population through viruria and result in dissemination of infected animals to the public (133).

The impact of chronic viral infection on the rodent is an unresolved issue. Most studies of LCMV have suggested that naturally occurring chronic viremic infection does not affect most aspects of the wild mouse's reproductive fitness, although some decrement in litter size may occur in carrier colonies and some transient effects have been found when virus is first introduced (179,276),. Neonatally infected reservoir hosts of Machupo and Junin viruses have somewhat retarded growth and in the case of Junin show an increased mortality; females reach adulthood with markedly decreased fertility. Pathologic lesions clearly attributable to the chronic arenavirus infection have been insignificant or found only in

studies of laboratory-adapted strains of LCMV inoculated into selected mouse strains (296).

Animal Models of Arenavirus Hemorrhagic Fevers

The strong evidence for immunopathogenesis of LCMV neurologic disease after i.c. inoculation of mice is not reflected in the arenavirus hemorrhagic fevers. Unfortunately, there are no realistic murine models that can be exploited, and most experimental studies rely on hamsters, guinea pigs, or nonhuman primates (245). Histologic evidence of tissue damage is minor, although viral antigens are often found in many apparently normal macrophages and parenchymal cells. The extensive T-cell infiltrates seen in murine LCMV are not present, and immunosuppression leads to fatal disease rather than prevention of disease (112,167).

Pichinde virus can be adapted to infect strain 13 guinea pigs with a virologic and pathologic picture that resembles that of human Lassa fever. Because Pichinde virus does not cause disease in man, this model has been exploited for data not easily obtainable from the more pathogenic viruses. After infection, the animal appears normal for approximately 7 days, and then fever and weight loss are seen. During this period, viremia is just beginning and most infected cells are macrophages. With time, macrophage infection becomes more abundant and epithelial cells of several organs begin to show infection. Interestingly, although arenaviruses infect endothelial cells readily in cell culture (11), there is relatively little involvement of endothelial cells *in vivo*, suggesting that indirect effects may be responsible for the increased permeability seen in patients and to some extent in this model. Few dramatic histologic lesions occur; there may be focal necrosis in liver and adrenal glands, mild interstitial pneumonitis in the lung, marginal zone necrosis in the splenic white pulp, and an unusual intestinal lesion with villus blunting. Immunohistochemistry shows that the degree of infection in the liver and adrenal is usually far more extensive than the mild areas of inflammation and necrosis visualized histologically. Furthermore, the intestinal lesion is not associated with infection of the epithelial cells themselves, but rather with extensive infection of the abundant underlying mucosal macrophages (68). Thus, the intestinal involvement may be similar to that seen in other conditions in which lymphokine secretion is thought to play an important pathogenic role; both tissue necrosis factor (TNF) and interleukin (IL)-6 are produced by macrophages from infected guinea pigs (16). The combination of TNF secretion and the intestinal lesion presumably accounts for the wasting, which reaches 25% of body weight (145,245). Viral antigen is extensively present in the perifollicular areas of the spleen and is presumed to be related to the failure of these animals to make a protective immune response either directly through infection or indirectly through an immunopathologic mechanism (323).

In contrast to the relatively modest pathologic lesions at the light microscopic level, there are extensive physiologic changes in the cardiovascular system, which are thought to lead to the death of the animal. There is a progressive decrease in cardiac index from 2 to 1 L/min/m^2 (an indication of the amount of blood pumped by the heart each minute, normalized to the body surface area), which is compensated for by a rise in the peripheral resistance to maintain the blood pressure until the last stages of infection around day 14 to 16 (253). The cause of this fall in cardiac index is not viral infection of the heart; extensive immunohistochemistry failed to detect viral antigens in cardiac muscle using the same techniques that readily found antigen in other organs. The cause seems to be related to the secretion of soluble mediators that decrease heart function, such as TNF-a (16), leukotrienes (189), platelet-activating factor (254), or endorphins (123). Abnormalities are also seen in catecholamines and serotonin (124). These changes, taken with the evidence of lymphokine secretion (16), suggest that the shock state here, and presumably in human arenavirus disease, has its origins in similar alterations of metabolism as seen in the septic shock syndrome (36). The pattern of mediators must be different, however, because the cardiac output is consistently low in Pichinde-infected animals but high in early septic shock. Interestingly, the cardiac output is low in lethal disease caused by hantaviruses, such as the newly described hantavirus pulmonary syndrome (88).

Significant pulmonary functional compromise is present as well. There is increased airway resistance, particularly late in the disease and in younger animals (122,253,272). This is associated with mild pulmonary edema, but it is primarily attributable to accumulation of lymphocytes near infected macrophages, or to bronchial epithelium in or near small bronchi. This would be an important element in the final collapse of the animals.

ARENAVIRUS INFECTIONS OF HUMANS

LCMV infections in humans are rarely fatal. Two fatalities resulting from overwhelming systemic disease resembled hemorrhagic fever cases (see later). A single well-studied encephalitis case showed mononuclear cell infiltrates in the meninges and around vessels and glial nodules in the deeper structures (307). Fluorescent antibodies detected viral antigen in meninges and in cortical neurons.

The gross and light microscopic lesions found at postmortem in arenaviral hemorrhagic fever patients rarely account for their demise (305). Petechial hemorrhages of the skin and internal organs, cutaneous ecchymoses, and evidence of mucosal bleeding are common. Serous effusions, interstitial pneumonitis and pulmonary edema, and evidence of secondary bacterial infection are sometimes seen. Microscopic evidence of disseminated intravascular coagulation or vasculitis is uncommonly found and is not a regular feature of these diseases. Adequate studies of vascular endothelium are not available.

Focal necrosis may be present in several organs including liver, kidney, and adrenal cortex; fluorescent antigen tracing or virus titration generally correspond to these lesions (197,304), as they do in experimental animal studies (68). These lesions usually contain a few mononuclear phagocytes as the only inflammatory cell contribution. Lymphoid depletion or necrosis in the marginal zone of the splenic periarteriolar lymphoid sheath are also present (304). Secondary changes associated with shock are usually found and may be responsible for the frequent presence of some degree of myocardial damage or myocarditis, but virus has not been detected in the limited cardiac tissue studied (245,304).

Hemorrhages are common in the South American hemorrhagic fevers, in keeping with the low platelet counts. Thrombocytopenia is probably caused, at least in part, by maturation arrest of the megakaryocytes attributable to the high levels of interferon present in these patients (184). In Lassa fever, thrombocytopenia is less marked, but liver

involvement is more extensive. Although death does not appear to be caused by hepatic failure, the liver is an important site of virus replication and the levels of aspartate transaminase (AST) in serum are proportional to the risk of dying (157,205).

Clinical Features

Arenavirus diseases begin with a gradual onset of fever and myalgia, followed by systemic and hematopoietic cell abnormalities. In the viral hemorrhagic fevers (VHF), a period of viremia lasting 1 to 3 weeks is accompanied by intense systemic symptoms; the occurrence of an effective immune response is concordant with clinical recovery and cessation of viremia. In LCMV infection, rare fatal cases have occurred with a pattern resembling that of VHF (279), but usually LCMV infection results in a febrile disease with accompanying viremia, often followed by CNS disease. During the CNS disease, there is no viremia, but virus is still detectable in cerebrospinal fluid (CSF), and the pathogenesis is thought to be immunopathologic.

Lymphocytic Choriomeningitis Virus Infections

The initial phase of LCMV infections is usually characterized by fever, myalgia, and other constitutional symptoms such as prostration, headache, photophobia, nausea, or vomiting, with occasional involvement of the testis or salivary gland (3,30,33,34,78,89,178,185,298). Leucopenia, thrombocytopenia, and sometimes mildly elevated AST or lactate dehydrogenase are expected during this period. Cough and chest pain may occur, and sore throat or mild abnormalities of the chest radiograph are occasionally found; indeed, LCMV cases have been serologically detected among patients examined for atypical pneumonia (216). Rash, arthralgia, and arthritis also are reported but are not common. Rarely, myocarditis has been attributed to LCMV infection (79,290).

Although LCMV is usually thought of as a viral meningitis, deeper neurologic involvement is manifest in a minority of cases, perhaps 10% or fewer in naturally observed outbreaks that provide some possibility of case-ascertainment (78,133,298). If a febrile prodrome is present, meningeal signs usually begin about 10 days later, often after a brief hiatus in symptoms and fever (Fig. 7). Encephalitis has been diagnosed in 5% to 34% of hospitalized patients with documented LCMV (4,97,211). Full recovery is usual, although occasional deaths do occur.

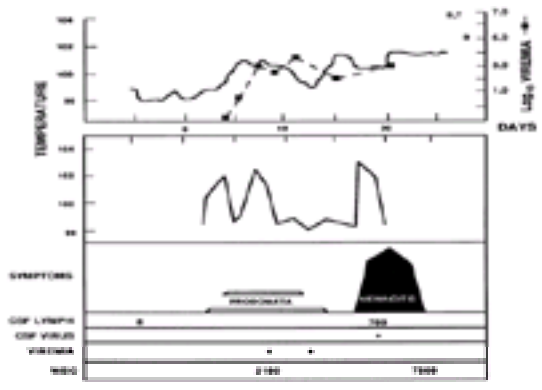

FIG. 7. Probable pathogenesis of human LCM. At the *bottom*, results of inoculation of a normal human volunteer with LCMV are shown (95). These and other human data (34,298) show an initial period of 1 to 2 weeks' viremia associated with fever, leucopenia, and systemic symptoms. This is followed by the onset of the cellular immune response with meningeal inflammation leading to mild transient CNS disease. Virus was isolated from the CSF. In the *top panel*, the course of infection in a patient with Hodgkin's disease, immunosuppressed by disease and chemotherapy, is shown. (Adapted from ref. 134, with permission.) LCMV was inoculated in hopes of favorably influencing the underlying disease. Viremia continued as long as measured; no IFA, CF, or neutralizing antibodies developed; and there was no overt CNS disease. At the time of death, possibly secondary to bacterial pneumonia, there were high titers of virus present in brain (*B*), spleen (*S*), and tumor tissue (*T*).

The clinical laboratory abnormalities at the time of CNS involvement are usually confined to the CSF, which shows an increase in cells into the hundreds or low thousands, predominantly mononuclear in type. Protein is usually modestly elevated (50 to 150 mg%) and sugar may be low in a fourth of the patients, sometimes reaching values below 20 mg/dL (4,33).

Rare neurologic presentations attributed to LCMV include ascending myelitis, transverse myelitis, and bulbar paralysis (4). The course of acute LCMV has also been complicated by hydrocephalus. One case was thought to have posterior fossa arachnoiditis and was treated with ventriculomastoidostomy (291). Another was transient (133), and a third required the placement of a ventricular reservoir (177). The latter case had evidence (by computed tomography) of periventricular edema and lateral ventricular enlargement, suggesting that the major lesion was ependymal inflammation. Both ependymal and meningeal inflammation are prominent lesions in experimental infections and in fatal LCMV encephalitis (307). Nerve deafness has been associated with LCMV infection in two cases (60,129,132). The occurrence of eighth nerve involvement in another Old World arenavirus disease, Lassa fever, suggests that these observations may represent a true causal relationship.

Lassa Fever

Infection with Lassa virus leads to the gradual onset of fever and malaise after an incubation period of about 10 days (range, 5 to 21 days). As the process develops, there is an increase in fever and myalgia, with severe prostration. Gastrointestinal manifestations such as abdominal pain, nausea and vomiting, diarrhea, or constipation are common.

Sore throat occurs in two thirds of cases and is usually accompanied by objective inflammatory or exudative pharyngitis. Retrosternal pain and cough are frequent, and pleural effusions may develop. Bleeding manifestations are seen in less than a third of patients but signal an unfavorable prognosis. Signs of increased vascular permeability such as facial edema or pleural effusions are present in a minority of patients and also suggest a poor prognosis. Mortality in hospitality patients is 15-20%.

A careful case-control study comparing Lassa fever to other febrile diseases seen in a west African hospital found several features significantly associated with Lassa fever, including bleeding, edema, exudative pharyngitis, conjunctivitis, and pharyngitis, but the positive predictive values were only 0.61 to 0.74 (204). The same study also found vomiting, sore throat, tachypnea, or bleeding to predict a 2.5-fold or higher increase of risk of death. In spite of the relative nonspecificity of the clinical findings, more than three fourths of patients thought to have severe Lassa fever are confirmed virologically. Lassa fever is a major pediatric problem as well (279,280). Disease is more difficult to diagnose clinically. Occasional cases of infants developing anasarca have been described.

The course of fatal Lassa fever is relentless, with progression of the signs and symptoms culminating in the onset of shock and death. In survivors, symptoms and viremia persist until, 2 to 3 weeks after onset, there is defervescence accompanied by the disappearance of virus from the blood. Pericarditis may occur in early convalescence, particularly in male patients. A case of polyserositis and recurrent pericarditis with constriction has been reported, which suggests that such complications should be sought more carefully (131).

Neurologic disease is not usually a dominant clinical manifestation in Lassa fever, but aseptic meningitis, encephalitis, global encephalopathy with seizures, and more subtle neurologic problems are well described (71,281,282). Cerebellar ataxia in convalescence is an uncommon but interesting occurrence. In convalescence, deafness is common; this is an important feature of Lassa fever, as it impacts on the community, and it provides an important diagnostic clue (100). Late in the course of disease or early in convalescence, unilateral or bilateral hearing loss was noted in 29% of prospectively studied patients (72). No treatment is available and the effects may be transitory or often permanent. The auditory patterns and clinical course resemble idiopathic nerve deafness (187).

The clinical laboratory provides few clues to the diagnosis. The leucocyte count can be low, normal, or modestly elevated. Platelet counts are generally normal but may be modestly decreased (98). Albuminuria is common. AST is usually at least mildly elevated and the degree of elevation, which parallels the viremia, is a useful predictor of mortality (157). Patients with AST values in the hundreds or thousands are at considerable risk of dying, even with ribavirin treatment. Chest radiography may show infiltrates, pleural effusions, or, more commonly, no abnormalities. Electrocardiographic (ECG) findings are often nonspecifically abnormal (70).

Argentine Hemorrhagic Fever

AHF begins insidiously with fever and malaise. Headache, myalgia, epigastric pain, and anorexia are common. Within 3 to 4 days, these symptoms give way to more severe prostration, nausea and vomiting, dizziness, and early indicators of vascular damage. The earliest signs are conjunctival injection, flushing over the head and sometimes upper torso, petechiae, and mild hypotension. Tremor of the tongue and hands is common and may resemble cerebellar disease. In the more severe cases, mucous membrane hemorrhages and ecchymoses at needle puncture points develop; shock supervenes and, with the hemorrhages, is an indicator of a poor prognosis. In some cases, there are extensive neurologic signs, including coma and convulsions, and these cases also have a high mortality (263). Usually around day 10 to 13, patients begin to improve as the appearance of IFA and neutralizing antibodies signals the onset of the immune response (74). Overall case fatality is 30% without therapy. Convalescence often lasts several weeks with fatigue, dizziness, and hair loss.

Clinical laboratory findings are quite helpful in the diagnosis of AHF. Leucopenia, thrombocytopenia, and proteinuria are present in virtually all patients with the disease and may be early manifestations. AST and alanine transaminase are usually normal or slightly elevated. The ECG may be nonspecifically abnormal, and chest radiography is usually normal in the absence of secondary infections.

Bolivian and Venezuelan Hemorrhagic Fevers

Bolivian hemorrhagic fever (BHF) resembles AHF clinically, just as the virus is closely related phylogenetically to Junin virus (154,287). Mortality is about 25% to 35%. Early information from the San Joaquin epidemic suggested that most Machupo virus infections resulted in disease sufficiently severe to be remembered as BHF (192), but a recent survey in the endemic region of the Beni has found ELISA IgG antibodies in persons with no previous history of BHF (C. J. Peters and T. G. Ksiazek, unpublished observations).

Venezuelan hemorrhagic fever also has a clinical spectrum similar to that of AHF, with thrombocytopenia, bleeding, and neurologic involvement being prominent (76,266,297). Sore throat and pharyngitis were noted with some frequency among initial cases, and deafness has occurred in convalescence. Although reported cases have had a somewhat higher mortality (34%), it seems likely that with increased case-finding there may be milder cases detected. Normal inhabitants of the endemic area have antibody prevalence rates of 0.1% to 3%, and household contacts, 10.5%.

Sabia Virus Infection

Sabia virus was isolated from a fatal case of hemorrhagic fever presenting in Sao Paulo, Brazil, in 1990 (188). Because of the extensive liver necrosis associated with the clinical presentation, yellow fever was a leading diagnosis, but it was excluded virologically. Later, the virus was shown to be an arenavirus, and a laboratory worker performing the studies developed severe disease resembling AHF (299). This virus once again infected a virologist in 1994, resulting in a febrile, leucopenic, thrombocytopenic syndrome that was promptly treated with intravenous ribavirin. There was an apparent clinical and virologic response. The reservoir remains unknown; it is presumed to be a rodent found around the

small community of Sabia outside Sao Paulo, where the only known natural infection occurred. Without additional information, it must be assumed that this virus has a high morbidity and mortality as well as the aerosol infectivity expected from an arenavirus.

Whitewater Arroyo Virus

Whitewater Arroyo (WWA) virus was first described as a zoonotic persistent infection in woodrats (*Neotoma albigula*) in New Mexico (104). This and related reservoirs are widely distributed throughout the southwestern United States. The virus is most closely related to Tamiami virus, an arenavirus originally found in cotton rats (*Sigmodon hispidus*) in South Florida (56). Little evidence for human infection or disease with either of these North American arenaviruses was found until the period from June 1999 to May 2000. Two fatal cases with a clinical picture suggesting acute hemorrhagic fever were shown to have preliminary evidence of acute WWA virus infection (54). Confirmation of these findings and a search for additional cases are underway.

Other Arenavirus Infections

Most arenaviruses are infectious for humans based on surveys of potentially exposed laboratory workers and residents of endemic areas. In most cases, actual infections have not been observed for their clinical effects, so information about the consequences is relatively limited. The newly described Argentine arenavirus, Oliveros, provides an example (213). This virus circulates in the same agricultural zones as Junin virus and LCMV, but *Bolomys obscurus* is its natural reservoir. Even though these rodents comprise about 4% of the captures during longitudinal studies of small mammals in agricultural areas, and one fourth are infected, no antibodies were detected in 200 normal residents of the area or in 100 patients suspected of having AHF but found to be seronegative to Junin virus. Nevertheless, it remains an open question whether this virus might not be pathogenic for humans.

Laboratory workers provide another source of information concerning arenavirus pathogenicity, because these viruses are quite infectious as small-particle aerosols. Pichinde virus has caused a number of laboratory infections without any overt disease (46). Flexal virus has resulted in two symptomatic laboratory infections and should be regarded as potentially dangerous. Tacaribe virus has also resulted in a single example of febrile disease with mild CNS symptoms (J. Casals, personal communication, 1980).

Little is known about the pathogenicity of Old World arenaviruses other than LCMV and Lassa virus (65,118). They are usually assumed to be less pathogenic for humans than Lassa virus, based on their low virulence for monkeys and guinea pigs (245,303). They are studied at biosafety level (BSL)-3, but with additional precautions to avoid aerosols of the substantial amounts of virus shed from infected animals.

Maternal and Fetal Infections

Several arenaviruses are known to infect the fetus of the natural host when pregnant rodents are viremic. In some cases, this results in no damage to the developing embryo, but in other situations there may be fetal death (see Table 3). Thus it is not unexpected that maternal infections of nonreservoir rodent species may also lead to fetal infections. The extent of fetal invasion in infected humans is surprisingly high as well, and the impact on the fetus is often severe (Fig. 8). LCMV infection of the fetus has been associated with both fetal death at early stages of development and fatal neonatal infection (175). Sheinbergas and his colleagues found an association between maternal infection with LCMV and neonatal hydrocephalus with chorioretinitis in Lithuania (275); isolated cases have also been also reported from Germany and France (62).

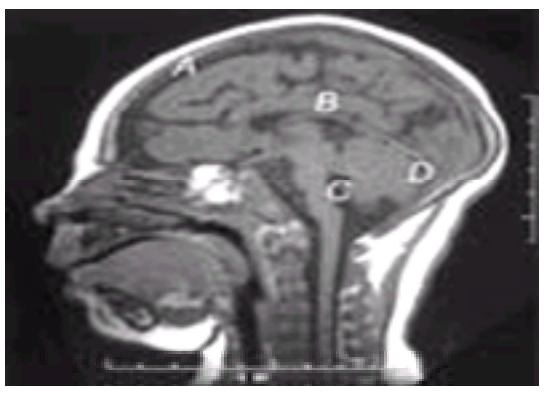

FIG. 8. T1-weighted magnetic resonance imaging (MRI) scan of the brain of a 10-month-old child with congenital LCMV infection. The child has severe developmental delay, spastic quadriparesis, and medically intractable epilepsy. The MRI scan reveals microcephaly, a lissencephalic frontal lobe (*A*), and hypoplasia of the corpus callosum (*B*), the brainstem (*C*), and the cerebellum (*D*). (Courtesy of D. Bonthius, University of Iowa.)

It is becoming increasingly apparent that LCMV is an important cause of fetal abnormalities in the United States. One report described the unusual occurrence of this syndrome in twins (27). Seven additional cases have been reported, primarily from the midwestern and southwestern states (28,32,318). The emerging picture from recent observations in the United States and Europe is of a congenital infection that follows symptomatic acute febrile disease or asymptomatic infection of the mother in mid-to-late pregnancy. The fetus is severely affected with combinations of psychomotor retardation, microcephaly, hydrocephaly, visual loss, and seizures, and it usually has evidence of aqueductal stenosis, periventricular calcifications, and chorioretinitis. The infants are not known to be chronically infected but may have a somewhat unusual antibody pattern (275). Any child with CNS or ocular disease who does not have clear-cut evidence of

intrauterine infection with one of the TORCH pathogens (toxoplasmosis, rubella, cytomegalovirus, herpes) should be evaluated for LCMV infection.

Lassa virus also causes unusually high fetal mortality. Gravid women have been recognized to have an increased risk of death from Lassa fever, and prospective studies have shown that this is particularly pronounced—30%—in the third trimester, compared to a 13% mortality in nonpregnant women (252). Fetal loss was 87%; all infants infected in the last trimester died *in utero* or during the neonatal period. Viremia, which is correlated with the risk of dying in Lassa fever patients, was higher in pregnant than in nonpregnant women. High concentrations of virus were found in fetal tissue, and in placenta as well (304). The biologic basis for these findings is unknown, but it seems likely that, once infected, the immature fetus is unable to mount an effective T-cell response to control the virus infection; maternal T cells would not be able to attack the placental infection because of the lack of MHC class I or II antigen expression on placental cells (140). Thus, the fetus and its supporting tissues would be a source of high-level virus production.

Pregnant women in the last trimester are also at an increased risk of dying from AHF, and the outlook for the fetus is grave (43). Anecdotal data for BHF also suggest that Machupo virus is abortogenic (86,154).

Differential Diagnosis

Lymphocytic Choriomeningitis

Lymphocytic choriomeningitis is probably greatly underdiagnosed because it is not sufficiently appreciated and because of the cumbersome methods of laboratory diagnosis formerly available (149). It is important to establish the diagnosis to prevent treatment for other conditions that can be confused with LCMV, and to signal the need to eradicate the virus-carrying rodents from the place of infection, particularly with the threat of maternal–fetal transmission. The diagnosis is often suggested by a history of pet rodent contact, but only during the hamster-borne epidemics of the 1970s was this commonly the actual source of LCMV. Most human LCMV infections are acquired from wild mice, and mouse exposure may not be noted in the typical clinical history. Useful clues to LCMV as a cause of aseptic meningitis include fall or winter season, a history of a distinct prodromal febrile illness, CSF cell counts that are unusually high compared to those of many other causes of aseptic meningitis, and hypoglycorrachia. Other clinical syndromes that should lead to a suspicion of LCMV infection would include nonbacterial orchitis, nonbacterial parotitis not thought to be caused by mumps virus, sudden-onset deafness, or fever, thrombocytopenia, and leucopenia.

Lassa Fever

Lassa fever should be suspected in virtually any febrile patient returning from endemic areas of Africa, particularly after a rural sojourn in Nigeria, Sierra Leone, Liberia, Guinea, or another west African country. Within a few days of onset, classical Lassa fever should progress to prostration and the other symptoms previously described, often including pharyngitis, retrosternal pain, gastrointestinal complaints, and proteinuria. However, mild or atypical cases can be diagnosed or excluded only with appropriate laboratory tests. Differential diagnoses should include malaria, shigellosis, leptospirosis, rickettsial disease, relapsing fever, and typhoid; if doubt exists, these entities should be treated empirically.

South American Hemorrhagic Fevers

Any patient from known endemic areas in South America should be under suspicion if fever, dizziness, and myalgia are accompanied by leucopenia, thrombocytopenia, and proteinuria. The relatively frequent discovery of “new” arenaviruses in the Americas implies that suggestive findings in patients with rural exposure or rodent contact anywhere in the Americas should lead to the consideration of arenavirus disease. Influenza, hantavirus pulmonary syndrome, and other febrile, myalgic diseases, as well as the more severe conditions noted for Lassa fever, enter into the differential diagnosis.

Laboratory Diagnosis

Lymphocytic Choriomeningitis

During the acute febrile phase, virus isolation from blood is the best approach. Viremia may also be detectable during the meningitic phase, but then the CSF may be more productive (34,95). Most clinical isolates of LCMV will be lethal for intracranially inoculated mice or intraperitoneally inoculated guinea pigs, but some strains will require back-challenge with a known virulent LCMV strain, or antibody measurement to demonstrate the presence of LCMV in the original inoculum; mice can also be injected with endotoxin to provoke lethality (137). Isolation in cell culture (e.g., Vero cells) is less expensive, less hazardous, and less likely to suffer cross-contamination, but it is probably slightly less sensitive than animal inoculation. Polymerase chain reaction (PCR) tests applied to CSF have also shown promise (239). Antibody is often present in serum and/or CSF during acute cases, and ELISA and IFA for IgM have been widely used to detect it (77,97,181,186). Neutralizing antibodies appear late after onset and are technically demanding to demonstrate, lessening their diagnostic importance (4,13,181). CF tests are relatively insensitive and antibodies disappear quickly; high CF titers are thought to indicate recent infection. The optimal test for serosurveys needs to be established by careful comparison of the major candidates, ELISA, IFA, and neutralization.

Lassa Fever

Lassa virus is easily isolated from blood or serum during the febrile phase of the disease up to 14 or more days after onset, even after the appearance of IFA antibody. Virus can also be detected in necropsy tissues (102,157). Vero cell cultures examined by FA allow a diagnosis in 5 to 7 days or sooner. Lassa virus antigen can be detected by ELISA capture in serum within 4 hours of beginning testing, and as it becomes negative, IgM antibodies appear (31). Antigen detection by ELISA is robust and reliable in rapidly fatal cases, even if the specimens are not handled properly for virus isolation (31). Reverse transcriptase (RT)-PCR is also a sensitive test for virus RNA, being positive in the blood of 23 of

29 patients at admission and of 29 of 29 patients by the third day of hospitalization (82,293).

Antibody can be detected by CF, IFA, or ELISA. IFA using Lassa-infected Vero cells as substrate is widely used (319). Interpretation is subjective, and discrepancies between laboratories are common. IFA IgG “seroreversion” has been reported and thought to represent loss of antibody by previously seropositive individuals (206). Lassa IgG and IgM can also be detected by ELISA (31,146,232). ELISA IgM titers appear earlier and persist longer than IFA IgM titers. IgG ELISA antibody persists for long periods, whereas IFA antibody appears to wane below detectable limits within several years.

South American Hemorrhagic Fevers

Like Lassa virus, Junin, Machupo, Guanarito, and Sabia viruses are infectious by aerosol and the human and rodent specimens should be processed with appropriate precautions in BSL-4 laboratories. Virus can be isolated from blood or serum during the acute febrile phase until 10 to 12 days after onset by inoculation of newborn hamsters or mice (41). Inoculation of cell cultures (Vero, BHK-21) is safer and more easily performed under the required BSL-4 conditions. Co-cultivation of peripheral blood mononuclear cells with Vero cells seems to be more sensitive than suckling mouse or Vero cell inoculation for the isolation of Junin virus from AHF patients (7). Virus can also be isolated from necropsy tissues, except from the brain. In rodent studies, virus is readily isolated from blood, urine, throat swabs, and autopsy tissues (156,162). Antigen-capture ELISA allows detection of viral antigen in blood, serum, or tissue homogenates. These tests could be used for acute diagnosis of patients suspected of having Junin, Machupo, Sabia, or Guanarito, and they are often the first available diagnostic result in rapidly fatal cases when patients die before the appearance of antibody. Antigen detection is also possible in rodent urine, blood, and throat swabs during ecologic surveys (213).

Serologic diagnosis of AHF and BHF is usually made by CF (193,315) and IFA (201,249,321). The lack of specificity and/or sensitivity of these tests is often a major problem. The plaque neutralization test can distinguish between antibodies to Machupo and Junin viruses and is used for evaluation of convalescent plasma units intended for therapeutic use in AHF (93). The ELISA test is the most useful and practical for rapid detection of IgG and IgM antibodies in a clinical setting and seroepidemiologic surveys (108,143). The antibodies detected by ELISA persist more than 30 years in some cases. Guanarito and Sabia IgG and IgM antibodies can also be detected by IFA and/or ELISA.

Treatment

Medical Management

Supportive therapy is important in the management of patients with arenaviral hemorrhagic fevers (246,248). Avoidance of travel and general trauma, gentle sedation and pain relief with conservative doses of opiates, the usual precautions for patients with bleeding diatheses (such as avoiding intramuscular injections and acetylsalicylic acid), and careful maintenance of hydration are indicated. Bleeding should be managed by platelet transfusions and factor replacement as indicated by clinical judgment and laboratory studies.

Management of shock is difficult. Modest increases in hematocrit indicate a generalized vascular permeability problem, but not of the magnitude seen in diseases such hantavirus pulmonary syndrome (88); nevertheless, vigorous infusion of crystalloid carries a high risk of pulmonary edema. Cautious administration of fluids and early use of pressors is indicated. Because of the low cardiac output seen in the Pichinde guinea pig model of arenaviral hemorrhagic fever, and based on clinical experience with the human disease, careful monitoring is important and Swan-Ganz catheterization is desirable.

Containment

Patients with arenaviral hemorrhagic fevers are thought to pose a minimal risk of contagion in the early stages of disease. As the process continues, more extensive viral infection of target organs and increasing blood virus titers may increase the opportunities for dissemination. Nosocomial outbreaks and infection of multiple contacts have occurred, but they are distinctly uncommon and the index patient has generally been severely ill at the time of the incident (58,172,219,244). The most dangerous exposure is parenteral and must be avoided through staff training. Thus, patients with these diseases should be treated in mask, gown, and glove isolation. Protection to care givers and other patients should be enhanced by the addition of respiratory protection against small-particle aerosols (23,99,246). Close personal contacts should be monitored for fever for a period of 3 weeks. The patient may continue to excrete virus in urine or semen for weeks after recovery, so body fluids should be monitored for infectivity before the patient is released; meanwhile, a program of counseling emphasizing addition of disinfectant to toilets before use and protection of sexual partners should be followed. Special precautions are indicated when blood and other body fluids are handled in the clinical laboratory (92).

Antiviral Drugs

Although several compounds have shown *in vitro* efficacy, only the guanosine analog ribavirin has had practical application. Although the mechanism of action is unknown, all arenaviruses tested have been inhibited in cell culture by similar concentrations of ribavirin, and the drug is effective in all arenaviral hemorrhagic fever models in which it has been studied (144,145,150,163,190,207,245,280,284). Ribavirin-treated experimental infections with Machupo or Junin viruses have sometimes led to a late neurologic disease, but activity against the visceral form of the disease has been a uniform finding. The drug is efficacious in Lassa fever and is the therapeutic agent of choice in that disease. Ribavirin has been of use principally in Lassa fever patients with a poor prognosis, usually being reserved for those with an AST value above 150. Preliminary results with ribavirin have been positive in AHF (94). Anecdotal data on early treatment of human Machupo and Sabia infections have been promising (26,171).

Ribavirin has been considered for the prophylaxis of persons exposed to arenaviral hemorrhagic fevers. In experimental

studies of Pichinde- or Lassa-infected guinea pigs, prophylaxis for periods such as 7 to 10 days only delayed the onset of acute disease by a similar period of time. Howver, drug administration for 14 days prevented disease (190,280,284). In the case of Junin virus, prophylaxis of guinea pigs for 14 to 21 days prevented acute disease, but it did not prevent Junin virus entering the CNS and causing fatal encephalitis (163). Thus, high-risk exposures to arenaviruses are probably best managed by expectant treatment at the first sign of fever, rather than dealing with the uncertainties of prophylaxis and its small but significant risk.

Passive Antibody

Therapy of Junin virus infections with convalescent plasma has been carefully studied in humans and experimental animals and is quite efficacious, with reduction of mortality from 15% to 30%, to 1% to 2% if initiated within the first 8 days of illness (93,196). The administration of convalescent plasma (usually two to three units, depending on the neutralizing titer) is the treatment of choice. About 10% of these patients will return 3 to 6 weeks later with neurologic signs such as fever, headache, cerebellar tremor, and cranial nerve palsies. This late neurologic syndrome is usually self-limited. Serum antibody titers peak later and at a higher level, and serum-to-CSF antibody ratios are increased in comparison with those in patients without this syndrome, suggesting the prior invasion of the CNS by virus. Late eradication of virus by T cells may be a factor in its pathogenesis. The syndrome resembles other experimental arenavirus neurologic diseases seen after passive antibody therapy (91,165). The *in vitro* neutralization characteristics and limited studies in animal models suggest that passive antibody therapy would probably be useful in Machupo and Guanarito virus infections (91).

Lassa virus infections are more difficult prospects for antibody therapy, because the volumes of plasma needed based on animal studies are large; experimental studies of IgG for intravenous administration indicate that this could be a useful means of treatment only if selected, highly active preparations were available (147,150,245). The future of antibody therapy in any of these diseases lies in development of standardized monoclonal antibody preparations of proven efficacy (264,271). Experimental studies of passive protection by monoclonal antibodies have been successful in the LCMV model (20,21,317).

Central Nervous System Disease

Ribavirin penetrates poorly into the CSF acutely; no established antiviral therapy exists for arenavirus infection in the CNS. LCMV may cause acute hydrocephalus from ependymal infection and inflammation, leading to a need for surgical shunting (177). Steroids have not been evaluated in this condition. The late neurologic syndrome seen after immune plasma treatment of AHF is generally self-limited and should be treated expectantly (93).

Epidemiology

The epidemiology of arenavirus diseases depends on the patterns of infection in the reservoir hosts and on the factors that bring man in contact with the rodents. Only in the case of LCMV infection of the colonized Syrian hamster has a rodent host besides the natural reservoir been shown to be responsible for human infection and, in spite of occasional virus isolations, no arthropod or other intermediate has been implicated. Tacaribe virus was isolated from 11 of 398 fruit-eating bats in Trinidad. The isolations occurred over a 3-year period, but experimental infection of bats and later attempts to isolate the virus failed, so the actual reservoir remains in doubt (87).

Interhuman transmission is uncommon except with Lassa virus. Nosocomial spread thought to be through aerosols has been a rare but devastating occurrence with Lassa (219,220), Machupo (247), and Junin viruses (195). Recent examples of person-to-person transmission of Lassa (P. E. Rollin, personal communication, 2000) and Bolivian (T. G. Ksiazek, personal communication, 2000) hemorrhagic fevers emphasize the occasional tendency of these diseases to spread among contacts, sometimes in a manner suggesting aerosol transmission. All three viruses can be transmitted to sexual partners by convalescent men. Although the mechanism of transmission is not precisely known, Lassa virus has been isolated from semen 6 weeks after acute disease.

All arenaviruses form stable, infectious aerosols and have been important causes of laboratory infections and deaths. Human pathogens must be handled with care and the VHF viruses (Lassa, Junin, Machupo, and Guanarito) are manipulated under BSL-4 containment.

PATTERNS

In Rodents

Very few longitudinal field studies have succeeded in integrating laboratory observations on pathogenesis and virus excretion of arenaviruses into a coherent description of how viruses are maintained and spread within rodent populations (64). It is thought that most LCMV and Lassa virus infections of reservoir hosts are congenitally transmitted, maintaining a tight linkage between virus and host, with little opportunity for interruption in the chain of infection. Indeed, there is evidence that carrier LCMV dams may transovarially infect their offspring (217). Horizontal spread from infectious nasal secretions, saliva, or urine may occur by aerosols or contact with infected materials in the environment, although the most efficient mechanism for infection is thought to be bite (278,295). Oral mucosa, conjunctiva, or intact skin are not efficient portals of experimental LCMV infection. Horizontal infection of weanling mice would produce only a transient immunizing infection; contact of newborn mice with infected mice from outside the nest is unlikely in the wild, and mothers excreting virus from a previous immunizing infection would protect their offspring via maternal antibody (20,294). However, if there is some marginal loss of reproductive fitness in chronically viremic animals, as suggested for LCMV, there must be a method to generate a compensatory number of carriers. *Mus* habits are such that this could most readily be achieved by an infected male mating with an uninfected female, leading to a transplacentally infected litter of carrier mice (277). The large number of infected wild mice in Europe and the Americas make the possibility of infection of mouse

colonies a real concern (225,244,281).

In the case of Junin virus, the cycle is even more complicated. Neonatally infected carrier females are virtually sterile as adults, as is the situation with Machupo virus, minimizing their role in producing chronically viremic offspring (300,301,311,312). Carrier males may simultaneously inseminate and infect virus-negative females, leading to production of congenitally infected offspring of both sexes. It has also been suggested that adult-infected Junin carrier females may be fertile (300). In spite of the complexity of this situation, which has been hypothesized to lead to cyclic, fluctuating interactions between infection and rodent population density (159), the field data from a 2-year study in the endemic area of Argentina suggested that during that period considerable virus transmission among rodents was through aggressive encounters between adult males. This was facilitated by the concentration of the Junin virus reservoir species, *Calomys musculinus*, along fence lines and roadsides leading to a focally highly populated area (213,215).

What determines the distribution of arenaviruses within the range of the host rodent species? There are partial answers for LCMV and Junin viruses. The genus *Mus* arose in Asia and radiated to form several species, most notably for this discussion *M. domesticus* in western Europe and the Mediterranean basin, and *M. musculus* in central Europe and east to China (39). Both these species have been shown to carry LCMV over much of their range, and introduction of *M. domesticus* to the Americas in post-Colombian times has also brought the virus to the New World. There are reports of LCMV antibodies in Australian *M. domesticus*, and there is an isolate from Japanese mice in a port setting. Thus, LCMV has established a tight linkage with two closely related species and appears to be found wherever they occur. The virus is not evenly distributed within that range. For example, murine LCMV infection in Germany is focal and variable in different regions and correlates with the presence of human antibodies (1,35). Focality can be extreme because of the structured social and breeding system of mice; variations in infection prevalence can be seen within neighborhoods and even between nearby homes in the urban setting.

Junin virus was first discovered in 1959 as a consequence of an epidemic of the very characteristic disease AHF. Epidemics of several hundred cases have occurred each year since the initial recognition of AHF. The geographic distribution of the virus can be inferred from the distribution of cases, which has progressively extended from the initial focus around the town of Junin to an area in excess of 120,000 km^2 with a population of 3.5 million (194,199). This progressive extension has not been explained, nor has it reached the limits of the populations of its reservoir rodent, *Calomys musculinus.* Studies of virus distribution within and outside the endemic area have shown that there is a direct correlation with the prevalence of rodent infection (21 of 549, or 3.8% Junin antigen-positive inside and nil outside) (214,313). However, virus is not completely absent outside the endemic area, as occasional isolates have been made from the abundant *C. musculinus* populations in other regions of the Argentine pampas. Thus, it is unknown whether the high prevalence of infected rodents was a consequence of a change in the virus, a change in the rodent host, or some interaction between the two leading to a spreading disease problem.

The pattern seen with most other American arenaviruses in their hosts has been one of focality. The viruses are discovered and seem to be prevalent in a particular area (Table 1 and Table 2) and have not been found elsewhere, although systematic attempts to map them have been infrequent. The distribution of the African arenaviruses and the taxonomy of their rodent reservoirs is not well enough known to comment on the exact distribution of the viruses or changes in their activity.

In Humans

Lymphocytic Choriomeningitis

LCMV infection is widespread wherever *Mus domesticus* or *M. musculus* occur and are infected. In the United States, observations in the 1930s placed human antibody prevalence at 11% (12). More recently, prevalence in inner-city Baltimore was shown to be 4.7% and in Birmingham 4.3 to 5.1% (285). In Germany, rates of 9.1% were found in rural residents of the north and 1.2% in the south, where the prevalence of murine infection was also shown to be less common (1). In Argentina, LCMV cases occur in the same settings as AHF, and the LCMV seroprevalence in male residents of the pampas was 2.2% with regional variations; some localities had rates as high as 4% to 10% (8).

Reported rates of LCMV disease are difficult to obtain because of the lack of widely available diagnostic testing and of interest on the part of clinicians. From 1941 to 1958, LCMV accounted for 9.2% of CNS disease of suspected viral etiology studied in a referral hospital. The annual incidence was relatively constant throughout the period and showed a maximum in the colder months. The fall-to-winter increase is believed to result from *Mus* entering residences for shelter and food. Disease occurs in adults and children of both sexes. Because urban antibody prevalence rates are similar today, the small number of reported cases presumably represents diagnostic apathy. In an attempt to examine this situation, LCMV infection was sought in patients admitted with CNS disease to a major hospital serving a southern U.S. city and the suburban and rural area around it (239). Surprisingly, no evidence of acute LCMV infection was found, and indeed the prevalence of past infection was only 0.3% in persons under 30 years of age. It is unknown if the change in risk is a consequence of human behavior, mouse distribution, or prevalence of infection in mouse populations, but the older persons in the same area had a seroprevalence of 5.4%.

LCMV-infected colonies of hamsters can sustain virus transmission without overt evidence of infection (240,244). Several outbreaks of LCMV infection in humans have been linked to exposure to persistently infected hamsters or tumor lines contaminated with LCMV (3,121,135). Several laboratory outbreaks were associated with virus-contaminated transplantable tumors (15,30,130). The largest number of infections resulted from distribution of pet hamsters in the United States (181 reported cases from Dec 1973 to April 1974) and Germany (47 cases identified in 1968 to 1971) (3). Infection resulted not only after close contact with the animals, but also in persons present in the same room, implicating airborne virus in transmission in at least some cases. Chronically infected hamsters were identified in home and laboratory settings, and human disease rapidly decreased when infected animals were destroyed and suppliers of infected animals ceased distribution.

It is of interest that there are still no requirements for LCMV testing in hamster colonies, and that investigation of a 1989 outbreak in nu/nu mice undergoing tumor xenotransplants found a frozen tumor cell line that must have been infected in 1975 during a hamster-associated LCMV outbreak (90). Nude mice lack the capacity to clear LCMV infection, and if they become infected either by wild mouse contact or by LCMV-contaminated tumors, they will be persistently infected and pose a threat to those working in the area. Van der Zeijst et al. reported the presence of LCMV antigen in numerous hamster cell lines from several sources. Infectivity was shown to be transferable to uninfected cell lines by exposure to cellular extracts from the infected lines.

Lassa Fever

Human disease occurs maximally during the dry season, following the multimammate mouse reservoir breeding during the rainy season. The rodents enter village houses, and they are also plentiful in surrounding savanna and other disturbed habitats, resulting in extensive human infection in all age groups and both sexes. The recent wars in Liberia and Sierra Leone have increased transmission and resulted in an enhanced risk to expatriates operating in the area. Nigeria has continued to export occasional cases to Europe.

Argentine Hemorrhagic Fever

Junin virus infection has a regular fall increase in incidence, which results from the harvest activities of humans in agricultural fields at the same time that infected rodent populations are high. As the reservoir rodent, *Calomys musculinus*, has a predilection for linear habitats such as fence rows, these may be a particularly dangerous area for AHF transmission (213,215). In addition, there is aerosol transmission from mechanical harvesting and other activities. Hundreds and occasionally thousands of cases occur annually, with the highest attack rates in adult males (197). In addition, the endemic area has been progressively increasing until it is now 10 times its initial extent (194). The quantitative interactions among an increased geographic area of transmission, decreased human contact with the cultivars because of mechanization, and effects of different crops on disease transmission are unknown, but the result has been a largely unchanged annual incidence of disease. An interesting feature of AHF epidemiology has been the regular occurrence of disease in wives of farm workers. The incubation period suggests this is the result of transmission after hospital discharge (42).

Bolivian Hemorrhagic Fever

Calomys callosus, the reservoir of Machupo virus, is particularly suited to the cleared areas used for small plots of food crops in the Beni department of Bolivia. This leads to occasional cases of disease among rural residents, principally adult men, who live or visit these areas. These rodents may also enter small towns in the area, leading to more extensive epidemics affecting both sexes and all ages (154). The most impressive town-based epidemic occurred in San Joaquin in 1963–1964, when there were 637 cases and 113 deaths among the 3,000 residents (192). This epidemic led to the isolation of Machupo virus, the identification of the virus as a chronic rodent infection, and eventually the definition of *Arenaviridae* as a virus family (154,155 and 156,160,262). Trapping of rodents was shown to stop disease transmission in towns (193). Indeed, no cases of BHF were recognized after 1975 until 1993, when one case was noted, and three more occurred in 1994. These infections were acquired outside towns, but subsequently one of the cases transmitted the virus to six of eight family members, all of whom died (T. G. Ksiazek, personal communication, 1995).

Venezuelan Hemorrhagic Fever

VHF was recognized in 1989 and the virus isolated in 1990. The emergence of the disease in rural residents of the municipality of Guanarito in Portuguesa State, Venezuela, appeared to result from clearing of forest and changing land utilization to small farms. The highest risk is among adult males, and there is a harvest predominance, but some cases occur in rural residents of both sexes and all age groups (297). The initial epidemic produced 88 cases between September 1989 and December 1991, but only a handful of cases were recognized annually until an upsurge in 1997–1998 (297). Interestingly, field studies in the endemic area between the two peaks of transmission to humans showed a high prevalence of infection among the *Zygodontomys brevicauda* reservoir rodents, as well as confirming infection in surrounding areas that had never recognized disease (289). Unfortunately, no formal studies were possible during this time, but there were no obvious differences in rodent density or prevalence, weather conditions, or virus genotypes.

PREVENTION AND CONTROL

Rodent Control

Consistent, affordable, and sustainable rodent control has been successful only in a limited number of instances. If food sources are eliminated, peridomestic sites of harborage removed, and entry to homes denied by adequate construction, it is possible to maintain houses free of rodents. In some cases, this cannot be achieved with arenavirus reservoirs because of economic circumstances and the broad distribution of the rodent host; furthermore, in some situations, contact occurs outside the home.

In the case of LCMV, it is practical to eliminate the house mouse from homes and thus minimize exposure. Contact still occurs in barns and other situations, but the danger to humans is much less. There is a need for improved monitoring of colonies that produce rodents commercially, particularly mice and hamsters (135,244,281). The increasing use of rodents as pets or to feed pet reptiles has also led to “cottage” breeding of rodents, for which there is no likelihood of quality control. A recent incident exemplifies this problem: For alimentation of tamarinds, a zoo obtained baby mice from a local supplier, and the contaminated dietary supplement resulted in the death of several animals (225). LCMV is pathogenic for several nonhuman primate species (67,178,245), including Callitrichidae (marmosets and tamarinds), and has resulted in several outbreaks in zoos or laboratories when naturally infected wild mice entered the animal pens. In fact, the original

isolation of LCMV may well have arisen from such an incident (14).

Reservoirs of Lassa virus in west Africa appear to be *Mastomys erythroleucus* and *M. huberti*, which are numerous and widely distributed; the latter readily enters homes. Some decrease in human disease can be obtained through rodent control efforts, but ultimately a vaccine will be necessary.

C. musculinus, the major reservoir of Junin virus, is mainly a rodent of pampas and fields (215). Control of this rodent to prevent disease is impractical, and suggestions that certain crops may be associated with lesser risk have not been proven. Changing agricultural practices from the 1950s to encompass modern machinery and decrease human time spent in the fields has probably resulted in some decrease in the incidence of AHF, but the disease has continued to be a serious problem. Aerosol infection is thought to be a common way of acquiring Junin virus infection, especially for combine and tractor drivers. Lessening human–rodent contact should be attempted now that it is established that infected *C. musculinus* is found preferentially along fence lines in cultivated areas.

C. callosus, the reservoir of Machupo virus, prefers open areas and particularly adapts to cleared fields in which crops are grown. In the 1960s, the rodent invaded towns and the resulting epidemics of BHF were devastating but were controlled by eradicating *C. callosus* by trapping. The marked splenomegaly found in chronically infected rodents serves as a useful marker of field infection rates (153). Sporadic cases in farmers and residents of remote houses cannot be prevented solely by rodent control.

The major reservoir of Guanarito virus in Venezuela is *Z. brevicauda* (106). There is insufficient information on the epidemiology of the disease or rodent habits to suggest specific control measures.

Vaccines

The development of vaccines for arenaviruses carries several inherent problems. These viruses have been associated with chronic infections, neurologic syndromes, immunopathology, and fetal infection. Their immunology is poorly understood and the development of humoral immunity, particularly to the Old World arenaviruses, is late and low-titered (245). Inactivated vaccines have usually had little success (65), but the chances of reversion to virulence, or inadequate attenuation of such pathogenic viruses, make development of live vaccines a difficult approach as well. There is perhaps no group of viruses for which a vectored-vaccine strategy would be more appropriate than the arenaviruses, particularly the American arenaviruses, which have multiple distinct antigenic types, a defined but restricted geographic area of circulation, and apparently a similar pathogenesis.

Junin Virus

A classical live attenuated Junin vaccine referred to as Candidate #1 has been developed and field-tested in Argentina. The vaccine was compared in its virulence properties to an experimental strain called XJ Clone 3, which had been tested in at-risk laboratory workers and more than 600 volunteers and found to have excessive reactogenicity but apparent safety (198). Candidate #1 was found to be more attenuated than XJ Clone 3 for mice, new-born guinea pigs, and nonhuman primates, and to have low neurovirulence, no evidence of persistence, and no demonstrable phenotypic reversion (24,69,208). Seroconversion rates are high if highly sensitive neutralization tests are used, but titers are low compared to those seen in convalescence from natural infection. Strong evidence of cellular immunity as measured by lymphocyte stimulation assays is found, even in serologic nonresponders. The mechanism of virus attenuation is unknown. There are 39 nucleotide differences when the 1,433 nucleotides coding for GPC of Candidate #1 are compared to the sequence of an unrelated Junin isolate; there are a limited number of amino acid coding changes corresponding to the amino-terminal region of G1 (258). A number of phenotypic differences exist that favor attenuation, including sensitivity to complement inactivation in the absence of antibody and increased ease of neutralization (25,170). Interestingly, attenuated strains such as Junin XJ Clone 3 and Machupo SM80 become virulent for their natural *Calomys* hosts (152,176).

In 1988–1990, a double-blind, placebo-controlled field trial was carried out in 6,500 volunteers; the vaccine reduced morbidity from serologically confirmed AHF from 22 cases in controls to a single case in vaccine recipients ($p < .001$) (198). Since then, 175,000 doses have been administered to high-risk residents of the endemic areas and only occasional mild cases of AHF have been reported among the vaccinees. The total annual number of cases has fallen from several hundred to less than 200.

The vaccine has only minor reactogenicity in adults as measured in phase II and III studies, with no serious reactions observed in any recipient. Because of the need to extend coverage beyond the highest risk groups of adult male residents of rural areas with high incidence of AHF, studies have begun to include children and women. To date, no adverse reactions have been observed in 142 children as young as 4 years of age, and seroconversion rates have been high. In spite of counseling and pregnancy testing to avoid vaccination of pregnant women, 49 of 17,000 recipients have given birth within 9 months of vaccination; the occurrence of one case of anencephaly and one of meningomyelocoel in the offspring suggest that caution should be exercised in the use of Candidate #1 in women of child-bearing age, but there has been no direct implication of the vaccine as invasive or pathogenic for the fetus.

The success of the AHF vaccine highlights other hurdles to the solution of VHFs by human vaccines. There is little financial incentive and perhaps inadequate justification given the world health budgets to develop vaccines for most VHFs. Even in the case of the successful AHF vaccine, there is presently no means of producing the vaccine in Argentina and no prospect of vaccine production elsewhere. Finally, without the indicator human cases, a new surveillance system is needed for the presence of rodent infection to define the continuing risk from and spread of Junin virus.

In guinea pigs and nonhuman primates, Candidate #1 and XJ Clone 3 cross-protect against Machupo virus challenge. Although there is little cross-neutralization between Junin and Machupo viruses, Junin-vaccinated animals produce a

rapid neutralizing antibody response when challenged with virulent Machupo virus, suggesting cross-priming or perhaps cellular immunity as a basis for the cross-protection.

Lassa Virus

Of all the arenavirus diseases, Lassa fever has the greatest health impact, and prospects for its prevention through rodent control are least. Three approaches to vaccine development are often discussed: (a) Other Old World arenaviruses, including the Armstrong strain of LCMV, can provide protection against virulent Lassa virus challenge, and it has been suggested that because of their low virulence for nonhuman primates they might serve as human immunogens (148,303). Unfortunately, developing information to ensure the safety and efficacy of strains of these viruses in humans may be as difficult or more so than developing a vaccine from Lassa virus. (b) The development of genetically engineered killed immunogens that would elicit neutralizing antibodies, while supported by passive protection experiments in LCMV-infected mice and realistic Lassa fever animal models, suffers from a lack of understanding of the necessary epitopes for protection. (c) The use of Lassa genes in living virus vectors has had impressive initial success in the vaccinia system. (d) Naked DNA vaccination has been developed using the LCMV system (126,127 and 128,256,257,322), and this demonstrates the induction of long-lived immunity to infection. Most interesting is a recent report demonstrating successful immunization of neonatal mice with plasmid DNA expressing the LCMV nucleocapsid protein (NP) (127). Neonatally immunized mice exhibited a long-lived CD8+ T-cell response to epitopes in NP.

Vaccinia-vectored Lassa genes are protective in both guinea pigs and nonhuman primates (17). N-gene immunization protected guinea pigs but not monkeys, whereas immunization with vaccinia expressing the GPC gene prevented mortality in both experimental systems. Low levels of virus replication and mild clinical signs were detected in some vaccinated, virus-challenged animals. No neutralizing antibodies were detected, so the mechanism of protection may have been by cellular immunity. These studies establish the feasibility of Lassa fever vaccination by the appropriate presentation of GPC antigen and may eventually lead to protection for the extensive affected populations of west Africa.

CONCLUSION

Arenaviruses have provided important model systems for the study of host–virus interactions for more than six decades, and study of these models has illuminated a wide range of principles including persistent infection, virus-induced immunopathologic disease, cytotoxic T-cell recognition, and immunologic memory. Despite this wealth of knowledge, and even though arenavirus infections of humans remain a significant public health risk in much of the world, prospects for control of these diseases remains remote because of poor diagnostic protocols and sparse resource allocation to vaccine development and other control measures. In this sense, the arenaviruses may provide a useful model for many localized viral diseases where the knowledge but not the financial incentive for control or eradication exists.

CHAPTER 51 Bornaviridae

Juan Carlos de la Torre

HISTORY AND CLASSIFICATION

Descriptions of horses with clinical signs likely to be Borna disease (BD) date back to the end of the 18th century, and by the late 1800s BD was recognized as a sporadically occurring encephalopathy that affected horses and sheep in central Europe (29). The disease name was derived from its continuous appearance between 1894 and 1896 around the city of Borna in Sauxony, Germany (29). Early studies demonstrated the infectious etiology of BD, and in 1926 its causative agent was identified as a virus, Borna disease virus (BDV). Since then, BDV has been found to cause central nervous system (CNS) disease in a broad range of vertebrate species, and it has become an important model for the study of persistent virus infection of the CNS (12). BDV has been molecularly characterized as a nonsegmented, negative-stranded (NNS) RNA virus (5,7). Based on its unique genetic and biologic features, BDV is the prototypic member of a new family, *Bornaviridae*, within the order *Mononegavirales* (8,32).

INFECTIOUS AGENT

Biologic Characteristics

Host Range

Horses and sheep have been regarded as the main natural hosts of BDV. In these species, BDV can cause BD, a fatal neurologic disease. Evidence indicates that the natural host range of BDV is wider than originally thought. Naturally occurring BDV infections have been documented in cattle and cats. In addition, sporadic cases of natural infection with BDV have been reported in other species including dogs, donkeys, mules, ostriches, alpacas, and pygmy hippopotami (15,28,29). Experimentally, BDV has a remarkably wide host range that includes species phylogenetically distant, from birds to rodents and nonhuman primates (15,28,29). Moreover, serologic data and recent molecular epidemiologic studies indicate that BDV can infect humans and might be associated with certain neuropsychiatric disorders (12,20).

The route of transmission is unclear. BDV infectivity and RNA have been detected in secretions and excretions of infected animals, suggesting that BDV could be transmitted through saliva, nasal and conjunctival secretions, urine, or feces (37). Infection may result from direct contact with these body fluids or by exposure to contaminated water and food (29). Different BDV isolates can exhibit significant diversity in phenotypic expression. However, despite its wide host range and phenotypic variability, molecular epidemiologic data have shown a remarkable sequence conservation, not only among BDV isolates within the same host species, but also among isolates from different animal species (12,15,28).

Cell and Tissue Tropism

BDV is noncytolytic and highly neurotropic. *In vivo* it replicates preferentially in neurons and astrocytes, but oligodendrocytes and ependymal cells can also be infected (29). In addition, cells derived from ectoderm become infected *in vivo* as a consequence of the centrifugal axonal spread of BDV to the periphery (29). The virus can also be present in peripheral blood mononuclear cells (PBMC) from naturally and experimentally infected animals (15,28,37). Besides brain-derived cells, other cell types can be infected in tissue culture by co-cultivation with infected brain cells or by inoculation with brain homogenates from infected animals (29).

Propagation and Assay in Cell Culture

BDV can be grown in a variety of neural and nonneural cell lines. None of these cells produce significant levels of extracellular cell-free virus, and cell-associated infectivity ranges from less than 0.01 to 0.1 infectious unit per cell. Hypertonic treatment of BDV-infected cells can release up to 50% of the total cell-associated infectivity (4). Homogenates from BDV-infected cells and tissues, as well as cell-free virus, can be quantified using an immunofocus assay.

Virion Morphology and Physical Characteristics

Electron microscopy studies of negatively stained cell-free BDV infectious particles have shown that virions are spherical with a diameter ranging from 70 to 130 nm (11,19,42). These particles contain an internal electron-dense core (50 to 60 nm) and a limiting outer membrane envelope, which appears to be covered with spikes approximately 7 nm long (19). Partially purified BDV infectious particles have a buoyant density in cesium chloride of 1.16 to 1.22 g/cm ^{3}, and in sucrose of 1.22 g/cm^3. Virus infectivity is rapidly lost by treatment at 56°C. Virions are relatively stable at 37°C, but after 24 hours incubation in the presence of serum, only minimal infectivity is recovered. Virions are inactivated below pH 5 and above pH 12, and by treatment with organic solvents, detergents, formaldehyde, and ultraviolet radiation.

Genome Organization and Encoded Proteins

BDV has a NNS RNA genome (about 8.9 kb in size, with a relative molecular mass (M_r) of about 3×10^6) (8,32). Extracistronic sequences are found at the 3' (leader) and 5' (trailer) ends of the BDV genome. As with other negative-strand RNA viruses, the ends of the BDV genome RNA exhibit partial inverted complementarity. Full-length plus-strand (antigenomic) RNAs are present in infected cells and in viral ribonucleoproteins.

There is no evidence for use of an ambisense coding strategy, and six major open reading frames (ORFs) are found in the BDV genome sequence (I to VI) (8,32) (Fig. 1). These ORFs code for polypeptides with predicted M_r of 40 kd (p40), 24 kd (p24), 10 kd (p10), 16 kd (p16), 56 kd (p56), and 180 kd (p180), respectively. Based on their positions in the viral genome and their abundance in infected cells and virion particles, together with their biochemical and sequence features, p40, p24, and p16 BDV polypeptides correspond to the viral nucleoprotein (N), the phosphoprotein (P) transcriptional activator, and matrix (M) proteins, respectively, found in other NNS RNA viruses. Two isoforms of the BDV N protein (p40 and p38) are found in BDV-infected cells. These two forms may be encoded by two different mRNA species (27), but differential usage of two in-frame initiation codons present in the BDV p40 gene could also contribute to the production of BDV p40/38. BDV p24 is an acidic polypeptide (predicted pI of 4.8) with a high Ser-Thr content (16%). Phosphorylation of serine residues is mediated by both protein kinase C and casein kinase II (33). An additional ORF, p10 or X, encodes a polypeptide of 10 kd present in BDV-infected cells (41). BDV p10 synthesis starts within the same mRNA transcription unit as p24, but 49 nucleotides upstream, and it overlaps, in a different frame, with the 71 N-terminal amino acids of p24. In contrast to other NNS RNA viruses, the putative BDV M protein is glycosylated, has a M_r of 18 kd (gp18), appears to be present in the virus envelope, and may participate in viral attachment to the cell (17).

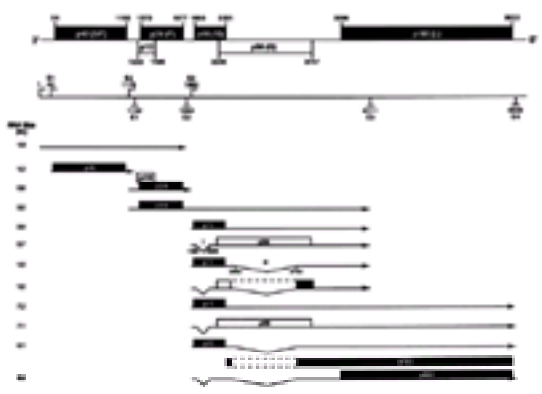

FIG. 1. Genomic organization and transcriptional map of BDV. BDV open reading frames are represented by *boxes* at the top. Different *shades* correspond to usage of different reading frames within the antigenomic polarity of the BDV genomic RNA. The location of transcription initiation and transcription termination sites are indicated by *S* and *E*, respectively. Positions of BDV introns I and II are indicated.

ORF p56 encodes the putative virus surface glycoprotein (G) and overlaps the C-terminus of ORF p16 in a different frame. The predicted protein is a 503-amino-acid polypeptide with a M_r of 56 kd. The p56 gene directs the synthesis of at least two glycosylated polypeptides of about 84 to 94 kd (GP-84/94) and 43 kd (GP-43), corresponding to the full length and C-terminus, respectively, of the p56 gene (10). GP-43 is produced via cleavage of GP-84/94 by the cellular protease furin. The cleaved N-terminal part of G has not been observed in BDV-infected cells. Whether this is because of its rapid degradation or the lack of suitable antibodies for its detection remains to be determined. GP-84 and GP-43 are sensitive to both endoglycosidases F and H. BDV ORF p180 is capable of encoding a polypeptide whose deduced amino acid sequence displays strong homology to other NNS RNA virus polymerases, members of the large (L) protein family (8,32).

CYCLE OF INFECTION

Virus Adsorption and Entry

There is evidence that a cellular receptor, of unknown identity, is required for BDV infection. Antibodies to both the virus G and M (gp18) proteins have neutralizing activity, suggesting that both are implicated in BDV adsorption and/or entry (11,17). Whether the carbohydrate modifications found in G and M (gp18) contribute to the adsorption process is unknown. Recent pseudotype studies have provided evidence that the N-terminal part (amino acids 1 to 244) of BDV p56 is sufficient for receptor recognition and virus entry. Lysosomotropic drugs and chemical treatments that cause depletion of cellular energy block BDV infection, indicating that BDV entry occurs by receptor-mediated endocytosis (10). Reduction in the pH of the endocytic compartment eventually triggers the fusion between viral and cell membranes. This fusion event releases the BDV ribonucleoprotein (RNP), which is then transported to the cell nucleus where viral

transcription and replication occur.

Transcription and Replication

BDV, unique among known NNS RNA animal viruses, has a nuclear site for genome transcription and replication (8,32). The nucleolus has been proposed as the site of BDV RNA synthesis (26). The genomic and antigenomic RNA molecules are neither capped nor polyadenylated. These RNAs exist as infectious RNP in the nucleus of infected cells (8).

Sequential and polar transcription results in decreasing molar quantities of BDV transcripts from the 3'- to the 5'-encoded cistrons. RNA species corresponding to the leader RNA have not been detected in BDV-infected cells. The viral mRNAs are polyadenylated and contain a 5' cap structure. Virus-specific mRNA synthesis is not inhibited by a-amanitin, and sequences at the 5' end of BDV mRNAs are homogeneous and genome-encoded. Thus, it is unlikely that transcription initiation of BDV mRNAs involves a cap-snatching mechanism similar to the one used by influenza viruses. Monocistronic viral mRNAs in BDV-infected cells are detected only for the N gene (see Fig. 1). The BDV genome contains three transcription initiation sites (S signals), and four transcription termination/polyadenylation sites (E signals) (8,32) (see Fig. 1). The S signals contain a semiconserved U-rich motif that is partially copied into the respective transcripts. A similar motif is not found within the S signals of previously described NNS RNA viruses. BDV E signals consist of six or seven U residues preceded by a single A residue, resembling the E signal motif found in other NNS RNA viruses. The BDV genome lacks the characteristic configuration of E signal–intergenic (IG) region–S signal found at the gene boundaries of other NNS RNA viruses. Instead, BDV transcription units and transcriptive signals frequently overlap.

Two of the BDV primary transcripts are posttranscriptionally processed by the cellular RNA splicing machinery (8,32). Two introns (I and II) have been identified in the BDV genome. BDV introns I and II span nucleotides 1932 to 2025, and 2410 to 3703, respectively, in the BDV antigenomic sequence. Splicing of intron I places the amino acid in position 13 of M, next to a stop codon, whereas splicing of intron II and I+II results in an mRNA containing a predicted ORF that corresponds to the first 58 amino acids of G fused to a new C-terminus of 20 amino acids. RNA species resulting from splicing of intron II and I+II are predicted to include an additional ORF that would encode a variant BDV L protein (p190) with 153 amino acids added to the N-terminus. Whether all these new predicted BDV polypeptides are synthesized in infected cells and tissues is unknown. RNA splicing can modulate the efficiency of termination-reinitiation of translation and leaky scanning mechanisms, thus contributing to the regulation of the expression of BDV gene products. A new BDV intron III, generated by alternative 3' splice site choice and comprising nucleotides 2,410 to 4,559 of the BDV genome, has been identified recently. Intron-III-spliced mRNAs were detected in cells from different types and species, and they have coding capability for two new viral proteins with predicted molecular masses of 8.4 and 165 (p165) kd. These findings underscore the proteomic complexity exhibited by BDV.

BDV-infected cells exhibit a heterogeneous pattern of viral antigen expression. BDV N, P, and p10 polypeptides are found in both the nucleus and the cytoplasm. N and P are the viral antigens expressed at highest levels. Only 1% to 10% of the infected cells express detectable levels of BDV G. Full-length BDV G (GP-84) appears to be restricted to the ER and nuclear envelope. The subcellular distribution of the BDV M has not been characterized. Both M and G are posttranslationally modified by glycosylation. M has been characterized as a biantennary complex type of glycoprotein, sensitive to endoglycosidase F, but not to endoglycosidase H or O-glycosidase (17). BDV G undergoes posttranslational cleavage by the cellular protease furin, with the resulting C-terminus (GP-43) reaching the cell surface (10,11). The newly exposed N-terminus of GP-43 is highly hydrophobic, and BDV-infected cells form extensive syncytia when subjected to low pH. These findings suggest that GP-43 may be involved in pH-dependent fusion after internalization of BDV by receptor-mediated endocytosis.

After infection, RNPs are transported into the nucleus for transcription and replication, and newly assembled RNPs are exported back from the nucleus to the cytoplasm. Thus, the nucleocytoplasmic transport of BDV macromolecules is an important factor in the life cycle of BDV. Co-localization studies suggest that in addition to NP and P, p10 is also part of the RNP complex (35). There is biochemical and genetic evidence for interactions between NP/P, P/P, and P/p10 (35). Nuclear localization signals (NLS) for NP and P have been characterized. The NP NLS has been mapped to the 13 N-terminal amino acid residues, with the motif 4KRR6 playing an essential role (18). Consequently, the p38 isoform of N lacks this NLS and accumulates in the cytoplasm. The biologic implications of the existence of two N isoforms with different subcellular targeting properties remain to be determined. P has two functionally independent proline-rich NLS located at its N- and C-terminal regions (36). The p10 sequence contains a characteristic leucine-rich nuclear export sequence (32). However, whether p10 has a nuclear export activity in BDV-infected cells remains to be determined.

Assembly and Release

Thin sections of BDV-infected cells show intracytoplasmic virus-like particles with morphologic characteristics similar to those described for partially purified cell-free BDV infectious particles (6). They have been observed below the plasma membrane of infected cells, and rarely in cytoplasmic vacuoles. These particles were not associated with cisternae of the endoplasmic reticulum, the Golgi complex, or other intracytoplasmic membranes. The assembly process and site of virus maturation have not been identified. Budding of BDV particles has been observed only at the cell surface of BDV-infected MDCK cells after treatment with *n*-butyrate (19). Whether this reflects the natural pathway for the exit of BDV remains to be determined.

PATHOGENESIS

Neuroinvasion and Propagation of BDV

The natural portal of entry for BDV has not been formally identified. However, field observations, together with results from experimental infections, suggest that a primary route of infection might be through the nose and the olfactory neuroepithelium (29). Experimental oral infection has been achieved in several animal species, suggesting that BDV

infection might also be initiated by the gastrointestinal route.

After initial replication in neurons located at the site of entry, BDV is transported intraaxonally in an anterograde or retrograde direction toward the CNS (29). Thus, following experimental intranasal inoculation of the rat, BDV initially replicates in the neuroreceptor cells of the olfactory epithelium. The virus then can gain access to the cells of the main olfactory bulb (MOB) by anterograde transport, subsequently reaching the MOB efferent targets. Further spread is then possible into numerous diencephalic and telencephalic areas, through polysynaptic neuronal connections. Likewise, experimental infection into the foot of a rat results in a retrograde transport of BDV in the sciatic nerve, and then from neuron to neuron into the CNS.

BDV spreads transsynaptically along neuronal chains and exhibits a preferential tropism for the limbic system (13). The hippocampus eventually harbors the highest viral load. Nevertheless, viral infection is not restricted to the limbic system and spreads throughout the CNS (13). Viral antigen accumulates in the nucleus, the perikaryon, and processes of infected neurons, whereas the nucleolus remains free of viral antigen. In the nuclei of infected neurons, aggregates of viral material form the Joest-Degen inclusion bodies characteristic of BDV infection (13). The inability to detect mature virus particles within the CNS during BDV propagation has led to the hypothesis that virus spreads in the form of RNP. BDV infection affects specific neurotransmitter pathways, and its distribution in the hippocampus coincides with that of some excitatory amino acid receptors, such as glutamate. This suggests that BDV might use these receptors for its transneuronal transfer (13). Glial cells are also permissive for BDV. Virus antigen and RNA appear rather early in astrocytes, followed by oligodendrocytes and ependymal cells, as well as Schwann cells in the peripheral nervous system. In the late stages of infection, BDV spreads centrifugally, probably by anterograde axonal transport, and viral markers can be detected in peripheral nerves of all tissues and organs, which eventually may become BDV positive. Neutralizing antibodies appear late during BDV infection and have been implicated in restricting virus replication to the nervous system, thus preventing generalized infection with BDV (40).

Neuropathogenesis of BD

BD is a nonpurulent polioencephalomyelitis caused by a T-cell-dependent immune mechanism. The rat is the most commonly used experimental model for the study of BDV pathogenesis (1,13,39). The age, immune status, and genetics of the rat, as well as viral factors and route of inoculation, can influence the course of infection. Adult rats infected intracerebrally or intranasally with BDV usually develop an immune-mediated biphasic behavioral disease. These rats display clinical signs and a histopathologic picture very similar to those found in horses with naturally acquired BD. Viral gene expression in limbic system structures, astrocytosis, and structural alterations of neurons within the hippocampus are the main histopathologic hallmarks of BDV infection (13).

The onset of clinical signs, including movement abnormalities and aggressive and hyperactive behavior, coincides with the appearance of an inflammatory reaction in the brain that reaches its maximum 30 to 40 days after infection. This extensive inflammatory reaction leads to neuronal destruction that may lead to hydrocephalus (1,13,39). Inflammatory cells form perivascular cuffs and also infiltrate the brain parenchyma. Both CD4+ and CD8+ T cells contribute to the immune-mediated pathology. CD8+ T cells are the effector cells, whereas CD4+ T cells play a helper role (1). Elimination, or functional blocking, of CD8+ T cells prevents both BDV-induced neurologic symptoms and histopathologic changes in the brain. In addition, lymphocytes isolated from rat brains during acute BD exhibit major histocompatibility complex (MHC) class I–restricted cytotoxic T-lymphocyte (CTL) activity *in vitro*. MHC class I antigens are expressed by astrocytes and neurons in BDV-infected rats, concomitantly with the peak of CD8+ T-cell infiltrate in the CNS and the onset of neuronal degeneration (1). The molecular mechanisms responsible for BDV-induced MHC class I expression by neurons are presently unknown. Inhibition of electric activity and exposure to specific cytokines can induce MHC class I expression in neurons (22). Virally infected neurons lacking MHC class I expression may avoid destruction by CTL. Antibodies do not seem to play any pathologic role in BD.

The initial aggressive hyperactive behavior is followed by apathy, somnolence, and depression. A significant number of chronically infected rats may develop obesity (28). This chronic phase is characterized by a steady decline in the inflammatory reaction, despite continuous high viral load in the CNS. A switch from a T_H1-like cellular immune response to a T_H2-like humoral immune response very likely contributes to this delayed immune tolerance (14).

Levels of interleukin (IL)-6, tumor necrosis factor (TNF)-a, IL-1a, and inducible nitric oxide synthase (iNOS) mRNAs are significantly increased in BD rat brains, and expression correlates with the degree of inflammation and severity of neurologic signs (1,39). Nitric oxide and these pro-inflammatory cytokines may contribute to BD neuropathogenesis or reflect nonspecific activation of microglia, thus being more a secondary than a primary pathogenic importance in BD.

BDV Chronic Infection in the Absence of CNS Inflammation

In contrast to the situation just depicted, BDV infection of the neonatal rat causes a life-long persistent infection that is characterized by the lack of a cellular immune response to BDV and the absence of clinical signs of BD. This infection has been designated a persistent, tolerant infection of the newborn (PTI-NB) rat (30). Brains of PTI-NB rats harbor a viral load comparable to that found in rats with acute BD, illustrating the noncytolytic replication of BDV. Although PTI-NB rats do not show clinical signs, they exhibit distinct deficiencies in emotional and cognitive functions, as well as physiologic and neurodevelopmental abnormalities resulting from damage to specific neuronal populations (30). BDV infection interferes with the development areas of the CNS that experience extensive postnatal maturation leading to cerebellar hypoplasia and progressive degeneration of the dentate gyrus of the hippocampus (12,16,30). Purkinje cells are the predominant, if not the only, cell type infected in the cerebellum. The central role played by Purkinje cells in supporting the multiplication, maturation, and migration of the granular cells could be altered by BDV infection. Astrocytes provide the physical track on which the granule cells migrate, as well as neurotropic support to surrounding cells. Hence, the intense astrocytosis observed in PTI-NB rats may also be involved in the cessation of granule cell migration. The hippocampus consistently harbors the highest viral load in PTI-NB rat brains, but there is little effect on the lifespan of these infected neurons, with the exception of the dentate gyrus (DG) where the neurons are progressively destroyed. The

majority (>85%) of DG granule cells are postnatally generated, and neurogenesis occurs in this area well into adulthood. The mechanisms underlying BDV-induced DG degeneration are presently unknown.

BDV and Brain Homeostasis

CNS alterations induced by BDV infection of immunocompetent adult rats can be attributed to the virus-induced cellular immune response. However, BDV-mediated impairment of brain activity can also occur without the hallmarks of inflammation and widespread cytolysis, because of the virus's ability to interfere with brain cell functions required to maintain CNS homeostasis.

Cytokines play an important role in CNS function, under both normal physiologic and pathologic conditions. Chronic up-regulation of proinflammatory cytokines IL-1a and b, IL-6, and TNF-a is observed in the hippocampus and cerebellum of PTI-NB rats (31). Brains of PTI-NB rats do not have immune cell infiltrates but exhibit marked astrocytosis. Astrocyte functions are essential to neurons; they provide a substrate for neuronal migration during brain development, and the astrocytic network participates in brain information processing in cooperation with neuronal networks. Astrocytes participate also in the elimination of neurotoxins and in the production of cytokines that can act as neuronal differentiation factors, and modulators of neuronal neurotransmitter gene expression. BDV-induced altered astrocyte function may affect complex animal behaviors and plasticity processes accompanying learning and memory, which are altered in PTI-NB rats.

PTI-NB rat brains have also increased expression levels of tissue factor (TF) (12). TF, a transmembrane receptor, is the primary initiator of the coagulation protease cascade that results in the generation of the protease thrombin. In the CNS, TF is produced by astrocytes. BDV-mediated TF up-regulation is caused by increased transcription of the TF gene and a stabilization of TF mRNA. There is increasing evidence that proteins of the coagulation and fibrinolysis systems may have functions in the CNS that are independent of blood clotting, such as regulating normal brain development and defending the brain against injury-related damage. Altered protease activities may contribute to neuronal damage, and thrombin has been implicated in several neurodegenerative diseases, including Alzheimer's disease. Interestingly, thrombin is predominantly expressed by dopaminergic neurons of the mesencephalon, suggesting a possible link between TF up-regulation and the dopaminergic abnormalities observed in BD rats (9,38).

BEHAVIORAL DISTURBANCES ASSOCIATED WITH BDV INFECTION

The acute phase of BD is characterized by movement disorders accompanied by excitability and hyperactivity. The later stages of the disease are frequently manifested by somnolence, depression, apathy, and anorexia. Mortality rates are as high as 80% to 100% in horses and 50% in sheep (29). Animals that survive remain chronically infected, and recurrent episodes with exacerbation of behavioral abnormalities may occur. Both host and viral factors influence significantly the behavioral abnormalities associated with BDV infection (29).

Pharmacologic studies indicate that behavioral disturbances associated with BD might be te result of BDV-induced alterations of the dopamine system. Dopaminergic activity is enhanced in the prefrontal cortex of BD rats, but dopamine receptor density is unchanged. Decreased numbers of D2 and D3 receptor binding sites are found in the nucleus accumbens of BD rats. This brain structure is a primary site of integration between limbic and motor information and participates in the control of motor, cognitive, emotional, and reward processes. Thus, abnormalities in the mesocorticolimbic dopaminergic network may constitute the neural substrate of hyperactivity in BD (38). Besides dopamine, alterations in other neurotransmitter systems have also been described in BD rats, including changes in mRNA levels of cholecystokinin, glutamic acid decarboxylase, and somatostatin (20). These pharmacologic abnormalities are likely to be a consequence of the inflammatory response. However, cortical cholinergic denervation has been observed in BDV-infected rats prior to the onset of encephalitis and in the absence of any significant cell destruction in the CNS (9).

In contrast to BDV-infected immunocompetent adult rats, PTI-NB rats develop a chronic infection with no overt signs of classic BD. Nevertheless, PTI-NB rats exhibit distinct cognitive, behavioral, and physiologic abnormalities (30). PTI-NB rats show impaired cognitive functions in different learning paradigms, including spatial discrimination and discriminated avoidance tasks. Results from open field and neophobia tests revealed emotional disturbances in PTI-NB rats. Moreover, these animals displayed hyperactivity when placed in a novel environment. Reduced body weight and length were also observed in PTI-NB rats, compared to age- and sex-matched uninfected controls. Impaired growth did not seem to be related to disturbances in growth hormone physiology. These differences in growth appeared only after weaning, suggesting that the feeding behavior might have been affected by perinatal BDV infection. In addition, PTI-NB rats exhibit an altered preference for salt.

BDV-infected tree shrews illustrate important aspects of the consequences of BDV persistent infection on the behavior of highly developed animals (29). Tree shrews (*Tupaia glis*) are phylogenetically at the root of the primate tree and exhibit a complex behavioral repertoire. Tree shrews inoculated with BDV develop a persistent infection associated with behavioral disorders related to limbic system functions. Interestingly, housing conditions have a strong influence on the behavioral manifestations of infection. Only a small number of animals kept in isolation show behavioral abnormalities, whereas all paired animals display profound sociosexual behavioral disturbances. These include a tendency to accept partners more quickly and a need for increased body contact, as well as a reversal in the role of the sex partners and an impaired breeding behavior of the females. Some animals kept in isolation also show neurologic symptoms. All these animals recover, but relapse of clinical symptoms occurs in some cases. It is unknown why clinical symptoms are observed only in some animals, although all have comparable viral load in the brain and similar titers of serum antibodies to BDV.

EPIDEMIOLOGY

Intranasal infection is very likely an important route of natural infection with BDV, allowing virus access to the limbic

system in the CNS by intraaxonal transport through the olfactory nerve (29). Animals may become infected by contact with saliva, excretions, or nasal secretions. Contact experiments have suggested that healthy carrier animals might represent a source of infection (29). BDV could also be transmitted by the oral/gastric route on exposure to contaminated food or water. Cases of BD are more frequent in some years than others and tend to occur in spring and early summer, suggesting that environmental factors can influence the circulation of BDV in the field (29). The extremely low levels of infectious virus shed by infected animals may explain the limited contagiousness of BDV.

Evidence indicates that the natural host range of BDV is wider than originally thought (15,28,29). Asymptomatic, naturally infected animals of different species have been documented in Europe, North America, Africa, and Asia, suggesting that the prevalence and geographic distribution of BDV may have been underestimated (15,28,29). It is an intriguing observation that clinical cases of BD appear to be restricted to central Europe. The natural reservoir of BDV has not been identified. BDV has not been isolated from insects, but ticks have been implicated in the transmission of an infectious encephalomyelitis similar to BD affecting ruminants and equidae in the Middle East. There is also some evidence for a possible role of rodents as a BDV reservoir (29).

Seroepidemiologic studies conducted in different laboratories over the last 10 years have consistently shown an increased BDV seroprevalence in neuropsychiatric patients (2,12,20). However, considerable variation in prevalence rates has been described, ranging from 1.6% to 30% in psychiatric patients and 0% to 3.5% in controls. Increased BDV seroprevalence has also been reported in immunosuppressed patients infected with human immunodeficiency virus (HIV) from Europe and Thailand, individuals with parasitic infections in Africa, and patients with neurologic disorders (2,12,15). However, the limited information about the composition of the subject groups analyzed, including geographic area, heterogeneity of diagnoses, and clinical status of patients may have significantly influenced these results. In addition, differences in the experimental procedures used to detect antibodies to BDV in human sera may also have affected the results.

Detection by reverse transcriptase polymerase chain reaction (RT-PCR) of BDV RNA sequences in tissues, secretions, and blood from naturally BDV-infected animals has been documented (15,28). Sequence analysis of amplified RT-PCR products is providing valuable information for the understanding of the epidemiology of BDV. The importance of these new molecular diagnostic tools is further stressed by the finding of a significant number of patients with asymptomatic BDV infection, who have low to nondetectable serum antibodies to BDV. Moreover, using RT-PCR procedures, several laboratories have detected BDV RNA in human blood (12,15,28). BDV RNA prevalences of 10% to 37% have been documented in the PBMCs of Japanese neuropsychiatric in-patients, whereas healthy blood donors had a prevalence of 0% to 4.6%. Similar findings have been described in studies done with German neuropsychiatric patients. A high BDV prevalence, RNA in both blood and serum antibodies, has also been documented in Japanese patients diagnosed with chronic fatigue syndrome. These findings remain controversial, because not all laboratories have found evidence of BDV RNA in human blood. As with naturally infected animals, a lack of correlation between detection of BDV RNA in blood and serum antibodies to BDV has been reported in humans. Sequence analysis revealed a high degree of conservation of both inter- and intrapatient BDV sequences, as well as a close genetic relationship between human and animal-derived BDV sequences (12,15,28). This finding is consistent with the remarkable genetic stability of BDV in animals. However, the recently identified subtype No/98 of BDV (23) differs at the nucleotide level from other known BDV strains by more than 15%. The identification of this new BDV field isolate that escapes detection by currently used diagnostic assays has important implications for the epidemiology of BDV in animals and humans. BDV has been isolated from PBMC (three cases) (3) and granulocytes (one case) (25) of neuropsychiatric patients. However, there are some concerns about possible contamination with laboratory sources of BDV, stressing the need for further studies to confirm these findings. BDV antigen and RNA have also been detected in human autopsy brain samples (12,15,28). These findings demonstrate that BDV can persist in the human CNS.

The source of BDV and routes for human infection are unknown. Circumstantial evidence suggests the possibility of a zoonosis (29). The close genetic relationship between BDV sequences derived from humans and animal strains provides support for this hypothesis. In this regard, it is of interest that domestic cats are susceptible to BDV, and a high BDV prevalence has been reported in domestic cats with “staggering” disease or with undefined neurologic symptoms, as well as in a significant number of asymptomatic cats (12,15,28). The detection of BDV RNA in PBMC and granulocytes suggests a possibility of blood transmission. As with other neurotropic viruses, a small number of BDV-infected cells present in a blood sample could reach the brain and initiate a persistent infection within the CNS. Thorough and comprehensive investigations will be required to accurately determine the prevalence and significance of BDV infection in humans.

PREVENTION AND TREATMENT

Live-virus vaccines have been used in the past to attempt protection against naturally occurring BD in horses and sheep. This practice was discontinued because of vaccine-related transmission of infectious BDV and other viruses. Experimentally, passive immunization with a BDV-specific CD4+ T-cell line (1) as well as inoculation of rats with a high dose of an attenuated BDV (24) have been shown to provide protection against BD.

Amantadine has been reported to effectively cure cells persistently infected with BDV. However, this finding has not been reproduced by other groups (33). Ribavirin inhibits BDV replication in MDCK cells persistently infected with BDV (21). Whether this finding can be extended to other cell types and to infected animals remains to be established.

PERSPECTIVES

BDV is the prototypic member of a new family of RNA animal viruses. Therefore, the investigation of BDV may uncover new aspects of the biology of these infectious agents. These investigations will greatly benefit from the establishment of a reverse genetic system, similar to those already developed for several NNS RNA viruses. The use of the newly established mouse model of BDV infection will be instrumental for detailed investigations of the mechanisms underlying the immune-mediated neuropathogenesis of BDV. The elucidation of the molecular mechanisms underlying BDV-induced

cerebellar hypoplasia and dentate gyrus neuronal degeneration will contribute to our understanding of neurodevelopmental disorders resulting from congenital and perinatal viral infections. There is compelling evidence that BDV can infect humans. However, the true prevalence of BDV infection in humans and its possible association with certain neuropsychiatric disorders remain to be determined. The development of standardized sensitive and reliable serologic and nucleic acid diagnostic tests will be necessary before this pressing question about BDV can be satisfactorily answered. These diagnostic tests will also permit rigorous examination of the prevalence of BDV in domestic and wild animals, and they will help to assess most of the implications for potential transmission to humans.

CHAPTER 52 Reoviruses and Their Replication

Max L. Nibert and Leslie A. Schiff

Viruses with double-stranded RNA (dsRNA) genomes illustrate the potency of evolution at exploiting credible strategies for genome organization and replication. The dsRNA viruses include several human pathogens, most notably the human rotaviruses and Colorado tick fever virus, and numerous pathogens of other organisms including mammals, birds, fish, insects, and plants. In addition, studies of the dsRNA viruses have contributed a number of fundamental concepts to the fields of virology and molecular biology. To name some examples, we draw from work on the nonfusogenic mammalian orthoreoviruses (reoviruses), which are the primary focus of this chapter. Reoviruses provided one of the first systems for *in vitro* studies of RNA synthesis (52,426,445) and evidence for the 5' cap structure on eukaryotic mRNAs, its mechanism of synthesis, and its importance in mRNA translation (165). Early evidence for the consensus sequence for translation initiation in eukaryotic mRNAs was also obtained from work on reoviruses (249). The use of reassortant genetics to identify allelic differences in reovirus genome segments that segregate with phenotypic differences between reovirus strains (416), demonstrated the value of genetic approaches to virology at a time when such approaches were not yet developed for many other animal viruses. Moreover, several of these early genetic studies with reoviruses concerned the basis of viral pathogenesis and yielded some of the first evidence for the role of animal virus receptor-binding proteins in tropism and/or virulence (494). Studies with reoviruses also provided early evidence for the role of M cells in viral penetration of the mucosal barrier during entry into an animal host (512).

CLASSIFICATION

dsRNA Viruses

Viruses with dsRNA genomes are currently grouped into six families: *Reoviridae*, *Birnaviridae*, *Totiviridae*, *Partitiviridae*, *Hypoviridae*, and *Cystoviridae* (Table 1). Viruses in only two of these families, *Reoviridae* and *Birnaviridae*, are known to infect vertebrates, and those in only one, *Reoviridae*, are known to infect mammals. The six families are distinguished by their genome organizations, protein coding strategies, virion structures, and other differences, in addition to host range. They are sufficiently different in their RNA polymerase sequences, for example, to have earned speculation that at least some arose from different plus-strand RNA virus ancestors (241). Certain structural features are nonetheless shared across family lines and beg explanations in evolutionary terms. For example, the outer capsid layer of *Reoviridae*, the single capsid layer of *Birnaviridae*, and the outer capsid layer of *Cystoviridae* are all arranged with T=13 (laevo) symmetry (63,71,310), which is not seen elsewhere in the virus world. Similarly, the inner capsid layer of *Reoviridae*, the single capsid layer of *Totiviridae*, and the inner capsid layer of *Cystoviridae* are arranged with a form of T=1 symmetry in which the icosahedral asymmetric unit is defined by an asymmetric dimer of the major capsid protein (71,79,378), also not in other viruses.

Family	No. of Genera	No. of Genome segments	Hosts
Reoviridae	9	10–12	
Turreted[a]			
Orthoreovirus		10	Mammals, birds, reptiles
Aquareovirus		11	Fish, molluscs
Cypovirus		10	Insects
Fijivirus		10	Plants, insects[b]
Oryzavirus		10	Plants, insects[b]
Nonturreted[a]			
Rotavirus		11	Mammals, birds
Orbivirus		10	Mammals, birds, arthropods[b]
Coltivirus		12	Mammals, arthropods[b]
Phytoreovirus		12	Plants, insects[b]
Birnaviridae	3	2	Birds, fish, insects
Totiviridae	3	1–4	Fungi, protozoa
Partitiviridae	4	2–4	Fungi, plants
Hypoviridae	1	1	Fungi
Cystoviridae	1	3	Bacteria

[a]Proposed division based on presence or absence of turret-like protein projecting around fivefold axes from innermost capsid layer (206).
[b]Serve as vectors for transmission to other hosts.

TABLE 1. *dsRNA viruses*

The *Reoviridae* Family

Of the six dsRNA virus families, *Reoviridae* is the largest and most diverse in terms of the host range of its members (see Table 1). The genomes of these viruses comprise 10, 11, or 12 segments of dsRNA, each encoding one to three proteins (usually one) on only one of the complementary strands. Their mature virions have characteristic sizes (60 to 85 nm, excluding the extended fiber proteins that project from the surfaces of some members), no lipid envelope, and proteins arranged in concentric layers that generally reflect icosahedral symmetry. A distinguishing feature of their replication cycles, also found in dsRNA viruses in other families, is synthesis of viral mRNAs by virally encoded enzymes within the icosahedral particles.

Despite these similarities, viruses in the nine recognized genera of this family (see Table 1) exhibit substantial genetic, biochemical, structural, and biologic differences. Regions of significant sequence similarity across genus lines are few and of limited size, and thus evolutionary connections among the genera remain a matter of speculation (but see later for a recent exception concerning the genera *Orthoreovirus* and *Aquareovirus*). Ongoing exchanges of genetic material between genera, such as genome segment reassortment, appear unlikely given the extent of differences. Viruses in a subset of the genera (see Table 1) have a turret-like protein projecting outwardly from the innermost capsid layer and surrounding the fivefold axes of their particles, which suggests a division of the family into turreted and nonturreted groups (206).

The *Orthoreovirus* Genus

The *Orthoreovirus* genus includes the prototype members of the *Reoviridae* family, the nonfusogenic mammalian orthoreoviruses, which are the primary focus of this and the next chapter. Fusogenic orthoreovirus isolates from mammals, birds, and reptiles are discussed as well, but in a more limited fashion. Designation of the latter isolates as fusogenic reflects their capacity to cause infected cells to fuse together into large multinucleated syncytia. This is an unusual property for nonenveloped viruses, which lack a classical fusion glycoprotein. The mechanism and functional roles of syncytia formation in the life cycles of these viruses is the subject of active investigation (139,307,340) but seems to involve a fusion-associated small transmembrane (FAST) protein encoded by each (438).

Viral isolates were first assigned to the *Orthoreovirus* genus based on similar traits, including a genome comprising 10 segments of dsRNA, the size and morphology of particles by electron microscopy, the number and arrangement of structural proteins within particles, and serologic reactivities. More recently, nucleotide sequences derived from the viral RNAs have confirmed the appropriateness of grouping these isolates, both nonfusogenic and fusogenic, within the same genus. The capacity of related isolates of these viruses to reassort their genome segments upon co-infection of cells, giving rise to infectious reassortant progeny viruses, plays an important role in their evolution (87,189,235). It also suggests a practical approach for designating species of virus within the genus: If particular isolates can reassort genome segments to produce infectious reassortant progeny, then they can be said to belong to the same species (134). Reassortment among nonfusogenic mammalian isolates and also among avian isolates has been demonstrated (373,409), but reassortment between these two groups has not. No reassortment has been reported for the fusogenic mammalian or reptilian isolates.

The name reovirus involves an acronym for respiratory and enteric orphan (397), reflecting that the initial isolates came from human respiratory and enteric tracts but were not associated with any serious human disease. With the isolation and characterization of other dsRNA viruses and the adoption of a standard virus classification scheme, this acronym was retained for the encompassing family of dsRNA viruses, *Reoviridae*, all members of which could then be called reoviruses. As a consequence, the prefix ortho- was added to the name of the initial isolates (orthoreoviruses) and their genus (*Orthoreovirus*) to distinguish them from other members of the family. Despite these formal changes in nomenclature, the orthoreoviruses are still commonly referred to as reoviruses.

Nonfusogenic Mammalian Orthoreoviruses

The nonfusogenic mammalian orthoreoviruses are ubiquitous agents (349) that infect and can be isolated from a wide variety of mammalian species including humans (390,459). Some recent studies have described new isolates from humans, pigs, dogs, and cats (162,189,222,240,316). There is little evidence for restrictions to the range of mammalian species in which a given isolate can replicate. Nonfusogenic mammalian orthoreoviruses can also be isolated from a variety of fresh- and saltwater sources (297,331), consistent with their pervasiveness and predominantly enteric route of infection. Although association with serious human disease is rare, sporadic cases suggest this can occur (222). In addition, although still debated (461), some data suggest that these viruses are a common cause of extrahepatic biliary atresia and other types of cholestatic liver disease in human infants (122,474). A recent survey of human sera collected

in Germany showed that 54% and 15% contained reovirus-specific IgG and IgA antibodies, respectively, indicating frequent human infections (412). The next chapter (Chapter 53) contains a current review of these viruses as agents of disease and tools for studies of viral pathogenesis. Some basic properties of the nonfusogenic mammalian orthoreoviruses are listed in Table 2.

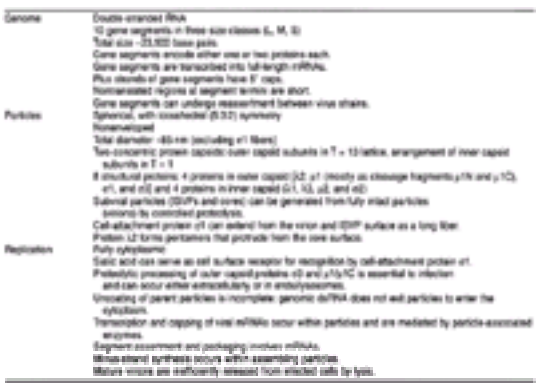

TABLE 2. *Properties of Nonfusogenic Mammalian Reoviruses*

Three distinct serotypes of nonfusogenic mammalian orthoreoviruses are identified by neutralization and hemagglutination-inhibition tests (390,397,459). An isolate from a healthy child is the prototype for reovirus type 1 (type 1 Lang); an isolate from a child with diarrhea is the prototype for reovirus type 2 (type 2 Jones); and isolates from a child with diarrhea (type 3 Dearing) and a child with an upper respiratory illness (type 3 Abney) are prototypes for reovirus type 3 (375,391,397). Although these prototypes are studied most extensively, other isolates from all three serotypes have been studied as well (209). Further discussions of the basis and significance of serotype, and its relationship to the evolution of these viruses, are found later. According to nucleotide sequences, the nonfusogenic mammalian isolates constitute one distinct phylogenetic group (species) within the *Orthoreovirus* genus (134), consistent with their capacity for genome segment reassortment.

Avian Orthoreoviruses

The avian orthoreoviruses remain less well characterized at the molecular level than the nonfusogenic mammalian isolates. They can be isolated from both domestic and wild birds, in which they can cause a variety of diseases including tenosynovitis (arthritis), a gastrointestinal maladsorption syndrome, and runting. The avian orthoreoviruses are divided into five or more serotypes by neutralization tests (501). Most avian orthoreoviruses promote the formation of multinucleated syncytia within infected cultures and are thus said to be fusogenic. Unlike the nonfusogenic mammalian orthoreoviruses, they lack the capacity to agglutinate red blood cells (340) and thus may lack the capacity to bind the cellular carbohydrate receptors that have been implicated in hemagglutination by the nonfusogenic mammalian orthoreoviruses (see later). Some isolates can be adapted for growth in mammalian cells (340,501) or will grow in mammalian cells under certain conditions (285). The particle forms and proteins of mammalian and avian orthoreoviruses have several features and properties in common (133,291,292). Recent sequence determinations for the small (S) genome segments of several avian orthoreovirus isolates showed that they constitute at least one other distinct phylogenetic group (species) within the *Orthoreovirus* genus (134), consistent with their capacity for genome segment reassortment.

Other Orthoreoviruses

Nelson Bay virus (NBV), an orthoreovirus isolate from an Australian flying fox, exhibits characteristics intermediate between the more classical mammalian and avian isolates. In particular, although it was isolated from a mammal and replicates in mammalian cell culture, it induces syncytia formation in those cultures and is thus fusogenic like the avian orthoreoviruses (171,508). A recent orthoreovirus isolate from a baboon research colony in Texas (designated baboon reovirus, or BRV) (262) exhibits properties similar to those of NBV, including replication and syncytia formation in mammalian cell culture, but it is distinguishable in certain respects (138). Nucleotide sequences determined for the S genome segments of these viruses indicate that the fusogenic viruses NBV and BRV represent two additional phylogenetic groups within the *Orthoreovirus* genus, distinct from both the nonfusogenic mammalian virus group and the fusogenic avian virus group (134). Fusogenic virus isolates from snakes have also been assigned to this genus (256,481), but identification of their relationships to the four defined phylogenetic groups awaits nucleotide sequence determinations. Recent evidence from structure determinations (338) and nucleotide sequences (149) suggests that most or all of the fusogenic viruses with 11 genome segments currently grouped in the genus *Aquareovirus* share significant homology with orthoreoviruses and may warrant grouping within the same genus.

The remainder of this chapter is devoted to a description of the nonfusogenic mammalian orthoreoviruses, which are henceforth called reoviruses for simplicity. When mentioned for comparison, other viruses are explicitly identified.

THE GENOME

Physical Characteristics

Double-Stranded

An observation that the viral inclusions in reovirus-infected cells stain orthochromatically green with acridine orange provided the first evidence that the genomic RNA is double stranded (188). Physicochemical properties and nuclease

sensitivities of the virion RNA, including resistance to the single-strand-specific nuclease S1, are consistent with its double-stranded nature (39,187,334,420). Moreover, S1 resistance suggests that the plus and minus strands of the genomic dsRNA are fully collinear and complementary (334). The base composition of the genome indicates both G/C and A/U ratios of one, again suggesting that the genome contains two complementary strands (39,187). X-ray diffraction studies of the isolated genomic dsRNA indicate that it adopts a classical A-form duplex structure, constituting a right-handed double helix with about 10 base pairs per turn, a 30-Å pitch (3-Å translation per base pair), and nucleotides oriented at 75° to 80° to the long axis (15). Other physical characteristics of the dsRNA genome as it is found within virus particles are discussed later.

Segments and Nomenclature

The dsRNA genome of reoviruses is routinely isolated from virus particles in the form of discrete segments. Early evidence from electron microscopy, sedimentation, and chromatography showed that these segments are divided among large (L), medium (M), and small (S) size classes (36,141,185,477,488). Separation on polyacrylamide gel electrophoresis provided the first evidence for 10 discrete segments: three large (L1, L2, L3), three medium (M1, M2, M3), and four small (S1, S2, S3, S4) (428,489). Both electron microscopy and quantitation of 3' hydroxyl groups demonstrated that the 10 isolated genome segments are linear and have two free ends (141,185,312,477). In addition to the different sizes, early evidence that each of the 10 segments is unique included that neither denatured segments from the different size classes nor plus-strand RNAs transcribed from them can cross-hybridize (39,488,489). Many subsequent studies, including sequence determinations and *in vitro* protein translations, have confirmed that reoviruses contain 10 distinct genome segments.

Because they are commonly isolated as discrete units, the 10 genome segments are thought to take this form within reovirus particles. Nevertheless, reports of longer-than-segment-length dsRNA molecules released from reovirus particles under certain conditions (141,185,190,233) might indicate that the genome segments are linked end to end within particles, either noncovalently or through a covalent interaction that is usually broken when the particles are disrupted. Relevance of the form of the genome segments within particles to plus-strand RNA synthesis is discussed later.

As mentioned earlier, the 10 genome segments are routinely distinguishable on polyacrylamide gels, and purified virions contain equimolar quantities of the 10 species (428). Homologous segments from different isolates commonly exhibit differences in their electrophoretic mobilities (370), despite having the same or very similar sequence lengths. The numbering scheme standardly used for the genome segments within each size class reflects the relative migrations in Tris-acetate polyacrylamide gels of the segments from isolate type 3 Dearing (419). Once the segments' protein-coding capacities were determined (302,332), this numbering scheme became meaningfully applicable to all isolates. For example, the genome segment that encodes the core turret protein l2 is always designated to be L2, because that is the case for type 3 Dearing using the standard gel systems. It is important to recognize, however, that with changes in gel system, the order of genome segments within each size class can change; for example, the medium segments of type 3 Dearing migrate in the order M1-M2-M3 in Tris-acetate gels, but M2-M1-M3 in Tris-glycine gels (373). In addition, homologous genome segments from different isolates can show different orders of migration; for example, the small segments of type 3 Dearing migrate in the order S1-S2-S3-S4, but those of type 1 Lang migrate in the order S1-S2-S4-S3 (373). Last, different genome segments from the same size class can co-migrate in certain cases, giving the appearance of nine or fewer segments.

The fact that reoviruses have segmented genomes has important biological and experimental consequences because of the phenomenon of genome segment reassortment. Differences in the electrophoretic migration of genome segments from two parental viruses used for co-infection provide a simple means for determining the parental origin of each genome segment in a reassortant virus (332,373,419). Differences in electrophoretic migration of the viral proteins and restriction fragment length polymorphisms defined using DNA copies of the genome segments have also been used in confirming the genotypes of reassortant viruses (346).

Modifications Including the 5' Cap

Each reovirus genome segment has an identical blocking group at the 5' end of its plus strand: a dimethylated cap 1 structure like that formed on cellular mRNA precursors by cell nuclear enzymes (91,166,313) (Fig. 1). In the case of the reovirus plus-strand RNAs, however, the cap is formed by viral enzymes within viral particles (165,168). The cap is important for efficient protein translation from the free plus-strand RNAs (61,333) because of recognition by cellular translation initiation factor eIF-4E, and it enhances the stability of the free plus-strand RNAs by protecting them from 5' exonucleases (164). In the reovirus life cycle, the cap may also be important for packaging into viral particles and/or minus-strand synthesis, because plus-strand RNAs either lacking a 5' cap or containing a 5' cap 2 structure (with a third methyl group added by a cell cytoplasmic enzyme) are found in large amounts in reovirus-infected cells but are not found in viral particles (121,166,313).

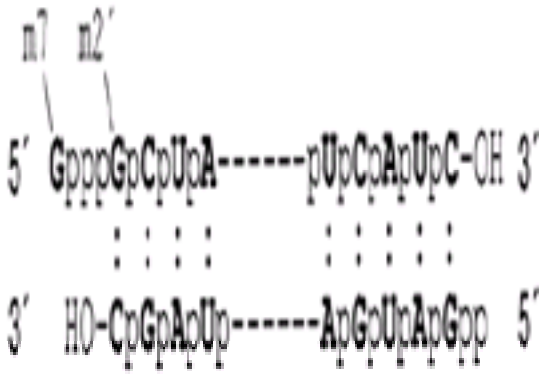

FIG. 1. Conserved features of reovirus dsRNA genome segment termini. Both plus (*top*) and minus (*bottom*) strands are shown. Nucleosides are shown in *bold. Dashes* in strand interiors indicate nucleotides that vary in number and sequence from segment to segment. *Colons* represent base-pairing.

The 5' end of each genomic minus strand is thought to be an unblocked diphosphate (25,91) (see Fig. 1); however, the resistance of this terminus to labeling with polynucleotide kinase provides some evidence for blockage by an unknown structure (313). The presence of a diphosphate at the minus-strand 5' end, and not a triphosphate as would be initially present following minus-strand synthesis from nucleoside triphosphate precursors, probably reflects the activity of an RNA triphosphate phosphohydrolase within reovirus particles (25,91). As stated earlier, both 3' termini of each genomic dsRNA segment take the form of unblocked hydroxyl groups (312) (see Fig. 1). Other modifications to the genomic ribonucleotides, such as methylation or deamination, have not been demonstrated.

Sequence-Based Features

Sequence Determinations

Initial sequence determinations were of terminal regions of the reovirus genome segments and mRNAs (12,170). Subsequent full-length determinations were made directly from genome-derived RNA strands using reverse transcriptase as the sequencing enzyme (31,120), from one or more cloned DNA copies of the segments (26,77,189,213,235,335,414,503,505,506), or from DNA copies of the segments obtained by reverse transcriptase-polymerase chain reaction (RT-PCR) without subsequent cloning (198,303). A complete genome sequence has been determined for prototype isolate type 3 Dearing and encompasses a total of about 23,500 bp (506). Lengths of the individual genome segments from this isolate range from 3,916 bp for L2, to 1,196 bp for S4 (Fig. 2). Nearly complete genome sequences have also been determined for prototype isolates type 1 Lang and type 2 Jones. The lengths of individual genome segments of type 1 Lang and type 2 Jones are either identical or very similar (give or take four nucleotides) to those of type 3 Dearing, except for the S1 genome segment, which encodes the serotype-determining and receptor-binding protein s1 and has lengths of 1,463, 1,440, and 1,416 bp in type 1 Lang, type 2 Jones, and type 3 Dearing, respectively. Several genes from other reovirus isolates have been sequenced as well.

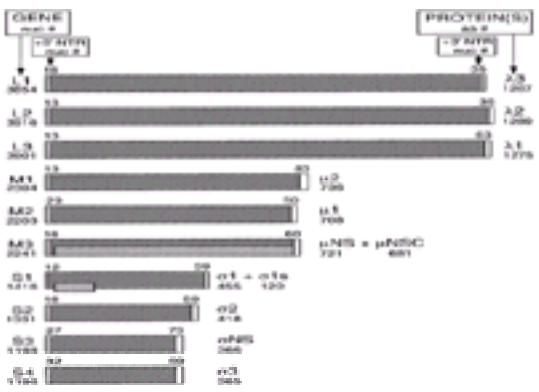

FIG. 2. Coding strategies of the 10 genome segments of reovirus type 3 Dearing. Segments are drawn approximately to scale and are oriented so that left-to-right corresponds to 5'-to-3' for the protein-coding plus strands. The segment names and lengths in nucleotides (*nuc* #) are listed at *left.* The portion of each segment encompassed by protein-coding sequences is *hatched.* Short nontranslated regions (*NTR*) at the ends of each segment remain unshaded, and the lengths of these regions in nucleotides (*nuc* #) are designated above. Names of encoded proteins and their lengths in amino acids (*aa* #) are listed at *right.* The S1 segment encodes two proteins as shown: The s1s protein (*offset, lighter hatching*) initiates at a second initiator codon in a different reading frame from s1 (*darker hatching*). A second protein, µNSC (*lighter hatching*) also arises from the M3 segment, but it is thought to initiate at a second initiator codon in the same reading frame as µNS (*darker hatching*).

Protein-Coding Strategies and Nomenclature

Proteins encoded by the 10 reovirus genome segments can be resolved by electrophoresis on different types of sodium dodecyl sulfate (SDS)-polyacrylamide gels (30,93,100,105,370,449,531). Twelve primary translation products are currently known, with eight genome segments coding for one protein each, and two coding for two each (see Fig. 2). Eight of the 12 proteins (l1, l2, l3, µ1, µ2, s1, s2, and s3) are structural—that is, present within mature reovirus particles—whereas four (µNS, µNSC, sNS, and s1s) are nonstructural and are thought to mediate functions during the intracellular steps in reovirus replication. Genetic analyses with reassortant viruses (332) and *in vitro* translation of isolated mRNAs (302) were used to determine which proteins are encoded by each of the gene segments.

The names of the reovirus proteins include Greek letter designations for proteins of large (l), medium (µ), and small (s) size classes. Each protein is encoded by a genome segment of the corresponding size class. However, the numbering scheme does not always correspond between proteins and their encoding genome segments. For example, although the second most slowly migrating genome segment L2 encodes the second most slowly migrating protein l2 in the standard gels, the third most slowly migrating genome segment L3 encodes the most slowly migrating protein l1 (see Fig. 2). There are several reasons for these discrepancies, including (a) that the numbers were first assigned to the proteins of reovirus type 3 Dearing according to their relative electrophoretic migrations in a standard phosphate-urea gel system (449)

before the protein-coding capacities of the genome segments were determined, and (b) that the two low-copy structural proteins l3 and µ2, as well as the four nonstructural proteins, were identified and named later than the others. In addition, the names of some proteins have been changed over time; for example, nonstructural protein µNS was originally called µ0 (531). Nevertheless, the protein names and their attribution to particular genome segments are now standardly defined as in Figure 2.

Each reovirus genome segment is transcribed end to end by enzymes within viral transcriptase particles to yield full-length, plus-strand copies that serve as mRNAs. Each mRNA includes one long open reading frame (ORF) that spans almost the whole length of the plus-strand sequence. In each case, this long ORF encodes a predicted protein that approximates the size of the larger protein attributed to that segment (see Fig. 2). In addition, the long ORF in each plus strand begins with an AUG that is protected from RNase degradation upon the binding of ribosomes (249). Reovirus translation is generally consistent with the scanning model for eukaryotic translation initiation. The AUG at the beginning of the long ORF in each plus strand is thus almost always the 5'-most AUG in the RNA sequence and is consistently located within an excellent to reasonable context for translation initiation according to the eukaryotic consensus (248). Some of the differences in translational efficiency among the reovirus plus-strand RNAs (169) may be attributable to differences in approximating this consensus, although other determinants are probably also important (see later). The S1 genome segment is unique in encoding a second protein product, s1s, in a separate but overlapping ORF from the larger product s1 (145,218,404). The initiation codon for s1s translation is the first out-of-frame AUG within the s1 ORF (29,78,328,335). The start codons for the s1 and s1s ORFs are separately protected from RNase degradation upon binding of ribosomes (246). The M3 gene segment also encodes a second protein, µNSC, but in this case translation appears to start from the second or third in-frame AUG within the same ORF as µNS (303,503). Important sequence determinants for translation from these downstream start codons in S1 and M3 remain to be fully defined (see later). Additional small ORFs are found in all reovirus genes, but evidence for their translation in cells is lacking. There is also no evidence that proteins are translated from the minus RNA strands of reovirus, consistent with the fact that free minus strands are not released into the cytoplasm as part of the replication cycle (410).

Terminal Nontranslated Regions

Nontranslated regions at the 5' and 3' ends of the reovirus plus strands (outside the boundaries of the long ORF in each) represent only a small part of the genome (see Fig. 2). The lengths of the 5' nontranslated regions range from 12 (S1 and L2 genome segments from certain isolates) to 32 (S4 genome segment) nucleotides. As shown for other eukaryotic mRNAs, such variations in length of the 5' nontranslated regions in the reovirus plus strands may affect their relative translational efficiencies (385). The 3' nontranslated regions range from 32 (L1 genome segment) to 80 (M1 genome segment from certain isolates) nucleotides. Among homologous genome segments from different isolates, lengths of the nontranslated sequences are often, but not always, conserved (135,303).

The plus strands of all genome segments analyzed to date contain the extreme 5' tetranucleotide 5'-GCUA and the extreme 3' pentanucleotide UCAUC-3' (12) (see Fig. 1). In addition, longer regions of sequences near the ends of the genome segments, extending through the nontranslated regions and into the protein-coding regions, are often less variable between isolates than more internal sequences (87,189,235). Sequences near the 5' and 3' ends of the reovirus plus strands also show a propensity to form base pairs in RNA secondary structure predictions, suggesting that these regions may interact in the free plus strands to form panhandle-like structures that may be important for RNA functions (87,274,526). Though a minimal portion of the genome, the nontranslated regions are likely to include sequences important for RNA packaging, recognition by the viral RNA polymerase for initiating plus- and minus-strand synthesis, and translational efficiency; however, the exact sequences that fulfill these functions have yet to be delimited for reoviruses.

PARTICLES

Virions and Partially Uncoated Derivatives

The mature reovirus virion contains all eight viral structural proteins (Fig. 3), but it is not known to contain any of the viral nonstructural proteins or any cellular proteins. The virion is the predominant form of particle released from infected cells in culture or animals or after artificial disruption of infected cell cultures in the laboratory. Virions can readily undergo partial uncoating to yield two distinct types of subvirion particles: infectious (or intermediate) subvirion particles (ISVPs) (51,223,425) and cores (298,426,449). These subvirion particles differ in protein content, in the conformation of certain proteins, and in other physicochemical and biological properties (Table 3, and see Fig. 3). The primary difference between ISVPs and virions is the lack of one outer capsid protein, s3, in ISVPs. The primary difference between cores and virions is the lack, in cores, of three outer capsid proteins: s3, s1, and µ1. ISVPs and cores can be routinely generated by treating virions with purified proteases *in vitro*. ISVPs and cores, or particles similar to these forms, also occur naturally in the course of infection and play specific roles in both early and later stages of reovirus replication (see later section). Some authors have discussed “subviral particles” (SVPs), in which case they are usually describing ISVP-like particles (16,84,440,443).

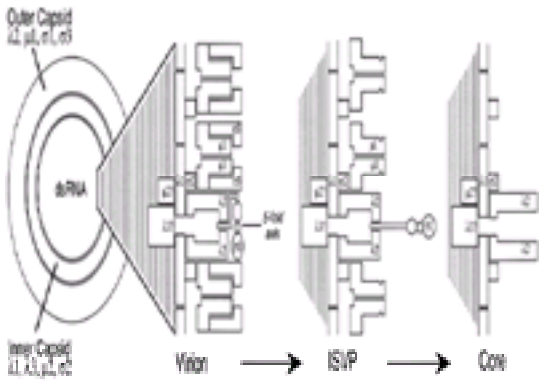

FIG. 3. Diagrams of reovirus structural elements. The two concentric capsids and centrally located dsRNA genome in reovirus virions are drawn in cross-section at *left.* Proteins in the outer capsid and inner capsid are designated. A wedge of the virion capsids, encompassing an axis of fivefold symmetry (labeled), is drawn in greater detail and shows approximate locations and interactions between reovirus proteins (labeled) as currently understood. Positions of open or potential channels through the outer capsid at axes of fivefold (P1) or sixfold (P2 and P3) symmetry are indicated (nomenclature from ref. 310). The position and interaction indicated for the l3 and µ2 proteins are hypothetical. The position of the nonextended s1 protein in virions is also hypothetical. Comparable wedges from a reovirus infectious subvirion particle (ISVP) and core are shown at *right* and reveal the loss and change in conformation of outer capsid proteins in these particle forms. The ISVP is distinguished by absence of the s3 protein, by an endoproteolytically cleaved µ1 protein (*notching*), and by a conformationally altered (extended) s1 protein. The core is distinguished by additional absence of the µ1 and s1 proteins and by a conformationally altered l2 protein. The conformational change in l2 and loss of s1 have opened a channel through the l2 “turret” that protrudes from the core surface.

Feature or property	Virion	ISVP	Core
Buoyant density in $CsCl_2$ (g/cm³)	1.36	1.39	1.43
Sedimentation value (S)	700	630	470
Molecular weight (MDa)			
From diffusion coefficient	100	ND	52
Estimated from components	127	103	49
Particles per mL at 1 OD_{568} (× 10^{12})	2.1	2.7	4.4
Diameter (nm)			
Negative-stain electron microscopy	73	64	51
Cryoelectron microscopy	85	80	60
Low-angle x-ray diffraction	83	ND	60
Outer capsid proteins			
σ3	Present	Absent (degraded)	Absent (degraded)
µ1	Present	Present as δ conformer (extended)	Absent (eluted)
µ1/δ1 C	Present	Present as δ1/δ1 + δ fragments	Absent (degraded)
λ2	Present	Present	Present as conformer
Inner capsid proteins	Present	Present	Present
10 dsRNA gene segments	Present	Present	Present
Oligonucleotides	Present	Variable	Absent
Infectivity after attachment to cell surface	High	High	Low

Transcription-related activities			
Initiation and capping	Yes	Yes	Yes
Elongation	No	No	Yes

TABLE 3. *Characteristics of common reovirus particle forms*

A representative study in which all three of the preceding particle types were compared by negative-stain electron microscopy indicated diameters of 73 nm for virions, 64 nm for ISVPs, and 51 nm for cores (51). Diameters obtained from cryoelectron micrographs, in which shrinkage artifacts common to negative staining (200) are minimal, were 85, 80, and 60 nm for virions (excluding the s1 fiber), ISVPs (excluding the s1 fiber), and cores (excluding the l2 turrets), respectively (131,310). The latter values concur with those obtained by low-angle x-ray diffraction (199). Virions, ISVPs, and cores exhibit distinct morphologies in negative-stain electron micrographs (51,109,163,238,278,298,309,449,478). Virions appear roughly spheroidal, with smooth perimeters, except for flattened areas that are apparent in certain orientations. Few details of subunit arrangement are apparent in negatively stained virions. ISVPs appear even more spheroidal than virions; furthermore, regions of their perimeters often have a saw-toothed appearance suggesting structural subunits (µ1 protein). Long fibers (s1 protein) are sometimes seen extending from the surfaces of virions and ISVPs (163). Negatively stained cores are more distinctive in that they have prominent turrets (l2 protein) protruding from their surfaces.

Radial and Axial Distributions of Proteins Within Particles

Observations from negative-stain electron micrographs first defined reovirus virions as icosahedrally symmetrical objects comprising two radially concentric, separable protein shells (inner capsid and outer capsid) surrounding the centrally condensed RNA genome (109,278,298,478). The description of two radially differentiated protein layers within reovirus virions was supported by data from dynamic light scattering (200) and low-angle x-ray diffraction (199). The latter studies also showed the outer capsid to be substantially thicker than the inner capsid and to have a higher water content. Some of these early studies suggested axial differentiation of proteins within reovirus particles as well, in that the protruding turrets of l2 protein were seen surrounding the fivefold axes in cores (298,426,449,500) and, somewhat later, the projecting fibers of s1 protein were seen to extend from the fivefold axes in certain virions and ISVPs (22,161,163). Evidence for extrusion of the viral plus-strand transcripts from the fivefold axes of actively transcribing cores supported the notion of axial differentiation of proteins and their associated functions (27,516).

Components of Viral Particles

Early studies used negative-stain electron microscopy to describe the precise arrangements of proteins and their symmetry relationships within the reovirus capsids. These studies, although accurate in several details for the outer capsid (238,309), were largely superseded by ones using cryoelectron microscopy and three-dimensional image analysis (130,131,310). An analysis of the structure of cores at 3.6 Å resolution using x-ray crystallography has recently defined the inner capsid structure in much greater detail (378). Information about each structural protein, in addition to that immediately following, can be found in the Proteins section.

Core Components

T=1 Core Shell

The core shell (inner shell in virions) is formed by 120 copies of the l1 protein. The l1 subunits are arranged with T=1 symmetry, with a parallel dimer of l1 composing the asymmetric unit. Five of these asymmetric units, containing a total of 10 l1 subunits, surround each icosahedral fivefold axis in the core. Twelve of these decameric units of l1 then interact to form the complete core shell. This shell is flat and thin but approximately continuous, being permeated by small, radially

directed channels at only a few positions including the fivefold axes (378). Such channels are seemingly required to allow entrance of ribonucleoside triphosphates and exit of newly synthesized mRNAs during transcription by cores (see later). The two l1 subunits per asymmetric unit have similar, but nonidentical, structures, which allows them to pack tightly within the decamers and intact shell. Five copies of l1 from each decamer approach the fivefold axis and interact with each other around it. The other five copies of l1 from each decamer approach the five surrounding threefold axes and interact with the homologous copies of l1 from adjacent decamers in the shell. An N-terminal region of l1 was not fully visualized in core crystals, but the portions of it that were visualized are located internal to the main core shell, they assume an extended conformation, and appear attributable to the copies of l1 that approach the threefold axes (378). Thus, an N-terminal region (240 amino acids) of the copies of l1 that approach the fivefold axes remains to be placed in the core structure.

Internal Transcriptase Complexes

A proteinaceous structure internal to the l1 shell has been visualized to date only at lower resolution by cryoelectron microscopy and x-ray crystallography (130,378). This structure has a flower-like appearance and projects below the shell by 65 Å (central stalk) to 80 Å (surrounding petals) at each of the 12 fivefold axes. Biochemical evidence suggests that it, or other poorly visualized internal structures, are formed in whole or part by an N-terminal region of l1 and the two low copy number core proteins l3 (12 copies) and μ2 (12 to 24 copies) (130). Functions assigned to these proteins through other studies (see later) have led to the proposal that these complexes represent the viral transcriptase complexes, which transcribe the genomic dsRNA segments into mRNAs (see later). Additional work is needed to define the structures of these complexes in more detail.

External Turrets and Nodules

Sitting directly atop the l1 shell are two other core proteins: l2 and s2. A pentamer of l2 forms each of the 12 characteristic turret-like structures or “spikes” that project by more than 100 Å above the l1 shell on the core surface, surrounding the fivefold axes (a total of 60 l2 subunits per particle). The individual monomers of l2 within each pentamer are identical and exhibit an extended, multidomain structure (378). Each monomer spirals around the fivefold axis, enclosing a large solvent cavity within the center of the turret and giving the turret walls an interlocking structure. Three domains in each monomer, including the one l2 domain that contacts l1, represent enzymes involved in mRNA capping (see later). The catalytic pockets of these enzymatic domains face into the central cavity of each pentameric turret. A channel through the base of the turret connects the fivefold channel through the l1 shell (see earlier) with the turret cavity and is very likely important for the movement of nascent transcripts. The opening at the top of the l2 turret exhibits variable diameter in different visualizations of cores, as determined by different orientations of a series of outermost, apparently nonenzymatic, flaplike domains of l2 (131,281,310,378). A more closed conformation of these flaps may be important for retaining nascent transcripts inside the turret for capping (378), whereas a more open conformation may be important for release of the transcripts after capping is complete (27,378,516). Specific mechanisms for regulating these conformational changes remain unknown. In virions and ISVPs, however, the flaps uniformly adopt a more closed conformation (130,131,310). The closed conformation may be important for the capacity of l2 to bind the s1 fiber protein at the fivefold axes (see later).

Monomers of s2 form the 150 ovoid nodules that sit atop the l1 shell and decorate the core surface at the twofold axes and surrounding the threefold and fivefold axes (131,310,378). Each of the 60 copies surrounding the fivefold axes makes a minor contact with one l2 subunit. The 60 near-fivefold and 60 near-threefold copies of s2 have similar, but nonidentical, structures, allowing them to make distinct contacts with the underlying l1 molecules. The 30 twofold copies of s2 were only partially resolved at high resolution in the crystal structure of cores, because they can adopt either of two equivalent, twofold symmetrical orientations at each of these positions. Each twofold copy of s2 appears to make minor contacts with surrounding near-fivefold and near-threefold copies of the protein. Because each s2 copy appears to make contacts with l1 across subunit boundaries within the l1 shell, s2 is proposed to serve as a stabilizing clamp for that shell (378).

Although they are core proteins and thus classically identified as components of the inner capsid, proteins l2 and s2 occupy structural positions that are clearly distinct from those of the core shell protein l1. They sit atop the l1 shell, at radial positions between the core shell and the T=13 outer shell (see later). In fact, the extended conformation of l2 allows it to extend upward into the outer capsid lattice and to occupy positions within the outer lattice surrounding each fivefold axis (see later). Thus, it is possible to describe s2 and the bottom, l1-binding domain of l2 (see earlier) as forming an incomplete, intermediate protein layer in reovirus particles, which separates the T=1 core shell and T=13 outer shell and is probably important for interactions between them. By extending up into the outer shell, l2 may be especially important for holding the two shells together.

Outer Capsid

T=13 Outer Shell

The reovirus outer capsid layer has been analyzed using a number of different styles of electron microscopy. The results of these studies agree that the outer shell has subunits arranged in a skewed, T=13 (laevo) lattice (131,238,309,310). The lattice is formed primarily by 600 molecules of protein μ1. The stoichiometry of μ1 fails to account for 180 of the expected 780 (13 × 60) subunits in a classical T=13 structure. The remaining positions are occupied instead by 60 molecules of protein l2, which substitute for μ1 around each fivefold axis such that one molecule of l2 occupies three of the μ1 subunit positions. This lattice exhibits a very similar structure in virions and ISVPs, except that in virions the s3 protein is also present (see later).

The μ1 protein appears to be organized in trimeric complexes within virions and ISVPs (131,238,309). The trimers are most apparent at higher axial radii in ISVPs, where adjacent trimers make contact across local twofold axes (131). At lower radii, other intertrimer contacts are seen, giving μ1 a structure that interlocks across the outer capsid. Because the

μ1 network is substituted around each fivefold axis by l2, not all μ1 subunits are in identical positions. The copies of μ1 adjacent to l2 appear to contact that protein directly. Only some of the 600 μ1 subunits appear to be in proper position to contact the s2 nodules projecting from the surface of the core.

The mass of μ1 and s3 is arranged around large solvent channels that pass axially through the outer capsid (131,310). Two different types of channels are present because of substitution by l2 around the fivefold axes. The two channel types are designated P2 and P3 and range in diameter from 2.5 to 11 nm at different axial radii in ISVPs. Each P2 channel is partially blocked by a l2 subunit. The diameters of both P2 and P3 channels are decreased at higher radii in virions by the presence of s3 (see later). The purpose of these channels is not known, but they may be required for conformational changes in μ1 involved in membrane penetration (see later).

An observation that the μ1 and s3 proteins bind to each other in solution (83,260,437,471) is reflected in intimate contacts between these proteins within the virion outer capsid (131). Difference maps between images of virions and ISVPs permit densities to be attributed specifically to s3 and suggest that each s3 subunit is elongated in an axial direction. The s3 subunits project 34 Å above the outer extent of μ1 and look like “fingers” on the virion surface (131,310). Each copy of s3 appears to contact as many as three adjacent μ1 subunits and may in this way serve to stabilize the outer capsid structure. Six and four subunits of s3 are placed around the perimeters of the P3 and P2 channels, respectively, and appear to contact each other side to side to form complete and partial hexamers. Because of the presence of l2, not all s3 subunits are in identical positions. One of the s3 copies adjacent to each l2 subunit appears to contact that protein directly.

The arrangement of μ1 in virions and ISVPs exhibits only minor differences (131,219), despite the fact that μ1 has undergone an additional endoproteolytic cleavage in ISVPs. Thus, the major difference between these two particle types is the loss of 600 s3 subunits without a major perturbation of underlying structures in the outer capsid or core regions. This observation contributes to an interpretation that the primary contacts within the outer shell are made among subunits of μ1 and l2, while s3 effectively decorates this lattice. However, only μ1 in complex with s3 appears to be competent for assembly into the outer shell (83,437).

Extending Fibers

In negatively stained images of some virions and ISVPs, s1 is seen as a long fiber that projects out more than 40 nm from the particle surface (131,163). The spacing of these fibers suggests location at the fivefold axes, as does work with antibodies indicating that s1 and l2 are in close proximity within virions (202,260). Small portions from near the base of the s1 fiber are all that is standardly visualized by cryoelectron microscopy and three-dimensional reconstruction of virions and ISVPs (130,131,310), probably because of the flexible nature of these fibers. The placement of s1 atop l2 is further supported by a recent study demonstrating the absence of s1-attributed density in a cryoelectron microscopy reconstruction of cores that have been “recoated” *in vitro* with the μ1 and s3 proteins, but not s1 (83). The s1 fibers seen extending from particles in raw micrographs (131,163) have a head-and-tail morphology, with the head distal to the particle-bound end. The extreme base of the tail is proposed to interact with l2, at a binding site created by five l2 subunits. Because each s1 fiber most likely represents a homotrimer of that protein (see later), binding of s1 to l2 appears to involve a three-to-five symmetry mismatch. Some evidence suggests that s1 can also assume a less extended conformation in virions (131,163), but the nature of this alternative conformation remains undefined. Different conformations of s1 may be important for its roles in mediating binding to cell surface receptors (see later). The s1 protein appears to be lost from cores by elution following conformational changes in the outermost flaplike domains of l2 (131).

RNA Components

Centrally Condensed dsRNA

Low-angle x-ray diffraction, cryoelectron microscopy, and x-ray crystallography all indicate that the genomic dsRNA is found in reovirus particles within a central sphere, about 49 nm in diameter, and that it is well ordered so that adjacent helices are locally parallel and separated by distances of 25 to 27 Å (131,199,378). Regions of local disorder in the parallel packing scheme are expected to permit the RNA to pack into the available space. Given the measured interhelix distances and the size of the 10 genome segments, calculations indicate that the central cavity should provide just enough room to accommodate the total genome (341). Thus, large quantities of protein are unlikely to be bound to the packaged dsRNA, consistent with other observations. An additional conclusion is that random packaging of more than 10 segments per particle is an unlikely explanation for the high ratio of particles to plaque-forming units (pfu) in reoviruses. The arrangement of the genomic dsRNA has relevance to the mechanism of reovirus transcription (see later). The dispositions of the segment ends are unknown, but the end containing the 3' end of the minus strand is expected to be bound by the RNA polymerase to permit efficient onset of transcription upon entry of the particle into cells.

Oligonucleotides

About 25% of the RNA in purified virions is in the form of small, single-stranded oligonucleotides (37,427), which can be grouped into two major classes (34). Quantities can vary widely with conditions of virus growth, including temperature (253), as well as between virions obtained from the same purification (150). About 70% of the oligonucleotides (~2,000 copies per virion) terminate with a 5'GC(U)(A) and are two to nine residues long (35,38,348). The conserved 5' sequences suggest that these are the products of abortive transcription. They are often termed initiator oligonucleotides, and those packaged into virions are generated in the final stages of morphogenesis (38,151). Oligoadenylates constitute a second major class of oligonucleotides, which are two to 20 residues long and present in about 850 copies per virion (34,348,462). Like the initiator oligonucleotides, they appear to result from an alternative activity of the viral transcriptase and are also generated in the final stages of morphogenesis (532). Whereas virions contain both classes of oligonucleotides, cores lack them (73,151,223,425,449). Whether oligonucleotides are present in ISVPs is controversial (84,223,425). Their exact locations within virions remain unknown (199). Functions of the oligonucleotides are also

unknown, but there is evidence that they are not required for infectivity (73,151).

Molecular Weights

Molecular weights for virions and cores of reovirus type 3 Dearing were determined from diffusion coefficients to be 129.5 and 52.3 megadaltons (MDa), respectively (150). The total weight of the genomic RNA is calculated to be 15.1 MDa from sequences of the 10 genome segments of this isolate. Oligonucleotides are estimated to contribute another 5 MDa to the weight of virions (348). Thus, proteins are expected to contribute roughly 109 and 37 MDa (85% and 70% of totals) to the molecular weights of virions and cores, respectively. These weights correspond well with those obtained by calculation from sequence-predicted masses of the proteins and current estimates for their copy numbers in particles (see Table 3). Similar estimates can be made for ISVPs (see Table 3). For these calculations, it was assumed that the proteins in virions are full length, given the lack of evidence for loss of mass by protein cleavage, and good correlations between molecular weights calculated from sequences and those estimated from gels. The crystal structure for the reovirus core indicates that the assembled forms of l2 and s2 are indeed full length (except for lacking their initiator methionines), and that the assembled form of l1 extends to its sequence-predicted C terminus (the N terminus of l1 was not well visualized in the crystal structure) (378).

Purification of Particles and Their Infectivities

Murine L929 cells are commonly used for plaque assay and for growing virions for purification. For purification, virions are released from cells by sonication and then dissociated from other components by treatment with deoxycholate and extraction with freon (39,128,163,223,420,449) or a newer freon substitute (308). Final purification of virions is commonly achieved by centrifugation through a cesium chloride (CsCl) gradient. Values for sedimentation and buoyant density of reovirus particles are shown in Table 3 (51,150,163,449). Banded virions are dialyzed into buffer (often 150mM NaCl, 10mM $MgCl_2$, 10mM Tris, pH 7.5) for storage at 4°C, where they can remain stable and infectious for extended periods. An average yield from this procedure is 1×10^{13} virions (~about 1.8 mg) per 1×10^{8} cells. The equivalence 1 OD_{260} = 185 µg protein per mL = 2.1×10^{12} virions per mL is routinely used for estimating the concentration of purified virions (449).

Chymotrypsin is most commonly used to convert virions to ISVPs or cores *in vitro* (51,163,223,344,425,426,449,454,467). At fixed conditions (buffer, enzyme concentration, temperature, time of treatment), the concentration of virions included in the mixture determines whether ISVPs or cores are obtained as products (51,54,57,60,163,223). The particular conditions yielding one or the other particle form can vary between isolates (101,127,223). ISVPs or cores generated by this treatment can be purified by centrifugation through CsCl gradients. Purified ISVPs are commonly stored in the same buffer as virions, but a different buffer (1M NaCl, 100mM MgCl2, 20mM HEPES, pH 8.0) was found to maintain cores in a nonaggregated state (101). Comparisons of protein quantities in virions and subvirion particles suggest the following equivalences: 1 OD_{260} = 2.7×10^{12} ISVPs per mL and 1 OD_{260} = 4.4×10^{12} cores per mL (100).

When purified virions are tested for infectivity by plaque assay in L cells, a particle-to-pfu ratio of from 50:1 to 500:1 is commonly obtained (14,144,226,467). The basis for this high ratio is unknown; it could reflect either that defective particles are present in the preparations or that productive infection involves a complex process that only a statistically determined subset of infectious particles can routinely complete. In a few studies, a ratio approaching 1:1 between particles and infectious units has been reported; however, these studies included special circumstances such as protease activation of viral particles and measurement of infectious units by a fluorescent focus assay (454). In general, the efficiency of infection is mildly enhanced in preparations of ISVPs, and reduced by several orders of magnitude in preparations of cores. An exception to the enhanced infectivity of ISVPs is seen with isolates type 3 Dearing and type 3 clone 31, which have a s1 cell-attachment protein that is sensitive to protease cleavage during the generation of ISVPs and that exhibits an associated loss in infectivity (85,342).

Other Types of Icosahedral Reovirus Particles

Top Component Particles

“Empty” virions, which contain markedly reduced quantities of dsRNA gene segments and oligonucleotides, account for a large proportion of the particles purified from reovirus-infected cells (380,449). Their buoyant density is 1.29 g/cm^3, lower than that of full virions and consistent with their lack of RNA (150,163,255,449); thus, they migrate above full virions in CsCl gradients and are called top component particles. Both their protein content and morphology are very similar to those of full virions, except that negative stains can enter their central cavity (449,500). Protease treatments of empty virions can be used to generate empty ISVPs and empty cores (130,277,449,500). Empty particles have been used in studies that address the function of reovirus proteins (196,277,416) and have provided evidence for the inwardly protruding transcriptase complexes within reovirus particles (130). The derivation of empty virions is unknown; however, they are unlikely to be precursors of full virions during morphogenesis (226). Methods for increasing the relative yields of empty virions from infected cells have been described (255).

Particle Assembly Intermediates from Infected Cells

Isolation of particles from infected cells can provide insight into reovirus assembly and other aspects of replication. Gradient fractionation of assembly intermediates from infected cells tentatively identified distinct particle populations engaged in minus-strand RNA synthesis (replicase particles) and plus-strand RNA synthesis (transcriptase particles) (323). The latter particles were found to represent cores that are associated with variable amounts of the nonstructural protein µNS (323,532). Particles obtained from infections with temperature-sensitive (ts) or other assembly-restricted mutants are useful for identifying putative assembly intermediates that accumulate behind the restrictive block. Core-like particles that accumulate at nonpermissive temperature with ts group B and G mutants provide evidence for generation of the core as a central intermediate in virion morphogenesis (322). Similarly, particles containing core proteins l1, l3, and s2, but lacking other core components, have been shown to accumulate at nonpermissive temperature with one

L2-segment ts mutant and have been proposed to suggest a role for this particle type in core assembly (204).

Particles Assembled In Whole or In Part from Recombinant Proteins

Coexpression of subsets of recombinant reovirus core proteins in HeLa cells using vaccinia virus vectors has resulted in production of empty core-like particles containing the following proteins: l1 and s2; l1, l2, and s2; l1, l3, and s2; and l1, l2, l3, and s2 (513). The minimal protein complement for core-like particle assembly in this system thus appears to be l1 and s2. These findings provide evidence for packaging of l3 independently of l2. Additional assemblies of core protein µ2, outer capsid proteins, or viral RNA in this type of system have not yet been reported.

ISVPs and cores, generated from virions by *in vitro* protease treatment and then purified, can serve as platforms for *in vitro* assembly of the missing outer capsid proteins. This process, recently termed recoating (219), was first indicated by the binding to ISVPs of s3 from infected cells (16). A subsequent study using *in vitro* translated, recombinant s3 demonstrated its feasibility for more controlled studies (430). The recent study demonstrates that approximately full levels of baculovirus-expressed recombinant s3 can be bound to ISVPs *in vitro*, yielding recoated particles that are very similar to virions in a large number of structural and biological properties (219). The recoating approach has also been extended to cores, to which baculovirus-expressed recombinant µ1 and s3 proteins, or µ1, s3, and s1 proteins, can be bound (83,151). The utility of this general approach lies not only in its capacity to address the structure and assembly of the reovirus outer capsid but also in the fact that the resulting particles demonstrate infectivity properties attributable to the *in vitro* assembled proteins (see later). Another variation to this approach involves the binding of nonstructural protein µNS to cores (66), yielding particles that appear to mimic transcriptase particles isolated from infected cells (323).

PROTEINS

The eight species of viral proteins in mature reovirus virions (structural proteins) have particle-based functions that are critical to initiation of infection and synthesis of the capped viral mRNAs (Table 4). These same proteins may also play regulatory or other “nonstructural” roles within the infected cell. General characteristics and functions of these proteins are discussed later. The five core proteins (l1, l2, l3, µ2, and s2) are described first, followed by descriptions of the three additional proteins in the virion outer capsid (µ1, s1, and s3). Examination of proteins in reovirus-infected cells initially revealed two other virally encoded proteins that are not present in mature virions (nonstructural proteins) and that are now called µNS and sNS (531). A smaller form of µNS, called µNSC, is also found in infected cells (260). Nucleotide sequencing (29,78,246,328,335) plus *in vitro* translation of viral mRNAs and comparison with proteins from reovirus-infected cells (80,145,218,404) identified an additional nonstructural protein, s1s (227), encoded by the second ORF in the S1 genome segment. All four nonstructural proteins are discussed in detail later (see Table 4).

Encoding segment	Protein	Mass (kd)	Copy no. per virion	Location in virions	Presence in particle forms*	Function or property
L1	λ3	142	12	Inner capsid	V, I, C	RNA-dependent RNA polymerase
L2	λ2	145	60	Outer capsid, core spike	V, I, C	Guanylyltransferase, methyltransferases
L3	λ1	143	120	Inner capsid	V, I, C	Binds RNA, Zn metalloprotein, NTPase?, RNA helicase?, RNA triphosphatase?
M1	µ2	83	20	Inner capsid	V, I, C	Binds RNA, NTPase?
M2	µ1	76	600	Outer capsid	V, I	N-myristoylated, cleaved into fragments, role in penetration, role in transcriptase activation
M3	µNS	80	0	Nonstructural	—	Binds core, role in secondary transcription, probable role in RNA assortment or replication
	µNSC	75	0	Nonstructural	—	Unknown
S1	σ1	49	36	Outer capsid	V, I	Cell attachment protein, hemagglutinin, primary serotype determinant
	σ1s	14	0	Nonstructural	—	Dispensible in cell culture
S2	σ2	47	150	Inner capsid	V, I, C	Binds ds RNA
S3	σNS	41	0	Nonstructural	—	Binds ss RNA, probable role in RNA assortment or replication
S4	σ3	41	600	Outer capsid	V	Sensitive to protease degradation, binds ds RNA, zinc metalloprotein, effects on translation

*V, virion; I, ISVP; C, core.

TABLE 4. *Reovirus proteins*

Structural Proteins in the Core

l1

The l1 protein (142 kd, 1,275 amino acids) is the primary constituent of the core shell (296,500,513) and is present in 120 copies per particle (100,378). In recombinant form, it requires coexpression with core nodule protein s2 to assemble into icosahedral particles (513). Recombinant l1 was also shown to interact with core turret protein l2 and low-copy core protein l3 (460). In native particles, l1 has extensive contacts with s2 and l2 (378), and it is thought to interact with one or both of the low-copy-number core proteins, l3 and µ2, as well (130,378). An N-terminal region of l1 was proposed to project into the core interior based on its protease sensitivity in top component particles (130) and to be more hydrophilic and flexible than the rest of the protein based on sequence analyses (198). This N-terminal region was not fully visualized in core crystals, but the portions of it that were visualized are located internal to the main core shell and assume an extended conformation (378). The l1 sequence contains a conserved CCHH zinc-finger motif near the junction between this N-terminal region and the rest of the protein (26,198), and l1 was shown to bind Zn^{2+} in a blotting assay (407) and in core crystals (378). The role of the zinc finger remains unknown.

Functions of the l1 protein are only partly understood. Recent reassortant analyses showed that the L3 genome segment encoding l1 contributes to determining differences in the NTPase activities of cores (354,355), consistent with the presence of nucleotide-binding motifs near the l1 N-terminus (26,44,354). Moreover, recent studies with partially purified recombinant l1 protein showed it to possess not only NTPase activity but also RNA triphosphate phosphohydrolase and helicase activities (44,45). These findings tentatively assign l1 to mediating the first step in mRNA capping by reovirus particles as well as to mediating RNA duplex unwinding during one or more step in reovirus plus- and/or minus-strand RNA synthesis. A conformational change in l1 during transcription by cores was previously noted (366). Consistent with

its RNA-directed enzymatic activities, the l1 protein was shown to have an RNA binding activity (both ssRNA and dsRNA, but ssRNA preferred) that is not specific for reovirus RNA and is mediated by sequences near the N-terminus of l1, not including the zinc finger (46,263,407). In another reassortant analysis, the L3 genome segment was shown to be a genetic determinant of isolate-dependent differences in viral yields in L cells (295).

s2

The s2 protein (47 kd, 418 amino acids) interacts with l1 to form the core shell (296,500,513). Initial estimates suggested 120 or 180 s2 copies per particle (100,449), but the recently determined core crystal structure showed that s2 forms 150 nodule-like features that reside fully external to l1 on the core surface (378). In addition to binding to l1, 60 copies of s2 in cores share a small region of interaction with l2 (378). Furthermore, it appears likely that s2, and not l1 as previously inferred (306), binds to the base of major outer capsid protein µ1 in virions and plays a role in anchoring it in the particle (378).

The functions of s2 remain poorly understood. The s2 protein shows weak affinity for dsRNA (120,407), but the significance of this finding appears uncertain given the external location of s2 in cores (378). In recombinant form, s2 must be coexpressed with core shell protein l1 for assembly of icosahedral particles to occur (513). A ts mutant whose lesion maps to the S2 genome segment encoding s2 (373) fails to assemble particles or to synthesize dsRNA at nonpermissive temperature, suggesting a role for s2 in one or more steps in replicase particle assembly, including RNA selection or replication (99,104,160,216,296). Selection and characterization of ts^+ revertants from this mutant showed the reversion events to be exclusively intragenic and to involve true reversion at s2 residue 383 in all instances (99). In reassortant analyses, the S2 genome segment encoding s2 was shown to be a genetic determinant of isolate-dependent differences in the induction of interferon a/b in cultured murine cardiac myocytes (436).

l2

Pentamers of the l2 protein (144 kd, 1,288 to 1,289 amino acids) form the turret-like projections that surround the fivefold axes of cores (367,500), providing a total of 60 l2 subunits per particle (100,131,367,378). There is evidence for l2 interactions with each of the other seven structural proteins: l1, l3, µ2, and s2 in cores and µ1, s3, and s1 in the outer capsid of virions (83,131,202,204,306,310,378,460,500). However, the evidence for l2 interactions with low-copy core proteins l3 and µ2 within particles remains weak or indirect, and these interactions now seem less likely given the recent core crystal structure showing that l2 sits fully atop the l1 shell (378). A l2 fragment lacking about 15 kd can represent more than 10% of the l2 molecules in certain preparations of virions (100,260), but the significance of this fragment is unknown. It may represent cleavage and loss of a C-terminal region of l2, as recently shown to occur *in vitro* after exposing cores to mild heat and protease (281).

The l2 protein plays important roles in particle assembly. Some ts mutants whose lesions map to the L2 genome segment encoding l2 (332) synthesize dsRNA and form core-like particles, but not whole virions, at nonpermissive temperature, suggesting a role for l2 in outer capsid assembly (160,322). A small C-terminal region of l2 appears to constitute the binding site for s1 after a larger C-terminal portion of l2 undergoes a structural rearrangement from its position in cores (83,131,281,378). Another ts mutant whose lesion maps to L2 was shown to accumulate core-like particles that are deficient in l2, the low-copy core protein µ2, and the genomic dsRNA segments at nonpermissive temperature (204). The characteristics of these particles suggest a role for l2 in replicase particle assembly (including RNA selection, replication, and packaging) as well as in outer capsid assembly (204). Also suggesting a role for l2 in RNA replication or packaging was a genetic study with reassortant viruses showing that the L2 genome segment determines an isolate-dependent difference in the generation of genome segment deletions and defective interfering (DI) stocks during serial passage of reoviruses at high multiplicity of infection (MOI) (67).

The l2 protein also mediates enzymatic activities in 5' capping of the reovirus mRNAs. A series of studies with native and recombinant l2 confirmed that it mediates the RNA guanylyltransferase activity in mRNA capping (93,152,279,280,286,424). Reovirus cores incubated with [a-^{32}P] GTP form covalent l2–GMP complexes, consistent with this activity (93,152,281,424). An early study localized the GMP linkage to lysine 226 in the N-terminal half of l2 (152), but a more recent study contested that finding and proposed lysine 190 as the linkage site (279). The latter study also showed that an N-terminal 42-kd region of recombinant l2 is sufficient for guanylyltransferase activity. The crystal structure of reovirus cores revealed that this region constitutes an independent domain that also provides the contacts to l1 and s2 in cores (378).

Evidence that l2 mediates one or both of the methyltransferase activities in mRNA capping, for which S-adenosyl-L-methionine (SAM) is the methyl donor (422), remains more indirect, as recombinant l2 has not yet been shown to mediate these activities (279,286). This lack of activity by recombinant l2 may reflect that it is monomeric whereas only the pentameric form of l2 in cores may be active at methyl transfer (279,286,378). Evidence for the methyltransferase activity of l2 includes that it is the only core protein labeled by 8-azido-SAM (414), that it includes a small central region of sequence with similarity to the SAM-binding motif of other viral and cellular methyltransferases (242), and that both l2 in cores and recombinant l2 bind to SAM in an ultraviolet (UV) cross-linking assay via a central region of sequence that overlaps the previously identified SAM-binding motif (242,280). Most recently, the core crystal structure revealed that a site in each of two separate domains formed by a large central region of l2 sequence can bind to S-adenosyl-L-homocysteine, the product of methyl transfer from SAM, suggesting that these two domains represent the two capping methyltransferases (378). Which domain represents the 7-N-methyl-transferase and which the 2'-O-methyltransferase remain undefined, but the domain formed by the more C-terminal sequences, and including the previously identified SAM-binding site (242,280), is proposed to be the 2'-O-methyltransferase (378). A small region of l2 sequence that approximates the A element of a GTP-binding motif (414) may constitute part of the RNA 5'-end binding site of one of the methyltransferases (the proposed 2'-O-methyltransferase) (378).

Conformational changes in an external portion of the l2 turret formed by C-terminal sequences of l2 are known to occur during generation of cores, resulting in an increase in the diameter of a channel through the top of the turret (130,131).

This conformational change may be important for allowing or regulating transcript capping and release from cores (27,378,516). It may also be important for allowing s1 loss during viral entry (83,131). The mechanism of this conformational change in l2 and its probable regulation by other viral proteins remain poorly characterized.

In other reassortant analyses, the L2 genome segment encoding l2 has been shown to be a genetic determinant of isolate-dependent differences in the crystallization of core particles (101), growth in enteric tissues of newborn mice after intragastric inoculation (49), transmission between newborn mice (237), growth and injury in different organs of mice with severe combined immunodeficiency disease (SCID) (194), induction of myocarditis in newborn mice (433), and induction of interferon a/b and sensitivity of viral growth to interferon a/b in cultured murine cardiac myocytes (436).

l3

l3 (142 kd, 1,267 amino acids) is a low-copy core protein (62,105,215), estimated to be present in only 12 copies per particle, or one copy per icosahedral fivefold axis (100). It has not been definitively localized within particles, but it was shown to be a component of the core shell that is not exposed to the core exterior (76). It is thought to be a constituent of the protein complexes that project into the interior of reovirus particles near the fivefold axes (130,378). Recombinant l3 was shown to interact with core shell protein l1 and core turret protein l2 (460). It is suspected to interact with those same two proteins, and perhaps also with the other low-copy core protein µ2, within particles (130,194,433).

The functions of l3 appear to relate to its role as a component of the reovirus RNA polymerase. A ts mutant whose lesion maps to the L1 genome segment encoding l3 (373) is severely reduced for dsRNA synthesis (104,216) and forms empty particles at nonpermissive temperature (160), suggesting a role for l3 in one or more steps in replicase particle assembly including RNA selection or replication. An early reassortant study indicated that the L1 genome segment determines an isolate-dependent difference in the pH optimum of core transcription, suggesting that l3 may be the viral transcriptase (127). A more recent reassortant study showed that L1 contributes to determining a difference in the amounts of transcripts produced by cores, consistent with the previous suggestion (519). A central portion of the deduced amino acid sequence of l3 includes sequence motifs common to the catalytic regions of RNA polymerases (69,241,243,326). Furthermore, recombinant, purified l3 demonstrates poly(C)-dependent poly(G) polymerase activity *in vitro* (460). These findings suggest that l3 represents the catalytic subunit of the reovirus RNA-dependent RNA polymerase, which is likely to mediate both plus- and minus-strand RNA synthesis within reovirus particles. The L1 genome segment encoding l3 was also shown to be a genetic determinant of isolate-dependent differences in growth in L cells and cultured mouse heart cells (295), growth in MDCK cells (383), induction of myocarditis in newborn mice (433), and growth and injury in different organs of SCID mice (194).

µ2

µ2 (83 to 84 kd, 736 amino acids) is another low-copy core protein, estimated to be present in about 20 copies per particle (100). It has not been definitively localized within particles but is thought to reside near the fivefold axes, either interior to (130,378) or within (204) the core shell and possibly contributing to the protein complexes that project into the interior of reovirus particles near the fivefold axes (130,378). It has not been demonstrated to interact with any other reovirus protein, but it was proposed to interact with the core turret protein l2 (204), the other low-copy core protein l3 (130,194,433), and perhaps with the core shell protein l1 as well (130,378).

The functions of µ2 are only partly understood. Temperature-sensitive mutants with a lesion in the M1 genome segment encoding µ2 fail to synthesize dsRNA at nonpermissive temperature, suggesting a role for µ2 in one or more steps in replicase particle assembly, including RNA selection or replication (99,503). Constitutive expression of µ2 in L cells allows complementation of one of these ts mutants (527). Recombinant µ2 protein was recently shown to have an RNA-binding activity (both ssRNA and dsRNA) that is not specific for reovirus RNA (65). Recent reassortant analyses showed that the M1 genome segment encoding µ2 determines a difference in the temperature optimum of core transcription (519) and contributes to determining differences in the amounts of transcripts produced by cores (519) and the NTPase activities of cores (355). Together, these findings suggest that µ2 represents a cofactor or second subunit of the reovirus RNA polymerase. The M1 genome segment was also shown to be a genetic determinant of isolate-dependent differences in plaque size and extent of cytopathic effect in L cells (318); growth in cultured murine cardiac myocytes and bovine aortic endothelial cells (294,295); growth in MDCK cells (383); induction of myocarditis in newborn mice (433,434), levels of viral RNA synthesis, induction of interferon a/b and sensitivity of viral growth to interferon a/b in cultured murine cardiac myocytes (432,436); and growth and injury in different organs of SCID mice (194). It was hypothesized that the role of µ2 protein as a determinant of viral cytopathology may explain its low level of translation *in vivo* (388), but a higher level of µ2 expression by reovirus type 1 Lang versus type 3 Dearing was recently demonstrated (527). Most recently, µ2 was suggested to play a role in determining the rate of viral inclusion formation in reovirus-infected cells (299).

More Structural Proteins in the Outer Capsid

µ1

The µ1 protein (76 kd, 708 amino acids), together with s3, forms the bulk of the virion outer capsid (449). It is present in virions in 600 copies, in the form of 1:1 complexes with s3 (100,220,260). It also interacts with core proteins l2 and s2 in virions (131,306,378). The µ1 protein is modified by addition of a myristoyl (C_{14} saturated fatty acyl) group to its N-terminus following loss of the initiator methionine (347) (Fig. 4). In virions, most µ1 appears to occur as a 72-kd fragment, µ1C, that is generated from µ1 by proteolytic cleavage (530). N-terminal sequencing localizes this cleavage between residues 42 and 43 in µ1 (220,364), indicating that µ1C is a C-terminal fragment of µ1 (see Fig. 4). The cleavage of µ1 to µ1C also yields a 4.2-kd myristoylated N-terminal fragment, µ1N, that is retained in particles in stoichiometric amounts (347) and is quite likely the same virion component identified as component viii in earlier studies (449). The capacity of µ1 to undergo this cleavage is sensitive to the residues surrounding the µ1N–µ1C junction, and these residues are also important for determining µ1 interactions with s3 (471). Based on sequence similarity to the

VP4–VP2 autolytic cleavage junction in the VP0 protein of enteroviruses, cleavage at the μ1N–μ1C junction is thought to be autolytic as well (347). A small amount of μ1 in virions (commonly £5%) appears to remain uncleaved, similar to the VP0 protein of enteroviruses. Genetic studies have implicated μ1 in determining isolate-dependent differences in the sensitivity of virions and ISVPs to inactivation with ethanol, phenol, and heat (129,208,497).

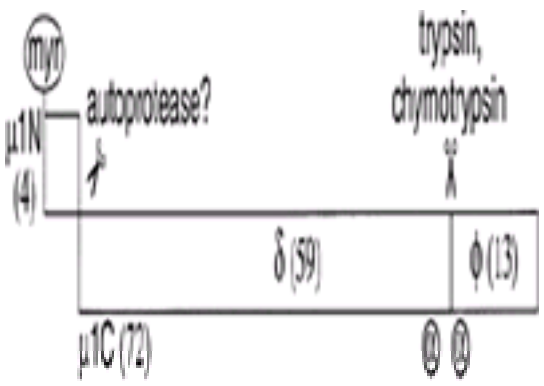

FIG. 4. Outer capsid protein μ1. Most (95%) of the μ1 protein (76 kd) in virions undergoes an assembly-related cleavage (*scissors*) into small amino-terminal and large carboxyl-terminal fragments designated μ1N (4 kd, as indicated) and μ1C (72 kd), respectively. An autoprotease activity appears to be involved in this cleavagen. The μ1N fragment (like uncleaved μ1) is modified by an amide-linked myristoyl group (*myr*), probably at its extreme amino terminus. When ISVPs are generated by the action of exogenous proteases, such as trypsin or chymotrypsin, on virion proteins, the μ1C fragment undergoes additional cleavage (*scissors*) nearer its carboxyl terminus. The products are large amino-terminal and small carboxyl-terminal fragments designated d (59 kd) and f (13 kd), respectively. The d–f cleavage junction is flanked by predicted long amphipathic a-helices (a) which are proposed to play a role in membrane interaction and penetration by reoviruses. The small amount of uncleaved μ1 protein in virions is also cleaved during generation of ISVPs to produce fragments μ1d [μ1N + d] and f.

In the cytoplasm of infected cells, 90% of free M2-encoded protein is μ1, whereas 95% of the protein complexed with s3 has been cleaved to μ1C (260). This finding suggests that the μ1N–μ1C cleavage is linked to formation of the μ1–s3 complex. This hypothesis is further supported by studies with ts mutant viruses and mutant s3 and μ1 molecules expressed in transfected cells (43,471). For example, μ1 expressed from an M2 genome segment that lacks the signal for myristoylation neither forms complexes with s3 nor undergoes cleavage to μ1C (471). Several lines of evidence suggest that when s3 and μ1 interact, both proteins undergo conformational changes that influence their functions in viral entry and assembly, respectively (430,437). μ1 interaction with s3 also inhibits the dsRNA binding activity of the latter and thereby interferes with its translational effects, suggesting a regulatory function for μ1 prior to its assembly onto particles (471,521). Complexes of μ1 and s3 are almost certainly the form of these proteins that is assembled onto cores in generating mature virions (83,260,430,437).

Several lines of evidence now indicate that a primary function of particle-bound μ1 is in penetration of the cellular membrane barrier during entry into cells at the onset of infection. A genetic difference in the capacity of ISVPs of reovirus isolates type 1 Lang and type 3 Abney to permeabilize membranes, causing ^{51}Cr release from L cells, was mapped with reassortants to the M2 genome segment encoding μ1 (277). Mutants of type 3 reoviruses Abney or Dearing, which were selected for ethanol resistance and (in the case of two of these mutants) shown by both reassortant analysis and M2 nucleotide sequencing to harbor resistance mutations in their μ1 proteins (208,497), show correlative changes in ISVP-mediated ^{51}Cr release and thermostability consistent with an effect of μ1-determined particle stability on membrane permeabilization (208). Certain μ1-specific monoclonal antibodies can block ISVP-mediated ^{51}Cr release from L cells at a postattachment step (207) and can also block virion-initiated infections of L cells at a step following both attachment and proteolytic processing (483). When assembled at nonpermissive temperature, virions of ts mutant A279 and also of reassortants containing the M2 genome segment of this mutant show a defect in entry into L cells characterized by accumulation of infecting particles within lysosomes (203). The strong hemolytic activity of ISVP-like particles derived from recoated core particles lacking s1, compared with the negligible hemolytic activity of cores, implicates μ1 in this form of membrane premeabilization as well (83). A role for the N-terminal myristoyl group on μ1/μ1N in membrane penetration was proposed (347) but remains unproven. Binding of alkyl sulfate detergents to virions, with an associated block to μ1 cleavage at the d–f junction by exogenous proteases (see later), was proposed to reflect an early, reversible step in membrane binding by μ1 during entry (82).

Another function of particle-bound μ1 appears to be in regulation of the particle-bound RNA transcriptase. An isolate-dependent difference in the conditions required for conversion of virions to cores, with associated activation of the transcriptase, was mapped with reassortants to the M2 genome segment encoding μ1 (127). Biochemical studies suggest an association between loss or rearrangement of μ1 and transcriptase activation (127,146), although the precise mechanism of this effect remains undefined. The structural changes in μ1 involved in transcriptase activation may be important for membrane penetration as well.

Despite marked sequence conservation among the M2 genome segments from different reovirus isolates (208,220,505), genetic analyses with reassortant viruses have associated M2 with a number of isolate-dependent differences in viral phenotypes, including the several described earlier. In addition, the reduced neurovirulence of reovirus type 3 clone 8 after intracerebral inoculation into newborn mice was shown to be determined by its M2 genome segment (210). Interference between reovirus isolates upon co-infection of L cells was shown to be genetically determined by the M2 genome segment and to involve steps in infection following uncoating (392,394). Polymorphisms in the M2 genome segment were also linked to isolate-dependent differences in reovirus-induced apoptosis and the inhibition of DNA

synthesis in cultured cells (383,475).

The µ1 and µ1C proteins undergo a distinct proteolytic cleavage near their shared C-terminus after exposure to proteases in vitro (51,220,223,344,425), within endocytic compartments of cultured cells early in infection (59,82,84,440,467), and within the intestinal lumen of newborn mice after peroral inoculation (28,50). This cleavage, which occurs after residue Tyr-581 with chymotrypsin and after residues Arg-584 with trypsin, generates a large (59 to 60 kd), acidic, N-terminal fragment named µ1d when derived from µ1, or d when derived from µ1C, as well as a small (12 to 13 kd), basic, C-terminal fragment named f (344) (see Fig. 4). The µ1d/d and f fragments remain bound to ISVPs in stoichiometric amounts (344). The C-terminal cleavage of µ1/µ1C was previously proposed to be required for the penetration of cell membranes during viral entry (344), but the normal infectivity and hemolytic activity of ISVP-like particles in which little or no cleavage at the d–f junction has occurred strongly suggest that this is not the case (82,83). Thus, at present, the biological significance of the d–f cleavage remains unknown. A small number of µ1/µ1C molecules remain uncleaved at the d–f junction in most or all preparations of ISVPs (100,344).

Several studies suggest that a fraction of µ1 and its fragments in virions undergo modifications in addition to myristoylation. It was reported that 2% to 4% of µ1C molecules in virions are O-glycosylated on serine or threonine residues (250). Evidence was also presented for the presence of one or more phosphoserine residues per molecule of µ1C in virions (251). It was further shown that several of the µ1C and component viii (µ1N) molecules in virions are both polyadenylated and ADP-ribosylated (75). Although cryo-electron microscopy reconstructions indicate that the µ1 protein in virions and ISVPs is centered in trimeric clusters (131), other data suggest that it is linked into disulfide-bonded dimers (211) through cysteine 679 in the f portion of µ1 (220). The role(s) of this disulfide bond in assembly or infection remains unknown.

s3

The s3 protein (41 kd, 365 amino acids), together with µ1, forms the bulk of the virion outer capsid (449), where it interacts with proteins l2 and µ1 and perhaps also with s1 (131,163,261,306,310,482). It is present in virions in 600 copies and in the form of 1:1 complexes with µ1 (100,220,260). Genetic studies with reassortant viruses implicated s3 in determining differences in the sensitivity of virions to inactivation with heat and SDS (129). In addition, by recoating ISVPs with recombinant s3 *in vitro*, the thermostability of those particles can be increased to approximately that of virions (219). Thus, s3 may play a role in stabilizing virions for survival in environments outside cells (345).

Balancing its stabilizing effects, the s3 protein must be removed from virions, by proteolysis in the natural setting, for infection of cells to proceed beyond the steps of receptor binding and endocytic uptake and trafficking (19,219,467,483,499). Within cells, s3 proteolysis is thought to occur within endocytic vacuoles, preceding penetration of viral particles into the cytoplasm, and to be predominantly mediated by acidic cysteine proteases of lysosomal origin (19,20,244,442,467). Genetic studies indicate that mutations in the S4 genome segment encoding s3 play a critical role in the establishment and/or maintenance of persistent reovirus infections, and that this effect at least partly involves mutations in s3 that enhance its sensitivity to proteolysis during entry into cells (6,19,499,511). Proteolytic removal of s3 from reovirus particles also occurs in the lumen of the small intestine during infection of newborn mice by the enteric route (28,50) and may be required for infection to proceed by that route in some cases (28), possibly by allowing viral particles to attach to M cells, through which they can be translocated across the epithelial barrier (10). Proteolysis of s3 is most likely mediated by alkaline proteases of pancreatic origin in the enteric system (28,50). A protease-sensitive region centrally located within the s3 sequence has been described (407), and additional C-terminal sequences have been identified to influence the rate at which s3 is cleaved by both acidic and alkaline proteases (219,499).

In addition to its functions before and during viral entry, s3 plays an important role in outer capsid assembly. A ts mutant whose lesion maps to the S4 genome segment encoding s3 accumulates dsRNA-containing core-like particles at the nonpermissive temperature (110,322,437). Biochemical studies with this mutant suggest that, at the nonpermissive temperature, s3 is misfolded such that it cannot interact with µ1 (283); thus it appears that s3 may be required to interact with and promote a conformational change in µ1 that enables these proteins to assemble onto core particles (437). The interaction between s3 and µ1 also causes a conformational change in s3 that renders it more susceptible to proteolysis (430), consistent with the requirement for s3 proteolysis during viral entry. Other evidence suggests that s3 may have a function early in particle assembly or RNA selection, replication, or packaging involving its association with the reovirus mRNAs soon after they are synthesized in infected cells and its continued association with these nucleoprotein complexes through the process of minus-strand synthesis and the consequent generation and selection of the 10 genomic dsRNA molecules (13). A role for s3 in RNA selection or packaging is also suggested by recent evidence that mutations in s3 are needed to permit mixing of genome segments from different reovirus isolates within certain reassortants (386).

Biochemical studies reveal that s3 binds dsRNA in a sequence-independent manner (211), and a dsRNA-binding activity has been localized to a C-terminal fragment of s3 (311,407). This C-terminal fragment contains two copies of a basic amino acid motif that has been proposed to contribute to dsRNA binding (115,282,311,485). The capacity of s3 to bind dsRNA is inhibited by association with µ1 and enhanced when certain N-terminal sequences of s3 are either removed by proteolysis or mutated (43,311,407,431,471,485,521). The positive effect of these N-terminal mutations in s3 is thought to occur through a reduction in µ1 binding to s3 and/or a reduction in steric hindrance to dsRNA binding provided by interactions between different s3 regions. Emerging evidence suggests that the dsRNA-binding activity of s3 is important for its function in translational control within infected cells (see later section).

The s3 protein occurs as a zinc metalloprotein in virions (407), and s3 binds Zn^{2+} in biochemical assays (283,407). A zinc-finger motif is found in an N-terminal portion of s3 (407). Current evidence indicates that this zinc finger includes a CCHC motif (283) similar to that found in retrovirus nucleocapsid proteins. The coordination of Zn^{2+} appears to play a structural role in s3, because mutations in the coordinating residues eliminate the capacity of s3 to bind to µ1 (431) and decrease its stability *in vitro* (431) and in cells (283). There is no evidence to support an association between the Zn^{2+}-

and dsRNA-binding activities of s3.

In most infected cells, s3 is localized to the cytoplasm and becomes concentrated in perinuclear regions where viral assembly takes place (408). However, in transfected cells and following infection with some reovirus isolates, s3 has been shown to localize to the nucleus (408,520). Nuclear localization of s3 is inhibited by mutations that destroy dsRNA binding and also by coexpression with µ1 (520). To date, no function has been ascribed to nuclear s3.

An early genetic study with reassortant viruses indicated that the S4 genome segment encoding s3 determines an isolate-dependent difference in inhibition of cellular RNA and protein synthesis (417). A recent study provided evidence that such differences in effects on translation of cellular mRNAs may be based in genetically determined differences in s3 localization within cells, with s3 proteins that are more broadly distributed in the cytoplasm providing greater sparing of cellular mRNA translation, possibly by blocking activation of the interferon-induced and dsRNA-activated protein kinase PKR (408). The differences in localization may be attributable to differences in s3–µ1 affinity between isolates (408). Other studies suggest roles for s3 in the regulation of viral transcription (16) and translation. The s3 protein was found to be enriched in the translation initiation factor fraction of eukaryotic cells expressing a cloned S4 genome segment (264) and was suggested to stimulate the translation of late (uncapped) viral mRNAs within infected cells (265,266). Several studies found that expression of s3 can stimulate expression of reporter genes (178,275,282,290,413,471,521). It was hypothesized that the effect of s3 on translation relates to its capacity to bind dsRNA and thereby sequester the activator of PKR, which phosphorylates eIF2a and inhibits translation initiation (214,275,463,521). This hypothesis is supported by the observation that s3 can substitute for the analogous dsRNA binding activity of vaccinia virus protein E3L (32).

s1

According to current estimates, the s1 protein (49 to 51 kd, 455 to 470 amino acids) is present in no more than 36 copies per virion outer capsid, or one s1 trimer per icosahedral vertex (100,465). In purified virions, some of the s1 trimers may be lost, yielding particles with fewer than one per vertex (257). A minimum of three s1 trimers per particle was found to be required for full infectivity (257). Earlier interpretations that s1 takes the form of a dimer or tetramer (22,29,30,161,343) appear to have been in error. The s1 protein interacts with l2 and perhaps also with s3 in the virion outer capsid (131,163,202,261,306,310,482). It may be capable of adopting two very different conformations, one in which it extends as an elongated fiber from the particle surface and another in which it is more folded or retracted (22,131,161,163,345).

Sequence analyses yielded a model in which residues in the N-terminal third of s1 adopt an a-helical coiled-coil structure (29,163,343). Two-dimensional reconstructions from electron micrographs of s1 fibers later revealed significant substructure within the tail region (161). Related work identified repeats of hydrophobic residues within a central portion of s1 sequences and suggested that different morphologic regions in the tail result from sequences assuming distinct supersecondary structures: alternating regions of a-helical coiled-coil and b-sheet motifs (161,343) (Fig. 5). The head appears to be formed by sequences in the C-terminal third of s1 and to have a more complex globular structure (29,136,161,163,343,473).

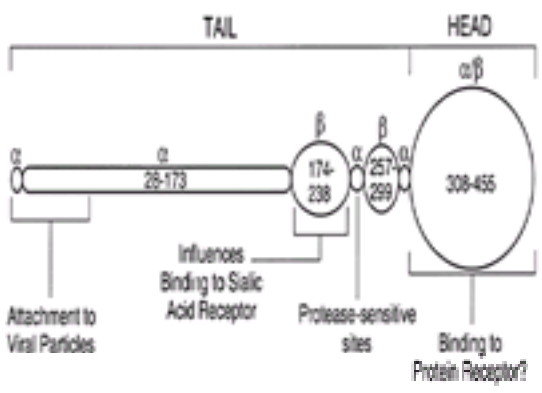

FIG. 5. Cell-attachment protein s1. Trimers of the reovirus s1 protein can be isolated from viral particles as extended fibers characterized by tail and head domains as shown. Distinct regions within the tail are proposed to be formed by sequences that assume a-helical coiled-coil and cross-b-sheet supersecondary structures as labeled [sequences assigned to the larger tail regions and head in s1 proteins from type 3 (*T3*) reovirus strains are indicated by position number]. Properties or activities associated with different regions of the type 3 s1 proteins are indicated.

Numerous studies have implicated s1 as the reovirus cell-attachment protein (14,22,124,144,261,293,363,470,490,491 and 492,517) and the protein against which serotype-specific neutralizing antibodies are directed (22,70,293,363,457,482,493,517). Sequencing of S1 genes from neutralization-resistant mutants identified two residues in the C-terminal third of type 3 Dearing s1 that influence neutralization by the monoclonal antibody G5 (31). Evidence that these mutants exhibit altered tropisms within the murine brain (234,455,456) led to a hypothesis that the C-terminal head region of s1 mediates receptor binding. Sequence similarities between type 3 Dearing s1 and an antiidiotypic monoclonal antibody directed against G5 identified other residues in the C-terminal third of s1 that may serve as receptor contacts (68,509). Other work based on the antiidiotypic antibody has identified candidate cellular receptors for this region of s1 (see later section). In contemporary work, a C-terminal proteolytic fragment of s1 and deletion mutants that retain a large C-terminal portion of s1 were found to retain L-cell binding activity (136,336,473,518). Deletion and site-directed mutagenesis within a C-terminal portion of s1 indicate that the extreme C-terminus and other conserved amino acids in this region contribute to the structure and function of the head domain (136,473).

The s1 protein also serves as the viral hemagglutinin (22,30,70,293,495,517). Hemagglutination by type 3 reovirus isolates involves binding of s1 to sialic acid residues on the erythrocyte surface (14,175,362), large amounts of which are

attached to the major erythrocyte surface protein glycophorin A (361). Strong evidence now indicates that the region of type 3 s1 that mediates glycophorin A binding and hemagglutination is distinct from the region that mediates L-cell binding. Early such evidence came from monoclonal antibodies that identify distinct s1 epitopes involved in neutralization and hemagglutination inhibition (70,457). Findings with deletion mutants (336) and proteolytic fragments (518) of type 3 Dearing s1 provided additional evidence that glycophorin A and L-cell binding are separable functions of this protein, most likely mediated by different protein regions. Analysis of deduced s1 sequences from 11 type 3 isolates that differ in capacity to agglutinate erythrocytes and bind glycophorin A subsequently provided evidence that a small central region in the s1 tail, characterized by b-sheet motifs, is involved in these properties (118). These findings were supported by studies on growth in murine erythroleukemia (MEL) cells, which indicate that growth in MEL cells is dependent on virus binding to sialylated receptors on the cell surface, that certain type 3 isolates defective for sialic acid binding (118) are also defective for growth in MEL cells, that these isolates can undergo selection for sialic acid binding and growth in MEL cells by serial passage in those cells, and that this selection involves genetic changes in the S1 genome segment resulting in amino acid changes in the central b-sheet region of the s1 tail that was previously implicated in sialic acid binding (see Fig. 5) (88,396). Recent work using chimeric and truncated recombinant s1 proteins concur with this localization (86). Binding to sialic acid appears not to be involved in hemagglutination or attachment to other cells by type 1 and type 2 reoviruses (118,360), but the alternative moieties that are bound by these isolates remain to be identified. The fact that neutralization and hemagglutination inhibition epitopes overlap in the type 1 Lang s1 protein suggests that the separation of protein and carbohydrate receptor binding functions indicated for type 3 s1 proteins may not hold true for type 1 s1 proteins (70,457). In addition, a more distal region of the s1 tail, closer to the head in primary sequence and putative structure, was recently implicated in hemagglutination by type 1 Lang s1 by using chimeric and truncated recombinant s1 proteins (86).

A flexible “neck” region has been described to separate the fibrous tail from the globular head of s1 (137). It has been recognized for some time that this region of isolated native or recombinant type 3 Dearing s1 protein is sensitive to proteolysis (22,136,137,465,518). Sequences that influence or impart this sensitivity have now been identified, as have the sites for proteolysis by intestinal serine proteases (85,137). The mechanism for protease sensitivity is proposed to involve disruption of a-helical coiled-coil structure within a limited region of the s1 tail (85). The sensitivity of type 3 Dearing s1 to proteolysis by intestinal proteases and the consequent reduction in infectivity provides a logical mechanistic explanation for the reduced capacity of reovirus type 3 Dearing to infect mice by the enteric route (85,342). In addition, because the protease-sensitive region is found between the s1 head and the sialic binding region in the tail (85,137), findings with ISVPs containing protease-cleaved type 3 Dearing s1 provide further evidence for the separation of the two receptor binding activities within two different regions of the protein (342).

The long a-helical coiled-coil tail region of s1 may allow for projection of the more distal receptor binding regions away from the particle for better accessibility for binding to those receptors. A recent study indicated that engagement of receptors on cells via the C-terminal regions of s1 leads to reversible conformational changes in more N-terminal tail regions of s1, as well as in other capsid proteins, suggesting that conformational changes in the s1 tail may be important for relaying information about receptor binding to other capsid proteins as part of the entry process (156). Consistent with this hypothesis is the finding that certain mutations in the long a-helical region of the s1 tail that are selected during persistent infections can reduce s1 oligomer stability and have effects on reovirus entry (511). Recent evidence suggests that s1 sequences near the base of the s1 tail (including residues 36 and 54) mediate a glycosyl hydrolase activity, which may be important for reovirus infections in the mammalian intestine by permitting hydrolysis of soluble or surface-bound mucin proteins and thereby better access to cell surface receptors (47).

Sequences near the extreme N-terminus of s1 are thought to form a virus-attachment region that anchors this protein to the l2 protein in viral particles (see Fig. 5). A small region of hydrophobic amino acids at the extreme N-terminus was first predicted to fulfill this function through a coupling of sequence analysis and electron microscopy (22,161,163,343). Subsequent work with C-terminally truncated recombinant s1 proteins demonstrated that residues between positions 3 and 34 (of reovirus type 3 Dearing s1) are required for virion anchoring (270,284).

A number of studies indicate that s1 folds into its native conformation via a multistep process that provides a useful model for folding of an oligomeric fiber protein (259). Monomers of s1 do not bind to cells and they exhibit extreme protease sensitivity, indicating the importance of oligomerization for s1 structure and function (268). Folding of s1 involves two distinct trimerization events. An N-terminal region of s1, which includes a portion of the predicted long a-helical coiled coil, possesses a capacity to undergo oligomerization independently of other sequences (23,136,269,271,473). N-terminal trimerization occurs co-translationally and does not require ATP or cellular chaperone proteins HSP70 and HSP90 (181,182,267,271). In contrast, trimerization of C-terminal s1 sequences is a posttranslational event that requires ATP and both of those chaperones (181,182,267,271). Additional maturation events in both N- and C-terminal regions are required to generate the final s1 structure (271).

A wide variety of phenotypic differences among reovirus isolates have been mapped to the S1 genome segment by reassortant analyses, and many of these have been proposed to relate to the function of s1 as the reovirus cell-attachment protein. Recent examples include studies that have implicated S1/s1 as a genetic determinant of phenotypic differences in inhibition of cellular DNA synthesis in L cells (416,475), induction of apoptosis in L cells (475,476) and MDCK cells (383), efficiency of infection of cultured murine cardiac myocytes (432), induction of biliary atresia in newborn mice (510), growth and injury in different organs of SCID mice (194), viral growth and neutrophil response in a rat model for reovirus-induced pneumonia (325), and the capacity of viral mutants selected during persistent infections to grow in the presence of ammonium chloride as well as in mutant cells that have been cured of persistent infection (499,511).

Nonstructural Proteins

sNS

The sNS protein (41 kd, 366 amino acids) is predicted to have a high a-helical content (381,504) but a low propensity to form a-helical coiled coils (303). It appears to exist as a small oligomer in free solution (179,183). A ts mutant whose

lesion maps to the S3 genome segment encoding sNS (373) is severely reduced in dsRNA synthesis at nonpermissive temperature, suggesting a role for sNS in replicase particle assembly including RNA selection or replication (104,216). sNS shows strong affinity for ssRNA, including, but not specific for, the reovirus mRNAs (179,180,183,184,211,382,458). It binds poorly to dsRNA (180,211,382). Binding to ssRNA is cooperative and can lead to displacement of short DNA oligonucleotides from RNA–DNA hybrids (180). A small region of sequence at the extreme N-terminus of sNS is important for ssRNA binding (179). Complexes containing sNS and ssRNA can be readily isolated from infected cells and resolved on columns or gradients (179,183,184,211,458). According to immunoprecipitation studies with protein-specific antibodies, sNS binds to the reovirus mRNAs shortly after they are synthesized in infected cells, and it remains bound in these complexes, along with other viral proteins, through the process of minus-strand synthesis and the consequent generation and selection of the 10 genomic dsRNA molecules (13). Thus, sNS appears likely to play one or more important roles in the selection, replication, and/or packaging of reovirus RNA for the assembly of progeny particles. A possible role in translation was also acknowledged (179). 15–19S complexes obtained from infected cells and containing sNS and ssRNA were reported to have poly(C)-dependent poly(G) polymerase activity (184); however, that activity was also demonstrated for purified reovirus l3 protein (460) and has not been demonstrated for purified sNS (179,382), suggesting that the activity in 15–19S complexes (184) was caused by contaminating l3.

µNS and µNSC

Although first thought to be a cleavage product of µNS (80 kd, 721 amino acids) (260), µNSC appears instead to be formed by alternative translation initiation at the second or third AUG in the M3 mRNA, in the same ORF as µNS (303,503). µNS and µNSC are thus likely to share the same sequences except for an extra 4 to 5 kd of sequence at the N-terminus of µNS. Possible functional differences between µNS and µNSC have not been addressed. A C-terminal portion of µNS/µNSC is predicted to have a high a-helical content and similarity with myosins (503), as well as a propensity to form a-helical coiled coils (303). It appears to take the form of a small oligomer in free solution (66). The µNS protein has been shown to associate with the cytoskeleton in infected cells, to which it may anchor other viral components during replication or assembly (319). According to immunoprecipitation studies with protein-specific antibodies, µNS and/or µNSC binds to reovirus mRNAs shortly after the RNAs are synthesized in infected cells and before the RNAs associate with other viral proteins (13). In addition, µNS and/or µNSC remains bound in these complexes, along with other viral proteins, through the process of minus-strand synthesis and the consequent generation and selection of the 10 genomic dsRNA molecules (13). Thus, µNS and/or µNSC appears likely to play one or more important role in the replication, selection, and/or packaging of reovirus RNA for the assembly of progeny particles. One reassortant study showed that the M3 genome segment encoding µNS/µNSC determines an isolate-dependent difference in the specific genome segments that undergo deletion during serial passage of viruses at high MOI, consistent with a role in RNA replication or packaging (67). Other studies found that µNS is a component of rapidly sedimenting particle assembly intermediates that can be isolated from reovirus-infected cells (323,322,532). Although disputed by subsequent work (446), one of these studies (323) provided evidence that µNS is a major component of the secondary transcriptase particles that produce most (95%) of the viral mRNAs within reovirus-infected cells (see later section). Recent evidence that recombinant µNS protein can bind to cores in large amounts *in vitro*, but does not inhibit their transcriptional and capping activities, is consistent with the original evidence of Morgan and Zweerink (323) and suggests that µNS may play a role in transcript production and outer capsid assembly within infected cells (66).

s1s

The s1s protein (14 to 15 kd, 119 to 125 amino acids) is highly variable between reovirus isolates, even within the same serotype (78,117,135). It is strongly basic, and an N-terminal cluster of basic residues is its most conserved feature. A role for this basic protein in binding to nucleic acid was proposed (218), and localization of s1s to both cytoplasm and nucleus was noted (40,384). As a second translation product derived from the S1 genome segment, s1s might be responsible for some of the differences in biologic properties that have been mapped to S1 and tentatively attributed to the other protein derived from this segment, the cell-attachment protein s1 (see earlier section). When expressed to high levels in uninfected mammalian cells, recombinant s1s does not affect cellular DNA synthesis or cause cytopathic effects; however, when expressed to high levels in cells that have also been infected with certain reovirus isolates, recombinant s1s potentiates the viral inhibition of cellular DNA synthesis and the cytopathic effects of infection as well (147). These findings suggest a role for s1s in reovirus effects on host cells. Recent evidence for a reovirus mutant having a stop codon early in the s1s ORF indicates that this protein is dispensable for reovirus growth in L and MDCK cells as well as for induction of apoptosis in L cells (384). Whether it is required for replication in certain cells or performs some other function related to growth and/or spread in host animals remains to be determined. The s1s protein has alternatively been called p14 (80), s1bNS (328), ss (404), and s1NS (40).

GENETICS

Mutants

Mutants Obtained by Selection, Screen, or Passage

Temperature-Sensitive Mutants

Reovirus ts mutants were classically defined by their reduced capacity to replicate at 39°C as opposed to 31°C (159). Recent studies indicate that 40°C is a more effective temperature for distinguishing certain ts mutants (102,203). Temperature-sensitive mutants from 7 of the 10 genetic groups (genome segments) of reovirus type 3 Dearing were first isolated after chemical mutagenesis with nitrous acid (groups B, D, and E), nitroso-guanidine (groups C, F, and G), or proflavin (group A) (159,212). Mutants from the other three groups were isolated from type 3 Dearing stocks subjected to serial passage at high MOI (group H) or from persistently infected cultures (groups I and J) (3,4,8). All groups but F were assigned to discrete genome segments by reassortant analyses (332,368,369,373). The prototype group F isolate was assigned to the M3 segment based on its capacity to complement ts mutants from the other groups (369). A recent study failed to confirm the original findings for the prototype isolates of groups F, H, and J (99), indicating that these isolates

cannot fulfill their initial promise of providing isolated ts lesions in the M3, M1, and S1 genome segments, respectively. The same and another recent study nonetheless described a new set of ts mutants (99,102), one of which has been shown to represent a new prototype isolate for ts group H (M1 segment) (99). To date, sequencing studies have identified nucleotide and amino acid changes in mutants from groups C (102,507), E (504), G (110), and H (99). Temperature-sensitive mutants in groups A, B, C, D, E, G, and H have been analyzed extensively with respect to their morphologic, biochemical, and biologic properties (discussed at other places in this chapter).

Suppressor Mutants

Reversion of ts mutants to the ts^+ phenotype might occur through a change in the same gene, either at the site of the original mutation (true reversion) or at a second site (intragenic suppression). Alternatively, mutation in a second gene might suppress the defect produced by the original mutation (extragenic suppression). A recent study found that one reovirus ts mutant (tsC447, with a lesion in the S2 genome segment encoding core nodule protein s2) undergoes true reversion exclusively (102); nevertheless, a number of revertants of other reovirus ts mutants result from extragenic suppression (371, 372, 374). A commonly described mechanism for extragenic suppression involves mutation in a gene product that interacts directly with the original ts product. Interactions between reovirus protein pairs µ1-s3, µ1-l1, and l2-s1 were inferred in this manner (221, 306).

Deletion Mutants and Defective Stocks

Some reovirus isolates accumulate deletion mutants during serial passage at high MOI (5, 67, 356, 358, 411). Genome segments L1 and L3 are most commonly deleted, but L2 and M1 deletions are also seen. A series of deleted M1 segments were analyzed and found to lack internal sequence regions (525). Based on the smallest deleted M1 segments, the minimum sizes for retained 5'- and 3'-terminal regions of the plus strand were 132 to 135 and 182 to 185 bases, respectively, suggesting that these regions contain the essential signals for RNA synthesis and packaging. One genetic study compared isolates type 1 Lang and type 3 Dearing, which differ in their capacity to accumulate deletion mutants (67). This study showed that the L2 genome segment determines whether or not deletions accumulate, and that the M3 genome segment determines in which segments the deletions occur. The L2 and M3 gene products l2 and µNS/µNSC may play a role in synthesis or packaging of reovirus RNA such that they influence the generation or amplification of deletion mutants.

Some reovirus stocks that have been serially passed at high MOI can be classified as DI stocks (3, 5, 6 and 7, 67, 119, 356, 358, 411). The traits of defective stocks include the presence of deletion mutants, the capacity to interfere with growth of wild-type (wt) virus (see later), and the capacity to establish persistent infections. The role of deletion mutants in the latter two properties is unclear, because defective stocks contain a variety of mutants, including a high frequency of tsG (S4 genome segment) mutants (3, 5), some of which are known to mediate interference (3, 81). Given that the nondeleted genome segments in defective stocks are normal with respect to transcription and reassortment, it was suggested that interference and facilitation of persistent infections are linked to specific mutations in nondeleted segments such as S4, rather than to the deleted ones (5, 6, 67).

Neutralization-Resistant Mutants

Neutralizing monoclonal antibodies directed against the cell-attachment protein s1 were used to select neutralization-resistant mutants of isolate type 3 Dearing, and changes in the mutants were localized to two residues in the C-terminal third of s1 (31, 456). The mutants were found to be altered in their pathogenic behaviors within newborn mice (234, 455, 456), possibly because their mutations fall in or near a receptor-binding region of s1.

Inactivation-Resistant Mutants

Physicochemical agents (e.g., heat or ethanol) can cause large reductions in reovirus infectivity, and differences between isolates in their sensitivities to these agents can be attributed to specific genome segments by reassortant analyses (128, 129). One such difference in ethanol sensitivity was genetically mapped to the M2 genome segment (129). Ethanol-resistant mutants were subsequently isolated in which relevant mutations were also localized to M2, within a 200-amino-acid central region of the encoded major outer capsid protein µ1 (208, 497). These mutants exhibit increased thermostability and a decreased capacity to permeabilize cells as detected by release of ^{51}Cr (208), a marker for membrane rupture during viral entry (56, 277). Thus, mutants selected with physicochemical agents may be used to study the structure and function of reovirus particles, as well as to define the mechanisms of inactivation by these agents.

Other Mutants

Other types of reovirus mutants obtained after passage in cells or animals, with or without a defined mechanism for selection, have been described. These include small-plaque mutants (7), cold-sensitive mutants (8), mutants selected during persistent infections in L cells and genetically mapped to the S1 and S4 genome segments (119, 499, 511), mutants selected for binding to sialic-acid-containing receptors by growth in MEL cells and genetically mapped to the S1 genome segment (88), and mutants with altered organ tropism and virulence obtained after passage in mice and genetically mapped to several genome segments including M1 and S1 (193, 194, 434, 435). A particularly fortuitous mutant is one of those selected for growth in MEL cells which, in addition to having a mutation in S1 that affects the sialic binding activity of s1, has a second mutation in S1 that introduces a stop codon near the beginning of the s1s-encoding ORF (88). This mutant was used to show that expression of s1s is dispensable for reovirus replication and induction of apoptosis in L and MDCK cells (384).

Genetically Engineered Mutants or Mutations

It has been demonstrated that reovirus mRNAs can be infectious after transfection into cells (386, 389), and this infectious RNA system has been used to construct a double ts mutant using virally produced RNAs obtained from two different

single ts mutants (387). Despite the clear promise of this approach for genetic engineering of reoviruses, it has not yet been modified to allow the efficient recovery of infectious particles containing genome segments derived from cloned and mutated DNA copies. As a result, genetic engineering with reoviruses has been largely restricted to studies in which isolated mutant gene products have been analyzed for activity *in vitro* or in transfected cells. In a recent study, recombinant µ2 protein constitutively expressed in L cells was shown to complement the growth of a tsH mutant (a lesion in the M1 genome segment encoding low-copy core protein µ2) at nonpermissive temperature (527). This offers a new genetic approach for identifying sequence determinants of µ2 function and promises to be applicable to other reovirus gene products as well. In addition, a series of recent reports have demonstrated that genetically engineered reovirus outer capsid proteins µ1, s1, and s3 can be bound to the surfaces of subvirion particles (ISVPs or cores), regenerating virion-like particles that are infectious (83,151,219). This offers another new genetic approach for identifying sequence determinants of µ1, s1, and s3 functions during the entry phase of productive infection.

Interactions Between Viruses

Reassortment

Reassortment of genome segments between reoviruses occurs not only in cultured cells but also in mice (496). Sequencing studies indicate that reassortment in nature is a major determinant of reovirus evolution (see later). Reassortment was first demonstrated in two-factor crosses (157,159). L cells were co-infected with two ts mutants at permissive temperature, and reassortants were detected by assaying for ts^+ progeny at nonpermissive temperature. If a cross between two ts mutants did not produce ts^+ reassortants, the mutants were considered to have lesions in the same genome segment. On the other hand, if a cross between two ts mutants resulted in ts^+ reassortants, the mutants were considered to have lesions in different genome segments. In this way, the available ts mutants were separated into five different genetic groups (157). The discovery of electrophoretic differences for protein µ1/µ1C in certain ts mutants provided an additional marker (µ+ versus µ–, to indicate wt versus faster mobility) that could be used in genetic crosses to evaluate reassortment (106). Three-factor crosses were performed using this mobility marker in combination with the ts phenotype and confirmed that reovirus genome segments behave as discrete genetic elements during reassortment (107). In subsequent experiments, ts mutants representing the five remaining genetic groups were identified, and separate co-infections involving one ts mutant and one wt isolate were used in reassortant analyses to assign each ts group to a particular genome segment (see earlier section). Reassortment of genome segments between wt isolates, irrespective of serotype, has been subsequently demonstrated in numerous studies.

If reassortment of genome segments from two co-infected isolates were a random process, then almost all of the progeny from the co-infection should be reassortants [1,022 of 1,024 (210) possible combinations of genome segments from the two parents]. In practice, however, a much lower frequency of reassortants has been seen among co-infection progeny [3% to 20% in one series of crosses (159)]. A variety of factors could contribute to reovirus reassortment's exhibiting such deviation from randomness, including that not all genome segments or their protein products from two isolates can be productively paired without accommodating mutations. Supportive data in this regard came from a statistical study of 83 reassortants derived from reoviruses type 1 Lang and type 3 Dearing. These reassortants showed significant deviations from randomness for the distributions of parental alleles in certain of the possible pairings of the 10 genome segments (346). Possibly reflecting the same or a similar phenomenon is evidence that reovirus reassortants commonly contain mutations in the S4 genome segment, suggesting that such mutations may be necessary to improve the fitness of certain reassortants for independent replication (228,229,386).

Complementation and Interference

Complementation refers to interactions of viral gene products in co-infected cells that result in enhanced yield of one or both parental viruses without a change in genotype. Interference refers to the capacity of certain viruses to decrease the yield of other viruses upon co- or superinfection. Although reassortants were readily identified after co-infections with reovirus ts mutants, enhanced yields of progeny at the nonpermissive temperature were often not observed (157,159). This lack of complementation was explained by the phenomenon of interference. Temperature-sensitive mutants from groups A, B, C, and G were found to interfere with the growth of wt virus, whereas those from groups D and E were not (81). Genetic crosses established that interference is a dominant trait. The degree of interference with the growth of wt virus can be substantial (50% or more), and it increases if the MOI of the interfering ts mutant is increased (81). Significant complementation occurs only if both parental ts mutants are noninterfering (81,216). Interference with growth of wt virus is also a property of defective high-passage stocks, which may reflect the frequent presence of interfering group G ts mutants (3,5).

The molecular basis of interference with reoviruses remains poorly defined in most cases. It was suggested that interfering ts mutants encode mutant proteins that become incorporated into progeny virions and reduce their infectivity (5). In support of this model, one study identified dominant-negative mutations in s1 that interfere with the capacity of wt s1 to assemble into functional oligomers (271). Mutant proteins from interfering ts mutants may act similarly to interfere with assembly and function of reovirus protein complexes. Recent studies on the mechanism of interference during co-infections with certain pairs of wt reoviruses revealed that interference occurs by 8 to 10 hours after infection, after viral entry and uncoating but before or during accumulation of newly synthesized dsRNA (392,394). These results are consistent with a model in which interference occurs at the stage of progeny particle assembly (394). Genetic evidence from one of these studies identifies the M2 genome segment (which encodes major outer capsid protein µ1) as the primary determinant of interference in this system (392).

Other Types of Interactions

There is no evidence for recombination between either homologous or heterologous reovirus genome segments. Reoviruses can undergo multiplicity reactivation after inactivation with genome-damaging agents like ultraviolet radiation (300), probably reflecting the capacity of viruses to reassort mRNAs produced from nondamaged genome segments. There is recent evidence for phenotypic mixing of proteins within progeny virions assembled during co-infections with

pairs of reovirus isolates that have distinguishable properties attributable to those proteins (393). A recent study found no evidence for super-infection exclusion during temporally asynchronous infections of cultured cells with pairs of reovirus ts mutants, which may have significance for the evolution of reoviruses in nature by allowing co-infection and reassortment even when different viruses infect cells at different times (236).

Naturally Occurring Variation

Exploitation for Genetic Studies

Reovirus isolates obtained from nature commonly exhibit qualitative or quantitative differences in phenotypes of biological interest. Substantial progress in attributing these phenotypic differences to individual genome segments, and thus presumably to specific sequence differences between the two parental alleles of these segments, has come from the generation and characterization of reassortant viruses derived from the two parents. Early studies used this approach to identify the S1 segment as the primary determinant of a difference between reoviruses type 1 Lang and type 3 Dearing in tropism and virulence for newborn mice after intracranial inoculation (492,494). Numerous subsequent studies, involving these and other isolates, have succeeded in attributing other phenotypic differences to single genome segments (127,210,237,354,417,434). In other cases, reassortant analysis has attributed the phenotypic difference to more than one genome segment at a time, indicating that genetic differences in two or more viral components are involved (49,194,355,433,499,519).

The availability of reovirus genome sequences has permitted another type of study that takes advantage of naturally occurring variation among isolates. In this approach, the protein sequences deduced from individual genome segments of different isolates are compared in an effort to link specific, variable sequences with a phenotypic difference that is known to be linked to these segments. In successful applications of this approach, a small variable region in the cell-attachment protein s1 was implicated in the failure of s1 from four type 3 isolates to bind sialylated proteins on the erythrocyte surface (118), and a single variable amino acid in s1 was implicated in the susceptibility of s1 from two other type 3 isolates to undergo cleavage by intestinal proteases (85). In each of these cases, additional studies have confirmed the reliability of the original conclusions (85,88). Other applications have been reported for studies of the l1 and s3 proteins (198,235).

Evolution of Reoviruses

Although useful for scoring reassortants, electrophoretic mobility differences between homologous genome segments and proteins of different reovirus isolates are not generally meaningful for classification (209,370). Nucleotide and deduced amino acid sequences provide the most reliable information for understanding reovirus evolution (241). Sequences are available for all 10 genome segments of the prototype isolates type 1 Lang, type 2 Jones, and type 3 Dearing. Except for the serotype-determining S1 segment, homologous segments from the prototypes are similar at the level of 70.6–97.8% and 80.0–99.3% identity in pairwise comparisons of nucleotide and deduced amino acid sequences, respectively. For every gene but S1, the type 2 Jones sequence is most distinct, which led to a suggestion that it diverged from a common ancestor prior to type 1 Lang and type Dearing (506).

The s1-encoding S1 genome segments of reoviruses exhibit the greatest extent of variability among the 10 segments. The variability includes differences in length, the need for multiple gaps to align deduced s1 sequences, and reduced sequence similarity (only 26% to 49% identity in s1 sequences in pair wise comparisons) (135,343). Among the three prototype isolates, the type 3 Dearing S1 sequence is most divergent. On the other hand, examination of S1 genes from a set of 11 type 3 isolates revealed no differences in length or need for gaps to optimize s1 alignments, and sequence divergence similar to that between prototypes for other genome segments was seen (86% to 99% identity in pair wise comparisons of deduced s1 protein sequences) (117). In sum, these findings suggest that three versions of the S1 genome segment, corresponding to the three serotypes, arose from progenitors at different times in the past and have diverged at a rate similar to that of other segments since those times.

Reassortment of genome segments between viruses is another important force in reovirus evolution. Variable rates of change in third codon bases seen for different genome segments from type 1 Lang and type 3 Dearing suggest that the segments in these two isolates were combined by reassortment after having had distinct evolutionary histories (506). A study of S2 genome segment sequences from 11 type 1 and type 3 isolates was the first to show convincingly that a segment other than S1 has diverged independently of the serotype of isolate from which it was obtained for sequencing (87). Subsequent studies have yielded similar findings for L2, S3, and S4 genome segment sequences from multiple type 1, type 2, and type 3 isolates and also showed topological differences in the phylogenetic trees drawn for these and S2 sequences obtained from the same isolates (87,189,235). These findings indicate that each of these genome segments has had an evolutionary history distinct from those of many or all of the other segments with which it is combined in the current isolates, consistent with ongoing reassortment of segments in nature. The same studies also showed that evolution of the genome segments is independent of host of origin. Despite this strong evidence for evolution at the level of individual genome segments, one study has shown evidence for the existence of coevolving sets of reovirus proteins (482) and another has shown evidence for nonrandom segregation of segments during generation of reassortants in the laboratory, indicating bias for or against certain RNA or protein pairings (346). The significance of these possible biases on the evolution of reoviruses in nature remains uncertain.

REPLICATION CYCLE

A diagram of the reovirus replication cycle is shown in Figure 6. Subsequent sections of this chapter discuss details of the depicted events, but a brief description follows here. The first step in reovirus infection is attachment of the virion (or ISVP) to receptor molecules on the cell surface. Following *attachment*, virion particles are taken up from the cell surface by receptor-mediated *endocytosis* and delivered into vacuoles resembling endosomes and lysosomes. Within these vacuoles, reovirus outer capsid proteins undergo specific proteolytic cleavages, which are acid dependent and represent an essential step in the infection process. In some situations, ISVPs are generated by *extracellular proteolysis*, and the

entry of such particles is acid independent and may not require endocytosis. The mechanism by which reoviruses interact with and penetrate the vacuolar or plasma membrane barrier is unknown, but it appears to depend on preceding *proteolysis*, as only the ISVP form exhibits *membrane interaction* in available assays. Coincident with or following *penetration*, a derivative of the ISVP (perhaps a core particle as shown in Fig. 6) becomes transcriptionally active and begins synthesis of the 10 capped viral mRNAs. These products of *primary transcription* are used for the translation of viral proteins by the cellular *protein synthesis* machinery. In addition, the early transcripts associate with newly made viral proteins to form progeny RNA *assortment* complexes. Within subsequently derived replicase particles, each of the 10 packaged plus strands serves as a template for *minus-strand synthesis.* Viral mRNAs are also transcribed by progeny subviral particles (*secondary transcription*), which have a unique protein composition. These "late" transcripts serve as the primary templates for viral protein synthesis later in infection. The final steps of virion *capsid assembly* are not well defined but may involve the addition of preformed complexes of outer capsid proteins to core-like particles. Mature virions undergo an inefficient process of *release* from infected cells following cell lysis.

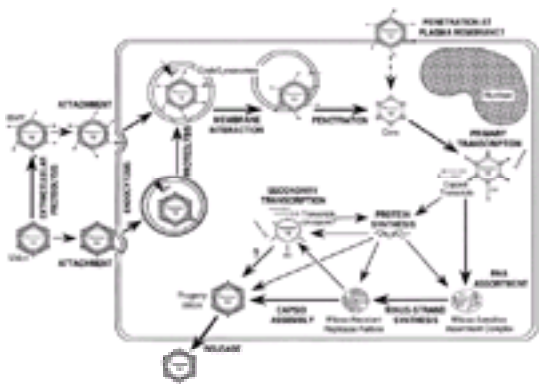

FIG. 6. Reovirus replication cycle. See text for detailed explanation. The primary steps in replication are labeled in *bold capital letters.* Virions, ISVPs, and cores, as well as other assembly-related particle forms are indicated. Capped plus-stranded RNAs—as part of the 10 dsRNA genome segments, as cytoplasmic transcripts, and as assortment elements—are indicated (*5'-terminal open circles* represent caps). Uptake from the cell surface is shown to involve receptor-mediated endocytosis, with viral particles sequentially associated with clathrin-coated pits, clathrin-coated vesicles, endosomes, and lysosomes (the last three compartments are acidic as shown). The roles played by individual reovirus proteins are not indicated here.

Early Steps in Replication: Entry into Cells and Production of Primary Transcripts

Attachment to Cell Surface Receptors

Numerous studies have investigated the attachment of reoviruses to erythrocytes and other cells, some of which are capable of undergoing productive infection. Most studies have utilized cells *in vitro* (see later), but some have investigated the binding of reoviruses to different cells within host animals. These studies generally indicate that defined receptor moieties, exposed on the cell surface, are responsible for binding reovirus particles via specific interactions with the viral hemagglutinin and cell-attachment protein s1. Attachment to surface receptors is considered a required first step in the productive infection of cells. Interactions of cell surface proteins with other reovirus proteins, contributing to attachment or subsequent steps in infection, remain possible but undefined.

Hemagglutination

Hemagglutination has been used as a convenient assay to study the attachment capabilities of reovirus particles. Isolates from all three serotypes agglutinate human type O erythrocytes, but only type 3 isolates agglutinate bovine red cells. This difference between strains type 1 Lang and type 3 Dearing was mapped to their S1 genes, implicating the encoded structural protein s1 as the reovirus hemagglutinin (495). Hemagglutination can also be mediated by purified s1, and biochemical and molecular genetic studies have suggested that a central region of sequences in type 3 s1 proteins is involved in this activity (see earlier section).

A decrease in hemagglutination is commonly noted after erythrocytes are treated with periodate or proteases, suggesting that one or more glycoproteins on the red cell surface serves as the receptor for virus binding prior to agglutination (14,421). There is strong evidence, including the sensitivity of hemagglutination to treatment of red cells with neuraminidase and to treatment of virions with sialoglycoproteins, that sialic (N-acetylneuraminic) acid residues are essential components of the erythrocyte receptor for type 3 reoviruses (14,88,175,361). Glycophorin A is the primary sialoglycoprotein found on human erythrocytes and is capable, in purified form, of binding to the s1 proteins of type 3 Dearing and other type 3 strains (118,336,361,482,518); thus, glycophorin A was specifically proposed to represent the erythrocyte receptor for type 3 reoviruses (361).

Hemagglutination by type 1 and type 2 reoviruses has been studied less thoroughly than that by type 3 isolates, but it does have some different characteristics. Unlike type 3 Dearing and some other type 3 strains, reovirus type 1 Lang is deficient in binding to sialoglycoproteins, including glycophorin A, as determined by its S1 gene (118,360). The erythrocyte receptor for type 1 and type 2 reoviruses remains undefined.

Attachment to Other Cells

Studies of reovirus attachment have been performed with a variety of cultured cells, utilizing different virus strains and techniques of analysis. Attachment to L cells by strain type 3 Dearing appears to be mediated by one or more

populations of saturable receptors. Estimates for the number of attachment sites per cell range between 1×10^4 and 5×10^5, and the receptors exhibit a dissociation constant for virus binding of 0.25 to 13 nM (9,14,144,173,406). Maximal attachment is generally achieved after 30 to 90 minutes regardless of temperature (14,144,173). Studies in other cell types or with strain type 1 Lang have provided similar estimates for the copy numbers and dissociation constants of receptors (9,144,173,288,406,479). Competition experiments have disputed whether type 3 Dearing and type 1 Lang bind to the same (261) or different (9,144,490) receptors on L cells; a recent study argues for one receptor being shared by these two strains, plus a second being restricted to type 3 Dearing (9). There is general agreement that attachment is mediated primarily or exclusively by the s1 protein.

The nature of the L-cell receptor(s) for reovirus type 3 Dearing is well studied but remains incompletely defined (reviewed in ref. 405). There is generally consistent evidence for involvement of a sialoglycoprotein based on the decreased virus-binding capacity of L cells treated with proteases, periodate, neuraminidase, or particular lectins (14,173,174,395). The capacity of type 3 Dearing virions or s1 protein molecules to bind L cells is similarly decreased in the presence of sialoglycoproteins (174,360,361,509), gangliosides (14), or free sugars that contain a-linked sialic acid residues (362). The latter observations have been used to argue that the L-cell receptor, like the erythrocyte receptor described earlier, includes sialic acid. One study suggested that the a-anomer of sialic acid is the minimal receptor determinant required for reovirus (type 3 Dearing) recognition (362). Correlation between the capacity of certain type 3 strains to bind glycophorin and their capacity to bind and productively infect MEL cells (88, 396) is consistent with a model in which binding to sialic acid is critically important for infection of at least some cells.

Other data suggest that one or more specific proteins, perhaps sialylated glycoproteins, can serve as cell surface receptors for type 3 Dearing. Initial data in this regard were acquired using an antiidiotype approach (reviewed in ref. 158). Antibodies were raised against the anti-s1 monoclonal antibody G5, which blocks the binding of type 3 Dearing to cells and thereby neutralizes its infectivity. These preparations of G5-specific antibodies, as well as similarly derived monoclonal antibodies, exhibited behaviors predicted for antiidiotypic antibodies: They were capable of blocking the binding of type 3 Dearing to cells, presumably by mimicking within their own structures a portion of the attachment site on s1 and thus binding to s1-specific receptors on the cell surface (68,339,509). A monoclonal antiidiotypic antibody was subsequently used to identify a 67-kd membrane glycoprotein, having notable structural similarity to the b-adrenergic receptor, as a probable receptor for reovirus type 3 Dearing (94). Subsequent studies have provided mixed support for this hypothesis (89,90,125,406), and it currently seems unlikely that this protein represents the sole or even primary receptor for reoviruses on many cells. Other reports describe receptors for reovirus type 3 Dearing that include the epidermal growth factor (EGF) receptor (469), a 54-kd protein on endothelial cells recognized by both type 3 Dearing and type 1 Lang (479), and multiple sialoglycoproteins on L and human erythroleukemia cells (89). Reports describing specific receptors for reovirus type 1 Lang are less frequent but include a 47-kd protein from mouse intestinal epithelial cells (490) and undefined moieties on Caco-2 cells (9) and mouse ependymal cells (339).

Whether sialic acid or another protein element(s) alone is sufficient to mediate reovirus attachment to cells resulting in productive infection remains in question. A two-step mechanism involving initial binding to sialic acid and subsequent interaction with a specific protein receptor has been suggested (362). Available data suggest that differences in receptors are likely to exist between cell types and between reovirus serotypes or strains. It may also be important to distinguish attachment that leads to productive infection from attachment that is nonproductive. The capacity of attachment to lead to virus uptake from the cell surface by endocytosis may be an important distinguishing feature in this case (89,395). The importance of multivalent attachment via two or more of the s1 oligomers present in viral particles remains undefined. Differences in the attachment process for virions and ISVPs are also unknown.

Endocytic Uptake and Proteolytic Activation

Thin-section electron micrographs of cells soon after infection reveal reovirus particles associated with clathrin-coated pits or vesicles at or near the plasma membrane, suggesting that uptake from the cell surface can occur by receptor-mediated endocytosis (56,59,395,467) (see Fig. 6). Particles are subsequently observed within vacuoles resembling endosomes and lysosomes (56,59,177,395,442,467). Treatment with colchicine and nocodazole does not inhibit endocytosis, but it does inhibit the movement of these virus-containing vacuoles toward perinuclear regions, suggesting that vacuole translocation occurs along microtubules (177). Only some of the proteins to which reovirus particles bind on the cell surface may be capable of signaling endocytic uptake (89,395).

Experiments with radiolabeled virions provide evidence for proteolysis of viral proteins within hydrolytic compartments of the endocytic pathway (late endosomes or lysosomes), starting 20 to 30 minutes after infection at 37°C (442,443,467). The proteolytic cleavages are notable in that they involve only certain outer capsid components. Specifically, degradation of protein s3 and conversion of protein µ1C to its stable cleavage product d are observed, generating particles very similar to ISVPs that result from *in vitro* proteolysis (59,84,344,440,467). The reproducibility of these limited cleavages suggested that the generation of ISVP-like particles by proteolysis within lysosomes may be a required step in reovirus infection.

More direct evidence for proteolytic activation as a required step in infection arose from an observation that infection is inhibited by the weak base ammonium chloride, which raises the pH within endosomes and lysosomes (72). Later experiments revealed that an early step in infections initiated by virions, but not ISVPs, is inhibited by this agent (50,119,287,467). In addition, the extent of inhibition was found to correlate with the extent to which cleavages of proteins s3 and µ1C in infecting virions are blocked. It was suggested that, by raising the pH within endosomes and lysosomes, ammonium chloride inhibits the activity of acidic proteases within those compartments and blocks the generation of ISVPs. ISVPs may resist the block to infection by ammonium chloride because they have undergone proteolysis *in vitro* and thus no longer contain an acid-dependent step in their replication cycle (467). Proteolysis appears to activate reovirus particles for the next steps in infection, membrane interaction and penetration (see later).

In certain settings, proteolytic activation of virions occurs outside cells, before attachment and endocytosis (see Fig. 6). When newborn mice are perorally inoculated with virions, proteolysis to generate ISVPs occurs within the lumen of the

small intestine and is probably mediated by pancreatic serine proteases (28,50). Extracellularly generated ISVPs are apparently required to initiate infection of mouse tissues by that route (10,28), but the basis for this requirement is unknown. ISVPs generated *in vitro* may have the capacity to bypass endocytic uptake and to penetrate into the cytoplasm directly through the plasma membrane (see later).

Interaction with and Penetration of Cell Membranes

As with other nonenveloped viruses, the mechanism by which reoviruses cross the membrane barrier during entry into cells (see Fig. 6) remains poorly defined. Three assays have demonstrated a direct interaction between reovirus particles and lipid bilayers. One involves the capacity of particles to effect the release of ^{51}Cr from preloaded L cells (56,277). Another revealed the capacity of particles to induce conductance through artificial planar bilayers (472). Finally, reovirus particles can mediate lysis of erythrocytes, resulting in the release of hemoglobin (82,83,219). Membrane interaction in all these assays is restricted to ISVPs: Virions and cores did not exhibit the activity. Moreover, the membrane interactions did not require acid pH. These findings are consistent with a model in which ISVPs are required intermediates in the process of reovirus entry into cells and in which the acid-dependent step in reovirus entry (the one inhibited by ammonium chloride) is proteolytic activation rather than membrane interaction (277,345,467,472).

Available data implicate the outer capsid protein µ1, which covers most of the surface of ISVPs, in mediating direct interactions with membranes. A strain difference in the capacity of ISVPs to mediate ^{51}Cr release from L cells was mapped to the M2 gene, which encodes µ1 (277). Changes in the ^{51}Cr release phenotype have been associated with certain µ1 mutations (208). Studies with recoated cores indicate that the µ1 protein is the only additional outer capsid protein that must be present in those particles for erythrocyte lysis to proceed (83). Features of the µ1 protein noted to be consistent with a role in membrane interaction include the modification of it and its amino-terminal fragment µ1N with a myristoyl group (347), and the presence of a predicted pair of long, amphipathic a-helices flanking the cleavage junction between the µ1d/d and f fragments of µ1/µ1C that are found in ISVPs (344). A conformational change in µ1 is expected to precede reovirus-membrane interaction according to one model (277,344,345). The relative importance to membrane interaction of s3 degradation and µ1/µ1C cleavage into fragments µ1d/d and f remains somewhat unclear (20); however, some data indicate that the µ1/µ1C cleavage into µ1d/d and f is dispensable (82,83).

Direct interaction of viral components with a cell membrane is expected to be one step in a process that gives reovirus particles access to the cytoplasm, where there are substrates for transcribing and capping the viral mRNAs and ribosomes for translating them (see Fig. 6). As nonenveloped viruses, reoviruses cannot use fusion as a general mechanism for this process, and little is known about the steps that follow membrane interaction and permit reovirus components to penetrate into the cytoplasm. Suggested possibilities are that membrane interaction results in local disruption of the bilayer such that virus enters the cytoplasm directly through a large breach, or that a more precise, pore-like structure is formed by viral proteins within the membrane, through which viral components enter the cytoplasm (56,59,344,345,472).

A current model (see Fig. 6) suggests that when ISVP-like particles are generated from virions by proteolytic activation within late endosomes or lysosomes, membrane interaction and penetration are most likely to occur within and from those vacuoles (56,59,345,467). When ISVPs are generated *in vitro*, however, they may be capable of penetrating directly through the plasma membrane, prior to endocytosis (see Fig. 6) (56,59,277), although other work suggests that ISVPs also undergo endocytic uptake and sequestration into vacuoles prior to penetration (467). Whether penetration through plasma membrane by extracellularly generated ISVPs occurs routinely during reovirus infections remains to be determined.

Plus-Strand RNA Synthesis (Transcription)

Notable features of reovirus transcription include the stability and productivity of the transcriptase and its encasement within icosahedral particles (24,52,127,230,272,426,445). A common system for *in vitro* transcription includes reovirus cores, ribonucleoside triphosphates, and an ATP-regenerating source. The products of transcription are single-stranded RNAs, which are released from the transcribing particle (24,27). Reovirus transcription is conservative and asymmetric (24,272,445). Ten distinct transcripts have been identified, which by hybridization and sequencing (247,301) represent full-length copies of the 10 genomic plus strands. Except for abortive initiation (see later), there is no evidence that any of the gene segments give rise to less-than-full-length transcripts as part of the viral replication strategy.

If appropriate substrates are provided, transcripts produced by purified reovirus particles *in vitro* can undergo capping and methylation at their 5' ends, indicating that the capping enzymes are also present within the particles (see later). Capping imparts increased stability to reovirus mRNAs (164) and increases the efficiency with which many mRNAs are translated within eukaryotic cells (424). Reovirus transcripts are not polyadenylated: their 3' ends are fully complementary to the 5' ends of the genomic minus strands that serve as templates for their synthesis.

Transcriptase Activation

Early studies showed that the virion-associated transcriptase can be activated by heat (52) or by treatment with proteases such as chymotrypsin (426). For protease treatments yielding cores as end products, transcriptase activation was correlated with loss of protein µ1 from particles (55,127,223). In addition, a strain difference in the treatment conditions needed to generate cores and activate transcription was mapped to the M2 gene, which encodes µ1 (127). A number of parameters (e.g., the concentration and nature of monovalent cations, divalent cations, proteases, and viral particles) were found to affect whether transcriptase activation occurs during protease treatments, in general correlating with whether cores were produced (51,54,55,60,127,223).

Although some studies suggest that ISVPs are transcriptionally active (16,84,425,440), others indicate that the transcriptase is latent in ISVPs but can be activated under certain conditions without additional proteolysis (54,55,58,146,403). One study correlated the switch-on of transcriptase activity in ISVPs with a change in the µ1d

fragment of μ1 (146). From these studies, a model was proposed in which virions undergo transcriptase activation via two steps (55,59,146,345). The first step requires proteolysis and produces ISVPs. The second step is protease independent, produces transcriptionally active particles, and may be linked to penetration during entry into cells.

Although virions cannot make full-length transcripts, they have been reported to synthesize short oligonucleotides when given appropriate substrates (151,515). This important finding suggests that the transcriptase is constitutively active in virions but capable of limited or no elongation. Capping enzymes are also active in virions (74,231,515); thus, transcriptase activation must primarily involve relief of a block to elongation. The nature of this block is unknown, but it may relate to movement of the dsRNA templates (151,226,424). Changes in the outer capsid are essential for activation (see earlier), implying that interactions between outer and inner capsid proteins may produce the elongation block. One study suggested that structural changes in the core occur at the onset of transcription (366), and it may be that these changes are required for elongation but are inhibited by the outer capsid proteins in virions and ISVPs. A conformational change in l2 (131) may be important for transcriptase activation in that it opens a fivefold channel through which the substrates or products of transcription may be required to pass.

Initiator oligonucleotides are the major transcription products produced *in vitro* by both virions and cores, even though cores can at low frequency elongate these into full-length transcripts (151,514,522). This and other findings indicate that the onset of elongation is the rate-limiting step in reovirus transcription (230,514,515,522). Three phases of transcriptase activity are thus suggested: efficient, repetitive initiation yielding large amounts of initiator oligonucleotides, an inefficient onset to the elongation process, and elongation yielding smaller amounts of full-length transcripts (515).

Primary Transcription Within Cells

Two phases of transcription by reoviruses are known to occur within infected cells, based on the derivation of the transcribing particle. Primary transcription is mediated by particles derived by partial uncoating of infecting particles (59,84,440,442,443). It results in production of capped transcripts that serve both as mRNAs for translation and as templates for minus-strand synthesis within progeny particles. Primary transcripts are detected by 2 hours after infection, reach a maximum at 6 to 8 hours, and decrease to undetectable levels by 12 hours (224,442,530). Secondary transcription is mediated by particles assembled from newly synthesized RNA and protein molecules and is the source of 95% of the transcripts produced during infection (216,523). Secondary transcripts have been reported to remain uncapped, but this has been disputed (see later section).

Primary transcription may be subject to regulation within cells, but some authors have disputed these findings as well (224,441,530). Transcripts from four “pre-early” genome segments (L1, M3, S3, and S4) have been reported to be preferentially synthesized during the first several hours of infection (357,451,489). Moreover, transcription from the six other genes was suggested to require new protein synthesis because it is blocked with cycloheximide (258,425,489). One hypothesis is that a cellular repressor prevents transcription of the six later genes and that a protein encoded by a pre-early gene interferes with its activity (258,357,523).

The nature of the primary transcriptase particle remains in question; however, because of their transcriptional activity *in vitro*, cores are assigned this role in one model (see Fig. 6). In one study, transcriptionally active particles derived from input particles were isolated from infected cells and were shown to have the characteristics of cores, perhaps indicating that additional uncoating occurs in association with or subsequent to penetration (59). Because proteinase K was used to separate the particles from cell debris in this study, however, degradation of outer capsid components may have occurred before the particles were characterized (523). Other studies suggest that the primary transcriptase particle is more similar to an ISVP, in that it still contains the μ1 protein (16,84,425,440,443).

The intracellular site of primary transcription also remains undetermined. Thin-section electron micrographs have been reported to show small numbers of core-like particles free within the cytoplasm of newly infected cells (49,59), suggesting that the primary transcriptase particle is introduced fully into the cytoplasm (see Fig. 6). In fact, most reovirus particles in such micrographs are located within endocytic vacuoles (59,442,467). Although these may be particles that have not yet succeeded in initiating infection, they might also represent the primary transcriptase particles. Thus, another model was proposed in which the primary transcriptase particle remains within a vacuole but inserts its l2 pentamers through the membrane so that mRNAs can be extruded into the cytoplasm (467).

Discrete Enzyme Activities in Reovirus Transcription and mRNA Capping

Each of the steps in reovirus transcription and mRNA capping (Fig. 7) (167) is mediated by an enzyme present in cores and encoded by a viral genome segment. The 5' cap of reovirus transcripts includes a 7-N-methyl guanosine linked by three phosphate groups to the 5'-terminal, template-encoded guanosine present in all reovirus mRNAs (153,165). The 5'-terminal, template-encoded guanosine is 2'-O-methylated (153,165). The next residue in all reovirus mRNAs is cytidine, which can also undergo 2'-O-methylation, but by a cellular cytoplasmic methyltransferase (121). Reovirus capping activities can be uncoupled from transcription and readily function when exogenous substrates, including preformed oligonucleotides and reovirus mRNAs in some cases, are incubated with viral particles (168,321,337).

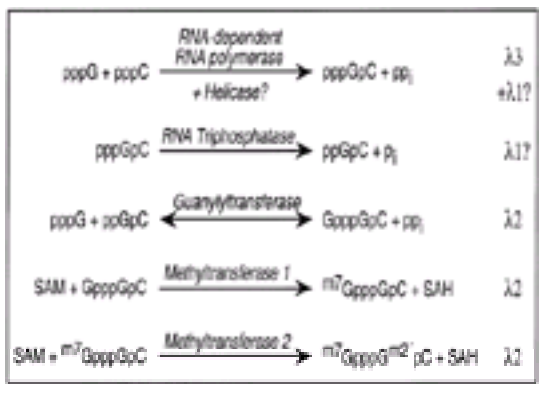

FIG. 7. Enzymatic activities in transcription and capping by reoviruses. Polymerization of nucleoside triphosphates (shown here for the first nucleotide pair) as specified by a genomic dsRNA template is mediated by the dsRNA-dependent RNA polymerase. The RNA triphosphatase generates a nucleosidyl diphosphate at the 5' end of the nascent mRNA and sets the stage for formation of the dimethylated 5' cap by sequential actions of the guanylyltransferase and methyltransferases. The role of an independent helicase in reovirus transcription is proposed but not proven. Individual reovirus proteins proven or suspected to mediate each activity are indicated at *right.* SAM, S-adenosyl methionine; SAH, S-adenosyl homocysteine.

RNA Polymerase

Early work failed to associate polymerase activity with any individual reovirus proteins after disruption of cores (226,230,500). The transcriptase (dsRNA-dependent RNA polymerase) was later suggested to be formed by portions of both core proteins l1 and l2 because of their apparent labeling by pyridoxal phosphate during transcription (320,321). Recent work indicates that the minor core protein l3 is likely to be the catalytic subunit of the transcriptase (69,127,243,326,460). A limited spectrum of activity [poly(C)-dependent poly(G) polymerase] has been reported for l3 expressed in isolation, which probably indicates that other core proteins are needed to form the complete transcriptase (460). The l3 protein is also likely to be a primary component of the ssRNA-dependent RNA polymerase that operates during minus-strand synthesis. Sequences in reovirus RNAs that are specifically recognized by the polymerase (e.g., initiation sites) have yet to be defined.

RNA Helicase

The double-stranded nature of the reovirus genome necessitates an RNA duplex unwinding activity for transcription to proceed. This activity might be inherent in the polymerase but also may be localized to another core protein and take the form of a classical RNA helicase (44,354,355,460). One report suggested that the antiviral drug ribavirin inhibits reovirus replication by interfering with helicase activity (376). Some recent evidence suggests that helicase activity may be associated with core shell protein l1 (44,354).

RNA Triphosphatase

An RNA triphosphatase (RNA triphosphate phosphohydrolase) initiates formation of the 5' cap on reovirus mRNAs by releasing inorganic phosphate from the originally triphosphorylated 5' end of the transcript, thereby yielding a 5' diphosphate group (see Fig. 7). An NTPase nucleoside triphosphatase has been found in reovirus virions and cores (53,231,354,355) and may represent this enzyme. Recent work with recombinant l1 protein indicates that it has such an activity, suggesting that it performs this function during 5' cap generation by reovirus particles (45).

RNA Guanylyltransferase

An N-terminal domain of protein l2 has been defined as the reovirus guanylyltransferase (280,378). Its enzymatic mechanism includes formation of a covalent l2–GMP intermediate, probably at lysine 190, using GTP as substrate (93,152,279,423). The GMP is subsequently transferred to the 5' diphosphate of reovirus mRNAs (see Fig. 7). The guanylyltransferase is promiscuous in its specificity for GMP-acceptors in that PP_i, GDP, GTP, and both ppG- and ppA-terminated oligonucleotides work as substrates (93,167). A GTP-dependent, pyrophosphate exchange activity associated with cores (484) represents guanylylation plus its reverse reaction. After methylation, transcript termini become resistant to pyrophosphate exchange (167); thus, reversibility of guanylylation may be required to ensure that proper 5'GpppG caps are formed on transcripts to act as substrates for methylation (see later).

RNA Methyltransferases

Final proof is lacking for the protein that mediates methyltransferase activities to modify the 5'-terminal guanosines of reovirus mRNAs (see Fig. 7), but a role for l2 is strongly indicated by the presence of two methylase-like domains identified in the crystal structure of core-bound l2 (378). SAM serves as methyl group donor for these reactions yielding S-adenosyl homocysteine (SAH) as a by-product (154,167). Indeed, SAH was found to bind both methylase-like domains of l2 in core crystals (378), and one of these regions was found to undergo cross-linking to radiolabeled SAM in other experiments (280). The 5'-terminal structure of reovirus mRNAs is specifically recognized by the methyltransferase(s), as GpppG and GpppGC can act as methyl acceptors but GppG, GppppG, and GpppGA cannot (424).

Organization and Mechanism of the Transcription Machinery

The sequential action of enzymes that synthesize reovirus mRNAs implies a precise structural organization within the

core. Some studies suggest that capping of nascent mRNAs occurs when they are only 2 to 15 nucleotides long (167,321), in which case the transcriptase and capping enzymes must be close together. Because preformed oligonucleotides and reovirus mRNAs can be capped by cores (168,321,337), the capping enzymes must be accessible to external solvent; however, antibodies have not been found to inhibit any transcription-related activity (424).

Transcription-related enzymes may be located in complexes near the fivefold axes of reovirus particles. Electron micrographs of transcribing cores suggest that mRNAs are released through the l2 spikes that protrude upward around the fivefold axes of cores (27,500). This idea is supported by reconstructed images from cryoelectron microscopy showing a channel through the l2 pentamer that is open in cores (131,310). The low copy number in which l3 is found in cores (about 12 copies) has also been used to argue that it is located near the fivefold axes.

Each of the 10 reovirus gene segments may represent an independent transcriptional unit. Both *in vitro* and in cells later in infection, transcripts from the 10 segments are produced at rates that are approximately proportional to the reciprocals of their lengths (24,225,445,489,530). Given that transcript elongation is the rate-limiting step in transcription (see later), this finding suggests a model for transcription in which each of the 10 genes is transcribed independently, and not as part of a linked array (225,226,424). A feature of this model is that it involves at least 10 transcriptases within the reovirus core (445). Electron micrographs of transcribing cores with multiple mRNAs being simultaneously extruded around the particle perimeter support this idea (27). Both moving transcriptase and moving template models for reovirus transcription have been proposed (226,424,515). Experiments in which transcription was inhibited by cross-linking genomic dsRNA are consistent with both these models (337,424); however, the moving template model is generally accepted. According to this model, a set of transcription-related enzymes is fixed near the base of each l2 spike within the core. It is proposed that the entire length of each dsRNA gene segment moves past the fixed transcriptase and that the nascent mRNA is directed past the capping enzymes and out the l2 spike (378,516). The liquid crystalline state of the packaged genomic dsRNA (131,199) may permit it the freedom of movement required by this model.

Later Steps in Replication: Amplification of Viral Products and Assembly of Progeny Virions

Translation of Viral mRNAs

Shortly after the onset of infection, there is a gradual increase in synthesis of reovirus proteins and a decrease in synthesis of cellular proteins (186,417). Newly synthesized viral proteins are detected by 2 hours after infection, and by 10 hours most of the proteins synthesized in the infected cell are viral in origin (530). The capacity of viral mRNA to associate with ribosomes may be a host-range determinant, as certain avian reoviruses can enter mammalian cells and transcribe their early mRNAs yet fail to initiate protein synthesis (42,285). The mechanism by which viral protein synthesis comes to predominate in infected cells is not well understood.

In addition to regulation of translation of viral versus cellular mRNAs, translation of the different reovirus transcripts is regulated. Reovirus mRNAs differ in translation frequency by as much as 30-fold (225). Because the different genome segments are transcribed at variable rates, inversely proportional to segment length, and because the transcripts appear to have similar stabilities, differences in the amounts of each viral mRNA provide one source of variability in the amounts of each protein that are synthesized (258,530). A second source of variability is in the translation frequency of the different mRNAs. Such variability has been found in both infected cells and *in vitro* translation systems (17,169,191,273,304,305,530,531). Nucleotide sequences of reovirus mRNAs at the –3 and +4 positions flanking the initiator AUG contribute to differing translation efficiencies *in vitro* (245); however, other nucleotide positions may influence the efficiency of translation of these mRNAs *in vivo* (41,329,385). Because the 5' nontranslated regions of the reovirus mRNAs are short (12 to 32 bases), this length may also contribute to translation rate; for example, the two reovirus proteins made in largest quantities—µ1 and s3—have the longest 5' nontranslated regions. For the S1 mRNA, from which two unrelated proteins are translated, it was proposed that translation rates are regulated at the level of polypeptide elongation (41,126,148). The observation that the M1 mRNA is translated much less efficiently *in vivo* than *in vitro* has suggested that its translation may be influenced by negative regulatory factors in cells (388). Reovirus mRNAs also may differ in capacity to compete for components of the translation machinery (64,285,377). Several studies suggest that levels of translation may be affected by the influence of different viral mRNAs on negative regulators of translation, such as the dsRNA-activated protein kinase (41,48,400).

Assortment and Packaging of the 10 Viral mRNAs

The mechanism ensuring that 10 unique dsRNA segments are assembled into each newly formed virion remains unknown. Pieces of evidence that the reovirus genes are assorted selectively are that a particle-to-pfu ratio as low as 1 has been reported (454), and that the central cavity of reovirus particles is not large enough to accommodate many more than the 10 unique segments (131,199,341). It is generally accepted that assortment of the 10 segments occurs at the level of the reovirus mRNAs, and that minus-strand synthesis to generate dsRNA occurs later, within a nascent viral particle (486,528,529) (see later and Fig. 6). It has been suggested that assortment and minus-strand synthesis may be more intimately linked than previously interpreted (13).

Assortment is likely to involve signals that identify an RNA as viral and not cellular, as well as signals that specify each of the 10 segments as unique. The relevance of either RNA–protein or RNA–RNA interactions to this process is unclear. All 10 reovirus gene segments contain short conserved regions at the 5' and 3' ends of their plus and minus strands, but it is not known if these sequences play any role in packaging. Sequences near the termini of some reovirus ssRNAs may interact in a panhandle-like structure, which may be important for packaging (87,274,526). Analysis of mutants containing internal deletions of their M1 genes identified sequences within 130 to 190 nucleotides of the 5' and 3' termini that contain the minimum required signals for packaging (525). The plus strand of each genomic segment contains a 5' cap identical to that on mRNAs made by primary transcriptase particles (166), so the cap might serve as a packaging signal as well.

One early study hypothesized that sNS plays a role in mRNA assortment and packaging because of its capacity to bind

ssRNA (211). Protein assemblies, containing primarily sNS and apparently capable of binding to selected regions of reovirus mRNAs, were subsequently isolated from infected cells, consistent with the idea that this protein plays a significant role in the earliest stages of particle assembly (183,184,458). In a more recent study, protein-specific antisera were used to precipitate protein–RNA complexes from infected cells in an attempt to identify components of the assorting particle (13). This work suggested that sNS, as well as μNS and s3, associate with individual reovirus mRNAs to form small nucleoprotein complexes soon after transcription, but that μNS or s3 (not sNS) binds to the mRNAs first. Recent evidence that sNS binds to ssRNA with positive cooperativity and demonstrates an ATP-independent, duplex-unwinding activity is consistent with a role for this protein in packaging and/or minus-strand synthesis (179,180).

Minus-Strand Synthesis: The Replicase Reaction

Each packaged plus strand serves as a template for synthesis of one minus-strand copy, which remains base-paired to the plus strand after synthesis and thereby regenerates the genomic dsRNA (1,398,399,410,528). Minus-strand synthesis proceeds from an initiation point at the extreme 3' end of each template, and once the minus strand is synthesized, it remains within the nascent progeny particle. The viral replicase catalyzes a single round of minus-strand synthesis. Initiation of minus-strand synthesis, but not elongation, appears to depend on continuing protein synthesis (489), but this effect remains poorly understood.

Although preparations of replicase particles are often heterogeneous and include particles with transcriptase activity (323,398,487,529), it seems likely that these two activities are associated with discrete types of particles (323). Particles with replicase activity have a buoyant density similar to that of virions, are morphologically indistinct, and contain the viral core proteins with reduced amounts of l2 and other outer capsid proteins relative to virions (323,529). The replicase activity associated with nascent particles is susceptible to RNase, but once minus-strand synthesis is complete, the particles become RNase-resistant (1). Recent work suggests that l3 acts as the ssRNA-dependent dsRNA polymerase of reoviruses (460), but the roles of other proteins in minus-strand synthesis remain undefined. At end of minus-strand synthesis, RNA polymerase is positioned to jump strands and begin plus-strand synthesis using the minus strand as template.

Secondary Transcription

Secondary transcription is defined as that mediated by newly assembled subviral particles within infected cells. These particles must be derived from those with replicase activity, and they are distinguishable by sedimentation behavior, by the presence of a full complement of dsRNA, by the presence of variable amounts of protein μNS, and by reduced amounts of l2 and the other outer capsid proteins (323,447,532). The appearance of “late” viral mRNAs represents transcription by progeny subviral particles (secondary transcriptase particles) (323,447,524,529). According to some studies, these secondary transcriptase particles contain latent capping enzymes and produce uncapped mRNAs (447,523,524). These uncapped viral mRNAs are proposed to be translated preferentially at later times in infection. Late viral transcripts begin to appear at 4 to 6 hours after infection, reach maximum amounts (greatly exceeding the quantity of primary transcripts) at 12 hours, and subsequently decrease (252,448,489,523). Whether they serve only for translation into proteins or whether they may also be packaged into progeny particles and serve as templates for minus-strand synthesis remains controversial (157,324,410,523). The recent evidence that recombinant μNS protein can bind to cores without inhibiting their transcription and capping activities, while at the same time blocking outer capsid assembly, is consistent with a model in which μNS serves to increase the production of capped transcripts within infected cells (66). It is not known if particles that engage in secondary transcription can go on to form mature virions (see Fig. 6).

Assembly of the Viral Capsids

A great deal remains to be understood about the protein and nucleoprotein complexes involved in assembling the inner and outer capsids in reovirus particles (see Fig. 6). The earliest reovirus particles may be ones that contain reovirus mRNAs primarily in complex with s3 and the nonstructural proteins μNS and sNS (13,183). The next particle along the assembly pathway is described to lack nonstructural proteins, to include both inner and outer capsid proteins, and to be RNase sensitive (1,323). These “replicase particles” contain an ssRNA-dependent dsRNA polymerase activity and appear to be engaged in minus-strand synthesis (323). With the completion of minus-strand synthesis, the replicase particles become RNase resistant, probably reflecting the occurrence of structural rearrangements within the particle (1,523). Additional copies of the outer capsid proteins may be added to form complete virion particles (323,532). A final step in morphogenesis is synthesis of the virion-associated oligonucleotides, which appears to occur as the viral transcriptase undergoes inhibition during outer capsid assembly (16,38,151,347,439,532).

Many of the reovirus structural proteins exhibit some degree of self-assembly, in the absence of viral RNA or a full complement of viral proteins. For example, cells coexpressing the major inner capsid proteins l1 and s2 form particles that are morphologically similar to core shells (513). When l2 and l3 are coexpressed with l1 and s2, they are incorporated into particles as well, the former creating spikes that project from the inner capsid surface as expected (513). Other findings suggest that l1 and s2 may self-assemble into oligomers (dimers or trimers) before or after interacting in larger assemblies (102,131). The l2 protein, however, does not form pentamers in the absence of other proteins (286). The exact order in which these proteins come together to form nascent infectious particles, and the roles of RNA and the minor core protein μ2 in this process, are unknown.

Assembly of the outer capsid is also poorly understood. The major outer capsid proteins s3 and μ1 bind together in solution to form hetero-oligomers (131,211,260,471,530). Whether the s3-associated cleavage of μ1 into fragments μ1N and μ1C (260,347,471) is required for assembly is unknown. The fact that a mutant with a ts lesion in S4 (which encodes s3) results in the accumulation of core-like particles as assembly intermediates (160,322) may suggest that preformed complexes of μ1 and s3 are required to bind to nascent particles. Similar observations with a ts mutant in L2 (which encodes l2) may suggest a role for l2 in initiating the binding of these complexes to particles (160,322,368). Recently developed systems for recoating reovirus cores with recombinant outer capsid proteins have provided additional evidence that preformed complexes of μ1 and s3 are required for assembly into particles and that the assembly of μ1 and

s3 can occur independently of s1 (83,151). A significant body of work has addressed the self-assembly of s1 oligomers. Sequences near the amino terminus of s1 are likely to mediate its interactions with l2 within virions (22,131,161,163,270,284,343).

Release from Cells

There is little or no evidence for a specific mechanism such as membrane budding or vesicular transport by which reovirus particles might be released from infected cells in the absence of cytolysis. Thus, release of newly assembled reovirus virions is thought to follow cell death and the associated breakdown of the plasma membrane. Recent evidence indicates that apoptosis is an important mechanism of reovirus-induced cell death in the case of type 3 reovirus isolates (114,383,475,476).

EFFECTS ON THE HOST CELL

Viral Factories and Interactions with the Cytoskeleton

Reovirus-infected cells develop cytoplasmic inclusions that are not bound by cellular membranes (11,188,379). Inclusions first appear as phase-dense granules scattered in the cytoplasm, but these move toward the nucleus and increase in size as infection progresses (160,379,415,453). Viral factories contain dsRNA (188,444), viral polypeptides (109,160,299,379,453), and both complete and incomplete particles (18,109,160,379), but they do not contain ribosomes (415). Particles are often found in crystalline arrays. The characteristics and temporal development of viral factories can vary with growth conditions and virus strain (160,299). The µ2 proteins of reoviruses type 1 Lang and type 3 Dearing appear to be the primary determinant of a difference in the rate of inclusion formation observed with these two strains (299). A mechanistic description of the viral factories as “organelles” for reovirus replication and assembly remains in its infancy.

Immunocytochemical studies reveal progressive disruption and reorganization of the vimentin (intermediate) filament network in reovirus-infected fibroblasts (415). Vimentin filaments are specifically incorporated into viral factories and may play a direct role in replication (109,415,418). The nonstructural protein µNS may associate with vimentin filaments to anchor structures involved in viral assembly to the network (319). Disruption or reorganization of intermediate filaments may cause changes in cell shape that typify the cytopathic effect of reovirus infection and may contribute to cell injury (415,418).

Immunocytochemical studies reveal little change in the distribution of microtubules and microfilaments within reovirus-infected cells (415). In addition, experiments with microtubule-disrupting agents suggest that intact microtubules are not required for productive reovirus infection in cultured cells (18,108,452). Microtubules extend directly through viral factories (18,108,109,160,415,453), nevertheless, and there is evidence to suggest that proteins s1 (18) and µNS (319) may each associate with them. Other studies implicate microtubules in the transport of reovirus particles within endocytic vacuoles early in infection (177).

Inhibition of Cellular DNA Synthesis and Induction of Apoptosis

One consequence of reovirus infection can be the inhibition of cellular DNA synthesis (142,186,416,475). Inhibition of DNA synthesis is detected 8 to 12 hours after infection of L cells with type 3 strains (142,186,416,475), occurs more rapidly as the MOI is increased (429), and has been suggested to involve a G1/S transition block (103,143,195,197). Inhibition of L-cell DNA synthesis also occurs with UV-inactivated virions, but not with cores or empty virions (196,255,416,429). In an early genetic study, the basis for a strain difference in inhibition by both live and UV-inactivated virions of T1L and T3D was mapped to the S1 genome segment (416), which encodes both the cell-attachment protein s1 and the nonstructural protein s1s. Genetic studies indicate that S1 is also the primary determinant of strain-specific differences in the induction of apoptosis (383,475,476). Like inhibition of cellular DNA synthesis, apoptosis can be induced by UV-inactivated, replication-incompetent virions and it can be blocked by antibodies directed against the cell-attachment protein s1 (476).

The observation that both strain-specific differences in DNA synthesis inhibition and apoptosis induction segregate with the S1 genome segment suggested that these two processes might occur through related pathways. Recent studies do not support this hypothesis. Studies using a s1s-deficient reovirus strain demonstrate that reovirus induces cell cycle arrest at the G2/M transition, that this effect requires the nonstructural protein s1s, and that it occurs in the absence of apoptosis (365). Current efforts are focused on understanding the cellular pathways that are involved in reovirus-induced apoptosis *in vitro* and *in vivo*. Evidence suggests that induction involves cellular proteases including calpains (114) and caspase 8 (92), is blocked by Bcl-2 overexpression (383), is dependent on NF-kB activation (98), and involves the TRAIL-receptor binding pathway (92). More work is needed to establish the relationships among the various molecules implicated to date in reovirus-induced apoptosis.

Given the fact that not all reovirus strains induce apoptosis to high levels, the importance of this process in reovirus replication and disease induction remains somewhat uncertain. Neither is it clear if any reovirus-encoded molecules function to block apoptosis. The results of several studies support the notion that reovirus-induced apoptosis does not negatively impact viral growth (383) and does not depend on efficient viral replication (114). However, virus-induced apoptosis may play a significant role in pathogenesis, as one recent study revealed a correlation between areas of viral growth in the central nervous system (CNS) and apoptosis within those tissues (359).

Effects on Cellular RNA and Protein Synthesis

Reovirus infection can also result in the inhibition of cellular RNA and/or protein synthesis (186,252,276,417,530). Viral replication is required for this effect; moreover, inhibition is MOI dependent, suggesting that increasing amounts of viral products have increasing effects (417). In one case, a strain difference in the inhibition of cellular RNA and protein

synthesis was mapped to the S4 genome segment, which encodes the s3 protein (417). This result was initially interpreted as evidence that s3 plays a direct role in the mechanism of translational inhibition, but more recent studies suggest that s3 functions to block an inhibitory signal in infected cells (408). Some cell lines support reovirus infection yet are resistant to inhibition of cellular protein synthesis (112,123,317).

The molecular mechanism(s) that result in protein synthesis inhibition in reovirus-infected cells have yet to be determined, but several lines of indirect evidence suggest that s3 may influence the level of translation by regulating the activation of the interferon-induced, dsRNA-activated protein kinase, PKR. Activation of the dsRNA-activated protein kinase results in phosphorylation of eIF-2a and inhibition of translation initiation. *In vitro* studies, and others in heterologous viral systems, indicate that s3 can down-regulate PKR by sequestering its dsRNA activator (32,214,275,521). The ability to interfere with PKR activation is consistent with the finding that expression of s3 in transfected cells can stimulate translation from a reporter gene (178,290,413,471,521).

As yet, we do not understand the molecular basis for reovirus strain-specific effects on cellular protein synthesis. The s3 molecules from strains with distinct phenotypes are highly homologous in regions proposed to mediate dsRNA binding (115,235). Several pieces of evidence are consistent with a model in which strain differences in s3–µ1 affinity determine the amount of free s3 available to bind dsRNA and block PKR activation (178,214,275,408,471,521). The finding that s3 is localized throughout the cytoplasm in cells in which cellular translation is not inhibited, but is localized to perinuclear viral factories in cells in which cellular translation is inhibited, provides support for a model in which s3 down-regulates the dsRNA-activated protein kinase locally, typically sparing viral but not cellular protein synthesis from the inhibitory activity of PKR (408).

There is some controversial evidence that late in reovirus infection there is a switch to cap-independent translation. There are reports that late reovirus transcripts may lack a 5' cap (446,524), and some studies suggest that reovirus infection induces a modification of the cell translation machinery such that uncapped mRNAs are preferentially translated over capped (cellular) mRNAs (447,448). In one study, extracts from reovirus-infected cells were shown not to support translation of capped mRNAs (450). It has been speculated that a cellular protein required for capped mRNA synthesis may be inactivated in these infected cells (523). To date, however, there is no evidence that either EIF-4G or EIF-4E, translation factors that are known to be modified or inactivated in other virus-infected cells, are inactivated in reovirus-infected cells (140,239). Other studies imply that infection does not result in modification of the existing translation machinery but instead induces a factor that stimulates translation of uncapped mRNAs (266); moreover, protein s3 can apparently function as such a factor *in vitro* (264,265). Reports in conflict with the preceding ones indicate that reovirus-infected cells can translate capped and uncapped mRNAs with equal efficiency (123,330), suggesting a hypothesis that the preferential translation of reovirus mRNAs in infected cells is mediated by mRNA competition for a limiting translation factor (64,285,377). The reasons for discrepancies between studies are unclear; they may reflect the complexity of mechanisms that contribute to regulation of translation in reovirus-infected cells.

Interferon Induction

Reoviruses can induce infected cells to express interferon (205,254,418,436). With ts mutants, interferon induction correlates with yields of infectious virus but not with amounts of viral dsRNA, ssRNA, or protein made in infected cells (254). Using myocarditic and nonmyocarditic reovirus strains, one genetic study mapped the viral determinants of interferon induction to the M1, S2, and L2 genome segments encoding core proteins µ2, s2, and l2, respectively (436). A subset of these segments determines myocarditic potential and mRNA levels in infected cardiac myocyte cultures (432). These results suggest that levels of viral mRNA may determine the extent of interferon induction.

It is generally accepted that the genomic dsRNA of reoviruses can serve as a potent inducer of interferon during infection (205,254,289). The reovirus replication cycle, throughout which the genome remains encased within a protein capsid, may have evolved in part to prevent the genomic dsRNA from inducing a florid interferon response. Regions of dsRNA formed within particular reovirus mRNAs (for example the S1 mRNA) (48) might also play a role in interferon induction. The induction of interferon b in certain cell types in response to reovirus infection was recently shown to depend on interferon regulatory factor 3 (353).

Treatment with UV has been used to study interferon induction by reoviruses (205,254). Interferon induction by viral particles is far more resistant to UV inactivation than is infectivity. UV-treated reoviruses induce interferon more rapidly than occurs during productive infection, suggesting that a different mechanism is involved. A range of UV doses was found to increase the potency of strain T3D as an interferon inducer; in addition, UV treatment turned one ts mutant (tsC447) into an extremely potent inducer, even at nonpermissive temperature. It was proposed that UV treatment destabilizes the viral core so that genomic dsRNA from input particles escapes into the cytoplasm (205).

Interferons may inhibit reovirus replication by a variety of mechanisms. In general, interferon a/b appears to block the translation of early reovirus mRNAs (502). As discussed earlier, interferon-induced expression of the eIF-2a kinase, PKR, may explain the inhibition of viral protein synthesis in some reovirus-infected cells (113,192,350,401); however, interferon g is a poor inducer of this kinase and decreases the yield of progeny virions without having a major effect on viral protein synthesis (176,402). In other studies, cells treated with interferon a/b were found to contain an 2',5'-oligo(A)-dependent endoribonuclease (RNase L) that cleaves reovirus mRNAs and may facilitate the antiviral state (21,314,315,351); however, whether an endoribonuclease contributes to inhibiting the translation of reovirus mRNAs within cells in which the dsRNA-activated protein kinase has been proposed to function remains controversial (314,315,352). Reovirus strains can differ in the extent to which their replication is inhibited by interferon (217). Several studies have demonstrated that reovirus can replicate efficiently in interferon-treated cells despite activation of antiviral effector enzymes (111,155).

Effects on Other Functions in Differentiated Cells

Some studies have identified reovirus effects on differentiated cells. In MDCK (polarized epithelial) cells, reoviruses

produced persistent infections characterized by failure to form tight junctions, reduced EGF receptor expression, and increased expression of the adhesion molecule VCAM (317). In 3T3 (primary fibroblast) cells, reoviruses also produced persistent infections, characterized in this case by decreased expression of EGF receptors and increased expression of insulin receptors (480). Thus, reovirus persistence in a variety of differentiated cells can significantly alter cellular functions, including some involved in cellular growth control.

A number of interesting early studies demonstrated that transformed cells are more susceptible to reovirus-induced cytolysis than are untransformed cells (132,201). Until recently, there were few clues to explain the molecular basis of these observations. Evidence now suggests the involvement of the EGF receptor-linked signal transduction pathway in the efficiency of reovirus infection in differentiated cells (464,466). More recent studies demonstrate that activation of the *ras* signalling pathway (an event downstream of EGF receptor activation) renders cells susceptible to reovirus infection, and it has been suggested that a component of the *ras* pathway might function to down-regulate PKR, thereby promoting translation of reovirus mRNAs and thus viral replication (463).

Other studies investigated how interactions between the reovirus cell-attachment protein and its cell surface receptor(s) affect functions in differentiated cells. In optic nerve glial cultures, ligand binding to the reovirus type 3 receptor stimulated expression of galactocerebroside and myelin basic protein (96,97). Ligand binding to the type 3 receptor in rats also caused changes in oligodendrocyte function resulting in altered myelin expression (95). In another study, interaction of reovirus with thyroid follicular epithelial cells caused induction of major histocompatibility complex (MHC) class II molecules (172). Because this occurred even in the absence of viral replication, reovirus attachment to cell surface receptors may be sufficient to affect the expression of cellular proteins, probably through receptor-linked signaling pathways.

Persistent Infections

Although commonly causing the death of cells in which they replicate (lytic), reoviruses can produce nonlytic, persistent infections in a variety of cultured cells (2,4,6,7 and 8,33,67,112,116,119,132,317,463,468,480,498). Continuous maintenance of persistently infected cultures for months or even years is possible. Reoviruses have not yet been reported to persist in host mammals in the natural world, but recent studies have shown evidence for delayed clearance or chronic infection in laboratory mice. One of these studies involved infection of normal mice with reoviruses selected during persistent infections in L cells and showed delayed clearance from the CNS (327). The other studies involved infection of SCID mice with wt reoviruses and showed selection of organ-specific variants during the course of the chronic infection (193,194). Mechanistic relationships between these chronic infections in animals and persistent infections in culture remain undefined. Persistent infections in cultured cells by reoviruses appear best described as carrier cultures (2,7,116,119,498) and have been proposed to involve two distinguishable phases, establishment and maintenance. Certain aspects of reovirus–cell interaction (e.g., proteolytic uncoating during viral entry) appear to influence both phases of persistent infection, however, suggesting that the two phases may not be as mechanistically separable as first proposed.

Establishment

Viral characteristics can influence the establishment of persistent reovirus infections. Establishment of persistently infected L cells can be facilitated with defective stocks obtained by serially passing viruses at high MOI (6,7,67,119). Defective stocks contain a variety of mutants (see earlier section) including some that favor the establishment of persistent infections (6). Wild-type isolates can differ in their capacities to establish persistent infections in L cells after undergoing serial passage at high MOI. In the case of reoviruses type 1 Lang and type 3 Dearing, this difference is determined by their L2 genome segments (67). A current model links the L2 gene product l2 to the generation or amplification of different mutants within defective stocks, including those that favor the establishment of persistent infection, but the mechanism of l2 activity in this regard remains unknown.

Cellular characteristics can also influence the establishment of persistent reovirus infections. Wild-type reoviruses can establish persistent infections in several differentiated cell lines (33,112,116,132,317,468,480,498). The basis for an apparent relationship between cell differentiation and establishment of persistent infection remains unclear, but the resistance of some cells to reovirus-induced inhibition of cellular macromolecular synthesis has been proposed to play a role (112,132). The resistance of some cells to reovirus-induced apoptosis, or other mechanisms of killing, may also be involved. Other evidence suggests that some differentiated cells may favor the establishment of persistent infection by restricting reovirus disassembly as part of the entry process (498). Consistent with the latter proposal is evidence that persistent infections in L cells can be established using wt reoviruses if the cells are treated with ammonium chloride, which interferes with viral entry, during the first few days of infection (72).

Maintenance

A variety of viral mutants accumulate in cultures during persistent reovirus infections. Some of these mutants may play no role in the maintenance of persistence but reflect that reoviruses undergo extensive genetic changes during long-term persistent culture (4,6,7 and 8). On the other hand, cell lines cured of persistent reovirus infection by passing with neutralizing antibodies (PI cells) are found to support reduced growth of wt reoviruses relative to viruses isolated from persistently infected cultures (PI viruses) (2,119,232). This finding argues that both viruses and cells undergo mutation during the maintenance of persistent infection, and the complementary nature of the effects of these mutations on viral growth suggests that a process of virus–cell coevolution is a characteristic feature of the maintenance phase (2,119,232). Current evidence suggests that at least an element of this coevolution is based on steps in reovirus entry, with PI cells evolving to resist one or more steps in viral entry, and PI viruses evolving to evade these cellular counter-measures (119).

Specific Mutations Involved in Persistence

Mutant S4 genome segments from defective stocks (3) appear to play a critical role in the establishment of persistent reovirus infections in L cells (6). Because persistent infection appears to require that cellular injury be attenuated, it was proposed (6) that these mutations in S4 might be required for attentuating the shut-off of host RNA and protein synthesis characteristic of most reovirus infections (417) or for enabling PI viruses to interfere with the growth of wt, lytic virus (5,81). Although the S4 gene product, s3, can influence the activation state of interferon-induced enzymes (214), interferon does not appear to play a protective role in persistent reovirus infection of at least one cell line (111).

More recent evidence suggests that mutations in the S4 genome segment are selected during the maintenance phase of persistent infection in L cells, as part of the virus–cell coevolution described earlier. Mutations in S4 determine the capacity of certain PI viruses to replicate in cells that have been cured of persistent infection (511). In addition, the S4 mutations in these and other PI viruses have been found to facilitate the proteolytic cleavage of the encoded outer capsid protein s3 (499). Interestingly, a recent study revealed that cured cells have a defect in the maturation of cathepsin L, a lysosomal cysteine protease that may be responsible for virion uncoating in L cells (20). These results provide support for the model in which viral mutations that increase the efficiency of disassembly enable reovirus to maintain a persistent infection in cells that have evolved to restrict this step. These findings lend support to the hypothesis that reovirus persistence in L cells involves a carrier culture in which continuing transmission of virus between cells by an extracellular route is required for maintenance (119).

Mutations in the S1 genome segment appear also to be selected during the maintenance phase of persistent infections in L cells and can determine the capacity of certain PI viruses to replicate in cells that have been cured of persistent infection, independently of any mutations in S4 (232,511). In these and certain other PI viruses, the mutations in S1 are linked to decreased stability of the s1 (receptor binding protein) oligomer and its decreased capacity to mediate sialic-acid-dependent hemagglutination (511). The decrease in s1 oligomer stability in these viruses has been proposed to play a determinative role in the maintenance of persistent infections (511), but further work is needed to clarify the relative roles of S1 and S4 mutations in this regard.

CHAPTER 53 Mammalian Reoviruses

Kenneth L. Tyler

HISTORY

Although the name *reovirus* was not introduced until 1959 (153), the first isolation of what would later be classified as a reovirus (type 3) was made in 1951 (182,195). In the summer of 1953, a virus was isolated from a rectal swab taken from a healthy child (“Lang”) living in Cincinnati, Ohio (131). This virus subsequently became the prototypic reovirus serotype 1 strain (reovirus serotype 1 strain Lang, T1L) (153). Ramos-Alvarez and Sabin subsequently isolated two additional viruses from children hospitalized with summer diarrheal illnesses. One of these isolates was initially referred to as D5 because it was the fifth unclassifiable isolate from a child (“Jones”) with a diarrheal illness. This isolate subsequently became the prototype for reovirus serotype 2 (reovirus serotype 2 strain Jones, T2J) (153). Another stool isolate from a child (“Dearing”) subsequently became the prototype for reovirus serotype 3 (reovirus serotype 3 strain Dearing, T3D) (153). In 1957, Rosen and colleagues (140,144) recovered a virus from an anal swab taken from a baby (“Abney”) living in an institution in Washington, D.C., which became a second prototype strain for reovirus serotype 3 (T3 Abney).

In 1959, Sabin (153) proposed that the viruses discussed above be included in a new group of respiratory and enteric viruses, for which he coined the name reoviruses (**r**espiratory **e**nteric **o**rphan viruses). The new name was intended to emphasize the fact that these viruses were isolated from the respiratory and enteric tracts and that they were not associated with any known disease (hence, *orphan*). The distinguishing features of this new group included their size (which was larger than other known enteroviruses), the capacity to produce cytoplasmic inclusions in monkey kidney tissue culture, pathogenicity for newborn but not adult mice, and hemagglutination (HA) of human type O erythrocytes. The wisdom of establishing a separate group for the reoviruses was quickly confirmed when it was discovered that reoviruses contained double-stranded segmented genomic RNA (dsRNA; see Chapter 52 for references).

Investigations of the nucleotide and amino acid sequence diversity of many reoviruses has led to an improved understanding of the evolutionary interrelationships between viruses (26,42,43,64,89). Regardless of the gene analyzed, there is no correlation between the relatedness of viral strains and the geographic site, date, or host species from which they were originally isolated (26,42,64). Phylogenetic trees constructed based on variations in the nucleotide sequences of the *S1, S2, S3,* and *S4* genes differ substantially from each other as a result of reassortment of reovirus gene segments in nature. *S1* gene–based phylogenetic trees suggest there are at least five lineages for reovirus strains (42). Analysis of lineages based on the *S2, S3,* and *S4* genes show no relationship to viral serotype and show a variable number of potential clades or lineages (26,64,89) (Fig. 1).

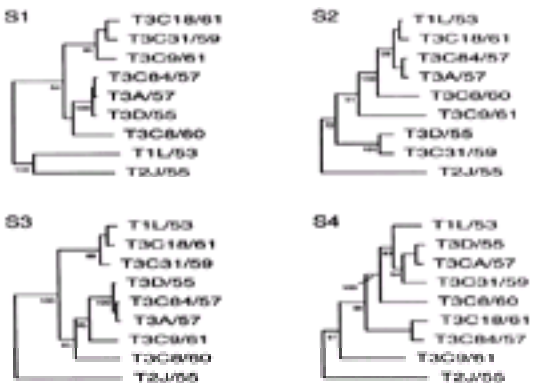

FIG. 1. Minimal-length phylogenetic trees for reovirus strains constructed from variation in the nucleotide sequence of the *S1, S2, S3,* and *S4* genes using the branch-and-bound algorithm of the parsimony program, PAUP. Trees are rooted at the midpoint of their longest branch. (Prepared by M. Goral and T. Dermody and reproduced from ref. 195, with permission.)

INFECTIOUS AGENT

The structure, genetics, and replication of reoviruses are described in detail in Chapter 52 (185). Reoviruses are nonenveloped viruses of about 850-Å diameter composed of two concentric icosahedrically symmetric protein capsids containing 10 discrete segments of genomic dsRNA. Each of the dsRNA segments encodes a single polypeptide, with the exception of the *S1* gene segment, which encodes two proteins derived from alternative reading frames. Most of the outer capsid shell is composed of complexes of two major proteins (µ1, s3). Trimers of a third protein, s1, are located at each of the virion's 12 vertices. The protein s1 is the viral receptor recognition protein (see later). The protein µ1 plays a crucial role in initiating membrane penetration and in facilitating access of virions and infectious subviral particles (ISVPs) to the cell cytoplasm during infection. The densely packed core capsid is composed primarily of four proteins (l1, s2, l3, µ2) and contains the segmented dsRNA genome. Another protein, l2, forms a spike extending from the core to the outer capsid.

During infection, reoviruses undergo partial uncoating, resulting in the production of ISVPs and cores (see Chapter 52 for review). ISVPs have lost s3 from the outer capsid, contain cleaved fragments of µ1/µ1C (designated µ1d, d, f), which remain virion associated and have the viral attachment protein s1 in an extended conformation. ISVPs are fully infectious and are generated at extracellular sites *in vivo* and within late endosomes or lysosomes of infected cells *in vivo* and *in vitro.* Subsequent conformational changes in µ1/µ1C facilitate interaction with membrane bilayers and allow subvirion particles to enter the cytoplasm where they become transcriptionally active.

Biologic Characteristics

Reoviruses grow in and produce cytopathic effects (CPE) in a wide variety of cultured cells. Although reovirus infection is usually cytocidal, under certain circumstances, noncytocidal persistent infection occurs (see Chapter 52 for a more detailed discussion of viral effects on host cells) (6,39). *In vivo,* chronic infections have been observed after infection of adult severe combined immunodeficiency (SCID) mice (62,65,66) and after inoculation of viruses derived from persistently infected *in vitro* cultures (PI viruses) into immunocompetent neonatal mice (113).

Mammalian cell lines derived from different species and tissues vary in the kinetics of viral multiplication, the time of appearance of infectious virus, and the rate of cell killing. CPE may correlate with the efficiency of virus-induced inhibition of host-cell protein synthesis and with the state of cellular differentiation (36). The M1 and S1 genes, encoding the µ2 core and s1 outer capsid proteins, respectively, are important determinants of reovirus strain-specific CPE in a variety of cell types (12).

The typical yield of virus is 1,000 plaque-forming units (pfu) per cell, with a particle-to-pfu ratio of 50:1 to 200:1 (6,81). Most viruses produced during infection remains cell associated, and physical disruption of cells (e.g., by several cycles of freezing and thawing) is required for complete recovery of virus during assay procedures. Studies of the one-step growth cycle in reovirus-infected L929 cells show an eclipse or lag phase lasting 6 to 10 hours followed by viral growth that peaks 15 to 18 hours after infection (81). ISVP-infected cells have viral yields similar to virus-infected cells, but the eclipse phase is shorter and maximal viral yield occurs earlier (81).

All three serotypes of reovirus agglutinate human red blood cells (HA) (41), but the capacity to agglutinate bovine red blood cells is restricted to certain T3 strains. Sialic acid residues present on glycophorin molecules are the reovirus receptor molecules on erythrocytes (see Cell and Tissue Tropism and Receptor Recognition for complete discussion and references). The s1 outer capsid protein is the viral hemagglutinin (199), and a discrete region (amino acids 198 to 204) of the s1 tail of T3 reovirus is crucial to HA (27,41) (Fig. 2).

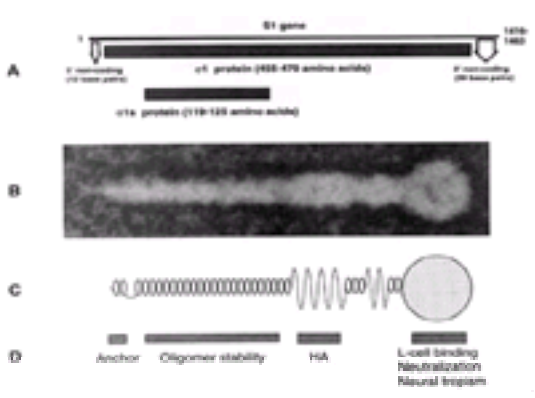

FIG. 2. Structure–function relationships of the T3 s1 protein. Model of s1 structure in which regions of proposed a-helical coiled-coil and b-sheet structure are depicted. Amino acid positions in the T3 s1 sequence are shown at *bottom.* Regions of sequence proposed to be important for hemagglutination (198,199,200,201,202,203 and 204), cell attachment (222–455), neutralization (340, 419), and a proposed receptor-recognition domain based on sequence similarity between s1 and antiidiotypic antibody (see text). (From ref. 195, with permission.)

Physical and Chemical Properties

Reoviruses are stable at room temperature and as aerosols. Reovirus T1L is more thermostable than T3D (72,182). Loss of infectivity is greatly accelerated at higher temperatures (81) and inhibited at 4°C. All the reovirus outer capsid proteins appear to play a role in virion thermostability. Loss of infectivity can result from heat-induced loss of the s1 viral attachment protein (47,48), and differences in thermostability between virions and ISVPs is determined by the s3 protein

(81). Mutations in the central region (amino acids 459 to 497) of the µ1 protein can enhance the thermostability of thermolabile T3D and T3A viruses.

Reoviruses are generally resistant to the effects of antibiotics commonly employed in tissue culture, including aminoglycosides and penicillin (141,169). Because they do not have an envelope, reoviruses are resistant to treatment with ether and other lipid solvents (168,182). They are also relatively resistant to a number of commonly used disinfectants, including formalin, Lysol, hydrogen peroxide, and phenol (47,48,168,182). Diluted Wescodyne (1/200) is of only limited efficacy in reducing reovirus infectivity (49). Most strains of reovirus T3 are inactivated by exposure to 95% ethanol (169). Ethanol-resistant mutants of T3D and T3A can be generated *in vitro* (72,200), making exclusive dependence on ethanol as a disinfectant problematic. Sodium hypochlorite (800 ppm chlorine) is extremely effective as a virucidal agent after brief exposure and should probably be considered the disinfectant of choice. Reoviruses are also sensitive to inactivation by ultraviolet light (106,133).

Viral outer capsid proteins appear to be particularly important in determining the susceptibility of reoviruses to inactivation by a variety of physical and chemical agents (see Chapter 52). For example, the *S4* gene, which encodes the s3 outer capsid protein, determines the relative susceptibility of reovirus strains to sodium dodecyl sulfate (SDS) and high temperature, whereas the *M2* gene, encoding the µ1 outer capsid protein determines sensitivity to phenol and ethanol (47,48). T3D mutants that are 100- to 1,000-fold less susceptible than wild-type virus to inactivation by ethanol contain point mutations in the *M2* gene, resulting in amino acid substitutions in the amino acids 425 to 459 region of µ1 (200).

The physical properties of reoviruses have practical implications for the storage of viral specimens and the disinfection of laboratory equipment and glassware. Reoviruses do not rapidly lose infectivity at room temperature, but optimal long-term storage should be at either –70°C or 4°C. Exposure of virus or specimens to ultraviolet light, which may be present in operating room suites or biosafety cabinets, should be avoided if isolation of reoviruses is desired. Disinfection of potentially contaminated materials can be done with either 95% ethanol, sodium hypochlorite solution (800 ppm chlorine), or preferably sequential application of the two solutions.

Propagation and Assay in Cell Culture

Mouse L929 fibroblasts (ATCC CCL 1) have been the most commonly employed cell line for experimental work, including viral growth, purification, and plaque assay, although Madin-Darby bovine kidney (MDBK), rhesus monkey kidney (LLC-MK2), and human embryonic intestinal (intestinal 407) cells are also sensitive lines for viral isolation (138). The standard assay for quantitating the amount of infectious virus present in infected tissues or culture stocks is the plaque assay, although assays of the 50% tissue culture infectious dose ($TCID_{50}$) are occasionally employed. The most commonly used plaque assay involves mouse L929 fibroblasts (57), although rhesus kidney cells can also be used (135). Plaque morphology varies with the virus strain and tissue culture system. In L929 cells, T1L and T3D generally form plaques 1 to 3 mm in diameter, whereas T2 plaques are significantly smaller (less than 0.5 mm) (109). The viral *S1* gene, encoding the s1 receptor-recognition protein, may be an important determinant of plaque size differences (109).

Host Range

Reoviruses are ubiquitous in their geographic distribution and host range. Virus is commonly found in river water, stagnant water, and untreated sewage (35). Reovirus concentrations in water supplies generally parallels the degree of contamination with *Escherichia coli,* suggesting that human feces may be a major source of virus (104,105).

Reoviruses have been isolated from humans, chimpanzees, Asian monkeys (*Macaca* species), African monkeys (*Cercopithecus* species), baboons, cattle, pigs, horses, cats, dogs, mice, birds, crustaceans, and even insects. Antibodies to reovirus have been found in an even larger group of animals, including dogs, cats, rabbits, rats, guinea pigs, horses, pigs, sheep, goats, bats, voles, camels, chickens and other birds, reptiles, fish, and 39 species of marsupials (182).

Naturally occurring reovirus infections have been described in wild mice and other small mammals, cattle and calves, sheep and lambs, pigs and piglets, horses, dogs, and cats (182). Serologic studies suggest that T3 strains can also infect laboratory rats and mice (91,99). The illnesses produced by reovirus infections in animals other than humans have involved primarily the respiratory, gastrointestinal, and nervous systems.

Perhaps the most interesting reovirus infections in animals are those in nonhuman primates. The close evolutionary relationship of these animals to humans raises the possibility that the reovirus-induced illnesses in these animals might also occur in humans. Cases of pneumonia and other respiratory illnesses have been found in both naturally and experimentally infected chimpanzees, macaques, marmosets, and *Cercopithecus* species (74,75,153,154,178). There are also isolated reports of other illnesses in primates, including cases of hepatitis and extrahepatic biliary atresia (T3) (145), meningitis (T2), and necrosis of ependymal and choroid plexus epithelial cells (T1) (153).

The isolation of reoviruses from humans and other primates, as well as cattle and calves and mice, suggests that biologic materials derived from these animals can potentially harbor reoviruses (40) and that these materials should be screened for reovirus before use in research studies or the derivation of biotechnology products.

Antigenic Composition and Determinants

Reoviruses are grouped into three serotypes, designated 1, 2, and 3, on the basis of neutralization (NT) and hemagglutination inhibition (HAI) tests (141). The s1 protein is the major serotype-specific antigen recognized in HAI and NT assays using type-specific polyclonal antisera (198,199). Serotyping has been facilitated by the availability of serotype-specific monoclonal antibodies (MAbs) specific for serotypes 1 (5C6) and 3 (9BG5).

Prototype viruses from the three serotypes are morphologically similar, but the cognate genes differ to varying degrees in their nucleotide sequences and in their migration patterns during polyacrylamide gel electrophoresis (see Chapter 52) (33). As would be predicted from the serologic studies, the greatest divergence between the prototypic T1L, T2J, and T3D strains occurs in the *S1* gene (24). At the amino acid level, the s1 proteins of T1L and T2J are more closely related (about 48% homology) than those of either strain to T3D (about 25% homology) (24,50). Despite this extensive divergence, there are at least five highly conserved domains of 22 to 34 amino acids (50). In contrast to s1, the other outer capsid proteins (l2, µ1, s3) of these strains have 90% or more, and in some cases 98% or more, homology (5,161,176,201). Similarly, high degrees of homology have been obtained from the available nucleotide sequence analysis of genes encoding viral core proteins (43,205).

Reovirus infection results in the production of both NT and HAI antibodies in the host. Studies with MAbs suggest that antibodies directed against the s1 and s3 outer capsid proteins, as well as antibody against the core spike protein l2, can neutralize reovirus infectivity. In general, the neutralizing l2 and s3 MAbs neutralize reovirus infectivity in a serotype-independent manner, although some MAbs show strain-specific patterns (69,84,94,183). By contrast, neutralizing s1 MAbs, as well as polyclonal monospecific s1 antisera, typically produce high-titer serotype-specific neutralization (21,69,84,94,166).

The NT epitope on the s1 protein of serotype 3 has been partially characterized through nucleotide sequence analysis of the *S1* gene of virus variants resistant to NT with s1 MAbs. Six mutants selected with two different MAbs contain single amino acid substitutions at either positions 340 or 419 of the s1 protein (10,11). These changes would result in nonconservative amino acid substitutions within the carboxyl-terminal globular head domain of s1 (58,119) (see Fig. 2). The importance of this region has been supported by studies of the binding of NT s1 MAbs to expressed truncated s1 proteins (115).

MAbs against the s1, s3, and µ1 proteins can all produce HAI (21,69,84,166,193). Analysis of the competition binding profiles of T3 s1 MAbs (21,166) suggest that the NT and HA epitopes on the T3 s1 protein are in distinct regions. These results are consistent with sequence data (11,199) and with the differential capacity of MAbs specific for other outer capsid proteins to inhibit s1-mediated HA and NT (193). MAbs specific for the s3 and µ1 outer capsid proteins may produce HAI through steric hindrance with the HA domains on s1 (193).

PATHOGENESIS AND PATHOLOGY

The capacity of reoviruses to produce disease depends on the outcome of a series of interactions between the virus and the host.

Entry Into the Host

Under natural circumstances, reoviruses are primarily respiratory and enteric viruses. A region of the s1 protein has sequence similarity with lysozyme (16). It has been speculated that this region of s1 might function as a glycosyl hydrolase (mucinase) and facilitate penetration of virions and ISVPs through the mucus layer overlying intestinal epithelial cells (16), although this remains unconfirmed. After oral inoculation into mice, reoviruses adhere to the apical surface of specialized intestinal microfold epithelial cells (M cells) overlying the dome of Peyer's patches (reviewed in 125) (Fig. 3). M cells are part of the gut-associated lymphoid tissue and are normally involved in the transepithelial transport of macromolecules from the intestinal lumen to the intercellular space and underlying Peyer's patches. Reoviruses can be sequentially visualized adherent to the luminal (apical) surface of M cells, inside intracellular vesicles, in the intercellular space between M cells and mucosal mononuclear cells inside Peyer's patch, and on the surface of mucosal mononuclear cells. A similar sequence of events occurs after reovirus entry through the respiratory tract in which viruses enter bronchial-associated lymphoid tissue through pulmonary M cells and then spread from the lungs to regional lymph nodes (111).

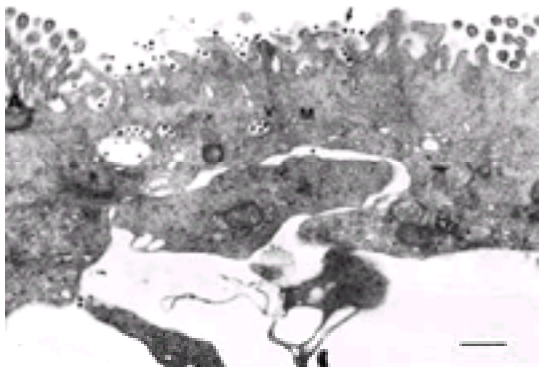

FIG. 3. Ileal epithelium overlying a Peyer's patch of an adult C $_3$H/Hej mouse. Thirty minutes after inoculation of an ileal loop with reovirus type 1, virions are found on the surface (*arrow*) and within vesicles (*V*) of an M cell (*M*). The apical surface of adjacent adsorptive cells (*A*) is virtually devoid of adherent virions (11,350× magnification). (From ref. 203, with permission.)

Binding to M cells, at least in the intestine, requires conversion of virions to ISVPs by endogenous intestinal serine proteinases (3). ISVPs are the predominant form of virus in intestinal tissues and in the intestinal lumen for the first 8 hours after peroral inoculation of virus and are the predominant form of virus that adheres to M cells and initiates infection (3,18). Inhibition of intraluminal proteolytic digestion, by peroral administration of serine protease inhibitors,

dramatically inhibits intestinal infection (3,9).

After oral inoculation of high doses of T1L, the epithelial cells of the ileum are infected, with relative sparing of the cells in the remainder of the small intestine and in the large intestine (reviewed in 125). Infection begins in epithelial cells adjacent to Peyer's patches in the crypts of Lieberkuhn. Infection of the crypt epithelial cells begins with viral binding to the basolateral membrane. This suggests that intestinal infection proceeds from the luminal surface through M cells to Peyer's patches and subsequently through the basolateral surface to epithelial cells. Attempts to demonstrate polarized infection of intestinal cells *in vitro* have yielded conflicting results, with studies indicating basolateral infection of isolated intestinal epithelial cells (197) but apical infection of cultured human colonic adenocarcinoma (Caco-2) cells (2). Reovirus T1L is also taken up by hepatic Kupffer's cells and subsequently excreted in the bile, raising the possibility that biliary excretion of virus may provide an additional mechanism of enteric infection (147,148).

Reovirus T1L and T3D show marked differences in pathogenicity after oral inoculation in suckling mice. T1L grows well in intestinal tissue after oral inoculation, whereas T3D does not (17,90,149,150). Both the *S1* gene (encoding the outer capsid protein s1) and the *L2* gene (encoding the core spike protein l2) determine the difference in capacity of T1L and T3D to survive in the gut, and the *L2* gene determines degree of viral shedding from the gastrointestinal tract (17,90). Recent studies suggest that the increased susceptibility of the s1 protein of some T3 reovirus strains to cleavage by intraluminal proteases may contribute to their reduced virulence after oral inoculation (25).

Spread of Virus

Reoviruses are able to spread from the gastrointestinal tract to extraintestinal organs and the central nervous system (CNS) after peroral inoculation (reviewed in 182,186, and 195). In newborn mice, T3C9 sequentially spreads from the intestinal tract into mononuclear cells of ileal Peyer's patches, through neurons of the myenteric plexus adjacent to Peyer's patches, and then ultimately through the vagus nerve to brain-stem neurons of the vagal dorsal motor nucleus (114). T1L follows a different pathway for extraintestinal dissemination. After transport across M cells, T1L can be sequentially detected in Peyer's patches, mesenteric lymph nodes, and, ultimately, the spleen, a pattern consistent with local lymphatic spread followed by bloodstream invasion (87).

Spread of reovirus to the CNS after peripheral inoculation into muscle has also been extensively investigated (180). After intramuscular inoculation, reovirus T3D spreads to the spinal cord through nerves (184). This spread, as well as the subsequent development of lethal encephalitis, can be prevented by surgical interruption of the nerve between the site of inoculation and the spinal cord as well as by antibody (see later). Studies using selective inhibitors of the fast and slow components of axonal transport indicate that the neural spread of T3 occurs by the microtubule-associated system of fast axonal transport (184). T3D appears capable of entering motor and sensory neurons as well as autonomic neurons (56,114). Viral antigen also appears to be transported both retrogradely and anterogradely through axons.

After intramuscular inoculation, the principal route of spread for T1L to the spinal cord is through the bloodstream. Viral antigen is detectable within the endothelium of blood vessels, although a limited degree of neural spread also occurs (56). Consistent with these results, T1L grows to significantly higher titer than T3D in cultured endothelial cells (103). Spread of T1L is not significantly inhibited by nerve section or by inhibitors of axonal transport, supporting the view that hematogenous rather than neural spread is the predominant pathway of dissemination to the CNS for T1L. Genetic studies using T1L × T3D reassortants indicate that the *S1* gene, which encodes the viral receptor-recognition protein s1, determines the pattern of spread of reoviruses from muscle to the CNS (184). These results are consistent with earlier studies suggesting that the s1 protein is also an important determinant of the extent of spread of virus from the gastrointestinal tract of mice after oral inoculation (87).

Cell and Tissue Tropism and Receptor Recognition

The s1 outer capsid protein serves as the receptor recognition protein (reviewed in 93)) (see Fig. 2). Topologically distinct receptor-binding domains exist in both the elongated fibrous “tail” domain of s1 and the distal globular head domain (93,118,158). A region of the s1 tail encompassing amino acids 198 to 204 is important for binding of T3 reoviruses to terminally sialylated oligosaccharides on erythrocytes, murine erythroleukemia, and L929 cells (27,31,41,152). Conversely, regions of the globular head of s1 contain receptor-binding sequences for neurons, neuroblastoma cells, murine thymoma cells, and L929 cells (93,118,158)). An antiidiotypic MAb (87.92.6) directed against a T3D s1-specific MAb (9BG5) contains an “internal image” of the binding domain of the T3D s1 protein (reviewed in 158). Amino acid sequence comparison of the antiidiotype MAb with s1 protein shows an area of homology that corresponds to amino acids 317 to 332 of s1. A synthetic peptide derived from this region of sequence homology can inhibit T3D binding to certain types of cultured cells, suggesting that this region of s1 may encompass a receptor-recognition domain. Studies of chronic reovirus infection in SCID mice indicate that organ-specific variants of reovirus are generated *in vivo* (65), but whether these variants include receptor-specific mutants or alterations in other proteins remains to be elucidated.

Perhaps the best characterized reovirus receptor is sialic acid. The reovirus receptor on erythrocytes are a-anomeric sialic acid residues on glycophorin molecules (128,129). Binding occurs to multiple sialoglycoproteins on other cells (30). Reovirus binding to sialic acid residues on erythrocytes and other target cells can be inhibited by treatment with neuraminidase or other sialidases and can be competitively blocked by sialylated oligosaccharides and brain gangliosides (4,60,61,126,129). However, reovirus binding to some cell lines, such as R1.1 thymoma cells, occurs in a sialic acid–independent manner (151), indicating that sialylated proteins cannot serve as the exclusive reovirus receptor.

P>A putative cell surface receptor for T3D has been isolated from murine neuroblastoma B104 and thymoma R1.1 cells using antiidiotypic antireceptor antibodies (reviewed in 158). The putative receptor molecule was a glycoprotein with a molecular mass of 67 kd. It was subsequently suggested that this receptor was structurally similar to the mammalian b-adrenergic receptor and that viral binding may occur on b_2-subtype receptors at a site distinct from that used by high-affinity ligands such as the antagonist iodocyanopindolol (ICYP) (97), although not all results are consistent with this

view (46). A substantial body of data appear inconsistent with the suggestion that a b-adrenergic receptor–like molecule serves as a receptor for T3 reoviruses. T3D clearly binds selectively and with high affinity to cells that lack detectable b-adrenergic receptor (159), does not trigger any of the pharmacologic activities associated with b-adrenergic receptor activation, and does not interfere with the binding or function of b-adrenergic receptor agonists (29,159). In addition, the binding of b-adrenergic receptor agonists and subsequent sequestration (down-regulation) of b-adrenergic receptors from the cell surface, does not reduce the capacity of reovirus to infect cells subsequently. Studies of the effects of competition between reovirions and b-adrenergic receptor antagonists have yielded conflicting results, with some studies indicating no effect (29,97) and others being consistent with a model in which reovirus binds to the antagonist domains of the b-adrenergic receptor (46).

Reovirus T3 can also bind to a heterodimeric cell surface receptor (designated p65/p95) composed of 65 kd and 95 kd subunits and expressed on the surface of some proliferating cells, include activated lymphocytes, neural embryonic precursor cells, and proliferating testicular cells (134,146,157). The p65 component of this receptor may be identical to the previously identified p67 receptor (see earlier). The heterodimeric p65/p95 receptor is associated with tyrosine kinase (TK) activity and may transduce a growth-inhibitory signal to proliferating cells (146,156).

Studies of the efficiency of reovirus infection in National Institutes of Health 3T3 cells suggest that receptor TKs may play a role in enhancing reovirus infection and cytopathicity. NR6 cells, 3T3 fibroblast derivatives lacking detectable epidermal growth factor (EGF) receptor, do not replicate T3D, fail to synthesize T3D proteins, and do not show detectable viral CPE (173). Transfection of these cells with the human EGF receptor gene, the *v-erbB* oncogene (172) or activated *Sos* or *Ras* (32,171), enables them to synthesize viral proteins, replicate virus, and become susceptible to viral CPE. The common denominator appears to be that efficient reovirus infection of 3T3 cells requires the presence of functional TK activity (172,173). NIH 3T3 cells transfected with a mutant gene encoding a kinase-dead EGF receptor are minimally cytopathic. The mechanism by which TK activity facilitates T3D infection has not been established. T3D can bind to the N-terminal extracellular domain of the EGF receptor, at a site distinct from the EGF ligand–inding site (174), but this does not appear to explain the effects of EGF and would not explain the results obtained with *v-erbB* or cells with activated *Sos* or *Ras*.

Perhaps the best synopsis of available data concerning reovirus receptor-recognition is as follows:

1. The s1 protein serves as the viral receptor-recognition protein, with distinct domains of the protein being involved in binding to different types of receptors on discrete populations of target cells.
2. One class of reovirus receptor, found on many cells including erythrocytes and L-cell fibroblasts, includes sialylated proteins. Binding to sialic acid residues is mediated by a domain in the s1 tail fiber (amino acids 198 to 204) (41).
3. There appear to be other, as yet incompletely characterized, reovirus receptors that are not sialylated proteins. Binding to these receptors may be mediated by regions of the s1 globular head (e.g, amino acids 317 to 332 or 340 and 419).

The importance of the s1 protein for tropism, particularly in the CNS, has been demonstrated *in vivo* as well as *in vitro.* After intracerebral inoculation into newborn mice, T3 reoviruses infect neurons and produce a lethal meningoencephalitis. T3 strains differ in their virulence and the peak titer they achieve in the brain but not in the topographic pattern of illness they produce (73), indicating that the general pattern of CNS tropism is serotype specific rather than strain specific. The pattern of injury produced by T1 reoviruses after intracerebral inoculation, as exemplified by the prototype T1L, is quite distinct from that produced by T3 reoviruses. The most striking difference is the failure of T1L to produce significant neuronal injury. Instead, T1L infects the ependymal cells lining the ventricles and produces ependymitis with associated hydrocephalus.

T1L × T3D reassortants demonstrate that the capacity of reoviruses to infect neurons (T3 pattern) or ependymal cells (T1 pattern) is determined by the viral *S1* gene, encoding the s1 receptor-recognition protein (reviewed in 180 and 195). Similar genetic studies have established the importance of the s1 protein in determining the capacity of reoviruses to infect discrete populations of cells in the pituitary and in the retina. The s1 MAb-resistant variants of T3D have attenuated neurovirulence and have impaired growth capacity in CNS tissue. After intracerebral inoculation, these viruses produce pathologic injury to only a subset of the regions damaged by wild-type T3D. These variants have single nonconservative amino acid substitutions within the globular head of the s1 protein (10,11) (amino acids 340 and 419) (see Fig. 2), suggesting that this region may play a critical role in CNS tropism and neuronal binding.

The importance of the s1 protein in neurotropism is also reflected in cultured neural cell lines. In primary explant cultures derived from fetal rat cortex, T3D, but not T1L, infects neurons. Both strains infect astrocytes. T1L, but not T3D, binds to the surface of isolated human and murine ciliated ependymal cells (175). The capacity of reoviruses to infect neural or ependymal cells is determined by the s1 protein (44). Infection of T3D in cultured neurons is inhibited by an antiidiotypic MAb containing a region of sequence homology to s1 (45), providing further evidence for the importance of s1 in neuronal cell binding.

Virus-Induced Cell Death

Reoviruses can induce apoptotic cell death in a variety of cultured cells *in vitro* (reviewed in 121). Apoptosis is characterized by specific changes in cell morphology, including nuclear chromatin condensation, margination, and fragmentation and shrinkage of cells with membrane blebbing (zeiosis). DNA isolated from apoptotic cells is cleaved at internucleosomal regions resulting in the appearance upon agarose gel electrophoresis of “ladders” of DNA fragments with sizes that are multiples of 180 base pairs. Reovirus strains differ in their capacity to induce apoptosis, with T3 strains typically inducing more apoptosis than T1 strains. Genetic studies using T1 × T3 reassortant viruses indicate that the *S1* and *M2* genes are key determinants of strain-specific differences in apoptosis (188,189). Apoptosis induction does not require viral replication and does not correlate with differences in the capacity of reovirus strains to replicate in infected cells (139,189). Apoptosis involves the activation of effector proteases, including calpains (38), and can be inhibited by

overexpression of *BcL-2* (139).

Reovirus-induced apoptosis also occurs *in vivo* (122) (Fig. 4). In the murine CNS, areas of virus-induced pathology, antigen istribution, and apoptotic cell death co-localize within the same brain regions. However, apoptotic cells may be either virus infected or merely in close proximity to infected cells, indicating that both direct and “bystander” mechanisms of apoptosis occur *in vivo.*

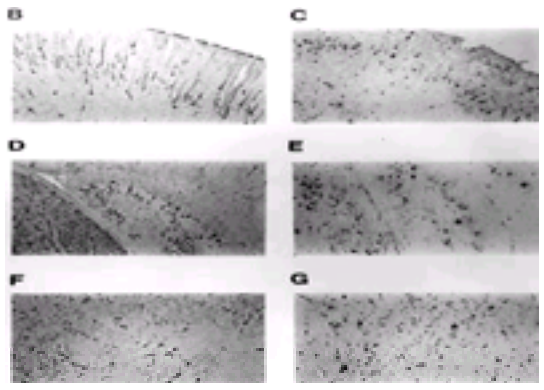

FIG. 4. Co-localization of reovirus T3D antigen detected by immunocytochemistry (*left panels*) and of apoptotic cells detected by TUNEL staining in the mouse brain after inoculation of T3D. Regions shown include cortex (*top row*), hippocampus with dentate gyrus (*center row*), and thalamus (*bottom row*). (From ref. 122, with permission.)

Reovirus-induced myocarditis is also associated with striking virus-induced destruction of cardiac myocytes in the absence of a significant inflammatory response (reviewed in 162). Cardiac myocyte injury is due to a direct cytopathogenic effect of virus and is not immune mediated. Genes encoding viral core proteins (164), notably M1 gene, are important determinants of the myocarditic potential of reoviruses. Cardiac injury *in vivo* correlates with cytopathicity in cardiac myocyte cultures *in vitro* (12) and in particular with the levels of viral RNA synthesis in infected cells (163). Myocarditic potential also inversely correlates with the amount of interferon-b (IFN-b) induced and the sensitivity of viral strains to its action (165).

Host Immune Response

Natural, as well as experimental, infections with reoviruses result in the induction of both humoral and cellular immune responses and have been used as models for the study of mucosal immunity in both the gut and respiratory tract (14,102,179,192,195). Type-specific and non–type-specific H_2-restricted cytotoxic T lymphocytes (CTLs) appear within the first week of intraperitoneal, peroral, or intranasal infection and can persist for at least several months (reviewed in 102,179,192, and 195). Reovirus-specific CTLs recognize epitopes on many reovirus proteins, including nonstructural proteins (70,71,98).

Peroral infection with reoviruses generates increases in virus-specific CD4+ and CD8+ intraepithelial lymphocyte populations. The cytokine profiles of reovirus-specific CD4+ helper T (T_H) cells indicate that T_H1 responses predominate over T_H2, with an associated increase in associated IFN-g (52). Similar results have been found in experimental reovirus serotype 2–induced murine diabetes (68). Virus-specific CD8+ CTLs generated within the intraepithelial lymphocyte population bear the a/b T-cell receptor (TCR) and are capable of major histocompatibility complex (MHC)-restricted lysis of virus-infected target cells (28). These CD8+ intraepithelial lymphocytes show disproportionate use of specific TCRs, including Vb-12, and -17, suggesting that infection results in a selective expansion of cells bearing TCR Vb (28).

The antibody response in mice depends on the route of viral inoculation and the H_2 haplotype of infected animals (100). Serum antibody titers are comparable after peroral and intradermal viral inoculation, and both routes of infection generate immunoglobulin G_{2a} (IgG2a) and IgG2b subclass antibodies (100). Antibodies generated in mice and rabbits recognize all the reovirus outer capsid proteins and the l core proteins (100). After peroral inoculation, mice develop an IgA antibody response in Peyer's patches as well as systemic IgG2a and IgG2b. Oral inoculation of neonatal mice with reovirus or microencapsulated virions induces IgA in the gastrointestinal tract (130), although this response is inhibited by transfer of maternal antireovirus antibodies through suckling (130).

In addition to inducing humoral and cellular immune responses, reovirus infection can also induce natural killer (NK) cell cytotoxicity (1,177) and the recruitment of neutrophils into infected tissues (112). Studies in SCID mice indicate that NK cell activity alone is insufficient to clear viral infection (177). In a model of reovirus-induced pneumonia, T3D induces a more prominent neutrophil response than T1L, and this difference is determined by the *S1* gene (112).

In an effort to understand better the roles of humoral and cellular immunity in reovirus pathogenesis, intestinal reovirus infection has been studied in mice deficient in all antigen-specific lymphocytes (SCID mice) (8,62,66,177) and in mice lacking CD8+ T cells (b_2-microglobulin–null mice) (8,101) or B cells (IgM transmembrane–null mice) (8). Although immunocompetent adult mice are not susceptible to reovirus infection, adult SCID mice orally inoculated with reovirus develop lethal infection (62,66). Passive transfer of reovirus-specific immune or normal lymphocytes from congenic mice protect SCID mice against infection (62). SCID mice fail to clear reovirus infection, indicating that antigen-specific lymphocytes are important for clearance of intestinal reovirus infection. Interestingly, the organ most prominently affected in reovirus-infected adult SCID mice is the liver (62,66). Viral virulence in SCID mice is associated with four reovirus gene segments (*S1, M1, L1, L2*) (66). Three of these genes (*S1, L1,* and *L2*) are significantly associated with viral titer in brain

and intestine, and three (*M1, L1, L2*) are associated with viral titer in liver or the presence of hepatic lesions (66) (Fig. 5).

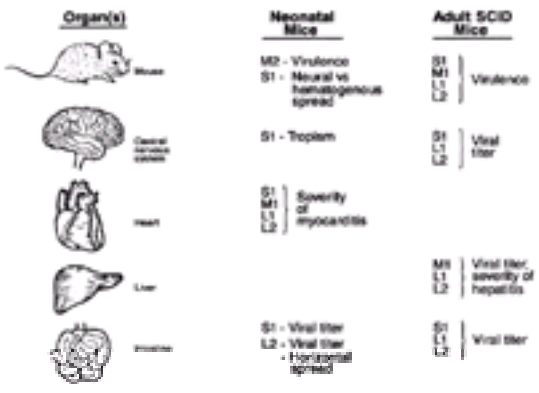

FIG. 5. Reovirus genes that determine virulence in different organs in immunocompetent neonatal and immunodeficient SCID mice. (From ref. 195, with permission.)

Mice lacking CD8 T cells clear infection normally (8,101), whereas mice lacking B cells and antibody have delayed clearance, indicating that both B cells and IgG play a role in intestinal clearance (8). Neonatal mice depleted of CD4+ T cells, CD8+ T cells, or both populations show enhanced pathology and higher viral titers in many organs (194).

The importance of immune cells in protection against reovirus infection has also been established in adoptive transfer studies. Transfer of reovirus-specific immune cells can protect neonatal mice against lethal infection with T3D and T3C9, and from neurologic disease produced by T1L (reviewed in 102,192). Protective cells can be derived from spleen after intraperitoneal immunization, or from Peyer's patches after peroral or intraduodenal immunization. Passive transfer experiments with reovirus-specific splenic lymphocytes indicate that both CD4+ and CD8+ immune cells are involved in protection and that removal of either population results in a significant decrement in the protective capacity of transferred cells. Intestinal lymphocytes mediating protection express CTL activity after secondary *in vitro* stimulation with reovirus-infected target cells (34). These cells are CD8+ and Thy-1+ and express TCRa/b (34).

Reovirus infection can result in up-regulation of class I and class II MHC expression in cultured cells *in vitro* and *in vivo.* For example, infection of human pancreatic b-cells or rat insulinoma RINm5F results in significantly increased class I, but not class II, MHC expression (22,23). Conversely, infection of rat FRTL-5 thyroid cells or murine M.5 thyroid epithelial cells does increase class II MHC expression (59,117).

Both polyclonal antisera and MAbs (neutralizing and nonneutralizing) directed against the T3 s1 protein can protect mice against lethal challenge with T3D and T3C9 as well as neurologic disease induced by T1L after peroral, intramuscular, or intracerebral viral challenge (reviewed in 102 and 192) (Fig. 6). *In vivo* protection can also be mediated by MAbs against each of the other outer capsid proteins, indicating that protective antibodies recognize multiple epitopes and that these are not confined to a single viral protein. *In vitro* properties of antibody, including isotype, complement-binding, capacity to neutralize infectivity or inhibit HA, do not directly correlate with their protective capacity *in vivo.* Antibodies that bind poorly are not protective, but among those that bind well, protection *in vivo* is not simply a function of relative binding avidity (183).

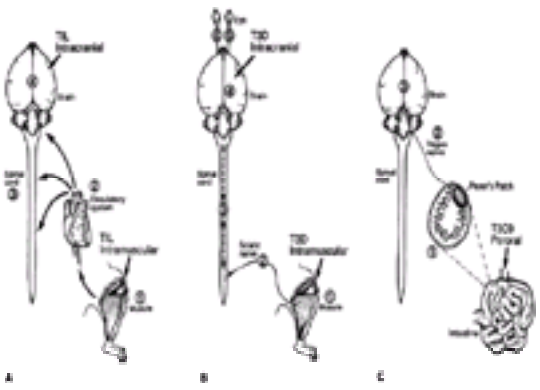

FIG. 6. Sites of antireovirus antibody action. For hematogenous spread after intramuscular or intracranial inoculation of T1L (**A**), antibody can inhibit primary replication in brain or muscle (*sites 1* and *4*) and the spread of virus through the bloodstream (*site 2*) to the spinal cord and brain (*sites 3* and *4*). For neural spread after intramuscular or intracranial inoculation of T3D (**B**), antibody can inhibit primary replication in muscle or brain (*sites 1* and *4*) and spread of virus through nerves to the spinal cord (*site 2*) and within the central nervous system (*sites 3* to *5*). For neural spread of virus after peroral inoculation of T3C9 (**C**), antibody can contribute to intestinal clearance of virus (*site 1*) and inhibit spread to (*site 2*) or growth within (*site 3*) the brain. (From ref. 195, with permission.)

Studies of the effects of protective MAbs on pathogenesis indicate that antibody-mediated protection may occur in the absence of a significant effect of antibody on primary replication of virus (183,191). However, antireovirus IgG can clearly play a role, independent of IgA, in the clearance of virus from mucosal primary sites of infection, such as the intestine (8). Protection against lethal T3D infection is associated with inhibition of neural spread of virus to the CNS and inhibition of growth and spread within the CNS (191). Protection against lethal peroral infection with T3C9 is associated with inhibition

of both viremic and neural spread of virus from intestinal tissue to the CNS and protection against T1L with inhibition of viremia (183,191) (see Fig. 6).

The effects of humoral and cellular immunity on reovirus infection appear complementary (194). Antibody is effective even when administered after CNS infection with reovirus has been established (190,196), whereas to be effective, passively transferred reovirus-specific immune cells must be given either before or within 24 to 28 hours of viral challenge. Antibody can protect against both peripheral and direct intracerebral challenge with virus, but immune cells are only protective against peripheral challenge with T3D, and fail to protect when virus is given intracerebrally.

In addition to humoral and cellular immune responses, cytokines and other mediators may play a role in modulating reovirus infection. Reoviruses can induce IFNs, tumor necrosis factor-a (TNF-a) and macrophage inflammatory protein-2 (MIP-2) (53,54,155). Induction of IFN depends on both the viral strain and the host cell and differs among mice of different strains (100). T3D, for example, is a better inducer of IFN in mouse L-cell fibroblasts than T1L. T3D also induces higher levels of chemokine mRNA expression for TNF-a and MIP-2 than T1L in pulmonary cells *in vitro* and within the lung after *in vivo* infection (53).

Reoviruses are susceptible to IFN-b, although strains differ strikingly in sensitivity, with T3D being much more sensitive than T1L (80,155). Differences in the levels of IFN-induced dsRNA-dependent protein kinase (PKR) may play a role in mediating effects of IFN-b on reovirus replication (155). The reovirus s3 protein inhibits the activation of PKR by preventing its interaction with dsRNA (13,15,204). Differences in IFN sensitivity of reovirus strains may depend in part on their s3 proteins (13,76). In cardiac myocyte cultures, reovirus induction of IFN-b is determined by viral core proteins and inversely correlates with the capacity of viruses to induce CPE *in vitro* and myocarditis *in vivo* (165). Depletion of IFN-b enhances the myocarditic potential of nonmyocarditic viral strains, suggesting a protective effect for IFN-b (165). These results contrast with studies of experimental reovirus serotype 2–induced murine diabetes, in which the severity of insulitis in mice correlates with increased expression of IFN-b and is ameliorated by administration of anti–IFN-b antibody (68), suggesting that IFN induction may play a pathogenetic rather than a protective role in this setting.

Under certain circumstances, reovirus infection may induce either autoimmunity or, conversely, a state of immunosuppression (67,124). Immunoregulatory abnormalities observed after reovirus infection may result, in part, from functional alterations in T-cell subpopulations (67,124). Infection of mice with T1L has been associated with the production of autoantibodies against a variety of host antigens, most prominently a variety of endocrine tissues and hormones (123). Suckling mice infected with T2J develop thymic atrophy with marked suppression of antibody production to both T-cell–dependent and T-cell–independent antigens. Transfer of splenocytes or thymocytes from normal uninfected mice restores the capacity of infected mice to produce antibody (124). Similar impairment of immune responses have been described after infection of suckling mice with T1L (124).

Pathology in Specific Organ Systems

A discussion of the pathology induced by reoviruses infection in different organ systems is beyond the scope of this chapter. Specific reviews detailing the effects of reovirus infection on the nervous system (180), heart (162), and gastrointestinal and hepatobiliary systems (125) are available.

CLINICAL FEATURES

Reoviruses remain as much orphan viruses today as when Sabin originally proposed their name. By early childhood, most individuals show serologic evidence of past reovirus infection. Despite this fact, it has been difficult to provide convincing evidence linking reoviruses to specific human diseases. Most reovirus infections must either be asymptomatic or blend imperceptibly with the minor respiratory and gastrointestinal illness of infancy and early childhood (77,82,95,167).

Some insight into the potential of reoviruses to produce human disease comes from studies of human volunteers. The most comprehensive of these studies involved intranasal inoculations of up to $10^{6.7}$ $TCID_{50}$ of reovirus into 27 adult (21 to 38 years old) male prisoners (142). Groups of nine volunteers were inoculated with either T1L, T2J, or T3D. After inoculation with T1L, virus was isolated from anal swab specimens of eight patients. The ninth patient had preexisting antireovirus antibodies, and virus was not isolated from his stool. Six of the eight (75%) initially seronegative patients seroconverted, with a significant increase in serotype-specific HAI antibody titers. Three of these individuals developed clinical illness, which began 24 to 48 hours after viral challenge and typically lasted for 4 to 7 days. The predominant symptoms included headache, pharyngitis, sneezing, rhinorrhea, cough, and malaise. A fourth individual had loose stools but was otherwise asymptomatic. In two other studies of human infection with T1L, a similarly high incidence of viral isolation and seroconversion was found. However, there was no clear association with clinical illness (78,79,86). None of the nine volunteers challenged with T2J developed clinical illness (142). T2J was isolated from throat or anal swab specimens in only two cases, although four individuals developed a serotype-specific HAI antibody response. Eight of the nine volunteers who received T3D had positive stool cultures (142). These eight individuals developed a serotype-specific rise in HAI antibody titer. One patient developed “mild rhinitis,” and the others remained symptom free.

In 1960, Rosen and colleagues (143) documented an outbreak of infection with T1 reoviruses among children in a welfare institution in Washington, DC. During a 9-week period, 22 of 73 children had at least one stool isolate of a T1 strain. Stool shedding lasted for at least 1 week in 54% of the children, and it lasted for at least 2 weeks in an additional 21%. In one case, virus shedding lasted for at least 5 weeks. All of the children with positive stool cultures developed a rise in serotype-specific HAI antibodies. In an attempt to define possible clinical correlates retrospectively, the record of patients with positive stool isolates were reviewed. During the time period of virus isolation, the children had rhinorrhea (81%), pharyngitis (56%), diarrhea (19%), and otitis media (19%). However, the frequency and nature of these complaints were not significantly different than those in the preisolation and postisolation periods.

There are similarities between the pathologic changes occurring in hepatobiliary disease produced in mice by reovirus

infection and those seen in human neonatal extrahepatic biliary atresia (EHBA) (reviewed in [187] and [202]). Serologic studies of infants with EHBA examining the prevalence of ant-reovirus antibodies or changes in antibody titer have yielded conflicting results, with some studies suggesting a possible relationship with reovirus infection ([7,63,110,137]) and others not ([19,20,51]). RT-PCR amplification of a region of the highly conserved L1 gene has been used to search for reovirus nucleic acid in fresh frozen liver and biliary tissues from infants with EHBA, choledochal cysts (CDC), and other hepatobiliary diseases ([187]). Reovirus RNA was detected in 78% (7 of 9) of tissue specimens from infants with CDC, in 55% (12 of 23) of those from infants with EHBA but in only 21% (7 of 33) of those with other liver diseases and in only 11% of autopsy controls without known hepatic or biliary disease. These differences were statistically significant and support an association between reovirus infection and both EHBA and CDC. Another study ([170]) using a different RT-PCR technique to amplify the *M3* gene on formalin-fixed tissue failed to detect reovirus RNA in 14 patients with EHBA or in 20 patients with neonatal hepatitis. The results may be in conflict owing to differences in RT-PCR methodology and the use of different tissue preparations (fresh frozen versus fixed).

Efforts have also been made to determine whether reovirus infection could be related to idiopathic cholestatic liver disease in adults, including primary biliary cirrhosis and primary sclerosing cholangitis ([107,108]), but no convincing data for an etiologic relationship exist.

Because one of the hallmarks of reovirus infection in rodents is CNS disease, it is perhaps not surprising that several case reports associating reoviruses with human CNS disease have appeared ([180]). One of the most convincing examples is a recently reported case of aseptic meningitis in a previously healthy 3-month-old infant ([83]). The child seroconverted, and a serotype 1 reovirus was isolated from cerebrospinal fluid (CSF) after inoculation onto green monkey kidney cells. There are similar but less well-documented cases of meningoencephalitis associated with both type 2 and type 3 reovirus ([92]). In some cases, virus was isolated only from stool and not CSF or neural tissue, and seroconversion was not documented ([116]), raising the possibility that reovirus infection was coincident rather than causal. In some cases with encephalitic as well as meningitic signs and symptoms, virus has been isolated from brain tissue ([85,92]).

It has been suggested that reoviruses may occasionally produce exanthemal illnesses in children ([96]). In one study, five children with maculopapular rashes and one with a vesicular rash were found to have seroconversion against T2. Two of these children also had virus isolated from throat or rectal swabs. In addition to rash, other symptoms included fever ([6]), malaise ([4]), anorexia ([4]), pharyngitis ([3]), cervical adenopathy ([2]), and diarrhea ([1]). The incidence of seroconversion and virus isolation was not significantly different than that in an asymptomatic age-matched population. Therefore, although it is clear that these children had reovirus infection, it remains in question whether it was responsible for the rash and other symptoms.

The list of other reported associations with reovirus infection ([182,195]) also includes keratoconjunctivitis and asymptomatic shedding of virus in urine.

In summary, most reovirus infections are asymptomatic or, at most, produce only minor upper respiratory or gastrointestinal symptoms that are indistinguishable from the upper respiratory infections and diarrheal illnesses that are regular features of infancy and early childhood. The potential association of T3 infection with extrahepatic biliary atresia must be considered possible rather than proven. Reoviruses may be an extremely rare cause of neurologic disease and exanthema, although there are a paucity of documented cases.

DIAGNOSIS

Diagnosis is based on isolation of virus from tissues or body fluids, detection of viral antigen in infected material, and serologic studies ([181]). Suitable specimens for virus isolation include stool, throat swabs, nasal washings, CSF, and urine. From a practical viewpoint, almost all isolates of virus have been from stool or, less commonly, respiratory secretions. For initial isolation from infected material, monkey kidney cells have generally been considered optimum. In addition to characteristic CPE, the presence of viral antigen can be confirmed using either immunofluorescence or immunocytochemistry ([181]). Immunocytochemical techniques can also be employed for the detection of reovirus antigens in tissue specimens ([181]).

An indirect immunofluorescence assay, using fixed infected cells as target antigen, has also been employed to detect antireovirus antibodies in human serum ([7,63,110]), although its sensitivity and specificity have never been established ([19]). Enzyme-linked immunosorbent assay (ELISA) techniques ([136,160]) have been widely used for detection of reovirus antibodies in serum and can be easily applied in most clinical laboratories. Results can be confirmed by plaque reduction and HAI assays, which are generally available only in research laboratories. The availability of nucleotide sequence information for a number of the reovirus genes provides the basis for the application of a variety of molecular techniques, including *in situ* and dot-blot hybridization and PCR for the detection of reovirus genomic and messenger RNA in infected tissues and cells. Reovirus RNA extracted from infected liver tissue has been detected by dot-blot hybridization using an *M2* gene–specific probe ([127]) and by RT-PCR using *L1, M2,* and *M3* gene–specific oligonucleotide primers ([127,170,187]).

Determination of the serotype of a viral isolate that has been identified as a reovirus has historically been based on the capacity of a panel of type-specific antisera to inhibit HA by the test isolate ([141]). Plaque-reduction NT assays can also be used to serotype unknown isolates, although they are generally not as reliable as HAI tests. The availability of type-specific neutralizing MAbs directed against the s1 protein of the prototypic T3D and T1L strains now allows serotyping based on plaque reduction assays or immunocytochemical reactions.

TREATMENT

Reoviruses are orphan viruses that have not been specifically shown to produce human diseases; hence, there has been limited investigation of antiviral therapy. Among the strategies that have been tested in experimental animals are the

administration of antiviral antibodies, virus-specific immune cells, and protease inhibitors (55). A number of vaccines have been developed for veterinary use. These typically contain either b-propiolactone or formalin-inactivated viruses and have been shown to induce high-titer antibody responses (178).

The activity of a number of agents, including ribivarin, acivicin, cicloxolone, and neplanocin A, has been tested in cell culture systems. Ribivarin has antiviral activity against reovirus *in vitro* (132) but has never been tested *in vivo.* The glutamine analog acivicin inhibits the growth of reovirus T3 in fibroblasts (88), although its mechanism of action has not been defined. Similarly, the monensin-like Golgi apparatus inhibitor cicloxolone sodium reduces reovirus particle yield and the proportion of infectious to noninfectious reovirus particles produced in infected cells (37). The *S*-adenosyl-L-homocysteine hydrolase inhibitor neoplanocin A and some of its derivatives have also been reported to have *in vitro* activity against reovirus (120).

EPIDEMIOLOGY

Epidemiologic surveys of the presence of antireovirus antibody in large populations of individuals in a variety of geographic and cultural settings have produced surprisingly uniform results. Most individuals have detectable antibodies against reoviruses of all three serotypes by the time they leave childhood (78,95,96,160). In an early study, the incidence of antireovirus antibodies rose from less than 25% in those younger than 1 year of age to more than 70% in those older than 3 years (96). A more recent ELISA study found that antibody prevalence increased steadily throughout life from about 35% of 6-month to 1-year old children, to 60% of 11- to 19-year-olds, to more than 85% in those older than 60 years of age (160).

Almost all reported or identified cases of reovirus infection are sporadic in nature, although one outbreak of serotype 1 infection in children has been described (143). Reovirus infections do not appear to have any striking seasonal predilection, although many of the original isolations of virus were from patients with summer diarrheal illnesses. The role, if any, played by animals as reservoirs for virus or as sources of human infection is unknown. Reoviruses of all three serotypes are also frequently isolated from water supplies and sewage effluents, presumably reflecting contamination of water with human and animal excreta. This could conceivably represent another source of virus for human infection.

CHAPTER 54 Rotaviruses and Their Replication

Mary K. Estes

Rotaviruses were initially characterized as agents associated with gastroenteritis in animals. The history of the discovery of the rotaviruses exemplifies how studies of animal diseases can provide crucial insights into human viral disease (see Chapter 55). Numerous epidemiologic studies have shown that rotaviruses are the most significant cause of severe gastroenteritis in young children and animals (see Chapter 55). Rotaviruses cause diarrheal disease primarily in the young, but infection and disease in older children and adults can occur. Some outbreaks in adults are caused by non–group A rotaviruses. Rotaviruses have also been reported in association with syndromes other than diarrhea (e.g., encephalitis, exanthem subitum, otitis media, necrotizing enterocolitis, liver abscesses, intussusception). However, at this time, no convincing evidence proves rotaviruses cause any of these syndromes.

The clinical significance of the rotaviruses stimulated basic research on these agents. Studies since 1973 on the biochemistry, biology, and molecular and antigenic properties of the rotaviruses have resulted in a fairly detailed understanding of virus structure and the replication cycle. Discovery that the rotaviruses code for two glycoproteins that are targeted to the endoplasmic reticulum (ER) led to studies of these glycoproteins as general models of intracellular polypeptide processing. These observations have brought the rotaviruses into prominence as biologic tools for understanding ER functions as well as virus–host interactions in the gastrointestinal tract. Studies on the structure of rotavirus and rotavirus–antibody complexes using electron cryomicroscopy and three-dimensional image-processing techniques have highlighted the usefulness of these new methods to obtain significant biologic and structural information about large, complex viruses. Recognition that one of the six nonstructural proteins acts as a viral enterotoxin has widened our understanding of rotavirus pathogenesis. Recognition that five of the six nonstructural proteins bind nucleic acids has resulted in the realization that these proteins have unique properties, and understanding their properties is providing new fundamental information about RNA synthesis and expression. The clinical syndromes, epidemiology, techniques for viral cultivation, diagnosis of rotavirus infections, and vaccine status are discussed in Chapter 55.

VIRUS CLASSIFICATION

The rotaviruses compose a genus within the family *Reoviridae,* and rotaviruses share common morphologic and biochemical properties (Table 1). Salient features are that (a) mature virus particles are about 100 nm (1000 Å) in diameter and possess a triple-layered icosahedral protein capsid composed of an outer layer, an intermediate layer, and an inner core layer; (b) 60 spikes extend from the smooth surface of the outer shell; (c) particles contain an RNA-dependent RNA polymerase and other enzymes capable of producing capped RNA transcripts; (d) the virus genome contains 11 segments of double-stranded RNA (dsRNA); (e) the viruses are capable of genetic reassortment; (f) virus replication occurs in the cytoplasm of infected cells; (g) virus cultivation *in vitro* is facilitated by treatment with proteolytic enzymes, which enhances infectivity by cleavage of an outer capsid spike polypeptide; and (h) the viruses exhibit a unique morphogenic pathway (i.e., virus particles are formed by budding into the ER) and enveloped particles are evident transiently at this stage of morphogenesis. Mature particles are nonenveloped, and these virions are liberated from infected cells by cell lysis or by nonclassic vesicular transport in polarized epithelial cells.

Structure
65- to 75-nm Icosahedral particles
Triple-layered protein capsid
Nonenveloped (resistant to lipid solvents)
Capsid contains all enzymes for mRNA production
Genome
11 Segments of dsRNA
Purified RNA segments are not infectious
Each RNA segment codes for at least one protein
RNA segments from different viruses reassort at high frequency during dual infections of cells
Replication
Cultivation facilitated by proteases
Cytoplasmic replication
Inclusion body formation
Unique morphogenesis involves transient enveloped particles
Virus released by cell lysis or by nonclassic vesicular transport in polarized epithelial cells

TABLE 1. *General characteristics of rotaviruses*

Rotaviruses are classified serologically by a scheme that allows for the presence of multiple groups (serogroups) and for the existence of multiple serotypes within each group. A rotavirus group (or serogroup) includes viruses that share cross-reacting antigens detectable by a number of serologic tests, such as immunofluorescence, enzyme-linked immunosorbent assay (ELISA), and immunoelectron microscopy. Rotaviruses comprise seven distinct groups (A to G). Group A, B, and C rotaviruses are those currently found in both humans and animals, whereas viruses in groups D, E, F, and G have been found only in animals to date. Viruses within each group are capable of genetic reassortment, but reassortment does not occur among viruses in different groups (390). The group antigenic determinants, or common antigens, are found on most (if not all) of the structural proteins and probably on many of the nonstructural proteins as well. This has been documented by showing that monospecific antisera and some monoclonal antibodies (MAbs) specific for individual polypeptides cross-react with strains in addition to those to which they were made. However, cross-reactive epitopes on the inner capsid protein (VP6) are those usually detected by diagnostic ELISA.

Group A rotaviruses have clearly been established as causing significant diarrheal disease in the young. Group B rotaviruses have been associated with annual epidemics of severe diarrhea primarily in adults in China (338). Group C viruses have been sporadically reported in fecal specimens from children with diarrhea and in several outbreaks; their clinical significance remains unclear. Rapid diagnostic tests (ELISAs) and MAbs to detect non–group A rotaviruses have been established, and these are beginning to facilitate determining the clinical importance of these viruses (245,391). Very few non–group A rotavirus strains (a single group C porcine, group C human virus, and group B porcine virus) have been successfully cultivated (315,318,328,380). This inability to grow most non–group A viruses has hampered obtaining information on these viruses, although gene-coding assignments and sequence data have been obtained. Unless noted otherwise, this chapter focuses on information about the group A rotaviruses. Reviews on the non–group A rotaviruses and comparisons between the proteins of the group A and non–group A viruses have been published elsewhere (38,223,314).

Within each group, rotaviruses are classified into serotypes defined by reactivity of viruses in plaque reduction (or fluorescent foci reduction) neutralization assays using hyperimmune serum prepared in antibody-negative animals. Using such assays, 14 VP7 serotypes have been identified (Table 2; see Chapter 55), and strains of animal and human origin may fall within the same serotype (Table 3). Neutralization assays can measure reactivity of antibody with the two outer capsid neutralizing antigens (VP4 and VP7, see later). However, in most cases, the predominant reactivity measured is with the glycoprotein VP7. This may be because VP7 composes a greater percentage of the virion outer capsid (Table 4), or alternatively, with hyperimmunization, VP7 selectively induces highly specific antibodies. Identical classification of the same virus isolates using MAbs to VP7 unequivocally demonstrates that plaque-reduction neutralization assays with hyperimmune serum primarily measure reactivities with VP7 (29,82,353).

TABLE 2. *Group A rotavirus VP7 (G) serotypes*

TABLE 3. *Rotavirus VP4 genotypes [P] and serotypes (P)*

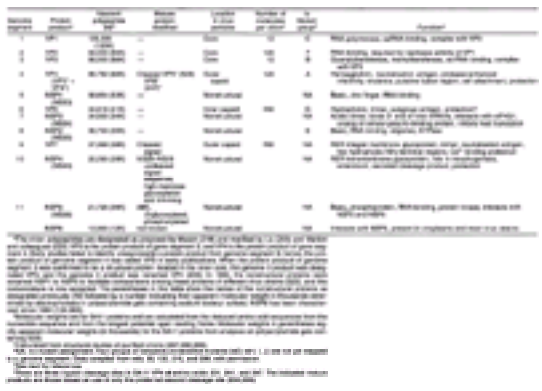

TABLE 4. *Rotavirus proteins*

In some cases, a rotavirus strain will not react clearly in reciprocal neutralization assays with hyperimmune antiserum. This is usually because the two viruses being compared possess distinct immunologic forms of VP4 (the second outer capsid protein), which is also a neutralization antigen (158). Because the genes that encode these separate neutralization antigens can segregate (reassort) independently, it is not surprising that some virus isolates can possess heterologous neutralization (VP4, VP7) antigens (158). Classification of rotaviruses is by a binary system (similar to that used for influenza viruses) in which distinct serotypes of VP4 and VP7 are recognized (141,160,304). However, a lack of readily available typing serum or MAbs to different VP4 types has hampered classification of VP4 (P) serotypes. Instead, properties of VP4 have been studied by sequence analysis, and current evidence suggests the existence of at least 20 different genotypes of VP4 (see Table 3). Genotypes of VP4 and VP7 are determined by sequence or hybridization analysis, whereas serotypes are determined by reactivity with polyclonal or monoclonal antisera (104). For VP7, a correlation between genotype and serotype has been established. Such a correlation is less clear for VP4, although sequence variation between amino acids 84 and 180 has been suggested to be useful to define P-type–specific epitopes (196).

Serotype designation thus reflects the expression of neutralization epitopes on both VP4 and VP7. Increasingly, epitope expression on these outer capsid proteins has been found to be dependent on the specific combinations of VP4 and VP7 in this complex capsid (57). Although the molecular basis of these interactions is not yet well understood, new structural information clearly documents the presence of specific interactions between VP4, VP6, and VP7 within this complex capsid. The serology of the epitopes in proteins that interact in the capsid is clearly complicated and likely will not be fully understood until high-resolution structural data on the capsid are available.

VIRIONS

Structure

The morphologic appearance of rotavirus particles is distinctive, and three types of particles can be observed by electron microscopy (Fig. 1 and Fig. 2). The complete particles resemble a wheel with short spokes and a well-defined smooth outer rim. The name *rotavirus* (from the Latin *rota,* meaning “wheel”) was suggested based on this morphology (119). The complete infectious particles historically were called double-shelled particles, but newer structural data show they are triple layered. Double-layered particles (previously called single-shelled particles) lacking the outer shell are described as *rough particles* because their periphery shows projecting trimeric subunits of the inner capsid. Single-layered core particles are seen infrequently; they usually lack genomic RNA and are aggregated.

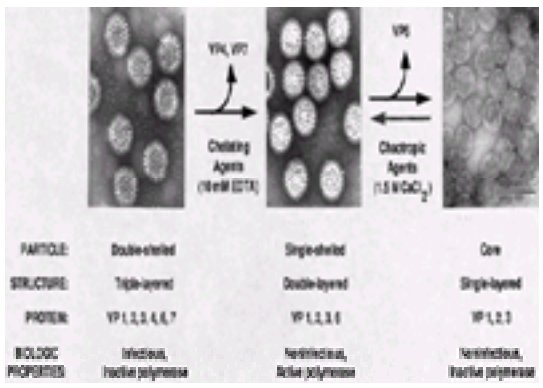

FIG. 1. Structural and biologic properties of rotavirus particles. Electron micrographs show typical triple-layered, double-layered, and single-layered core particles seen after staining with 1% ammonium molybdate. The double-layered and core particles can be produced by sequential degradation of infectious triple-layered particles as shown. The proteins and biologic properties of the particles are detailed in the text. Bar = 100 nM. (Modified from ref. 113, with permission.)

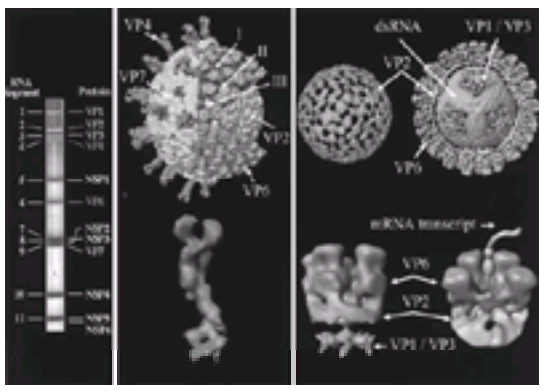

FIG. 2. Gene coding assignments and the three-dimensional structures of rotavirus particles. **Left:** A polyacrylamide gel shows the 11 segments of dsRNA that comprise the rotavirus genome (A:Si:SA11 strain in this case) and the proteins encoded by each of these genes. **Center:** A cutaway of the 23 Å three-dimensional structure of a complete rotavirus particle showing the outer, intermediate, and inner shells of the capsid structure. The proteins in the different shells and channels are indicated. The structure of a single spike, shown in the *bottom center panel,* illustrates the dimeric nature of the spike, which is most pronounced in the exterior portion. The globular shape of the interior portion may allow the VP4 spike to make multiple contacts with the VP6 trimers that surround the type II channels. **Right:** The three-dimensional structure of the single-layered particle at a threshold where the boundaries of the two molecules of VP2 that make the icosahedral asymmetric unit are shown. On the right, a cutaway from the 19 Å structure of a double-layered particle in which the VP6 and VP2 layers have been partially removed, shows the mass densities due to the genomic double-stranded RNA and the enzymatic complexes composed of VP1 and VP3. The *left portion of the bottom figure* illustrates a side view of the enzymatic complex found at the fivefold positions in the particles beneath the VP2 and VP6 layers; the *right portion* shows a proposed pathway for the nascent mRNA molecule exiting through a type I channel. These structures were determined by image processing of electron micrographs of particles embedded in vitreous ice (287,288,289,290 and 291). (Modified from ref. 79, with permission; also including an unpublished structure of the VP4 spike kindly prepared by B.V.V. Prasad.)

Three-dimensional reconstructions using cryoelectron microscopy and image processing techniques to study triple- and double-layered rotavirus particles embedded in vitreus ice have provided the most detailed description of particle structure (287,289,324,388) (see Fig. 2). These studies unequivocally establish that particles possess icosahedral symmetry with a T=13*l* (levo) icosahedral surface lattice for the two outer layers. A distinctive feature of the virus structure is the presence of 132 large channels spanning both shells and linking the outer surface with the inner core.

Three types of channels can be distinguished based on their position and size (see Fig. 2). Twelve type I channels run down the icosahedral fivefold axes, 60 type II channels are those on the six-coordinated positions surrounding the fivefold axes, and 60 type III channels are those on the six-coordinated positions around the icosahedral threefold axes. Type III channels are about 140 Å in depth and about 55 Å wide at the outer surface of the virus. On entering the particle, these channels constrict before widening to their maximum width, which is close to the surface of the inner shell. Similar features and dimensions are seen in the other two types of channels, except that type I channels have a narrower (about 40 Å) opening at the outer surface of the virus. These channels are involved in importing the metabolites required for RNA transcription and exporting the nascent RNA transcripts for subsequent viral replication processes. The channels at the fivefold axes are conduits for the export of messenger RNA (mRNA) that first interacts with the enzyme complexes composed of VP1 and VP3 that are present at the inner surface of the fivefold axes of the single-layered particle (198,199,291) (see Fig. 2). The single-layered particle possesses a T=1 symmetry and is composed of 120 molecules of VP2 arranged as 60 dimers that surround the genomic dsRNA that is highly ordered, with about 25% of the genome making up an internal dodecahedral structure (291) (see Fig. 2). This organization with two molecules in the icosahedral asymmetric unit has also been referred to as a T=2 structure (145). All segmented dsRNA viruses contain 120 molecules of a core protein (VP3 for bluetongue virus, lambda 1 for reoviruses, the single capsid protein for cytovirus) that surrounds an ordered genome (145,154,300,399). Although the inner shell protein shares similar features among these dsRNA viruses, rotaviruses and orbiviruses are distinguished by housing their enzymatic functions entirely *within* the inner shell, leading them to be called *nonturreted viruses,* and nascent mRNA transcripts are released through channels penetrating the two capsid layers at the icosahedral vertices (154,200). This capsid architecture contrasts with the structure of the turreted reoviruses, aquareovirus and cypovirus, where the polymerase enzyme is housed within the core, but the capping enzymes are incorporated as pentameric turret-like projections that extend through the inner capsid layer at each icosahedral vertex (154).

The VP2 layer is surrounded by 780 molecules of VP6 arranged in trimers and positioned at all the local and strict threefold axes of the T=13 icosahedral lattice. The addition of the VP6 layer to virus-like particles formed from VP2 imparts greater morphologic homogeneity and long-term stability to the particles (396), suggesting that VP6 may play a major role in providing structural integrity to the rotavirus capsid. The double-layered particle is about 705 Å in diameter, and the structure of the VP6 shell is very similar to the VP7 shell of bluetongue virus; both these proteins consist of two distinct domains: a distal eight-stranded b-barrel domain and a lower a-helical domain (292,301).

Studies of virus particles revealed structural features not seen previously (287). Sixty spikes extend from the smooth surface of the outer shell (see Fig. 2). These protein spikes are situated at an edge of the type II channels surrounding the fivefold icosahedral axes and are composed of the hemagglutinin (VP4). This was first demonstrated by showing that 2 Fab subunits of a monoclonal antibody that recognizes VP4 bind on the sides near the tips of the spikes (288). Higher-resolution reconstructions of native particles, of a reassortant lacking spikes, and of spikeless particles (formed by removing VP4 by treatment at high pH) confirmed that VP4 is the spike and showed that the spike is multidomained with a radial length of about 200 Å, with about 120 Å projecting from the surface of the virus (324,388). The head of the spike is bilobed and attached to a square-shaped body formed by two rods. The anchoring base displays a pseudo-sixfold symmetry, and this may represent a novel folding motif in which the single polypeptide of VP4 contributes

similar but nonequivalent domains to form the arms of the hexameric base (324,388).

In the VP4 spike, no twofold axis of symmetry is strikingly evident. The location of the spike does not correspond to any local or strict twofold axis of the icosahedron, and thus, the dimeric configuration is apparently asymmetric. This is consistent with the observation that the two Fab fragments of a VP4 MAb bind to the sides near the tip of the spike at different angles, indicating that the antigenic sites are not in structurally identical environments (288). It is unclear whether this asymmetry in the spike serves a specific function. The VP4 spike extends inward about 80 Å into the outer virion surface and interacts with two molecules of VP7, but inside, it appears that the large globular domain of VP4 interacts with all six of the VP6 molecules surrounding the type II channel. However, there may be more specific interactions between the VP4 dimer and two of the six VP6 molecules. The extensive VP4–VP7 and VP4–VP6 interactions imply that VP4 may participate in maintaining the precise geometric register between the inner and outer capsids as well as affect functional domains. The VP7 outer layer consists of trimers, or 780 molecules, of this protein. VP7 interacts with the tips of the VP6 trimers.

The existence of each shell and the ability of VP7 and VP4 to interact directly with VP6 have been demonstrated by the production of virus-like particles composed of VP2, VP2/6, VP2/4/6, VP2/6/7 by expression of the respective proteins (84,194) or coassembly of purified proteins of each layer onto preformed VP2 particles (62,63,398). These results show that the structural proteins have the intrinsic properties of self-assembly and suggest high-affinity interactions among the proteins.

Although VP4 appears to be a dimer, its elongated shape with multiple domains resembles the hemagglutinin of influenza virus, which is a trimer and has distinct rodlike and globular domains (see Chapter 46). The rodlike portion of the influenza hemagglutinin forms a triple-stranded coiled-coil of a-helices. VP4 is predicted to contain extended a-helical heptad repeats typical of coiled-coils (193,223), and higher-resolution analyses will be required to discern whether the rodlike domains of VP4 are folded as a-helices. A similar coiled-coiled region is also present in the homotrimeric reovirus 1 hemagglutinin, although this protein is much longer and structurally distinct (94) (see Chapter 52). Coiled-coils have been found to participate in both intracellular vesicle and viral membrane fusion activity (330) and are found in the fusion proteins of a variety of viruses, including retroviruses, coronaviruses, paramyxoviruses, filoviruses, and influenza viruses. Although rotavirus is not an enveloped virus, similarities exist between rotaviruses and viruses whose surface glycoproteins mediate fusion. For example, the spike proteins of all these viruses (a) are involved in binding to the cellular receptor, (b) are synthesized as precursors and require a proteolytic cleavage for their function, (c) contain a fusion peptide region that is part of a polar hydrophobic sequence, and (d) contain one or more heptad repeats. It remains to be determined whether the a helical heptad repeat or putative fusion domain in the rotavirus spike protein are important for virus entry or during viral morphogenesis in cells, a process that involves a budding of particles through the membrane of the ER (see later).

Physicochemical Properties

The different rotavirus particle types possess distinct biophysical and biologic properties (see Fig. 1). Infectivity depends on the presence of the outer capsid. Calcium is required for particle stability apparently by stabilizing the outer capsid glycoprotein VP7, and the crucial concentration of calcium needed to stabilize the outer capsid is dependent on the virus strain (124,311). Treatment of particles with calcium-chelating agents (e.g., EDTA and EGTA) removes the outer capsid and results in a loss of infectivity (40,110). Calcium has been detected in triple-layered but not double-layered particles, and this may represent binding to potential calcium binding sites present in the protein sequence of VP7 (16,92,323). Single-layered particles can be produced by disruption of double-layered particles with chaotropic agents such as sodium thiocyanate or high concentrations of calcium chloride (7,77).

Triple- and doubled-layered particles can be separated by centrifugation in gradients of cesium chloride (CsCl) or sucrose, where they possess distinct densities and sedimentation values. Triple-layered particles have a density of 1.36 g/cm^3 in CsCl and sediment at 520S to 530S in sucrose, whereas double-layered particles have a density of 1.38 g/cm ^{3} and sediment at 380S to 400S (346). Single-layered core particles have a density of 1.44 g/cm ^{3} in CsCl and a sedimentation coefficient of 280S (28). The three types of particles can also be separated in agarose gels (125).

Rotavirus infectivity and particle integrity are generally resistant to fluorocarbon extraction and exposure to ether, chloroform, or deoxycholate (110,117,346,378), reflecting the absence of an envelope on mature particles. Chloroform treatment reduces infectivity slightly and destroys hemagglutinating activity (31,110). Sodium dodecyl sulfate (0.1%) inactivates infectivity, but exposure to nonionic detergents can enhance infectivity, presumably by disrupting aggregates (372).

Rotavirus infectivity is relatively stable to inactivation, and it survives well on porous (paper, cotton cloth) and nonporous (aluminum, china, latex) environmental surfaces (1). Infectivity is stable within the pH range of 3.0 to 9.0 (110,215,259,377,378), and bovine and human samples have retained infectivity for months at 4°C or even 20°C, when stabilized by 1.5 mM $CaCl_2$ (329). The infectivity of bovine and simian rotaviruses is relatively stable even at 45° to 50°C, but hemagglutinating activity is lost rapidly at 45°C. Infectivity and hemagglutinating activity are destroyed by repeated freezing and thawing (23,31,110), and the hemagglutinating spikes are removed by treatment at high pH (11).

Virus infectivity can be inactivated by disinfectants such as phenols, formalin, chlorine, and b-propiolactone (320,367). Ethanol (95%), perhaps the most effective disinfectant, exerts its effect by removing the outer capsid (23,31,37,192,347).

In general, studies of the structure and inactivation of rotaviruses have yielded similar results whether the viruses studied were of animal (bovine or simian) or human origin. However, human rotavirus strains are distinguishable by being more difficult to cultivate, and their hemagglutinin, if present, is more difficult to detect (186). In addition, human strains seem to lose their outer capsid more easily than other strains. For example, purification of triple-layered human rotavirus particles is generally difficult in gradients of CsCl because of loss of the outer capsid; instead, metrizamide gradients may be required for purification of these viruses (352). Analysis of the determinants of density and stability by characterization

of reassortants has shown that a reassortant may have an intermediate density compared with two parental viruses, and physical interactions among the structural proteins appear to be responsible for heterogeneity in particle density (61). In addition, the stability of infectivity during fluorocarbon extraction, CsCl gradient purification, and subsequent storage at 4°C can be dependent on the type of genome segment 4 (VP4) in particles (61).

Genome Structure

The viral genome of 11 segments of dsRNA is contained within the virus core capsid. Deproteinized rotavirus dsRNAs are not infectious, reflecting the fact that virus particles contain their own RNA-dependent RNA polymerase to transcribe the individual RNA segments into active mRNAs. Hydrodynamic studies of the flexibility or “stiffness” of isolated rotavirus RNA segments in solution indicate that packaging of these RNA segments into the rotavirus capsid requires intimate protein–RNA interactions (177). The proteins directly responsible for segment packaging remain unknown; the structural proteins present in core particles (VP1, VP2, and VP3) are obvious candidates, but nonstructural proteins may also play a role. The genome RNA is highly ordered within the particle, with about 25% of the genome making up a dodecahedral structure, and VP2 interacts with the RNA. Several points of contact between the inwardly protruding portion of VP2 interact with the RNA surrounding each fivefold axis (195,291) (see Fig. 2).

The nucleotide sequence of all of the 11 rotavirus RNA segments for several rotavirus strains (SA11, human KU, bovine Rf) is now known. The prototype simian SA11 strain was the first genome completely sequenced. The sequences from different rotavirus strains show general features (Fig. 3) around the structure of each of the genome segments. Each positive-sense RNA segment starts with a 5'-guanidine followed by a set of conserved sequences that are part of the 5'-noncoding sequences. An open reading frame (ORF) coding for the protein product and ending with the stop codon follows, and then another set of noncoding sequences, which contains a subset of conserved terminal 3' sequences and which ends with two 3'-terminal cytidines, is found. Almost all mRNAs end with the consensus sequence 5'-UGUGACC-3', and these sequences contain important signals for gene expression and genome replication. The lengths of the 3'- and 5'-noncoding sequences vary for different genes, and no polyadenylation signal is found at the 3' end of the genes. All of the sequenced genes possess at least one long ORF after the first initiation codon. This is usually a strong initiation codon based on Kozak's rules (191). Although some of the genes possess additional in-phase (genes 7, 9, and 10) or out-of-phase (gene 11) ORFs, current evidence indicates that all the genes are monocistronic, except gene 11 (224). The last 4 nucleotides of the mRNAs can function as translation enhancers (66).

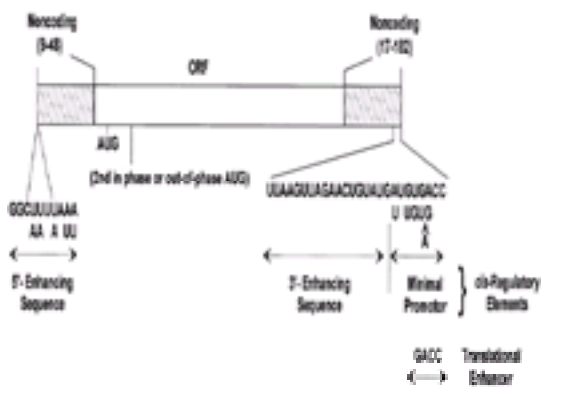

FIG. 3. Major features of rotavirus gene structure. Schematic shows the overall structure of rotavirus genes from the published sequences of genes 1 to 11. All eleven rotavirus genes lack a polyadenylation signal, they are A + U rich, and they contain conserved consensus sequences at their 5' and 3' ends. Variations in the conserved ends are also shown. The prototype SA11 genome segments range in size from 667 (segment 11) to 3302 (segment 1), with a total 18,556 base pairs. The *bottom arrows* show cis-regulatory elements of rotavirus mRNA required for replication of transcripts assayed in a cell-free replication system (268,381). The 5'- and 3'-noncoding regions at the termini of the mRNA are predicted to interact and stably base-pair to form a panhandle structure (265,268), and interactions between the 38-terminus with the nonstructural protein NSP3 may promote translation of the viral mRNA (368). The penultimate 5'-GACC-3' is a translation enhancer (66).

The rotavirus gene sequences are A + U rich (58% to 67%), and this bias against CGN and NCC codons is shared with many eukaryotic and viral genes. The dsRNA segments are base-paired end to end, and the positive-sense strand contains a 5' cap sequence $m^7GpppG^{(m)}GPy$ (165,227). Similar features of the RNA termini (capped structures and 5'- and 3'-conserved sequences) are found in the primary structures of the genome segments of other viruses (e.g., reovirus, cytoplasmic polyhedrosis virus, orbivirus) in the *Reoviridae* and in other virus families with segmented genomes (*Orthomyxoviridae, Arenaviridae,* and *Bunyaviridae*). One of the most intriguing aspects of rotaviruses and all segmented dsRNA viruses relates to how these viruses coordinately replicate and package the 11 viral mRNAs. The 11 mRNAs must share common cis-acting signals because they are all replicated by the same polymerase, and these signals are likely to be formed by secondary structures rather than by primary sequences. In addition, each mRNA must also contain a signal that is unique to it alone because the 11 mRNAs must be distinguished from one another during packaging. Generally, the conserved terminal sequences in genome segments contain cis-acting signals important for transcription, RNA translation, RNA transport, replication, assembly, or encapsidation of the viral genome segments. Some of the cis-acting signals for rotavirus RNA replication and translation have been identified (see Fig. 3), but assembly or encapsidation signals remain unknown (266).

Rotaviruses are the only known agents of mammals or birds that contain 11 segments of dsRNA. In most cases, the electrophoretic pattern of the genome of the group A viruses is composed of four high-molecular-weight dsRNA segments (1 to 4), two middle-sized segments (5 and 6), a distinctive triplet of segments (7 to 9), and two smaller segments (10 and 11). When this basic pattern is not seen, the rotavirus being analyzed may be either a group A avian virus, a non–group

A virus, a group A virus that contains rearrangements within individual genome segments (Fig. 4), or a new unique group A virus. Analysis of genomic electropherotypes is a relatively easy, rapid, and popular technique for virus detection and for molecular epidemiology studies to monitor virus outbreaks and transmission. However, because distinct RNA patterns can arise by different mechanisms (shift, drift, rearrangements), these profiles cannot be used as the sole criterion for classification of a virus strain (54,107).

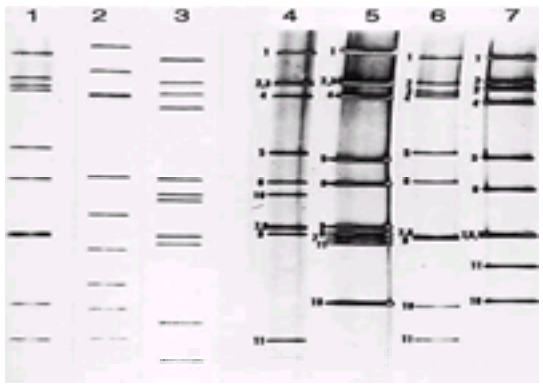

FIG. 4. Electropherogram of rotavirus RNA segments. The RNA segments were separated by electrophoresis in a 10% polyacrylamide gel and visualized by staining with silver nitrate. The RNA patterns of a group A rotavirus (SA11, *lane 1*), a group B rotavirus (adult diarrhea rotavirus isolate from China, *lane 2*), and a group C rotavirus (porcine pararotavirus, *lane 3*) are shown. The rearranged RNA patterns of three group A rabbit rotavirus strains (C11, *lane 4*; Ala, *lane 5*; and R2, *lane 7*) and their cognate segments compared with those of SA11 (*lane 6*) are also shown. The cognate genes were identified by hybridization with cDNAs for each SA11 RNA segment (348).

Nucleic acid hybridization combined with Northern blot is a second assay used to classify viruses based on the relatedness of genome segments (113). This method has been found to be useful to classify genetically related viruses into different genogroups (244) and to identify the origin of specific RNA segments in virus reassortants. This method has also been useful to characterize viruses possibly involved in cross-species transmission (242,243).

In viruses with genome rearrangements, typical RNA segments are missing or are decreased in concentration in an electrophoretic profile, and these are replaced by additional, more slowly (or rarely more rapidly) migrating bands of dsRNA (see Fig. 4). The slowly migrating bands represent concatemeric forms of dsRNA containing sequences specific for the missing RNA segments (reviewed in 89). The more rapidly migrating bands appear to represent deletions. Viruses with genome rearrangements of this type have been isolated most frequently from immunodeficient, chronically infected children (164,269), asymptomatically infected immunocompetent children (27,219), and animals [calves (279), pigs (26), or rabbits (348,358)]. They have also been obtained *in vitro* after serial passage of a tissue culture–adapted bovine rotavirus at high multiplicity of infection (163). Virus isolates with rearrangements in segments 5, 6, 8, 10, and 11 have been characterized, with the greatest number having rearrangements detected in segments 5 and 11. Viruses with a rearranged segment 11 have some selective advantage (better growth or stability) (221), so they are detected more easily, rather than occurring more frequently.

Viruses isolated and characterized that contain rearranged genome segments are generally not defective, and the rearranged segments can reassort and replace normal RNA segments structurally and functionally (6,30,140). Biophysical characterization of such particles has shown that up to 1,800 additional base pairs can be packaged in particles without causing detectable changes in particle diameter or apparent sedimentation values. However, the density of particles containing rearranged genomes may be increased, and the increase in density is directly proportional to the number of additionally packaged base pairs (228). These results indicate that rotaviruses have considerable capacity to package additional genomic RNA, although the upper limit is unknown. Whereas a total of 11 RNA segments are invariantly packaged, there appears to be much less constraint on the length of individual RNA segments assembled into the maturing virus particle. Because the amount of viral RNA present in virions can vary by as much as 1,800 nucleotides, a headfull mechanism for RNA packaging as seen for the dsRNA phage phi 6 (235) may not operate for rotaviruses.

In most cases, the profiles of virus-encoded proteins in cells infected with rotaviruses with rearranged genomes are similar to those seen in cells infected with standard rotavirus strains (6,30,220,230,279,321,348). This indicates that the rearrangement of the sequences in a segment apparently has left the normal reading frames and their expression unaltered. Sequence analyses of rearranged genome segments have confirmed this and revealed mechanisms by which the rearrangements arise.

In most cases, the rearrangements result from a head-to-tail duplication that occurs immediately downstream from the normal ORF, and hence the rearranged segment retains its capacity to express its normal protein product. For one rearranged virus, the protein profile was distinct from that seen with standard virus. In this case, the gene rearrangement was in genome segment 5, and no protein of normal or larger size was detected in infected cells (163). Further characterization of this rearranged segment showed that because of the introduction of a point mutation in the ORF, a truncated protein lacking the C-terminal half of the protein is made. Because this rearranged virus is nondefective, the C-terminal half of this protein is nonessential for rotavirus replication, at least in cell culture (162). Another mutant lacking the cysteine-rich zinc finger motif in the genome segment 5 protein, NSP1, is also viable (350). Genome rearrangements (concatemerization and deletion) are thought to be a third mechanism of evolution (in addition to antigenic shift and drift) of rotaviruses (89,361). Studies of rearranged segments are helpful to identify sequences critical for replication and RNA packaging (89).

CODING ASSIGNMENTS AND ROTAVIRUS PROTEINS

The coding assignments and many properties of the proteins encoded in each of the 11 genome segments are now well established (see Table 4 and Fig. 2), although new protein functions continue to be identified. Protein assignments have been determined by *in vitro* translation using mRNA or denatured dsRNA and by analyses of reassortant viruses. The information on SA11 was completed first, and SA11 became the prototype virus. Comparative studies of other rotavirus strains have shown that the absolute order of migration of cognate genes may differ among virus strains. Therefore, identification of cognate genes must be based on hybridization with gene-specific probes, on reassortant analysis, or on biochemical or immunologic identification of the protein synthesized in a cell-free translation system programmed with mRNA specific to the gene. The ability to obtain sequence information directly from dsRNA or single-stranded RNA (ssRNA) and the accumulating nucleic acid sequence databases make it possible to identify cognate genes based solely on sequence homology.

The rotavirus genome segments code for structural proteins found in virus particles and nonstructural proteins found in infected cells but not present in mature particles (Fig. 5; see Table 4 and Fig. 2). Six of the genome segments code for structural proteins found in virus particles. Another six proteins are nonstructural, although a few virus strains may lack NSP6. Early studies often presented conflicting conclusions concerning the numbers and locations of the rotavirus proteins. Many of these conflicts were resolved, as reviewed elsewhere (25,112,155,223,231), when it was recognized that posttranslational modifications (glycosylation, trimming of carbohydrate residues, and proteolytic cleavages) occur after polypeptide synthesis. In addition, strain variations (such as the presence of more than one glycosylation site on VP7 in some bovine, equine, porcine, and human rotavirus strains) provide explanations for other differences in polypeptide patterns.

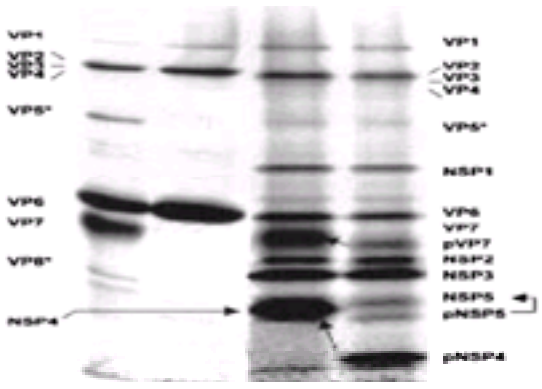

FIG. 5. Rotavirus polypeptides in purified virus particles and in infected cells. ^{35}S-methionine–labeled polypeptides in purified triple-layered virus (*lane 1*), double-layered virus (*lane 2*), or monkey kidney cells infected with SA11 and labeled for 1 hour, 6 hours after infection (*lanes 3 and 4*), were separated on a 12% polyacrylamide gel. The polypeptides were visualized by fluorography. The glycoprotein precursors to VP7 (pVP7) and to NSP4 (pNSP4) are seen only when N-linked glycosylation is blocked by treatment of the cells with the inhibitor tunicamycin (*lane 4*). The structural polypeptides are labeled on the *left* and the nonstructural polypeptides are labeled on the *right.* The two NSP5 bands (an unmodified and a modified form) are only seen clearly in cells treated with tunicamycin (*lane 4*). The VP2 and VP3 polypeptides were not resolved in this gel. To resolve VP2 and VP3, the polypeptides in purified virus must be separated on gels with a different cross-linking ratio than the standard used in the gels to analyze the infected-cell polypeptides (203). The triple-layered virus was grown in the presence of protease, so that uncleaved VP4 is not detected, but the VP4 cleavage products VP5* (60K) and VP8* (28K) are seen (*lane 1*). NSP6 was run off this gel and thus is not detected.

The nomenclature of the viral proteins (as originally proposed for SA11 proteins) designates structural proteins as viral protein (VP) followed by a number, with VP1 being the highest-molecular-weight protein, and proteins generated by cleavage of a larger precursor being indicated by an asterisk [VP4 is cleaved to produce VP5* and VP8* (103,108)]. Initial studies referred to the nonstructural proteins as NS followed by a number indicating the protein's molecular weight. This nomenclature has been replaced by NSP1 to NSP6 to facilitate comparisons among cognate nonstructural proteins of different molecular weights (223) (see Table 4). In fact, much of the literature before 1988 on “VP3” refers to the genome segment 4 product; before 1994, NS53, NS35 referred to NSP1, NSP2, and so forth (see Table 4). The new nomenclature is used throughout this chapter.

The Core Proteins

The proteins of core particles (VP1, VP2, VP3) function as structural proteins and each have affinity for ssRNA, but only VP1 shows sequence-specific recognition of viral RNA. Each of the core proteins plays a role in the processes of RNA transcription and replication. Viral transcription is easily studied *in vitro* by assays using double-layered particles (75), and replicase activity is assessed by studying negative-stranded RNA synthesis produced *in vitro* by single-layered particles that can function to replicate exogenously added mRNA (64,268). Several findings indicate that VP1 is the viral RNA polymerase and functions as both the viral transcriptase and replicase: (a) all VP1 sequences share the four common motifs conserved in the sequences of all RNA-dependent RNA polymerases (76,223); (b) VP1 binds nucleotides and cross-linking of the photoreactable nucleotide azido–adenosine triphosphate (ATP) to VP1 inhibits transcription (366); (c) VP1 specifically binds to the 3' end of viral mRNA (261); (d) temperature-sensitive (ts) mutants of VP1 do not synthesize ssRNA at the nonpermissive temperature (58); (e) VP1 is a component of baculovirus-expressed particles and replication intermediates that have replicase activity (264,396). Although VP1 is the candidate RNA polymerase, reconstitution experiments have shown that VP1 requires VP2 for replicase activity (264).

VP2 binds RNA nonspecifically (36,195) and interacts with the dsRNA lining the VP2 shell (291). However, ts mutants mapping to VP2 do not synthesize dsRNA (216). VP1 and VP2 are both required for replicase activity (264,396), and the essential role of VP2 in replication is linked to its ability to bind mRNA (264).

Of the core proteins, the least is known about VP3. Studies with virus-like particles have shown that VP3 can bind to the N-terminus of VP2, a region of the innershell protein to which VP1 and ssRNA also bind that is required for RNA replication (195,397). VP3 covalently binds a-^{32}p-guanosine triphosphate (GTP), indicating it is a guanylyltransferase (202,278), and VP3 is a methyltransferase (59), indicating that VP3 is a multifunctional capping enzyme. It is expected that one of the rotavirus core proteins should possess helicase activity needed for the transcription process, but to date no rotavirus core protein has been associated with this activity.

The Nonstructural Proteins

The rotavirus genome codes for six nonstructural proteins (NSP1, NSP2, NSP3, NSP4, NSP5, NSP6), which are variously involved in replication (NSP1 to 3, 5, 6) and morphogenesis (NSP4). All these nonstructural proteins, except NSP4, interact with nucleic acid. The effects and necessity of the nonstructural proteins for viral replication remain to be studied in more detail. However, the predictions or observations that most of the nonstructural proteins possess a basic charge [see Table 4], their demonstrated ability to bind RNA (36,161,178,222,280), their presence in subviral particles with replicase activity (260), and the dsRNA-negative phenotype of ts mutants that map to their genome segments (58,130) suggest these proteins function as part of replication complexes, as chaperones to transport RNAs or proteins to the sites of RNA replication, translation, assembly, or to gather the genome segments for packaging. A better understanding of the functions of the nonstructural proteins in the replication cycle is being obtained as these proteins are expressed and studied using recombinant DNA methods, often in conjunction with confocal microscopy.

NSP1 appears to be nonessential for virus replication, at least in cultured cells, and some studies have implicated this gene as a virulence factor in mice (41), but not in piglets or rabbits (39,70). NSP1 is the least conserved of the viral proteins, showing even more sequence variation than VP4 and VP7. It contains a relatively conserved zinc finger domain, but this domain is missing in some virus strains, showing it is not essential for virus replication and genome segment reassortment (257,364). NSP2 is an oligomeric NTPase that is localized to viroplasms, possesses helix destablizing activity, and may be involved in RNA encapsidation and virulence (53,354). NSP3 binds to the 3' end of viral mRNAs and represents a prototype of a new kind of sequence-specific RNA-binding protein that requires only four nucleotides for RNA recognition (281). NSP3 functions similarily to the cellular poly(A)-binding protein and binds eIF4G and inhibits cellular protein synthesis by this novel mechanism (Fig. 6) (276,277,280). NSP3 also enhances the translation of viral mRNA (368). NSP5 is an *O*-glycosylated phosphoprotein that self-assembles into dimers (132). NSP5 has autokinase activity and exists in several phosphorylated isomers in infected cells (4,32). When coexpressed in uninfected cells, NSP2 induces the hyperphosphorylation of NSP5 (3). The mechanism by which NSP5 hyperphosphorylation occurs are not known, but may involve a cascade of events initiated by the NTPase activity by which NSP2; NSP5 has been shown to interact with NSP2 (3,134,282,379). NSP6 is encoded in an alternative ORF on gene segment 11 of most rotaviruses and is known to interact with NSP5 and accumulate in viroplasms (224,363). NSP1 and NSP3 show a diffuse cytoplasmic staining in cells, and both fractionate with cellular cytoskeletal elements rather than concentrating in viroplasms (12,162,222). NSP2, NSP5, and NSP6 are associated with viroplasms and coexpression of NSP2 and NSP5 (probably NSP6 too, from the construct that made NSP5—although this was not evaluated) is sufficient for the formation of viroplasms (114). NSP2, NSP5, and NSP6 may function to recruit or move other viral proteins from their sites of synthesis into the viroplasms, or they facilitate RNA encapsidation or movement of nascent viral particles from the viroplasms to the ER membrane.

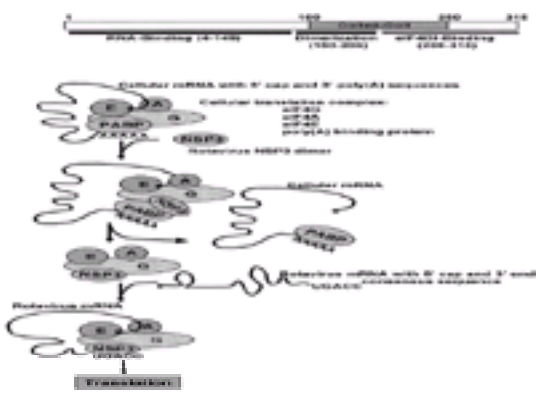

FIG. 6. Modulation of host cell translation initiation by rotavirus NSP3. **A:** Schematic of features of NSP3 defined by sequence and mutational analyses (276). **B:** Model of how NSP3 affects host cell translation. The rotavirus NSP3 functions similarly to the poly(A)-binding protein (PABP) and binds the same site on the cellular translation initiation factor eIF4G, thus evicting PABP bound to cellular mRNAs from the cellular translation initiation complex. The 3' sequence GACC on rotavirus mRNAs functions as a viral-specific translation enhancer by a process that involves recognition by NSP3. Rotavirus-specific mRNAs containing NSP3 are preferentially translated in virus-infected cells. (Modified from ref. 368, with permission).

NSP4 is the only nonstructural protein that does not bind to RNA. NSP4 has been studied extensively because it plays a role in viral morphogenesis and is important in virulence by functioning as an enterotoxin. NSP4 is a nonstructural glycoprotein that has multiple domains (Fig. 7). NSP4 is a 20K primary translation product, it is cotranslationally glycosylated to a 29K species, and oligosaccharide processing yields the mature 28K protein that is a transmembrane protein of the ER (101,171). The 175–amino acid polypeptide backbone of NSP4 consists of an uncleaved signal

sequence, three hydrophobic domains with two N-linked high mannose glycosylation sites being in the first hydrophobic domain, and a predicted amphipathic a-helix that overlaps a folded coiled-coil region. The H2 transmembrane domain traverses the ER bilayer, and the C terminus, which is hydrophilic, forms an extended cytoplasmic domain (35,51,102,171). The carbohydrate moieties remain sensitive to endoglycosidase H digestion, and oligosaccharide processing of the Man9GlcNAc carbohydrate added to NSP4 stops at Man8GlcNAc, with the mannose-9 species predominating (35,171), indicating that no further trimming occurs in the Golgi.

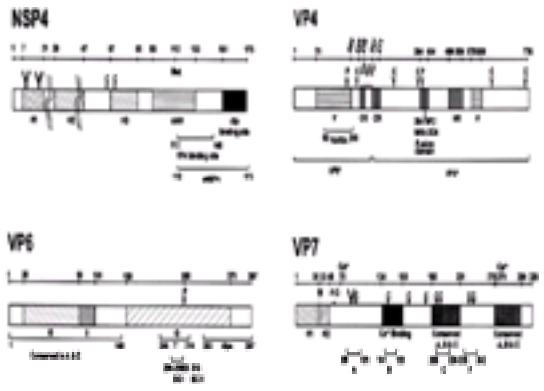

FIG. 7. Features of four rotavirus proteins: NSP4, VP4, VP6, and VP7. **Top left:** Schematic of structural properties of NSP4 and its proposed topography in the membrane of the endoplasmic reticulum. H1, H2, and H3 indicate the three hydrophobic domains and (Y) the glycosylation sites. Most of H2 and a small part of the upstream amino acids traverse the endoplasmic reticulum (ER) membrane ( ). Residues in the H1 domain are localized in the ER lumen, whereas amino acids from the end of the H2 domain to amino acid 175 are cytoplasmic. The amphipathic a-helical (*AMINO ACIDH*) domain overlaps a coiled-coil regin. The conserved cysteines (*C*), putative VP4, and double-layered particle (*dlp*)-binding sites are shown. This diagram is based on sequence data and biochemical analyses (51,102,171,274,357). **Top right:** Schematic of structural and antigenic properties of VP4 based on the analyses of nucleotide sequences of different virus strains and escape mutants selected with neutralizing monoclonal antibodies (MAbs). The two major cleavage products (VP8*) and (VP5*), the trypsin cleavage sites for SA11( ), predicted heptad repeat (*HR*), variable region (*V*), conserved region (*CR*), conserved cysteines (*C*) and prolines (*P*), hemagglutination (*HA*) and sialic acid (*SA*)-binding domain, one neutralization-positive (*NP*) NP2 (amino acid 394) MAb site, and the putative fusion domain are indicated. Other escape mutants selected with neutralization positive MAbs have been mapped to amino acids 150, 155, 180, 183, 187, 188, 190, and 194. The numbering shown here for VP4 is based on a protein of 776 amino acids as determined for SA114fM, rhesus rotavirus MMU18006, and bovine rotavirus 486. VP4 of human rotavirus strains are 775 amino acids, having lost an amino acid between residues 134 and 136. This diagram is based on sequence data and on analyses of neutralization escape mutants (213,351). **Bottom left:** Schematic of structural properties of VP6. The hydrophobic (*O*), hydrophilic (*I*), trimerization (*T*), double-layered particle assembly domain (*dlpa*), conserved proline (*P*), SGI MAb 255 and SGII MAb–binding sites, and conserved sequence domains among group A and C rotaviruses, are indicated. **Bottom right:** Schematic of structural and antigenic properties of VP7. The two hydrophobic domains H1 and H2 (amino acids 6–23 and amino acids 33–44), conserved sequence domains among group A, B, and C rotaviruses, putative Ca^{2+}-binding site, conserved cysteines (*C*), the signal cleavage site ( ), second in-frame methionine with a strong initiation codon (*M*), glycosylation site (*Y*), and neutralization epitopes A, B, C, and F are shown. The mature VP7 starts at Q51. This diagram is based on sequence data and on analyses of neutralization escape mutants (97,212,349).

NSP4 plays a distinct role in virus assembly. The C-terminal cytoplasmic domain (amino acids 161 to 175) functions in viral morphogenesis by acting as an intracellular receptor on the ER membrane (17,355,356). NSP4 binds newly made double-layered particles and mediates the budding of these particles into the ER lumen (see later). A receptor role for NSP4 is supported by the observation that double-layered particles bind to ER membranes containing only NSP4 (15,16,233). The amphipathic a-helix region, distinct from the receptor domain, is predicted to adopt an a-helical coiled-coil structure, and this region is thought to mediate oligomerization of the virus-binding domains into a homotetramer (357). Sequence analyses have identified at least four genetic groups of NSP4 (Table 5). The highest sequence diversity of NSP4 is located in the cytoplasmic domain. It is unclear whether this sequence diversity is important and driven by interactions with specific residues on VP6 or divergent regions on VP4 or VP7, or both.

TABLE 5. *Group A rotavirus NSP4 genogroups*

Glycosylation of NSP4 or of a cellular protein is required for removal of the transient envelope from budding particles.

This is known because if cells are infected with a rotavirus variant that possesses a nonglycosylated VP7 and the cells are treated with tunicamycin (that only prevents glycosylation of NSP4), all the particles observed in the ER remain enveloped (155,270,341). Glycosylation of NSP4 is not required for its binding activity to double-layered particles or for oligomerization, but it is required for interaction with calnexin (15,236,356). NSP4 also has a binding site for VP4 (17), and NSP4 may play a role in removing the transient envelope (359). Heterooligomers of NSP4, VP4, and VP7 have been detected in enveloped particles (210,284), and calcium has been shown to be important for oligomerization of these proteins in the ER (285) and for proper folding of VP7 epitopes and outer capsid assembly (92,322). The precise mechanism of how (a) the envelope on particles is removed, (b) the heterooligomeric complexes function in particle budding through the ER, and (c) the outer capsid is assembled onto the newly made double-layered particles remains poorly understood. Rotavirus particle transport, maturation, and assembly remain an interesting model to understand the transport of protein complexes across the ER membrane as well as envelope particle formation. Recently, a fraction of VP4 and VP7 has been detected at the cell surface of virus-infected cells (247), and a cleavage product of NSP4 has been detected in the media of cells before release of virus (400). These new data indicate that our understanding of rotavirus protein trafficking and particle formation and exiting from cells is incomplete.

NSP4 has other pleiotropic properties besides its intracellular role in morphogenesis. In 1996, NSP4 was shown to induce age-dependent diarrhea in mice that mimics disease caused by rotaviruses (19,156). This provides one possible explanation for how NSP4 might function as a virulence factor as determined by reassortant analyses (157). Further work showed that NSP4 functions as an enterotoxin and that the extracellular administration of NSP4 to the intestinal mucosa or to crypt cells from mice, and to human intestinal cell lines, can trigger a signal transduction pathway that leads to mobilization of intracellular calcium [Ca^{2+}]i and chloride secretion (19,91,237).

The complex structure of the intestinal architecture and potential cross-talk among the many distinct intestinal cell types highlights that many possible pathways may influence the response of host-differentiated enterocytes or secretory crypt epithelial cells to rotavirus replication and its enterotoxin (Fig. 8). The current model for the mechanism of action of intracellular and extracellular NSP4 indicates this protein may reduce glucose absorption in epithelial cells as well as induce chloride secretion (149,237). NSP4 can also affect the cytoskeleton in polarized epithelial cells (345), but how these pleiotropic properties of NSP4 influence the function of NSP4 in morphogenesis or pathogenesis remains to be clarified.

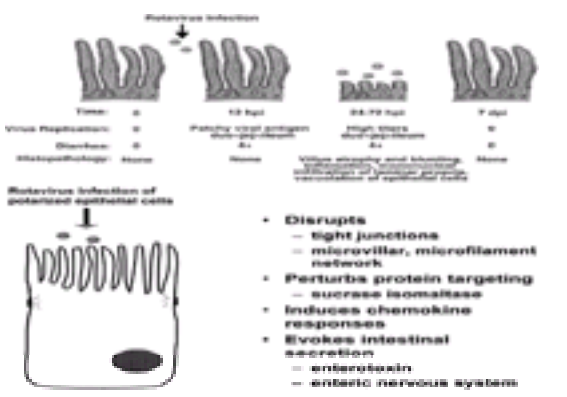

FIG. 8. Rotavirus pathogenesis. **Top:** Schematic of the histopathologic and clinical effects of rotavirus infection of intestinal cells. Rotaviruses-induced diarrheal disease occurs early after infection before significant histopathology of the infected mature enterocytes of the intestine. This diagram is based on studies in piglets infected with virulent porcine rotavirus (371). It is thought that the early, profuse, secretory diarrhea is caused by the action of the rotavirus enterotoxin, NSP4 (111) (see text). Histologic changes are seen at later time points when virus titers are high and loss of the differentiated enterocytes leads to malabsorption. The acute infection and disease normally resolves within 7 days in immunocompetent hosts. **Bottom:** Rotavirus infection of polarized epithelial cells triggers many effects that contribute to pathogenesis. Disruption of epithelial cell structure and function occurs slowly (18 to 24 hours after infection) and may lead to cell death and alterations of paracellular pathway of fluid movement (43,68,168,170,234,251,343). Rotavirus infection of epithelial cells activates epithelial cell signaling that can trigger cross-talk among the diverse types of cells that make up the villus architecture and activate the enteric nervous system, intestinal secretion, and immune responses (111,209,305).

Rotavirus, and NSP4 alone, induce age-dependent diarrhea and age-dependent chloride permeability changes in mice lacking the cystic fibrosis transductance resistance (CFTR) channel (10,237). These results indicate that NSP4 is a novel secretory agonist because other known secretogues that induce chloride changes by activating cyclic adenosine monophosphate, instead of by mobilizing [Ca^{2+}]i as a secondary mediator, fail to cause disease in CFTR knockout mice (237). The ability of NSP4 to elevate [Ca^{2+}]i has been exploited to identify novel calcium-binding proteins in cancer cells (386). Some virulent/avirulent pairs of rotaviruses contain mutations in NSP4, and these sequence changes correlate with altered protein function (182,401). However, not all attenuated viruses have been shown to contain mutations in NSP4 (10,52,373), a finding that is not unexpected because there are many mechanisms of virus attenuation, and other viral proteins (NSP1, NSP2, VP3, VP4, VP7) are virulence factors (44). Immunization with NSP4 can induce immunity that protects neonatal mice from disease induced by virus (19,20,395). The identification of NSP4 as the first viral enterotoxin highlights similarities between viruses and other microbes that cause diarrheal diseases and emphasizes a greater complexity of toxin action and gastrointestinal track–pathogen cross-talk than previously recognized.

The Major Structural Proteins

Three of the rotavirus structural proteins (VP4, VP6, VP7) have been studied extensively because of their unique biochemical, antigenic, and biologic roles in rotavirus replication and assembly (see Fig. 7). Known functions of these

proteins are described below. Antigenic properties and the role of these proteins in pathogenesis and immunity are considered in Chapter 55.

VP4, the protein product of genome segment 4, is a nonglycosylated outer capsid protein (13,218,226). Knowledge of the diverse properties of VP4 resulted in an increased awareness of the importance of this protein in the biology of the rotaviruses. VP4 is the hemagglutinin in many virus strains (173) and the cell attachment protein (84,308). Proteolytic cleavage of VP4 into VP5* (molecular weight about 60,000 [60K]) and VP8* (about 28K) results in an enhancement of viral infectivity (103,108). Cleavage of VP4 enhances penetration (but not binding) of virus into cells (73,122,175). Particles containing cleaved VP4 also possess lipophilic activity and may cause rapid release of ^{51}Cr from cells and of fluorescent dyes from liposomes or intestinal vesicles (309). VP4 is also associated with restriction of growth of certain rotavirus strains in tissue culture cells (142) and with protease-enhanced plaque formation (173). Finally, VP4 has been implicated as a virulence determinant in mice and piglets (253). VP4 induces neutralizing antibodies (158,252) and antibodies directed to VP4 neutralize virus *in vitro* (45,80,144,158,184,352) and passively protect mice against heterologous rotavirus challenge *in vivo* (256). Further studies have shown that VP4 effectively induces protective immunity in animals (214,255) and is immunogenic in children and animals (78,325,344).

Features of VP4 with potential biologic relevance have been found by analyzing nucleotide and predicted amino acid sequence data (see Fig. 7). Direct amino acid sequence analysis revealed the sites of proteolytic cleavage of VP4 of SA11 (205). Both VP4 and VP8* have blocked NH2-termini, and VP5* of SA11 is composed of two polypeptide species with slightly different amino acid sequences at their NH2-termini. Comparison of these data with the nucleotide sequence of VP4 identified two trypsin cleavage sites (arginine 241 and arginine 247), with position 247 being the preferred cleavage site (205). In some cases, a third cleavage may occur at arginine 231 (14). These arginines 241 and 247 are conserved in every rotavirus VP4 sequence analyzed, and cleavage at arginine 247 correlates with enhancement of infectivity (14,127,206,223).

Comparison of the properties of the VP4s of distinct sizes is useful to map conserved domains (223,263). In most animal rotavirus strains studied to date, VP4 contains 776 amino acids. A VP4 of animal (bovine B223) and human rotavirus strains containing 772 amino acids have been described (96,126,150). In most human rotavirus strains, the deduced VP4 contains 775 amino acids instead of 776 amino acids, with the difference being that the human strains have one less amino acid between residues 134 and 136 (136,176). VP8* of the human strains is, therefore, one amino acid shorter. In several human rotavirus strains, a third potential trypsin cleavage site of either lysine or arginine is found just upstream of the 3'-proximal arginine site (amino acid 246 in human strains, amino acid 247 in animal strains) (137,260). There is no direct evidence that this additional cleavage site in some human viruses correlates with virus virulence.

The mechanism of cleavage activation of infectivity is not clear from either sequence or biochemical analyses. It is unknown whether cleavage at both sites results in removal of the small intervening peptide and whether the minor and major cleavage sites shown for SA11 are really the same for other virus strains. It is assumed that cleavage of VP4 activates an early step of replication, which may be triggered by one or both of the regions generated by cleavage or by a possible conformational change in the VP4 cleavage products. The new NH2-terminus generated by cleavage in the rotavirus VP4 is not hydrophobic; however, it contains many polar amino acids (some of which may be charged at neutral pH), and cleaved VP4 possesses lipophilic activity (246,309). The mechanism of activation of rotavirus infectivity is not understood, but it appears to be different from that demonstrated for other viruses, such as the orthomyxoviruses and paramyxoviruses; in these viruses, cleavage activation of the hemagglutinin or fusion protein generates a highly conserved apolar amino-terminus, which is brought toward the membrane by a significant conformational change of the spike protein, and virus infectivity can be blocked by oligopeptides that mimic this sequence (see Chapter 40 and Chapter 45).

A region in VP4 (amino acids 384 to 401) has been identified that shares some homology with internal fusion sites in Semliki Forest and Sindbis virus proteins (213). This region in the alphavirus E1 protein has been implicated in cell fusion, leading to the hypothesis that these sequences might perform a similar function in VP4 (213). If this sequence is indeed a fusion domain, it remains unknown whether the fusion activity functions to mediate virus entry into cells, to mediate virus maturation during budding across the membrane of the ER (see below), or both. Conservation of this putative fusion region among rotaviruses lends credence to the suggestion that it has an important function in the replication cycle. Recent studies have shown that VP5* can permeabilize lipid vesicles (88).

The predicted amino acid sequence of VP4 indicates that the amino terminal 70% of the protein is rather hydrophobic (193,223). The predicted amino acid sequence of VP4 has a net negative charge at pH 7.0, and secondary structure predictions reveal that the amino-terminus before the trypsin cleavage site contains numerous random coils and turns, suggesting a globular structure. Analysis of the secondary structure of VP8* predicts the presence of 11 b-strands separated by loops and flanked by two small a-helices (166). Four cysteines (at amino acids 216, 318, 380, and 774) are conserved in the VP4 of all rotavirus strains sequenced (136,176,213), except those of the bovine rotavirus B223 (150). An additional cysteine is present at position 266 in the human M37 strain (136) and at amino acid 203 in SA11 4fM, bovine 486, and rhesus rotavirus. *In vitro* studies of the intrachain disulfide bonds in the VP5 and VP8 cleavage fragments of the rhesus and simian SA11 viruses have indicated that many animal rotaviruses contain two intrachain disulfide bonds: one in VP8 and one in VP5 (263). In contrast, human rotaviruses appear to contain only a single bond in the VP5 fragment (263). Sequences flanking the trypsin cleavage sites (amino acids 224 to 235 and 257 to 271) are relatively conserved in different virus strains and may be structurally important in keeping the trypsin cleavage site accessible.

The sequences of segment 4 from viruses in different serotypes have been compared to look for regions of divergence. Sequence variation is not evenly distributed across VP4 (see Fig. 7). The greatest variation is seen between amino acids 71 and 204 in VP8*, and sequence analyses between amino acids 84 and 180 have been found to correlate with VP4 P types (196,197). Because VP8* contains the locations of greatest sequence diversity, the binding sites of strain-specific neutralizing MAbs, and hemagglutination activity (118), although cross-reactive neutralizing MAbs bind to sites mapped to VP5* (213,351), it initially was tempting to speculate that VP8* is more externally exposed on the virus particle. A mechanism of immune selection could then explain the regions of sequence diversity in VP8*. Contrary to this

hypothesis, a cross-reactive neutralizing MAb that induces mutations at amino acid in VP5 was shown to bind to the sides near the tip of the spike (288). Thus, it appears that at least part of the VP8 domain may interact with VP6, and VP5 is more external. This is consistent with the observation that a neutralizing MAb that destabilizes the outer capsid and appears to affect VP4–VP7 interactions induces substitutions in neutralization escape mutants at amino acid 180 and amino acid 183, which flank a conserved proline (402). Analyses of mutants that have lost hemagglutination activity have suggested that amino acid residues 150, 155, 187, 188, 190, and 194 in VP8* are involved in binding to sialic acid (166,207,402). High-resolution structural information is needed to resolve the precise folding of VP4 and its interactions with VP6 and VP7.

VP6 is the major structural component of virions, and it plays a key role in virion structure because of its interactions with both the outer capsid proteins VP4 and VP7 and the core protein VP2. VP6 spontaneously forms trimers (105) and is extremely stable; these characteristics and the presence of conserved epitopes among many virus strains explain why this is the major antigen targeted in diagnostic assays. VP6 trimers can be disassociated and reassembled by changing pH (365). Removal of VP6 from double-layered particles results in a loss of polymerase activity, but it is unknown whether VP6 plays a structural or functional role in this process (28,317). VP6 is a hydrophobic protein that is highly antigenic and immunogenic (105,138,313), and VP6 may play a role in inducing protective immunity. Delivery of a nonneutralizing MAb to VP6 to severe combined immunodeficient mice can reduce chronic virus excretion (46), and 2/6–virus-like particles (VLPs) can induce protective immunity in mice (249), but not in rabbits (67) or piglets (393). Analyses of deletion mutants, virus variants, ts mutants, and chimeric proteins have begun to dissect the domains of VP6 (see Fig. 7). Thus, the trimerization domain is reported to be between amino acids 246 and 315, and a domain necessary for the formation of double-layered particles is located between amino acids 281 and 397 (2,365) (see Fig. 7). Residues 296 to 259 and 305 are important for determining the subgroup I epitope recognized by MAb 255/60 (327). Proline 308 has been implicated in trimer stability (326). The N-terminus is predicted to be an amphipathic a-helix and to be crucial to virus assembly, possibly by functioning in transporting VP6 to viroplasmic inclusions (217). Studies with MAbs to VP6 have suggested that amino acids 58 to 62 are not accessible in viral particles, and these could be located at the interface with VP2; other domains may be accessible through the outer shell of the virus (364).

VP7 is an outer capsid glycoprotein that is the second most abundant protein species in the virion. VP7 was initially thought to be the only antigen containing neutralization determinants (142,174), and this stimulated numerous studies of its structure, biosynthesis, and function. Biochemical analyses rapidly determined that VP7 is a glycoprotein that contains only N-linked high mannose oligosaccharides, which are processed by trimming (13,101,171). $Man_8GlcNAc_2$ and $Man_6GlcNAc_2$ oligosaccharide residues are found on intracellular VP7 and Man $_6GlcNAc_2$ (and to a lesser extent Man5GlcNAc2) is found on mature virus particles (171,172). VP7 is cotranslationally glycosylated as it is inserted into the membrane of the ER, and insertion is directed by a cleavable signal sequence found at the amino-terminus of the protein (34,102,171).

Comparisons of the deduced amino acid sequence of VP7 from a number of animal and human strains reveal interesting and potentially biologically relevant features about VP7 (see Fig. 7). The ORF of 326 amino acids begins with an initiation codon with a weak consensus sequence. A second, in-frame initiation codon with a strong consensus sequence is located 30 codons downstream. Each of these first two initiation codons precedes two regions of hydrophobic amino acids (H1 and H2), which can act as the signal sequence to direct VP7 to the ER, although the second codon is thought to be the major species used in cells. A third in-frame initiation codon is also present downstream from the second hydrophobic domain in some strains. One glycosylation site, at amino acid 69, is used in the SA11 VP7. Other virus strains contain up to three potential glycosylation sites; only two glycosylation sites are apparently used, but the locations of the used sites are unknown (189,190,319). The site of cleavage of the signal peptide in VP7 is glutamine 51, and this amino-terminal residue in VP7 from purified virus is blocked by pyroglutamic acid (337).

Studies to determine the signals specifying retention of VP7 in the ER have shown that VP7 does not contain the sequence KDEL found to confer retention for some other ER proteins (239). Two regions (one spanning amino acids 51 to 61, and the second between amino acids 61 and 111) that mediate retention of VP7 in the ER have been identified (283,286,337,382). Further sequence analyses identified a consensus peptide LPXTG [STGAE], where X indicates any other amino acid, within the ER retention domain of VP7 (223). This sequence is of interest because it is found in bacterial surface proteins and is proposed as being responsible for a posttranslational modification necessary for proper anchoring of proteins to the bacterial plasma membrane. The LPITGS sequence is highly conserved and found in rotavirus VP7 between amino acids 57 and 63 (223), and mutation analyses have shown the ITG are essential residues for ER retention (211). Although these residues are critical for retention, the method by which VP7 remains in the ER is unresolved. After its insertion into membranes, VP7 is resistant to digestion with proteolytic enzymes, suggesting it is not a membrane-spanning protein (101,171). VP7 remains membrane associated after high salt treatment and release of microsomal contents at alkaline pH (171). These findings suggest VP7 is an integral membrane protein with a luminal orientation. Further studies are required to determine why VP7 is retained in the ER, and whether posttranslational modification or conformational properties are responsible for membrane association. Structural reconstructions of virion VP7 have shown it is trimeric and VP7 forms oligomers with other proteins (VP4 and NSP4) in infected cells (210). These oligomers, and protein rearrangements and interactions with calcium, appear to be important in the assembly of VP7 into the outer capsid (92,284,285,323).

The normal site of VP7 synthesis and processing is exclusively in the ER, and rotaviruses are not transported to the Golgi apparatus. However, this pathway of protein targeting can be altered. Deletion of the two regions shown to mediate VP7 retention in the ER results in the processing of VP7 through the Golgi and into the extracellular medium. When transported through the Golgi, VP7 is modified to a form that contains complex carbohydrates (9,286). These results could be of practical significance for the production of soluble forms of VP7 for vaccines. Although these studies have only followed the fate of an individual protein, it would also be interesting to determine whether infectious virus could be redirected through such alternative pathways. Unfortunately, a method to alter a specific rotavirus gene and recover it in infectious virus is not yet available.

Mature VP7 lacks all amino acids proximal to Gln 51 but many conserved amino acids (18 of 35) are present before the second hydrophobic domain. In addition, none of the 11 amino acids in the second hydrophobic domain is highly

conserved, raising the question of what causes this extensive sequence variation. VP7 is the dominant target for cytotoxic T-lymphocyte (CTL) activity in mice (120,254), and the second hydrophobic domain has been shown to be the CTL target within VP7 (120). Four of six other regions showing sequence variation in VP7 are major neutralization sites in virions (97) (see Chapter 55).

THE ROTAVIRUS REPLICATION CYCLE

Overview of the Replication Cycle

Figure 9 shows a schematic of the rotavirus replication cycle. Many of the details of this cycle are from studies of rotaviruses infecting monkey kidney cells in cell monolayers. New insights about virus replication are coming from studies in polarized intestinal epithelial cells. Other information has come from assays to probe the specific steps in the replication cycle based on the expression and interaction of individual proteins and RNAs in *in vitro* systems, and conclusions from these studies are slowly being confirmed in the context of virus replication systems using confocal microscopy.

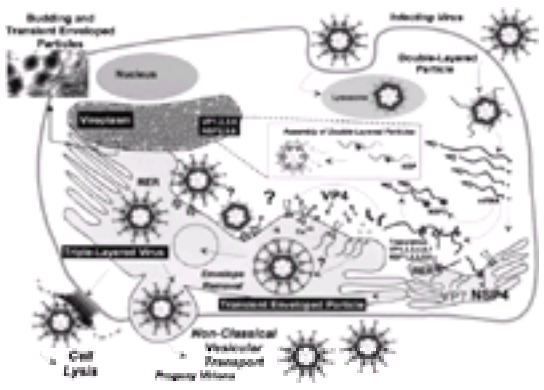

FIG. 9. Major features of the rotavirus replication cycle: VP4 , VP7 , NSP4 representations. For details, see section on the replication cycle. The unique rotavirus assembly process involves NSP4, which serves as an intracellular receptor for particle budding into the endoplasmic reticulum. The insert shows a thin section illustrating enveloped rotavirus particles budding into the endoplasmic reticulum. The viral glycoproteins do not traffic to the Golgi. In polarized epithelial cells, particles are released by a nonclassic vesicular transport mechanism (170).

Although the natural cell tropism for rotaviruses is the differentiated enterocyte in the small intestine, rotavirus replication has been studied primarily in continuous cell cultures derived from monkey kidneys. In these cells, the replication cycle is fairly rapid, with maximum yields of virus being found after 10 to 12 hours at 37°C or 18 hours at 33°C when cells are infected with high multiplicities (10 to 20 PFU/cell) (72,225,294). Recent studies examining rotavirus replication in differentiated human intestinal cell lines (CaCo-2 cells) grown on permeable filter membranes have reported that the virus replication cycle is slower with maximal yields of virus being detected on the apical surface of cells 20 to 24 hours after infection (169,170). Significantly, electron microscopic studies of virus replication in polarized intestinal cells indicate that the replication process in these differentiated polarized cells has some distinct differences compared with the virus replication cycle in nonpolarized cell cultures. These emerging differences are described later.

The general features of rotavirus replication (based on studies in cultures of monkey kidney cells) are as follows:

1. Cultivation of most virus strains requires the addition of exogenous proteases to the culture medium. This ensures activation of viral infectivity by cleaving the outer capsid protein VP4.
2. Replication is totally cytoplasmic.
3. Cells do not contain enzymes to replicate dsRNA; hence, the virus must supply the necessary enzymes.
4. Transcripts function both to produce proteins and as a template for production of a negative strand. Once the complementary negative strand is synthesized, it remains associated with the positive strand.
5. The dsRNA segments are formed within nascent subviral particles, and free dsRNA or free negative-stranded ssRNA is never found in infected cells.
6. Subviral particles form in association with viroplasms, and these particles mature by budding through the membrane of the ER. In this process, particles acquire their outer capsid proteins.
7. Cell lysis releases particles from infected cells grown on monolayers.

In polarized intestinal cells, virus entry may occur almost exclusively through the apical membrane or through both the apical and basolateral membranes, depending on the virus strain (see later). In addition, virus replication in polarized enterocytes alters differentiated enterocyte cell function by perturbing cellular protein trafficking, the cytoskeleton, and tight junctions (43,168,251). Finally, virus is released from polarized enterocytes by a novel vesicular transport that does not result in extensive cytopathic effects (170).

Stages of the Replication Cycle

Adsorption, Penetration, and Uncoating

The initial stages of virus replication have been examined by biochemical and morphologic (electron microscopic) procedures, and the molecular details of the early event of rotavirus infection are complex. Only triple-layered particles containing VP4 attach to cells when monitored by electron microscopy (168,272) or by cell binding (84) or infectivity

assays (40). Virus attachment is by VP4 (84,308) or its cleavage product VP5 (394). Binding to cells does not require cleaved VP4 (73,122) or glycosylated VP7 (271). Rotavirus entry into cells appears to be a multistep process (232) that likely requires both VP4 and VP7.

The identity of the cellular receptor for all rotaviruses is not known, but a study of the binding of radiolabeled SA11 to MA104 cells found about 13,000 receptor units per cell. Initial binding is sodium dependent, pH insensitive between 5.5 and 8.0, and dependent on sialic acid residues in the membrane; virus binds but is not internalized at 4°C (121,180,272,383), and probably involves more than one molecular species on the cell (335). A glycoprotein of 300K to 340K on murine enterocytes that binds to rhesus rotavirus and to VP4 has been reported, but whether this is a receptor remains unknown because this crude enterocyte extract was not purified or tested for its ability to compete directly for rotavirus binding to host enterocytes (22).

Demonstration that neuraminidase treatment of red blood cells reduces virus binding first indicated a role of sialic acid in virus attachment (23). Sialic acid–containing compounds, such as fetuin and mucin, also inhibit virus binding to cells (180,392), adding rotaviruses to an increasing number of viruses (such as reoviruses and influenza) that require sialic acid for binding to cells. However, these studies did not determine whether virus binds directly to sialic acid or whether sialic acid maintains the configuration of the binding site without directly interacting with the virus.

Additional evidence indicates that the type of glycoconjugate (i.e., ganglioside, neutral glycolipid, glycoprotein) that actually functions as an *in vivo* receptor for a given rotavirus strain depends on the rotavirus strain or type of host cell being studied. For example, the use of mouse-derived host cells with a heterologous simian rotavirus may not be the most advantageous combination to identify an *in vivo*–relevant simian rotavirus receptor. Initially, it was thought that most animal rotaviruses recognize sialic acid as an active receptor epitope (121), whereas the infectivity of tissue culture cells by human rotaviruses is resistant to neuraminidase (121,392). This apparent dichotomy of binding activities of different rotavirus strains appeared to have been resolved by the demonstration that binding to sialic acid is not an essential step for animal rotavirus entry into cells (231); thus, neuraminidase-resistant mutants can be selected that retain full infectivity for cells, indicating that animal rotavirus particles contain at least two binding sites for cells. In addition, human rotavirus strains initiate infection of cultured cells by a sialic acid–independent mechanism (121,180). Recent studies have found that most rotaviruses initiate infection by a sialic acid–independent mechanism and that this represents a change in paradigm (69). Perhaps more important, sialic acid–dependent viruses initiate infection of polarized intestinal epithelial cells efficiently only by the apical membrane, whereas sialic acid–independent viruses can efficiently infect polarized cells by either the apical or basolateral surfaces (68). These results indicate that sialic acid–dependent and –independent rotaviruses likely use different receptors, although studies in nonpolarized cells have suggested that they may share a second receptor (232). The consequences of these differences in modes of cell entry are not fully understood at this time, but it is likely that further studies on rotavirus entry into cells will reveal other virus–host interactions that affect the outcome of infection and pathogenesis.

A cell surface monoganglioside functions as an *in vivo* receptor for the OSU porcine rotavirus strain, and sialic acid is required for OSU virus–binding activity (306). Taken together, all the studies on rotavirus binding and entry suggest that unusual mechanisms may be involved. These include binding two different sites on the cell membrane, possibly with two different proteins on the virus, and direct membrane penetration of bound viruses rather than conventional receptor-mediated endocytosis. It is possible that rotavirus binding occurs initially by interaction with a sialic acid–containing receptor followed by a separate interaction with a second, nonsialylated receptor. Conformational changes in viral binding proteins induced by initial binding events may also mediate some of the early events. Other studies have suggested that a_1b_1-, a_xb_2-, a_vb_3-, and 4_4b_1-integrins are involved in rotavirus cell entry, probably functioning as postbinding coreceptors (81,148,153).

After binding occurs, virus is internalized. The enhancement of rotavirus infectivity by proteolysis is reportedly due to facilitating the penetration step (73). Internalization does not take place at 0° to 4°C, indicating that this step requires active cellular processes (180,272). All virus is internalized by 60 to 90 minutes after binding (180). The mechanism of internalization (penetration) into cells is controversial.

Both morphologic and biochemical approaches have been used to investigate the mode of entry of rotaviruses into cells. Early electron microscopy studies suggested that virus entry (SA11 strain) occurs by endocytosis (272,293) and that incoming particles are rapidly transported to lysosomes. Clear documentation of uptake of trypsin-treated virus particles into coated pits, coated vesicles, and secondary lysosomes by electron microscopy confirms that rotavirus particles (porcine OSU strain) enter cells by receptor-mediated endocytosis and suggests that uncoating might occur by the effect of lysosomal enzymes (208). Use of the calcium ionophore A23187 to increase the intracellular Ca^{2+} concentration during the early stages of replication can block uncoating (208). These results supported early hypotheses that low Ca^{2+} concentrations in the intracellular microenvironment may be responsible for uncoating. This idea was originally proposed because it was known that removal of the outer capsid of particles and activation of the endogenous polymerase could be accomplished by calcium chelation (77,155).

Studies of the uptake of a human rotavirus whose infectivity is independent of sialic acid binding and absolutely dependent on trypsin cleavage suggest that the mode of rotavirus entry into cells differs depending on whether virus particles have been pretreated with trypsin (339). Infectious virus pretreated with trypsin apparently enters cells by direct penetration of particles through the cell membrane into the cell cytoplasm. In contrast, non–trypsin-treated particles were taken up by phagocytosis, and such virions were sequestered into lysosomes 20 minutes after virus attachment to the cell membrane. Mere phagocytosis of particles into lysosomes was thought to be unrelated to rotavirus replication (339). Direct release of nucleic acid through spaces between the capsomeres and cell membrane pores after the attachment of trypsin-activated virus particles onto cells has also been proposed; this mechanism is considered to be analogous to injection of nucleic acid into bacteria by phages (340). The inability to detect virus shells lacking nucleic acid attached to cells makes this observation difficult to interpret.

The concept that trypsin-treated and non–trypsin-treated virus enter cells by different mechanisms is supported by a

study of the kinetics of entry of the sialic acid–dependent rhesus rotavirus into MA104 (175). Trypsin-activated rhesus rotavirus is internalized with a half-time of 3 to 5 minutes, whereas nonactivated virus disappears from the cell surface with a half-life of 30 to 50 minutes. Only trypsin-activated virus results in productive infection. Trypsin-treated virus can mediate the rapid release of ^{51}Cr from infected cells and this activity does not occur at 4°C. The specificity of the permeability alterations was examined by showing that double-layered particles do not mediate them and that neutralizing anti-VP4 MAbs (but not nonneutralizing antibodies to VP6 or VP7) inhibit the ^{51}Cr release. Unfortunately, permeability results with non–trypsin-treated virus were not reported. However, these data suggest that virus entry occurs by direct penetration of the cell membrane, which results in permeabilization of the cell membrane (175).

Other viruses that initiate infection by mechanisms involving receptor-mediated endocytosis often depend on the acidification of endosomes for partial uncoating or entry into the cell. The importance of acidification of endosomes for the initiation of infection of rotaviruses has been studied by several groups (123,175,179,208). In all cases, lysosomotropic agents (ammonium chloride, chloroquine, methylamine, amantadine) have little inhibitory effect on virus replication as measured by viral RNA synthesis, polypeptide synthesis, virus yields, or shutoff of host protein synthesis. Energy inhibitors (sodium azide and dinitrophenol) have a minimal effect on rotavirus infection, and this has been taken to suggest that rotaviruses do not use endocytosis to enter cells (175). Other endocytosis inhibitors, such as dansylcadaverine and cytochalasin D, or the vacuolar proton–ATPase inhibitor bafilomycin A1, also do not block rotavirus entry. These results indicate that neither endocytosis nor an intraendosomal acidic pH or a proton gradient are required for rotavirus entry into cells.

It seems clear that the passage of rotaviruses from endocytic vesicles to the cytoplasm does not occur by a pH-dependent fusion mechanism, but this does not rule out the possibility that rotaviruses are still taken up by endocytosis. Direct demonstration of virus fusion with membranes or hemolysis is lacking, and without this, the data suggesting direct penetration can have other interpretations. Protease cleavage of VP4 is important for rapid entry into cells, and particles containing cleaved VP4 possess lipophilic activity and can affect release of fluorescent dyes from liposomes and isolated membrane vesicles. Rotavirus entry into cells can also be monitored by coentry of toxins, such as a-sarcin, into cells (85,201) and by a cell–cell fusion from without assay (115). Most observations are consistent with the hypothesis that virus enters cells after direct interactions with a receptor on the plasma membrane (246,309,310).

The outer capsid proteins of rotavirus that are solubilized from virus particles are able to permeabilize cellular membranes (310), and it has been proposed that the outer capsid proteins are solubilized within an endocytic vesicle because of low Ca^{2+} concentrations. The decrease in calcium concentrations within the endosomal vesicle might trigger conformational changes in the capsid, capsid solubilization, and vesicle lysis (310). In this Ca^{2+}-dependent endocytosis model, acidification of the endosome would not be needed for the infectious process. It is also possible that more than one mechanism, including endocytosis and direct entry, is operative for rotaviruses, as has been proposed for poliovirus and reoviruses (33,90). Further studies are needed to determine whether the common endocytosis-mediated entry pathway exists for rotaviruses as originally thought.

A single report that the protein product of genome segment 10 influences virus adsorption to cells further complicates the question of the mechanism of virus attachment to cells (312). This study of a series of reassortants suggests that the nonstructural protein NSP4 may be indirectly involved in adsorption by influencing the arrangement of outer shell proteins assembled in infectious particles. This observation remains to be confirmed but is of interest based on the new information that NSP4 can affect calcium mobilization in cells and the proposal that rotaviruses may enter cells by a Ca^{2+}-dependent endocytic mechanism.

Transcription and Replication

The synthesis of viral transcripts is mediated by an endogenous viral RNA-dependent RNA polymerase (transcriptase), which has a number of enzymatic activities. The transcriptase is a component of the virion, and this enzyme complex of VP1 and VP3 has been localized to a flower-shaped structure attached to the top of VP2 at all the fivefold axes. Properties of the transcriptase have been inferred by studying the characteristics of products from *in vitro* transcription reactions and by electron microscopy analysis of transcribing particles (75,198,218,226,317). Rotavirus particles contain the enzymatic activities needed for synthesis of capped messenger RNA, including transcriptase, nucleotide phosphohydrolase, guanyltransferase, and methylases. These activities have either been demonstrated biochemically or they are inferred are because rotavirus transcripts made *in vitro* in the presence of *S*-adenosyl methionine possess a methylated 5'-terminal cap structure, $m^7GpppGm$ (165), and transcription is inhibited by pyrophosphate (334). Particles also contain a poly(A) polymerase activity whose precise function remains unknown; it has been postulated to be responsible for the synthesis of oligo(A) molecules (135).

The virus-associated transcriptase is latent in triple-layered particles and can be activated *in vitro* by treatment with a chelating agent or by heat shock treatment (77,334). Such treatments result in removal of the outer capsid proteins with conversion of triple-layered particles to double-layered particles (77). In infected cells, triple-layered particles have been shown to be uncoated to double-layered particles, and it is thought that transcription in cells occurs from such particles (74). Consistent with this idea, cells are susceptible to infection by liposome-mediated transfection of double-layered particles, indicating that simple delivery of these particles into the cell cytoplasm permits transcription to proceed (21). Transcription is asymmetric, and all transcripts are full-length positive strands made off the dsRNA negative strand (227). The exact site of transcription within the cytoplasm has not been precisely localized, although it is thought to occur in viroplasms.

The dynamic transcription process is beginning to be understood. Rotavirus transcription occurs within structurally intact double-layered particles and requires a hydrolyzable form of ATP, and studies with analogs that inhibit transcription suggest that ATP is required in reactions other than polymerization (334). ATP may be used for initiation or elongation of RNA molecules. Structural studies of transcribing particles indicate that RNA synthesis occurs within the core of the virion, near the fivefold axes, because this is the location of the transcriptional complexes composed of VP1 and VP3. Newly transcribed RNA exits the core through the type I channels in the VP2 layer, and multiple mRNA transcripts can be

released simultaneously from an actively transcribing particle (198) (see Fig. 2). Each genome segment is thought to be transcribed by a specific polymerase complex, and the resulting transcript exits through the channel system at the axis adjacent to its site of synthesis. This mechanism of transcription offers an explanation of why no dsRNA virus contains more than 12 genome segments.

The synthesis of positive- and negative-stranded RNA has been studied in SA11-infected cells (336), in a cell-free system using extracts from infected cells (260), and in an electrophoretic system that allows separation of the positive and negative strands of rotavirus RNAs in acid urea agarose gels (267). Analysis of the kinetics of RNA synthesis in infected cells showed that positive- and negative-stranded RNAs are initially detected 3 hours after infection (336). After 3 hours, the level of transcription increases until 9 to 12 hours, at which time the levels of positive-stranded RNAs are maximum. The ratio of positive- to negative-stranded RNA synthesis changes during infection, and the maximal level of negative-stranded RNA synthesis occurs several hours before the peak of positive-stranded RNA synthesis.

The delay in obtaining maximal positive-stranded RNA synthesis has been hypothesized to be due to a requirement for the accumulation of stoichiometric amounts of a protein (e.g., VP6) necessary for the assembly of transcriptase particles. Both newly synthesized and preexisting positive-stranded RNA can act as templates for negative-stranded RNA synthesis throughout infection (260). The observation that the level of RNA replication does not increase continually in conjunction with the increasing levels of positive-stranded RNA suggests that RNA replication is regulated by factors other than simply the level of positive-stranded RNAs in the infected cell. Based on nuclease sensitivity in this system, about 20% of the RNA made *in vitro* is double-stranded, and 80% is single-stranded. The synthesis of dsRNA *in vitro* has been determined to be an asymmetric process in which a nuclease-sensitive positive-stranded RNA acts as template for the synthesis of negative-stranded RNA.

It is assumed that rotavirus RNA replication, like that of reovirus, takes place in a conservative fashion; that is, both parental dsRNA strands remain within partially uncoated particles. After its synthesis, dsRNA remains associated with subviral particles, suggesting that free dsRNA is not found in cells. Characterization of the subviral particles (complexes separable by sedimentation through sucrose gradients and by equilibrium centrifugation in CsCl gradients), in which dsRNA synthesis occurs both in infected cells and in the cell-free system, indicates that these replicase complexes consist of core proteins, VP1 and VP2, small amounts of the protein VP6, large amounts of the nonstructural protein NSP3, and lesser amounts of NSP1 and NSP2 (152). These types of results indicate that some of the NSPs (NSP2, NSP3, NSP5) might be involved in the RNA replication process based on (a) the presence of these NSPs in replication complexes isolated from infected cells (125,262), (b) the nucleic acid–binding properties of some of the NSPs (42,162,178,222,280,379), (c) localization of some NSPs to viroplasms (12,273), and (d) the RNA negative phenotype of ts mutants mapped to the genes that encode these NSPs (58,131)).

A model was hypothesized in which rotavirus double-layered particles were assembled by the sequential addition of VP2 and VP6 to a precore replication intermediate consisting of VP1, VP3, NSP2, NSP3, and NSP5 (125). Because of the inability to separate particles completely with transcriptase and replicase activities with these methods and problems of contamination of some fractions with proteins from neighboring fractions, it has remained unclear whether the components characterized in this system are those necessary for RNA replication or simply present in these complexes for other reasons. A foreign reporter molecule was also engineered into a rotavirus genome segment and tested for expression in cells co-infected with a helper virus (139). This system identified cis-acting nucleotides at the 3' end of the genome necessary for gene expression, but the lack of direct evidence of synthesis of negative strands did not permit determination of whether these signals were necessary for RNA replication. Unfortunately, the efficiency of these systems was too low to ensure clear evaluation of the roles of cis- and trans-acting sequences and proteins required for replication and packaging. Instead, it seems likely that detection of an increased reporter signal was due to enhanced translation in rotavirus-infected cells, possibly owing to the presence of the 3'-translation enhancer on the expressed reporter gene (66).

The role of individual proteins and specific protein complexes in RNA replication and viral morphogenesis will probably not be solved until they are studied *in vitro* with pure species of native rotavirus proteins and viral RNAs. Progress toward this goal came with the development of a template-dependent replication system that uses only viral core proteins and exogenously added purified mRNAs (64). Virus-like particles expressed and self-assembled in insect cells also possess replicase activity (64). The conversion of exogenous mRNA to dsRNA by subviral particles has facilitated studies of (a) the specificity of viral proteins in recognition and replication of rotavirus mRNAs and (b) the effect of adding exogenous synthetic RNAs containing specific mutations on replication. Those cis-acting sequences required for replication are being identified (see Fig. 3). This system is unique for mammalian RNA viruses because it supports the *de novo* synthesis of genome-length negative-stranded RNA in the presence of only viral proteins and in the absence of host extracts. Adding viral mRNAs containing deletions of the 3'-consensus sequence, 5'-UGUGACC-3', to the replication system, has shown that this sequence contains a cis-acting signal that is essential for negative-stranded synthesis (268,381). Other studies identified parts of the 5'-untranslated region as containing sequences that stimulate RNA replication (268,381). Similarily, sequences upstream of the 3'-consensus sequence in the 3'-untranslated region contribute to the efficient synthesis of dsRNA by open cores. Based on the location of the cis-acting sequences and computer modeling, it has been hypothesized that the ends of the viral mRNAs interact in cis by complementary terminal sequences to form panhandle structures that promote the synthesis of dsRNA (60). An important feature of the predicted secondary structure of the rotavirus mRNA is that within the panhandle structure, the 3'-consensus sequence is either not base-paired or only partially base-paired to the 5'-terminus. It appears that the 3'-consensus sequence of the mRNA must be single-stranded for efficient dsRNA synthesis (60). Work is proceeding to enhance the efficiency of this *in vitro* replication system and to develop a cell-free system to support rotavirus RNA replication and the assembly of RNA into particles. To date, there is no evidence of RNA encapsidation in this system.

This *in vitro* template-dependent replication system is surprising because it does not absolutely require the nonstructural proteins for replicase activity (64). However, the nonstructural proteins may play a role in increasing the efficiency of replication or play other roles in the replication cycle. Clearly, much remains to be learned about the NSPs and RNA binding, transport, replication, and assembly. It is anticipated that these studies will be of general interest because the

rotaviruses contain a larger number of NSPs than some of the other viruses within the *Reoviridae* family.

RNA Encapsidation and Virion Assembly

The selective packaging mechanism that leads to the presence of equimolar genome segments within rotaviruses, or any of the other members of the *Reoviridae* family, remains a challenging puzzle. Several models have been proposed (reviewed in 266). Based on the characterization of replication intermediates from rotavirus-infected cells, one model proposes the formation of precore replication intermediate precursor complexes composed of viral mRNA, the viral RNA-dependent RNA polymerase, and the capping enzyme that would serve as nucleation sites for the binding of the VP2 core protein and the assembly of the T=1 core. Based on the ability of the rotavirus capsid proteins to self-assemble into empty virus-like particles (84,194), and on data on the dsRNA bacteriophage phi 6 (235), a second model suggests that empty cores are first made and that mRNAs would be inserted into these cores. A third model is based on structural data indicating that the core represents a collection of functionally separate pentameric units, with each unit containing its own RNA-dependent RNA polymerase activity and capping enzyme complex and being responsible for transcription of one of the genome segments (200). In this model, this enzymatic complex would associate with a specific mRNA and attract the VP2 core protein and assemble into pentamers. RNA–RNA interactions between the mRNAs of the distinct pentameric units would then drive the assembly of the icosahedral core from the pentameric units. Structural changes in the core lattice protein, as a consequence of pentamer–pentamer binding, may activate the RNA-dependent RNA polymerase and stimulate negative-stranded RNA synthesis to form the genome. Future work will determine which of these models, if any, may be correct.

A distinctive feature of rotavirus morphogenesis is that subviral particles, which assemble in cytoplasmic viroplasms, bud through the membrane of the ER, and maturing particles are transiently enveloped (see Fig. 8). This is one of the more interesting aspects of rotavirus replication differing from members of other genera in the *Reoviridae* family. The envelope acquired in this process appears to be lost as particles move toward the interior of the ER, and the envelope is replaced by a thin layer of protein that ultimately constitutes the outer capsid of mature virions.

The sites of synthesis or localization of the viral proteins have been examined by ultrastructural immunocytochemistry using polyclonal monospecific or monoclonal antibodies (273,302) and by studying the distribution of proteins by immunofluorescence or by subcellular fractionation (172,333). Taken together, the morphologic and biochemical data are consistent with rapidly assembling double-layered particles serving as an intermediate stage in the formation of triple-layered virions. Most of the rotavirus structural proteins and the nonstructural proteins are synthesized on the free ribosomes, although the nascent proteins on free ribosomes have not been analyzed. Instead, this conclusion has been drawn based on the absence of signal sequences that would indicate targeting to the ER and lack of protection from digestion in *in vitro* protease protection studies (102,171). In contrast, the glycoproteins VP7 and NSP4 are synthesized on ribosomes associated with the membrane of the ER and are cotranslationally inserted into the ER membrane as a result of signal sequences at their amino-termini.

The sites and precise details of RNA replication remain unclear. However, electron-dense viroplasms are probably the sites of synthesis of the double-layered particles that contain RNA (270,302). This conclusion is based on the localization of several of the viral proteins (VP2, NSP2, NSP5, NSP6) to viroplasms and of VP4 and VP6 to the space between the periphery of the viroplasm and the outside of the ER (133,274), and on the observation that particles emerging from these viroplasms often seem to bud directly into the ER that contains VP7 and NSP4. A fraction of VP4 has recently been detected in a filamentous array (133) and at the plasma membrane associated with microtubules, although the function of this protein in viral morphogenesis remains unclear (247).

Two pools of VP7 that can be separated biochemically by fluorocarbon extraction or by immunologic methods using two classes of antibodies are detectable in the ER of SA11-infected cells (172). One pool is found only on intact particles and is detected only by a neutralizing monoclonal antibody. The second pool of VP7 is unassembled, remains associated with the ER membrane, and is detected by a polyclonal antibody made to denatured VP7 (172). Distinction of these two forms of VP7 permitted a kinetic study of the assembly of VP7 and of other structural proteins into particles. The incorporation of the inner capsid proteins into double-layered particles was found to occur rapidly, whereas VP4 and VP7 appeared in mature triple-layered particles with a lag time of 10 to 15 minutes. Kinetic analyses of the processing of the oligosaccharides on the two pools of VP7 showed the virus-associated VP7 oligosaccharides had a 15-minute lag compared with that of the membrane-associated form, suggesting that the latter is the precursor to virion VP7. This lag appears to represent the time required for virus budding and outer capsid assembly (172).

Rotavirus maturation is a calcium-dependent process, based on the observation that virus yields are decreased when virus is produced in cells maintained in calcium-depleted medium (323). Viruses produced in the absence of calcium are often found to be exclusively double layered, and budding of virus particles into the ER is not observed (322). Among the viral proteins, reduced levels of VP7 are observed, owing to the preferential degradation, not the impaired synthesis, of VP7 (322). An interesting finding of these studies is that unglycosylated (but not mature) VP7 made in the presence of tunicamycin is relatively stable in a calcium-free environment. Although the role of calcium in morphogenesis was not completely revealed in these studies, it is possible that calcium stabilizes or modulates folding or compartmentalization of the newly glycosylated VP7 for subsequent assembly into particles. The budding process occurs in the absence of calcium, but VP7 is retained within the ER (5). VP7 does not fold properly unless it is expressed with other rotavirus proteins, and calcium must be present in cells for correct epitope formation (92,93). Calcium deprivation may destabilize the ER or ER proteins required for the stable association of glycosylated VP7 with the membrane. Outer capsid assembly also requires proper formation of disulfide bonds on VP7 (342).

Understanding viral morphogenesis has been facilitated by the expression of the rotavirus structural proteins individually or in combinations in insects cells using recombinant baculoviruses (84,194,299,398). This approach first showed that the single-layered VP2 particle shell self-assembles when VP2 is expressed alone, and all of the other capsid proteins have been shown to self-assemble into virus-like particles when coexpressed in the proper combinations (Fig. 10). Virus-like particles composed of VP2, VP1/2, VP1/2/3, VP2/3, VP2/6, VP2/6/7, VP2/4/6/7, and VP1/2/3/6 can be made (84,307,398). The outer and inner capsid proteins of different virus strains have also been shown to reassociate and be

able to be transcapsidated onto other virus strains (62,63). These results demonstrate that the structural proteins contain the intrinsic information required to form particles and that coexpression of mutant proteins is a feasible approach to analyze the domains responsible for the structural interactions between the proteins composing the virus particles. These particles have been useful to analyze the role of cleavage sites in the spike protein in infectivity (127) and the role of individual structural proteins in inducing protective immunity (67,83,167,249,250), to probe the inner structure of particles by analyzing difference maps of particles with distinct protein compositions (307), and to analyze RNA transcription and replication (64,258) and RNA packaging and assembly. These latter studies offer hope that a reverse genetics system will be established for the rotaviruses. Future studies should delineate what mechanisms control packaging of the viral genome and virus assembly.

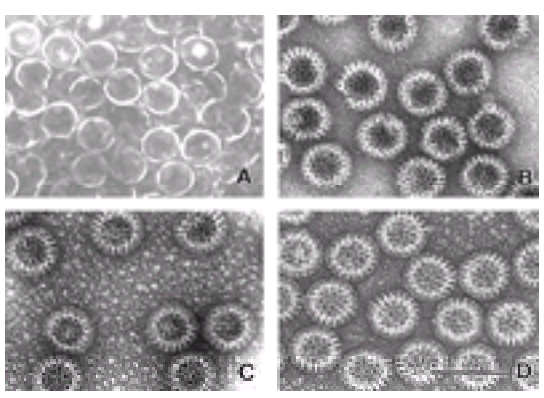

FIG. 10. Rotavirus-like particles self-assemble when the capsid proteins are coexpressed in eukaryotic cells. **A:** VP2. **B:** 2/6-VLPs. **C:** 2/6/7-VLPs. **D:** 2/4/6/7-VLPs. VPL, virus-like particle. (Modified from ref. 84, with permission.)

Virus Release

Electron microscopy studies have shown that the infectious cycle ends when progeny virus is released by host cell lysis in nonpolarized cells (8,55,229). Extensive cytolysis late during infection and drastic alterations in the permeability of the plasma membrane of infected cells result in the release of cellular and viral proteins (240). Despite cell lysis, most double-layered and many triple-layered particles remain associated with the cellular debris, suggesting that these particles interact with structures within cells. Interactions with cell membranes and the cell cytoskeleton have been suggested (240). Whether the cytoskeleton provides a means of transport of viral proteins and particles to discrete sites in the cell for assembly or acts as a stabilizing element at the assembly site and in the newly budded virions, or if particles are simply trapped by the cytoskeleton, remains to be determined.

GENETICS (TYPES OF MUTANTS AND VARIANTS)

Genetic studies have been exploited to understand rotavirus gene structure and function. Temperature-sensitive (ts) mutant collections have been isolated from several rotaviruses, including SA11, UK, and RRV (116,143,294,296,297). The most extensive mutant collection is for SA11, in which 10 of the expected 11 reassortment groups have been identified and six assigned to genome segments. The phenotypes of some of these mutants are consistent with functions inferred from biochemical data or recent sequence information (see Table 4). For example, mutant groups B and C, which mark genome segments 3 and 1, respectively, are defective in the synthesis of single-stranded and double-stranded RNA (58). Because these proteins are likely candidates to be part of the transcriptase particle, further biochemical and sequence analyses of these mutants or establishment of complementation systems with expressed gene products may permit dissection and localization of specific enzymatic domains on VP1 or VP3, or both.

Characterization of the genetic interactions between ts mutants has shown that recombination between pairs of ts mutants of SA11 occurs in the all-or-none fashion expected for recombination by a mechanism of reassortment of genome segments (294). Genetic interactions of rotaviruses are influenced by factors similar to those that affect such interactions of other segmented viruses, including multiplicity of infection and the time of infection (295). Maximal, or near maximal, reassortment frequency is obtained at the earliest times when reassortment can be detected. This suggests that reassortment occurs early in the infectious cycle and that there is a single round of mating, an observation consistent with the particle association of progeny dsRNA. Reassortment is efficient at nonpermissive temperature and mutants from all reassortment groups can interfere with the growth of wild-type virus at both permissive and nonpermissive temperatures. These results are important to consider when trying to produce reassortants.

Reassortment of genome segments among the progeny of *in vitro* mixed infections has been exploited to derive reassortant viruses with desired subsets of genome segments from each parent. Such reassortants have been used to assign ts mutants to specific genome segments and to correlate biologic properties with specific genome segments. For example, the genetic approach has been used to show that genome segment 4 is associated with the properties of hemagglutination, restriction of growth in tissue culture cells, protease-enhanced plaquing, reactivity with neutralizing antibody, and induction of diarrhea in a mouse model (131).

This approach will continue to be used to probe rotavirus gene function; therefore, it is worthwhile to note the criteria needed to reach firm conclusions. The early studies to examine the genome segments responsible for inducing neutralizing antibody identified one member of the genome segment 7, 8, or 9 complex with this property. However, in these studies, no reassortants containing genome segment 4 from a human virus was cultivated and characterized (142). Subsequent studies revealed that genome segment 4 also contains neutralization determinants, highlighting the importance of analyzing reciprocal reassortants in such studies, and the usefulness of selection with specific neutralizing

antibodies to obtain reassortants with desired combinations of VP4 and VP7 (187).

In addition, unexpected properties of parental viruses may influence the interpretation of studies of reassortant viruses. For example, two bovine viruses (UK and NCDV) have been found to share highly related VP7 antigens, but their VP4 antigens are distinct. Reassortant analyses between these two viruses will only allow examination of properties related to the distinct genome segment 4. Because the common properties of parental viruses may not be known in advance, it may be useful to confirm results from reassortment studies using different parental virus strains. The identity of naturally occurring intertypic rotavirus strains (158,159) and the direct demonstration that rotaviruses can undergo reassortment *in vivo* (129) highlight the fact that the genetic background of any rotavirus isolate cannot be assumed.

Naturally occurring rotavirus variants have also been found to be useful probes of gene function. Studies of a variant of the simian rotavirus SA11, which lacked a glycosylated VP7, showed that glycosylation was not essential for virus infectivity or hemagglutination (109,270) and that glycosylation of NSP4 was required for removal of the transient envelope from maturing particles (271). Further studies with neutralization escape mutants made from this variant have shown that glycosylation can affect rotavirus antigenicity (50). Studies with another variant of SA11 that has an altered genome segment 4 have also shown that the phenotype of certain reassortant constellations of genome segments depends on the parental strains used for analysis (56). This phenomenon has been confirmed with other reassortants containing specific combinations of VP4 and VP7, and this is beginning to explain some unexpected antigenic properties of some virus strains (57,95,181,188,241,387,402).

EFFECTS ON HOST CELLS

Rotaviruses have a rather limited tissue tropism, in most cases only infecting the villus epithelium of the small intestine. In addition, the virus generally shows a substantial host range restriction, and symptomatic infection is usually restricted to the young of a species (see Chapter 55). Previously, it was thought that the diarrheal disease resulting from infection is a consequence of a cytocidal infection. Increasing evidence indicates that disease may also result from the actions of viral proteins (e.g., the enterotoxin) as well as other proteins produced by infected epithelial cells (209,401). In nonpolarized tissue culture cells, rotaviruses are normally cytocidal viruses that rapidly kill the permissive cells they infect. Adaption of rotaviruses to culture can be difficult and may require initial passage of virus in primary monkey kidney cells before adaption to growth in continuous monkey kidney cell lines. In permissive cells, cytopathic effect is generally evident, and cell death is preceded by the shutoff of host RNA, DNA, and protein synthesis (48,101,225). Cell death probably results from the function of a viral gene on a specific target rather than from cumulative effects on host metabolism because certain ts mutants (ts groups F, G, H, and I) do not efficiently shut off host cell protein synthesis (104,298). NSP4 is one protein that mediates cell death by causing intracellular calcium levels to increase as well as by affecting the plasma membrane permeability and tight junctions of cells (234,248,345,360). NSP3 reduces host protein synthesis (277).

Upon infection of nonpolarized cells, rotavirus induces early alterations in vimentin (375), in the cytoskeleton organization (376), and in the biochemistry of the host cell (277). A dramatic decrease in the level of host cell proteins and a high level of viral proteins is observed (101). Four proteins that are specifically up-regulated in rotavirus-infected cells have been identified, two of which correspond to the ER chaperones BiP and endoplasmin; however, the role of these proteins in the replication and morphogenesis of rotavirus particles remains to be established (385). In general, little is known about the involvement of host proteins in the diverse steps of the rotavirus replication cycle. It can be expected that a cascade of signals that the virus elicits in the host cell, the cytoskeletal changes induced, and the temporal program of cell gene expression after virus infection will be dissected with the future application of microarray analysis to infected cells *in vivo* or in cultured cells.

Rotavirus infection in polarized human intestinal epithelial (CaCO-2) cells has been studied to determine whether infection occurs asymmetrically from either the apical or basolateral membranes. Initially, rhesus rotavirus was reported to infect polarized Madin-Darby canine kidney (MDCK) and CaCO-2 monolayers in a symmetric manner as does influenza virus (343). However, a reanalysis of rotavirus replication in polarized CaCO-2 cells grown on smaller pore—sized (0.4-µm) membrane filters (where cells do not grow through the filters) shows that RRV only infects polarized cells efficiently through the apical surface (68). Additional studies have shown that rotavirus infection induces microvillar F-actin disassembly (168), and an increase in $[Ca^{2+}]i$ is associated with release of a viral protein or peptide from infected polarized cells that induces a Ca^{2+}-dependent microvillar F-actin alteration in uninfected CaCO-2 cells (43). In addition, rotavirus infection causes alterations in tight junctions independent of virus-induced cytoskeletal rearrangements (251). MDCK cells support only restricted replication of rotavirus, but in both CaCO-2 and MDCK cells, infected cells show transmembrane leaks or opening of tight junctions before the development of cytopathic effect and extensive virus release. Additional studies have shown that RRV rotavirus is released through the apical surface of polarized cells by a nonclassic Golgi-independent vesicular route (170). Attachment and entry of virus into CaCO-2 cells does not cause any measurable transmembrane leak during the first hour of infection. These results suggest that infected epithelial cells could be sloughed from the intestine owing to the loss of tight junctions during the viral replication cycle and before development of cytopathic effect.

The epithelial cell response to rotavirus infection has also been examined in nonpolarized human intestinal cell lines, CaCO-2 and HT-29 cells (49,327). Interleukin-8, growth-related peptide-alpha, and RANTES (*r*egulated upon *a*ctivation, *n*ormal *T*-cell *e*xpressed and *s*ecreted) are secreted from rotavirus-infected cells, and chemokine production is time and dose dependent. Interferons and granulocyte-macrophage colony-stimulating factor have also been detected in mice infected with rotavirus (305). The chemokine secretion response by enterocytes is an active component of the host response to rotavirus infection and may play a role in viral pathogenesis and the in immune response to rotavirus infection.

Finally, rotavirus replication has been examined in polarized neuronal cells, where cytopathic effect again is not obvious. These infections are of interest because expression of VP7 is targeted to axons and dendrites by a pathway that does not involve the Golgi apparatus (374). In contrast, NSP4 is localized solely in the cell body. Rotavirus infection stimulates

alterations of specific neuronal proteins. Thus, the distribution of microtubule-associated protein 2, which is normally restricted to nerve cell bodies and dendrites, is altered and found in axons of cultured dorsal root ganglia and spinal cord neurons. This study indicates that selective interactions between certain viral and neuronal cytoskeletal proteins can occur and that noncytolytic viral infection can cause alteration in the polarized sorting of neuronal proteins (376). These studies are of interest because they highlight the usefulness of monitoring rotavirus protein transport to understand new intracellular trafficking and signaling pathways. It is not known if rotaviruses naturally infect neurons or if such infections might result in activation of the enteric nervous system, which is reported to be a component of the pathogenesis of diarrheal disease (209).

Rotaviruses also have the ability to establish persistent infections in cell cultures (18,65,106,238) and in mice with severe combined immunodeficiency disease (SCID) (303). Persistently infected cells that release low levels of virus for multiple passages have been established in semipermissive (simian rotavirus in rabbit kidney cells) and in fully permissive (bovine rotavirus in bovine kidney and simian rotavirus in MA104) cells. Characterization of these carrier cultures showed that a small percentage of cells were infected and that host–cell resistance to infection was partially overcome by the addition of trypsin to the media (65,106). In another case, a particular bovine rotavirus (strain 2352) that failed to destroy infected BSC-1 cells was apparently important in inducing persistence. Most of these cells (more than 80%) synthesized viral antigen during the S phase of the cell cycle, and the number of cells expressing antigen decreased as the cells moved into mitosis and cell division (18). Permissive MA104 cells that became persistently infected produced higher titers of virus, most of the cells expressed viral antigen, and virus was released from cells without producing cell lysis (238). Analysis of these cells showed that both viruses and the cells coevolved, and mutations in the virus were shown to confer trypsin-independent growth, suggesting that a protease requirement for efficient viral growth is a point of balance for viral growth and cellular survival during maintenance of persistent infection (238). Recognition that rotaviruses cause persistent infections in SCID mice suggests that the *in vitro* observations of carrier cultures may have clinical relevance but that normally such infections are cleared by immune mechanisms. The prolonged excretion and occasional extraintestinal spread of rotaviruses in immunocompromised children indicates that cell-mediated immunity is important in limiting and clearing virus infections (128,164,269,384). However, antibody also plays a role in overcoming persistent infections in animals and children (46,146,147). The detailed mechanisms that regulate persistent virus–cell interactions remain to be elucidated.

INHIBITORS OF REPLICATION AND THEIR MECHANISM OF ACTION

Relatively few studies have evaluated inhibitors of rotavirus replication. Replication is inhibited by fetal bovine serum, most probably owing to its antiprotease activities (110,332) or to other components in serum, such as lecithin, whose mechanism of action is uncharacterized (370).

Evaluations of the effects of antiviral agents as inhibitors of rotavirus replication have shown the following:

1. Nucleoside analogs are effective, probably owing to inhibition of *S*-adenosylhomocysteine hydrolase, a key enzyme regulating methylation of viral mRNA (185).
2. Ribavirin and 3-deazaguanine prevent rotavirus polypeptide synthesis and may exert their antiviral effect by inhibiting the production or modification (capping) of viral-specific mRNA. Polymerase activity is not affected (331).
3. 9-*S*-2,3-dihydroxypropyl adenine is an effective inhibitor of replication with low toxicity *in vivo,* but its mechanism of action is not known (331).
4. Clioquinol, an 8-hydroxyquinoline derivative, may reduce infection of mice if given at frequent intervals, possibly by removing the outer virus capsid (24).
5. Mucin, protease inhibitors, and human milk reduce infectivity in cultured cells or animals (98,99,151,369,392), and some evidence suggests that treatment with probiotic bacteria, live bacteria that survive passage through the gastrointestinal tract and have beneficial effects on the host, may shorten the diarrheal phase of rotavirus infection (87).

Recently, racecadotril, an enkephalinase inhibitor that decreases intestinal hypersecretion but not motility in animals and humans, has been shown to reduce rotavirus-induced diarrhea in hospitalized children (275,316). This is of interest because it supports the new evidence in animals that the pathophysiology of rotavirus diarrhea involves secretory pathways mediated by enterotoxins or neurotransmitters in addition to malabsorption. Additional inhibitors can be expected to be found as the structure and function of the unique rotavirus proteins are characterized and as the molecular mechanisms controlling virus–cell interactions are better understood.

PERSPECTIVES

Our knowledge of rotavirus structure, classification, evolution, and replication continues to increase rapidly. Despite these advances, the world remains without a rotavirus vaccine; the first live attenuated rotavirus vaccine, which was licensed in 1998, was withdrawn from the market in 1999 owing to possible association with induction of intussusception (100). This vaccine failure emphasizes our need to better understand the mechanisms of rotavirus pathogenesis, including details of the molecular interactions between rotaviruses and cells of the intestinal tract. It remains unknown if intussusception will be a problem with all live rotavirus vaccines or whether this adverse event will only be associated with the rhesus rotavirus tetravalent vaccine. If intussusception is found to be associated with all rotavirus infections as a rare event, one might expect to uncover other rare outcomes of rotavirus infection with further epidemiologic studies. As pathogens that infect the gastrointestinal tract, rotaviruses will continue to serve as useful models to understand mucosal virus–cell interactions. The interactions of viral and cellular proteins that influence virus entry into cells, trigger epithelial cell responses, and modulate function of the differentiated epithelial cells or neighboring cells in the complex architecture of the intestine remain to be understood. This requires new studies of virus pathogenesis *in vivo,* and such studies require multidiscliplinary efforts to understand fully the complex biochemical and physiologic consequences of infection. Analysis of cellular responses using microarray analysis will be a start to defining pathways of cellular signaling that may influence the outcome of infection as well as cellular genes important for replication. Future studies on rotaviruses that represent the majority of human and animal rotavirus strains that do not require sialic acid to initiate infection and that

replicate less efficiently in cultured cells clearly are needed to understand how these viruses differ from the well-studied sialic acid–dependent viruses. Will study of these viruses discover that they have other unusual properties that affect their stability or transmission? Development of a reverse genetics system for the rotaviruses, and other double-stranded RNA viruses, remains an important goal that will facilitate future probing of viral gene function in great detail. Achieving this goal may require more knowledge about the unique processes by which rotaviruses inhibit host cell translation as well as enhance virus-specific RNA replication and encapsidation that may be linked and compartmentalized within the cytoplasm of cells. Expanded studies that apply new techniques in cell biology to understand the structural and biochemical basis of the unusual processes of rotavirus entry into and exit from cells can be expected to unravel new mechanisms of protein and vesicle trafficking in cells. Structural knowledge of rotavirus and its proteins should help lead to new methods and inhibitors to interrupt virus transmission, prevent virus replication, and treat disease.

CHAPTER 55 Rotaviruses

Albert Z. Kapikian, Yasutaka Hoshino, and Robert M. Chanock

Rotaviruses are the single most important cause of severe diarrheal illness in infants and young children in both developed and developing countries worldwide (26,385). Although diarrheal diseases are one of the most common illnesses in this age group throughout the world, they assume a special significance in developing countries, where they constitute a major cause of mortality among the young.

The scope of the problem in the United States was addressed in the Cleveland Family Study, in which infectious gastroenteritis (considered nonbacterial) was the second most common disease, accounting for 16% of approximately 25,000 illnesses over a period of about 10 years and averaging 1.52 episodes per person per year (111). This incidence has remained remarkably consistent in two other family studies conducted about 20 or 30 years later (1.2 to 1.9 enteric illnesses per person per year) (188,343,344). Although diarrheal diseases are not a prominent cause of mortality in infants and young children in the United States, a review of vital statistics indicated that between 1973 and 1983, 5,539 children 1 month to 4 years of age died from diarrheal disease (average, 504 deaths per year) and 79% of these deaths occurred in the less-than-1-year age group (206).

The toll from diarrheal diseases in developing countries is staggering. It is estimated that 1 billion diarrheal illnesses and 3.3 million deaths from diarrhea occur annually in the under-5-year age group in developing countries of Africa, Latin America, and Asia (excluding China) (26). Furthermore, diarrheal illnesses consistently rank as one of the top six causes of all deaths, one of the top three causes of death from an infectious disease, and one of the top two causes of death when considering years of life lost (352,353,523,524).

HISTORY

Despite the magnitude of the problem of infantile diarrhea, the search for important etiologic agents—bacterial, viral, or parasitic—was unrewarding until the 1970s. This was especially disappointing for virologists, because with the advent of tissue culture technology, scores of enteric viruses were discovered in the 1950s and 1960s, but none was found to be an important etiologic agent of infectious diarrhea (539).

This frustration ended with the discovery in 1972 by Kapikian et al. (262) of the 27-nm Norwalk virus and its association with epidemic viral gastroenteritis in older children and adults, followed by the discovery in 1973 by Bishop et al. (38) of the 70-nm human rotavirus and its association with severe endemic diarrhea in infants and young children. Both of these fastidious agents were discovered without the benefit of tissue culture technology; by necessity, their identification relied on direct visualization by electron microscopy (EM). The Norwalk virus was identified in feces by immune electron microscopy (IEM), whereas the first human rotavirus was visualized by thin-section EM of duodenal mucosa. Shortly afterward, rotavirus was identified in feces by EM by Flewett et al. (130), Bishop et al. (39), and others (261,333). The Norwalk and related viruses described in Chapter 27 cause over 50% of community outbreaks of nonbacterial gastroenteritis in older children and adults, and although these viruses are associated with mild gastroenteritis in infants and young children, they have not been established as an important cause of severe diarrhea in this age group (242).

It soon became apparent that the 70-nm particle (Fig. 1), subsequently designated rotavirus, was an important etiologic agent of diarrhea of infants and young children, causing about 35% to 50% of the hospitalizations for this form of gastroenteritis during the first 2 years of life (245). In a relatively short period, investigators from many countries reported

the detection of rotaviruses in feces of pediatric patients with diarrheal illness, and it was soon established that rotaviruses were the long-sought-after major viral etiologic agents of severe diarrhea of infants and young children in both developed and developing countries, consistently outranking in importance other known etiologic agents of severe diarrhea (Fig. 2).

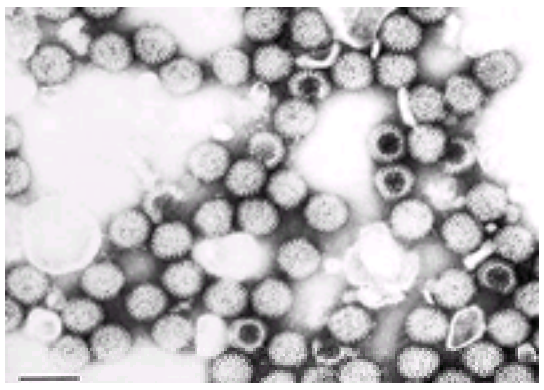

FIG. 1. Human rotavirus particles observed in a stool filtrate (prepared from a stool of an infant with gastroenteritis) after incubation with phosphate-buffered saline and further preparation for negative-stain EM. The particles appear to have a double-shelled capsid. Occasional “empty” particles are seen. Scale bar: 100 nm. (From ref. 261, with permission.)

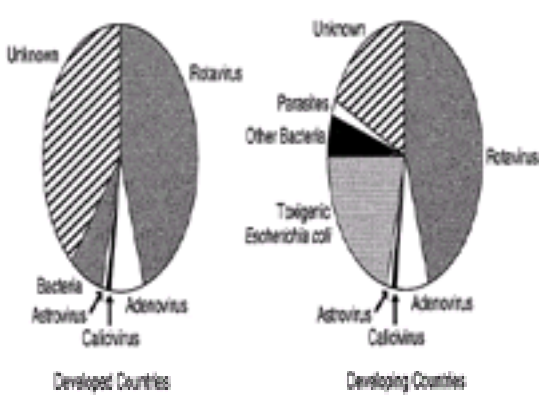

FIG. 2. An estimate of the role of etiologic agents in severe diarrheal illness requiring hospitalization of infants and young children in developed countries and in developing countries. (From ref. 245, with permission.)

Although the human rotaviruses were discovered in 1973, it should be noted that in 1963, Adams and Kraft, using thin-section EM, described virus-like particles in intestinal tissue of mice infected with epizootic diarrhea of infant mice (EDIM) virus (2). These particles were similar to those observed by Bishop et al. (38). In 1963, Malherbe and Harwin (311) described the isolation of a 70-nm virus designated SA11 (simian agent 11). This virus, derived from a rectal swab obtained from a healthy vervet monkey, was recovered in vervet monkey kidney cell culture. In 1967, Malherbe and Strickland-Cholmley (312) described another virus similar to SA11, the O (offal) agent, which was isolated in vervet monkey kidney cell culture from the mixed washings of intestines of cattle and sheep. In addition, in 1969, Mebus et al. (327) demonstrated the presence of 70-nm virus particles in stools from calves with a diarrheal illness and showed that this agent could be passaged serially in calves with production of disease. In 1971, Mebus et al. (328) reported successful cultivation of the Nebraska calf diarrhea virus (NCDV) in primary fetal bovine cell cultures; in 1972, Fernelius et al. (129) reported that the NCDV resembled the reoviruses morphologically but was distinct antigenically. The murine, simian, O, and bovine agents were later found to exhibit characteristic rotavirus morphology and to share a group antigen with other rotaviruses (131,250).

CLASSIFICATION

Rotaviruses are classified as a genus in the family *Reoviridae*, which contains eight other distinct genera (408). The unifying features of the rotaviruses that are responsible for their classification into a separate genus are detailed in Chapter 54.

INFECTIOUS AGENTS

Morphology and Morphogenesis

Rotaviruses have a distinctive morphologic appearance by negative-stain EM. Complete particles measure about 70 nm in diameter and have a distinctive double-layered icosahedral protein capsid that consists of an outer and an inner layer when viewed by transmission EM (see Fig. 1). Within the inner capsid is a third layer, the core, that contains the virus genome consisting of 11 segments of double-stranded (ds) RNA. The complete particles are also designated smooth particles because the outermost margin of the outer capsid layer has a well-defined, smooth circular appearance. Particles lacking the outer capsid layer measure about 55 nm in diameter and are designated rough particles because without the smooth outer layer, the capsomeres of the inner capsid project to the periphery, giving a circular, “bristly” appearance. The core, which appears to be hexagonal in outline in certain negative-stain preparations, measures about 37 nm in diameter. The term *rotavirus* is derived from the Latin word *rota*, which means wheel, and it was suggested because the sharply defined circular outline of the outer capsid gives the appearance of the rim of a wheel placed on

short spokes radiating from a wide hub (131).

Studies of the three-dimensional structure of unstained, unfixed, rotavirus particles using cryoelectron microscopy and image processing techniques have yielded important new information on the ultrastructure of rotaviruses. These and other findings relating to ultrastructure and morphogenesis are described in Chapter 54.

Physicochemical Properties and Genetics

The physicochemical properties of rotaviruses, and their genetics (including genome organization and coding assignments of the 11 RNA segments) are presented in detail in Chapter 54.

Genome

The rotavirus genome contains 11 segments of dsRNA, which have a size range of 0.6 to 3.3 kilobase pairs (319). The RNA segments fall into four size classes based on contour length measurements by EM and confirmed by nucleotide sequence analysis of each of the 11 genes (see Chapter 54). The distribution of the 11 segments into these four size classes is also evident by polyacrylamide gel electrophoresis (PAGE) of RNA as shown for representative human serotypes in Figure 3. Characteristically, these RNA segments are numbered in order of migration during PAGE, with the slowest RNA segment designated gene 1, and so on. For group A rotaviruses, there are four large segments, two medium-sized segments, three smaller segments, and the two smallest segments. This pattern contrasts with that of the reoviruses, which contain 10 RNA segments that are distributed into three size classes—large, medium, and small. These size designations are relative, because the tenth (i.e., the smallest) RNA segment of reovirus is larger than the five smallest segments of rotavirus (208).

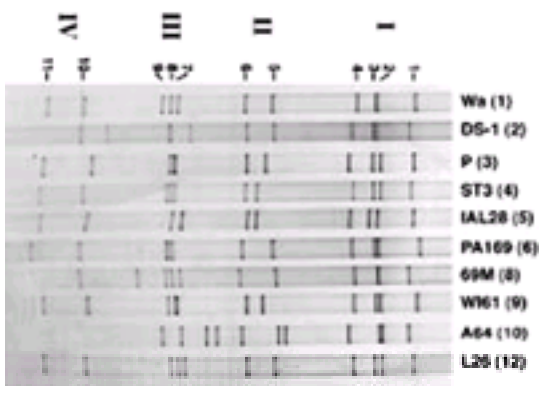

FIG. 3. Electrophoretic migration pattern (electropherotype) of RNAs of the 10 human rotavirus G serotypes. The viral RNAs were analyzed by electrophoresis in a 10% polyacrylamide gel and visualized by staining with silver nitrate. The *number in parentheses* shows G serotype. The strains DS-1 (G serotype 2) and 69M (G serotype 8) demonstrate the so-called short and supershort electropherotypes, respectively. The A64 strain (G serotype 10), which was isolated from a chronically infected immunocompromised child (228), carries rearranged RNA segments 8, 10, and 11.

Some group A rotaviruses do not display the characteristic RNA migration pattern just described (425). For example, murine rotavirus segment 11 migrates close to segment 10, whereas avian rotavirus segment 5 migrates close to segment 4, and segments 10 and 11 are difficult to resolve (Fig. 4). A lapine rotavirus that had a pattern of 4,2,4,1 instead of the usual 4,2,3,2 distribution is also shown in Figure 4. In some human rotavirus strains, the 11th (cognate) RNA segment migrates more slowly than usual and is thus located between the 9th and 10th (cognate) segments, yielding a “short” pattern characteristic of almost all antigenic subgroup I human rotaviruses [which are almost always viral protein 7 (VP7) serotype 2 strains] (see Fig. 3) (209,216). Similarly, a “long” 10th and 11th RNA segment pattern of human rotaviruses is characteristic of almost all subgroup II human rotaviruses. Moreover, several “super-short” patterns of RNA migration in which the 11th (cognate) gene segment migrated even more slowly than the “short”-pattern rotaviruses have been observed for viruses recovered from humans, bovines, porcines, and lapines (320) (see Fig. 3 and Fig. 4). These strains also exhibit subgroup I antigenic specificity. In addition, several human, porcine, bovine, ovine, caprine, canine, rodent, and avian rotavirus strains that do not share the common group antigen of conventional (group A) rotaviruses (but also have a genome with 11 double-stranded segments of RNA) display quite distinct migration patterns (Fig. 5) (49,424). Such strains, which belong to group (i.e., serogroup) B, C, D, E, F, or G, are referred to as non–group A rotaviruses. They were formerly termed pararotaviruses. Because of the segmented nature of the rotavirus RNA genome, individual gene segments reassort at relatively high frequency following co-infection *in vivo* or *in vitro* (401). However, reassortment between members of different groups (e.g., between groups A and B viruses) has never been documented, suggesting that each group may represent a separate gene pool.

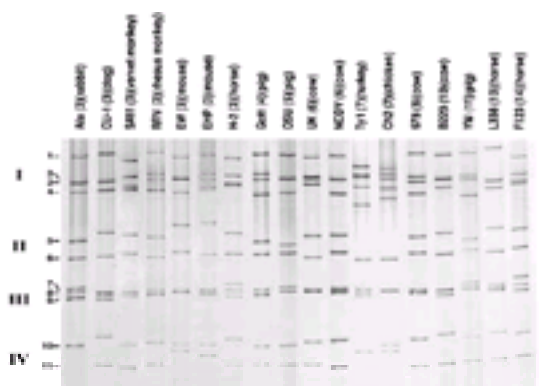

FIG. 4. Electrophoretic migration pattern of RNAs of 10 of the 13 animal rotavirus G serotypes. The viral RNAs were analyzed by electrophoresis in a 10% polyacrylamide gel and visualized by staining with silver nitrate. The *number in parentheses* shows G serotype followed by the animal species from which the virus was isolated.

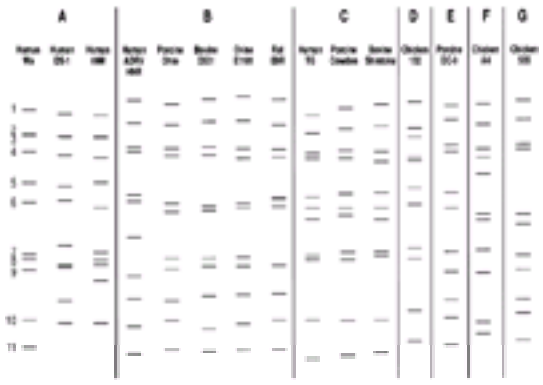

FIG. 5. Schematic diagram of electrophoretic migration patterns of RNAs of representative rotaviruses belonging to groups A to G.

Because human rotaviruses could not be propagated initially in tissue culture, comparison of the migration patterns of RNA during PAGE became an important laboratory and epidemiologic technique for characterization of strains. The term *electropherotyping* was applied to this method of differentiating strains (123,209). It soon became apparent that human rotaviruses exhibited a wide variety of electropherotypes and that these patterns differed from those observed with animal rotavirus strains. However, it was not known whether differences or similarities in electrophoretic pattern had any relationship to antigenic specificity of the human strains as defined by neutralization (i.e., serotype). Subsequent studies indicated that viruses of the same serotype can exhibit different electropherotypes, and that viruses of the same electropherotype can belong to different serotypes.

The extent of genetic relatedness among rotavirus strains has also been studied using labeled (+) single-stranded (ss) RNAs transcribed from viral cores as hybridization probes (Fig. 6) (356). The (+) ssRNAs represent messenger RNAs that are transcribed from the negative strand of genomic RNA by the viral polymerase. These (+) mRNAs appear to be colinear and coterminal with genomic (–) RNA. Early studies established that human, simian, and bovine rotaviruses were completely distinct when analyzed by this technique using hybridization conditions of high stringency (135).

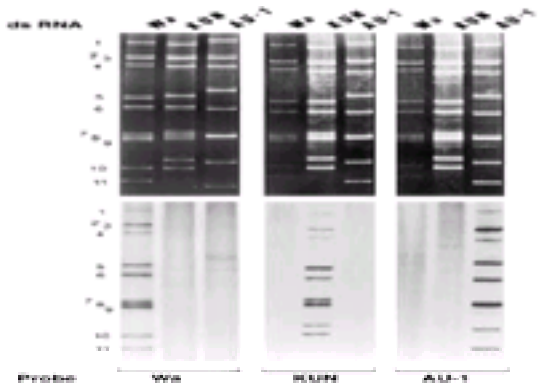

FIG. 6. RNA–RNA hybridization as used for study of genetic relatedness among three human rotavirus genogroups (families). ^{32}P-labeled RNA transcripts (probe) of the strain Wa, KUN, or AU-1 were hybridized to denatured genomic double-stranded (ds) RNAs of the Wa, KUN, or AU-1 virus. After hybridization at 65°C for 14 hr, the hybridized RNAs were pelleted and subjected to polyacrylamide gel electrophoresis. The resulting pattern was visualized by staining with ethidium bromide (**top panel**) and then by autoradiography (**lower panel**). Note that there was no significant homology among the three strains, as demonstrated by lack of formation of significant genomic length hybrids as observed by autoradiography. The homologous reaction yielded hybrids of 11 bands. (From ref. 355, with permission.)

Examination of rotaviruses obtained on a single day from children with gastroenteritis in Venezuela revealed numerous electropherotypes by PAGE (135). However, when these rotaviruses were tested with hybridization probes prepared from the human Wa (serotype 1) or DS-1 (or an equivalent serotype 2 strain KUN) virus, the RNA segments of each rotavirus exhibited significant hybridization to either the Wa probe or the KUN probe, but not to both. This observation led to the suggestion that there are at least two distinct families of human rotavirus (135). Subsequently, the existence of a third genetic family of human rotavirus designated AU-1 was demonstrated (see Fig. 6) (356). Additional studies revealed that gene segments with similar migration patterns by PAGE did not necessarily exhibit homology by hybridization; on the other hand, some gene segments that exhibited homology by hybridization varied in their electrophoretic migration (135).

Rearranged genome segment(s) have been observed in strains recovered from both immunocompetent and immunodeficient hosts (106). As noted, the 11th (cognate) segment of the “short” (DS-1) or “supershort” (69M and Ala) strains (see Fig. 3 and Fig. 4) is an example of such a rearranged genome that possesses a partially duplicated genome

structure (106). A rotavirus strain isolated from an immunodeficient, chronically infected child often displays multiple forms of genome rearrangements. The A64 strain (see Fig. 3) exemplifies such a virus with rearranged RNA segments 8, 10, and 11 (228). In addition to partial gene duplication, partial gene deletion also occurs in ature (106). Furthermore, genome rearrangement can be generated readily *in vitro* by passaging a rotavirus strain at high multiplicity of infection in cell cultures (227). Of note are the observations that (a) a VP7 serotype 2 human rotavirus strain that occurs worldwide consistently displays a rearranged “short” pattern (see Fig. 3), suggesting that a rotavirus with rearranged gene 11 is stable and “fit” in both *in vivo* and *in vitro* replication; (b) genome rearrangements occur exclusively in genes encoding nonstructural proteins, except for a rare example of a VP6 gene rearrangement (445); and (c) a rearranged genome segment encoding VP1, VP2, VP3, VP4, or VP7 has never been detected. Genome rearrangements (concatemerization and/or deletion) have been proposed to be a third mechanism of rotavirus evolution in nature, besides genomic point mutations and accumulations, as well as genetic reassortments (472).

Gene Coding Assignments

The gene coding assignments and rotavirus proteins are described in detail in Chapter 54.

Analysis of the gene coding assignments for each of the 11 genes established that there are six structural and six nonstructural proteins (408). The proteins of SA11 have been studied more thoroughly than those of other rotaviruses, in part because this virus was among the first of this group of agents to be propagated efficiently in cell culture (311). As shown in Figure 7, RNA segment 1, 2, or 3 of SA11 encodes a core or subcore structural VP, designated VP1, VP2, or VP3, respectively, whereas segment 6 encodes the major inner capsid protein VP6. Segments 4 and 9 encode the outer capsid structural proteins VP4 and VP7, respectively (319). The six nonstructural (NS) proteins, which are found in infected cells but not in virions, are encoded by segments 5, 7, 8, 10, and 11 and are designated as NSP1, NSP2, NSP3, NSP4, NSP5, and NSP6.

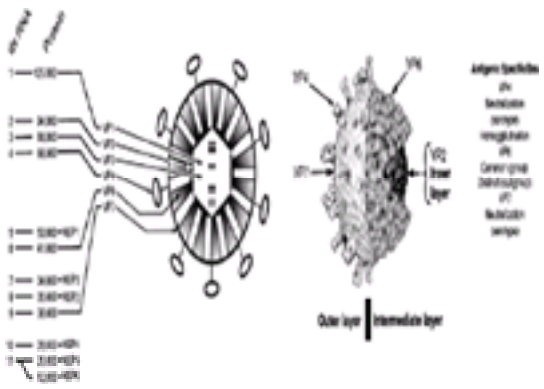

FIG. 7. Left: Schematic representation of the rotavirus particle. **Right:** Surface representations of the three-dimensional structures of the outer layer of the complete particle (*left*) and a particle (*right*) in which the outer layer and a small triangular portion of the intermediate layer have been removed, exposing the inner layer. (Modified from ref. 260, with permission. The three-dimensional figure on the right is courtesy of B. V. V. Prasad.)

VP4 is cleaved specifically by the proteolytic enzyme trypsin to form cleavage products designated VP5* [molecular weight (MW) 60,000] and VP8* (MW 28,000) (319). Proteolytic cleavage of VP4 potentiates infectivity by enhancing penetration of virus into cells. VP4 is a multifunctional protein, as discussed later in this chapter. The sixth gene encodes VP6, which contains the subgroup antigen as well as the antigen that acts as the main determinant of group reactivity (319). The ninth gene (or the seventh or eighth gene in certain rotavirus strains) encodes the neutralization protein VP7, which is largely responsible for serotype specificity defined by neutralization with hyperimmune antiserum (318).

Propagation and Assay in Cell Culture

Various animal rotaviruses, such as SA11 and the O agent, grow readily in cell culture. However, the human rotaviruses are rather fastidious agents that were not grown efficiently in tissue culture until relatively recently (437,484,527). Initially, they were observed to induce an abortive infection of cells in culture; viral antigens were produced, but infectious virus could not be passaged serially (526). The first human rotavirus to be grown efficiently and reproducibly in cell culture was a mutant of the Wa human rotavirus (VP7 serotype 1) that emerged during 11 serial passages of this strain in gnotobiotic piglets (527). Efficient growth of the mutant required pretreatment of virus with trypsin.

Because early attempts to propagate the noncultivatable human rotavirus DS-1 (VP7 serotype 2) in piglets were not successful, another strategy to cultivate this virus was adopted (179). This strategy took advantage of the well-known property of the *Reoviridae* to undergo genetic reassortment with high efficiency during co-infection in cell culture. Cell cultures were co-infected with a “noncultivatable” human rotavirus (such as DS-1) and a cultivatable bovine rotavirus temperature-sensitive (ts) mutant. Subsequently, the growth yield at restrictive temperatures from the co-infected cultures was analyzed for cultivatable reassortants (i.e., viruses with a mixed genotype) that were antigenically similar to the human rotavirus parent. Rescue of noncultivatable human rotavirus was achieved using two types of selective pressure that favored cultivatable reassortants with the neutralization specificity of the human rotavirus parent: (a) the bovine rotavirus ts mutant parent and reassortants bearing ts genes were selected against by incubating cultures inoculated with the growth yield at restrictive temperature; and (b) viruses with bovine rotavirus neutralization specificity were selected against by incubating the growth yield with bovine rotavirus antiserum. The reassortants that were selected in this manner grew efficiently in cell culture, produced plaques at the restrictive temperature, had the neutralization specificity of the noncultivatable human rotavirus parent, and were of mixed genotype. With this technique, 33 of 52 human rotaviruses were successfully rescued, and the serotypic diversity of these viruses was demonstrated by conventional

neutralization assays (181).

Later, efficient techniques were developed for the direct cultivation of most human rotaviruses in cell culture; these methods have undergone slight modifications as presented later (437,484). Cultivation is achieved by pretreatment of virus with trypsin (5 to 10 µg/mL), incorporation of trypsin (0.5 to 1 µg/mL) in the maintenance medium, the use of roller-tube cultures of simian MA104 cells, and incubation of inoculated cultures at 37°C. Following growth in roller-tube cultures, most human rotavirus strains also produced plaques under an overlay medium containing 0.6% agarose with 0.5 µg/mL trypsin. Virus present in positive fecal samples can be isolated successfully in roller-tube cultures with over 75% efficiency. However, cultivation of rotaviruses from rectal swab specimens is not nearly as efficient. Primary African green or cynomolgus monkey cell cultures, as well as continuous human colon adenocarcinoma cell lines (CaCo-2 and HT-29), appear to be more efficient than MA104 cultures for isolation of rotaviruses from clinical specimens (93,461,508). The non–group A rotaviruses have also proven to be quite fastidious. For example, only a single porcine group B strain and only a few porcine, human, or bovine group C strains have been successfully cultivated (426,429,446,469,477).

ANTIGENIC COMPOSITION

Designation of Serotypes and Subgroups

Rotaviruses have three important antigenic specificities: group, subgroup, and serotype. The group antigen is shared among all rotaviruses of a particular group. At present, groups A, B, C, D, E, F, and G are recognized (49,424). These cross-reactive (group) epitopes are present on all the structural proteins and most likely on the nonstructural ones, but in diagnostic assays VP6 is the predominant group antigen that is detected, perhaps because it constitutes 51% of the virion (319). VP6 also mediates subgroup specificity, which serves as an important epidemiologic marker because most strains belong to either subgroup I or subgroup II (249,319). The group and subgroup antigens do not induce neutralizing antibodies, although *in vivo* protection by selected anti-VP6 IgA monoclonal antibodies (MAbs) was recently described in a “backpack tumor” murine model (59). These antibodies were not active when applied directly to the intestinal lumen. It is speculated that this activity is caused by *in vivo* intracellular viral inactivation during transcytosis. In addition, it is of interest that a VP6 DNA vaccine induced protection in mice from rotavirus challenge (199).

Distinct serotypes among the group A rotaviruses have been identified by neutralization assay using hyperimmune antisera raised in various animals. Although neutralization assays measure antibodies to VP4 and VP7, the major reactivity of such sera is a function of antibodies to the VP7 outer capsid protein. However, a serotype scheme for VP4 based on neutralization was recently developed (166,216). Thus, in designating the antigenic composition of a rotavirus, four antigenic specificities must be considered: group, subgroup, and serotype mediated by VP7 (designated a G serotype because VP7 is a glycoprotein), and serotype mediated by VP4 (designated a P serotype because VP4 is protease sensitive) (319). For example, the human Wa virus is group A, subgroup II, G1, and P1A, whereas the DS-1 virus belongs to group A, subgroup I, G2, and P1B. Roman letters are used to designate group; Arabic numbers, both G and P serotypes; and Roman numerals, subgroup (13). A VP4 classification system based on genotype was recently adopted and is discussed later in this and the VP4 sections.

Because of the increasing number of “exceptions to the rule,” the tidy distinction between subgroup I and II strains by PAGE is not as clear-cut as presumed from earlier studies when human viruses with the “short” electrophoretic pattern formed a homogeneous group, VP7 serotype 2 by neutralization, whereas human viruses with the “long” pattern belonged to VP7 serotypes 1, 3, or 4 (216). It should also be noted that several human or animal rotaviruses have been detected that cannot be classified into either subgroup I or subgroup II, or that have both subgroup I and subgroup II specificities (216).

The development of techniques for cultivation of human rotaviruses in cell culture made it possible to identify virus serotype by conventional assays, which include (a) neutralization of cytopathic effect (CPE), (b) reduction of virus yield in roller-tube or multi-well plate cultures, (c) plaque or focus reduction, and (d) viral interference (216). The criterion for establishing a distinct VP7 serotype is a reciprocal, greater-than-20-fold difference in serum antibody titer when a candidate serotype is tested against prototype viruses representing established serotypes (225). With this standard among the group A rotaviruses, 14 VP7 (G) serotypes have been identified, 10 in humans and 13 in animals (Table 1) (216). Two or possibly three serotypes of group C rotaviruses have been reported (476).

TABLE 1. *Serotypic and genotypic classification of group A rotavirus VP7 and VP4*

Although the sharing of subgroup specificity by certain animal and human rotaviruses was surprising, the sharing of VP7 neutralization specificity by certain human and animal viruses was completely unexpected (225) (see Table 1). Initially, rhesus rotavirus and SA11 were shown by plaque reduction to be similar, if not identical, to human rotavirus serotype 3.

Further studies that involved extensive reciprocal cross-neutralization tests among human and animal rotaviruses revealed that (a) only one of the 10 human rotavirus serotypes (i.e., serotype 12) is restricted to humans; (b) serotype 3 viruses have the broadest host range, which includes humans, monkeys, dogs, cats, horses, pigs, mice, rabbits, and sheep; and (c) serotypes 11, 13, or 14 strains are restricted to horses or pigs, whereas serotype 7 appears to be restricted almost exclusively to birds (216). Although there is extensive sharing, certain serotypes occur almost exclusively in either humans or animals—for example, serotypes 1 and 2 are found often in humans but rarely in animals. It is of interest that the porcine rotavirus strains Gottfried and SB-2, which share serotype specificity, belong to different subgroups (216). This was the first example of shared neutralization but not subgroup specificity. It is surprising that this dissociation had not been observed more often, since serotype and subgroup specificities are encoded by different genes.

A system for categorizing rotaviruses according to VP4 has been proposed based on nucleic acid hybridization and sequence analysis of the VP4 gene (122). Currently, 21 VP4 genotypes have been described (216, 403). A recently developed VP4 classification scheme based on neutralization assay, using the same criteria as described previously for VP7, identified 13 distinct VP4 serotypes, including three subtypes (see Table 1) (216; and Hoshino et al., unpublished studies). The results of this classification were concordant, in general, with the genotypes established by hybridization or sequence analysis. To integrate the VP4 serotype and genotype designations, the letter *P* followed by an open Arabic number is reserved for serotype as determined by neutralization assay, whereas the VP4 genotype is designated by an Arabic number shown in brackets following the serotype designation (e.g., Wa virus is designated P1A [8]) (216).

Antigenic Specificities of Various Proteins

The VP6 Protein

VP6, which is located on the inner capsid of the virus, has a molecular weight of 41,000 and constitutes 51% of virion protein. Murine MAbs to the VP6 of human Wa (VP7 serotype 1, subgroup II) or rhesus rotavirus (VP7 serotype 3, subgroup I) react with almost all mammalian group A rotaviruses in various immunoassays (176). Although other structural proteins may show group reactivity under selected conditions, VP6 specifies the major group reactivity measured by such assays. However, two MAbs that immunoprecipitate VP6 have a more restricted activity (176). One of these antibodies, induced by rhesus rotavirus, reacted only with subgroup I viruses; the other antibody, induced by Wa rotavirus, reacted only with subgroup II viruses. When reassortant viruses of known genotype derived from co-infection of cells with Wa (a subgroup II rotavirus) and UK (a subgroup 1 rotavirus) were studied, it was observed that the MAb with subgroup II specificity reacted only with reassortants whose sixth gene was derived from Wa virus, whereas the subgroup I–specific MAb reacted only with reassortants whose sixth gene was derived from the UK rotavirus. None of the other rotavirus genes segregated with MAb reactivity. Thus, a domain of the sixth rotavirus gene product, VP6, specifies subgroup reactivity, whereas a separate domain(s) of this protein contains the major determinant of group A rotavirus antigenic reactivity (319). The site of attachment of VP6 subgroup MAbs on rhesus rotavirus (RRV) has been visualized clearly by IEM (248). These antibodies attach to the inner but not the outer capsid of the rhesus rotavirus.

The amino acid composition of the VP6 protein of several group A, B, and C rotavirus strains has been determined. Immunodominant sites of VP6 that contain group-specific epitopes for the group Arotaviruses have been localized in four regions on VP6 (amino acid residues 32 to 64, 155 to 167, 208 to 294, and 380 to 397) (280). In addition, amino acid residues 172, 305, and 315, and region 296 to 299 were reported as contributing to subgroup epitopes (302,466).

The VP6 protein is a target of both G serotype-specific and G cross-reactive cytotoxic T lymphocytes (CTLs) in mice (372). The serotype cross-reactive CTL epitope on the VP6 has been mapped to amino acid residues 376 to 384 (144). The VP6 protein has also been shown to carry an epitope that stimulates proliferation of cross-reactive helper T cells of $L3T4^+$ phenotype (53).

It was assumed until recently that all human and animal rotaviruses share common antigenic determinants present predominantly on VP6. However, several human and animal rotavirus strains do not share these determinants. Rotaviruses that share the group antigen are now classified in group A, whereas rotaviruses that lack this antigen are classified as non–group A viruses (49,424,468). The latter viruses also do not share subgroup antigens with group A viruses. The non–group A viruses have been given various names, such as pararotaviruses, rotavirus-like viruses, novel rotaviruses, antigenically distinct rotaviruses, and adult diarrhea rotaviruses. Currently, these viruses are classified as belonging to group B, C, D, E, F, or G. Group B viruses have been recovered from humans, pigs, cattle, sheep, goats, and rats; group C viruses from humans, pigs, cattle, dogs, and ferrets; group D viruses from chickens, pheasants, and turkeys; group E viruses from pigs; group F viruses from chickens and turkeys; and group G virus from chickens (49,108,187,380,424). A group B rotavirus was associated with (a) several large outbreaks of severe gastroenteritis in China that predominantly involved adults, (b) a mild outbreak of diarrhea in neonates in China, and (c) an outbreak of diarrhea in adults in India (97,287,308,468). Moreover, group C rotaviruses that have been detected in various locations of the world have not assumed epidemiologic importance (308,379). The non–group A rotaviruses appear to be of minor importance outside China.

The VP7 Protein

The VP7 glycoprotein is the major neutralization antigen of rotaviruses detected by hyperimmune antiserum and has served as the basis for identification of serotype (216). VP7, which has a MW of 38,000, is located on the outer capsid, forming the smooth external surface of the outer shell, and it constitutes 30% of the virion protein, thus making it the second most abundant rotavirus protein as well as the major constituent of the outer capsid (see Fig. 7) (319). VP7 is a glycoprotein that contains one to three potential sites for N-linked glycosylation, but carbohydrate side chains are not required for infectivity because a fully infectious mutant of simian rotavirus SA11 that lacks a glycosylation site has been described.

Early studies in which reassortant rotaviruses were analyzed for genotype and antigenic specificities indicated that most

neutralizing antibodies in hyperimmune antiserum were directed against the VP7 protein, which is encoded by the seventh, eighth, or ninth gene, depending on the strain (178,319). Also, many rhesus rotavirus MAbs that react with the outer capsid VP7 glycoprotein neutralize rhesus rotavirus to high titer (180). The site of attachment of these VP7 MAbs has been identified by IEM as the outer capsid of the virus (248). Thus far, group A rotaviruses have been classified into 14 distinct serotypes in reciprocal neutralization tests with hyperimmune antisera (see Table 1). Serotype identification of rotaviruses has been facilitated by the isolation of VP7 MAbs that are specific for the epidemiologically important human serotypes (1, 2, 3, or 4) as well as various other serotypes (215,216). Strains within a serotype that vary in their capacity to be neutralized by serotype-specific MAbs have been termed monotypes (88). VP7 has also been proposed to be responsible for attachment of virus to host cells, but most studies suggest that VP4 functions in this capacity (319).

The amino acid sequence of the VP7 of strains belonging to each of the 14 serotypes has been deduced from the nucleotide sequence of the VP7 gene. A comparison of the deduced amino acid sequences for all 14 serotypes indicates that there are nine regions of the linear amino acid sequence of VP7 that are highly divergent (Fig. 8) (172,363). Each of these regions is highly conserved in rotavirus strains within the same serotype. There is sufficient conservation of sequence of human rotavirus strains within a serotype that it is possible to predict the serotype of an isolate by direct sequence analysis of two of these variable regions (VR5 or A, and VR8 or C) of VP7 (174).

FIG. 8. Comparison of the deduced amino acid sequences of the VP7 protein from rotavirus strains of 14 different G serotypes. The conserved regions are *shaded*; hydrophobic regions are denoted by ▬; the hydrophilic regions are denoted by ⋀⋀⋀; variable regions (VRs) are denoted by [ ]; potential glycosylation sites are enclosed in o; conserved prolines are indicated by ▼; conserved cysteines are indicated by n; and the signal peptide cleavage site (amino acids 51) is indicated by an *arrow*.

Representative levels of identity of the nucleotide sequence of the VP7 gene as well as the deduced amino acid sequence of the VP7 protein among homotypic and heterotypic strains of VP7 serotypes 1 to 14 are shown in Figure 9. Within each serotype, amino acid homology was high (91% to 100%); however, between strains of different serotypes, conservation of sequence was significantly less. Thus, there was complete concordance between relationships among rotaviruses as determined by neutralization or sequence analysis of VP7. Conservation of VP7 amino acid sequence has been examined in more detail within serotype 3; this serotype has the broadest host range, encompassing ten different host species, including humans. Comparison of the deduced VP7 amino acid sequence of 27 strains recovered from eight of ten species indicated an overall homology of 85% or greater (363). With the exception of two feline strains, which had 90.8% deduced VP7 amino acid homology, conservation of VP7 sequence was greatest among strains recovered from the same species, with homology being 95% or greater. For example, among 13 serotype 3 human rotavirus strains, there was 95.3% or greater identity of VP7 sequence.

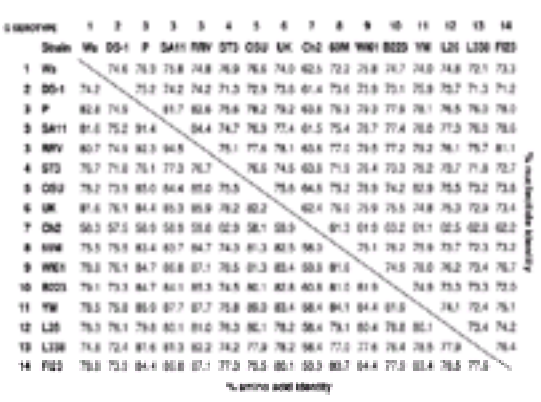

FIG. 9. The nucleotide and deduced amino acid identities among the VP7 genes of 14 rotavirus G serotypes. Three G serotype 3 rotavirus strains are included to show high nucleotide as well as deduced amino acid identities among them.

The major neutralization epitopes on VP7 have been identified by analysis of the deduced amino acid sequence of mutants that are resistant to neutralization by the VP7 MAb used for their selection (112). These were designated as antigenic region A (i.e., amino acids 87 to 99), B (amino acids 145 to 150), or C (amino acids 211 to 223) (Fig. 10). Each of the neutralization escape mutants analyzed sustained a single amino acid substitution in VP7, and these mutations occurred predominantly in VR5, 7, or 8, which corresponded to regions A, B, or C, respectively. The location of amino acid substitutions in mutants selected with hyperimmune sera were in general agreement with sites selected by MAbs (see Fig. 10). However, some additional sites in both conserved and variable regions on the VP7 were selected by MAbs

or hyperimmune antisera (167). It should be noted that monotype-specific as well as serotype-specific and serotype-cross-reactive epitopes have been mapped to the three major antigenic regions A (VR5), B (VR7), and C (VR8).

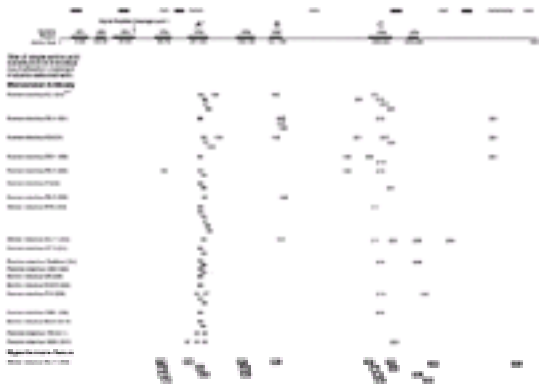

FIG. 10. Linear structure and antigenic organization of rotavirus outer capsid VP7. *Boldface numbers* indicate amino acid substitutions in mutants selected with monoclonal antibody exhibiting cross-reactive (i.e., heterotypic) neutralizing activity; *numbers not in boldface and not in boxes* indicate amino acid substitutions selected with MAb with homotypic neutralizing activity. *Numbers in boxes* indicate amino acid substitutions in mutants selected with hyperimmune serum to SA11 virus. At the *top* of the figure, hydrophobic regions are denoted by ▬, whereas hydrophilic regions are denoted by ⩘. (Adapted from ref. 215, with additions from refs. 73,74,89,159,219, and 293, with permission.)

The importance of glycosylation in the antigenicity of VP7 was shown by the effect of a single amino acid substitution at position 211 of simian virus SA11 (64). This mutation created a new glycosylation site, and the resulting mutant was rendered significantly resistant to neutralization by hyperimmune antiserum. Based on these observations, it was suggested that VR8*, which contains amino acid 211 (or a region contiguous to it in the folded protein), constitutes an immunodominant site that is rendered inaccessible to its corresponding neutralizing antibodies by the addition of a new carbohydrate side chain. This region appears to be the dominant antigenic site on SA11 VP7, but a generalization of its dominance to the whole virus is probably not valid because the role of VP4 in neutralization is not taken into consideration. Consistent with this view is the observation that the 211 mutant that bears a new glycosylation site is fully susceptible to neutralization by mouse postinfection sera, even though it is resistant to neutralization by hyperimmune antisera. This difference in susceptibility to neutralization probably reflects (a) the presence of sufficient VP4 neutralization antibodies in the former sera and (b) the low level of these antibodies in the latter sera.

Although various structural and nonstructural rotavirus proteins have been reported to elicit a CTL response in mice, the VP7 protein is a major target of rotavirus-specific CTLs. This CTL activity to VP7 is either G serotype specific or cross-reactive (109,372,374). The CTL epitopes on the VP7 have been mapped to amino acid residues 5 to 13, 8 to 16, and 31 to 40 (58,145,197).

The VP4 Protein

Study of rotaviruses by cryoelectron microscopy indicates that VP4 is present on the outer capsid as a series of 60 short spikes approximately 10 to 12 nm in length, with a knoblike structure at the distal end that comprises the region containing its proteolytic cleavage product, VP5* (see Fig. 7) (399,400). VP4 is nonglycosylated, has a MW of 88,000, and constitutes 1.5% of virion protein (319). Although it is a minor constituent of the outer capsid, VP4 performs a number of functions that have been defined by genetic and immunologic analyses (319). Analysis of rotavirus reassortants indicated that VP4 is encoded by the fourth gene (i.e., RNA segment 4) (319). Restriction of growth of human rotaviruses in tissue culture was assigned to VP4 during a study of reassortants produced during dual infection of cell cultures by a cultivatable bovine rotavirus and by a poorly cultivatable human rotavirus initially designated to be noncultivatable (179). Study of reassortants produced during dual infection of a rotavirus that has hemagglutination activity (RRV), and a rotavirus that lacks this property (bovine UK rotavirus) identified VP4 as the viral hemagglutinin (239). This assignment was confirmed when it was observed that MAbs to RRV that inhibited hemagglutination immunoprecipitated VP4 (180). This activity has been mapped to the region between residues 93 and 208 of the VP8* trypsin cleavage fragment (149); the sialic acid binding domain has also been mapped to this region (232). Trypsin cleavage of VP4 must occur for virus to become infectious and initiate penetration of the cell membrane (282,319). Furthermore, genetic mapping of various rotavirus reassortants indicated that VP4 is the major rotavirus cell attachment protein both *in vitro* and *in vivo* (306). More recently, both VP8* and VP5* proteins have been shown to mediate attachment of rotaviruses to cells (541). Rotavirus attachment and entry into cells involves a complex multistep process that requires initial interaction with various asialo- and sialoglycoplipids as well as gylcoproteins on the cell membrane (288,332).

Recently, VP4 and VP7 were shown to contain tripeptide sequences previously shown to act as recognition sites for integrins in extracellular matrix proteins, and to interact with different integrins in the early stages of infection of cells (90). Furthermore, two integrins a_2b_1 and a_4b_1 were shown to mediate simian SA11 attachment and entry into cells (200). It is suggested that binding of rotaviruses to cells involves initial carbohydrate recognition, particularly on integrins and integrin-associated glycosphingolipids, followed by a closer protein–protein interaction of virus with integrins via integrin ligand sequences on VP4 and possibly VP7. It was further proposed that rotavirus binding to integrin could facilitate virus–cell membrane interactions, including membrane permeabilization induced by VP5* or VP7 fusion and endocytosis (105,160,309,419).

Some RRV MAbs to VP4 were found to neutralize infectivity (180). This was unexpected because in earlier studies, VP4 had not been shown to play a role in neutralization, and it was thought that this function was mediated exclusively by VP7

(178). In these early studies, antiserum to bovine rotavirus strain NCDV was used to exert selective pressure on the bovine UK rotavirus in order to generate reassortants bearing genes of a cultivatable bovine UK rotavirus and a poorly cultivatable human rotavirus. However, the antiserum contained neutralizing antibodies directed only to the VP7 shared by the NCDV and UK strain, whereas neutralizing antibodies directed to UK VP4 were absent because these strains possessed disparate VP4s that did not induce cross-reactive neutralizing antibodies (see Table 1) (216). Hence, the role of VP4 in neutralization was not observed because all of the cultivatable reassortants recovered in this study bore the VP4 of the UK bovine rotavirus.

The ability of two outer capsid proteins (VP4 and VP7) to separately induce neutralizing antibodies necessitated a reevaluation of serotype classification that had been based on neutralization mediated primarily by VP7. The need for a reevaluation also became apparent when various strains were discovered that shared neutralization specificities with two distinct serotypes. The first such “intertypic” virus recognized was the M37 strain, which was recovered from an asymptomatic infant in a newborn nursery (222). Hyperimmune antiserum to strain M37 neutralized both serotype 1 and serotype 4 reference rotaviruses to high titer; similarly, antiserum to serotype 1 rotavirus neutralized M37 to high titer, whereas antiserum to serotype 4 virus neutralized M37 to low titer (222). Analysis of (a) M37 reassortants in which the genes coding for VP7 and VP4 had segregated independently and (b) antisera to these reassortants, demonstrated that the neutralization of serotype 1 virus by M37 antiserum was mediated by VP7, the ninth gene product, whereas the neutralization of serotype 4 virus by M37 antiserum was mediated by VP4, the fourth gene product. The serotype 4 reference strain ST-3, which was also recovered from an asymptomatic infant, has a VP4 sequence which is highly conserved among other nursery strains (165). A binary system of classification of rotaviruses is now available to identify the independent role of VP7 and VP4 neutralization specificities (see Table 1) (222,370). However, reagents for identification of VP4 neutralization specificity are available for only a few selected strains (84).

Although VP4 antigenic specificity had not been assigned for all rotavirus strains, RNA–RNA hybridization and/or sequence analysis of various human rotaviruses has defined the existence of at least 10 distinct VP4 gene groups (alleles) (see Table 1) (216). It is clear that independent segregation of VP7 and VP4 neutralization antigens occurs, and this has led to the confusing situation in which certain human strains with VP7 serotype 1, 2, 3, or 4 specificity can share a highly conserved VP4 (165). In addition, strains with identical VP7 specificities can possess antigenically distinct VP4 antigens (see Table 1).

The extent and distribution of VP4 polymorphism of human rotaviruses was recently elucidated when antisera to recombinant VP4 derived from strains exhibiting VP7 serotypes 1, 2, or 3 were used to analyze various human rotavirus strains by neutralization. Three distinct VP4 serotypes and one subtype were identified: serotype 1A (associated with VP7 serotypes 1, 3, 4, or 9); serotype 1B (associated with VP7 serotype 2); serotype 2A [associated with VP7 serotypes 1, 2, 3, or 4 (diverse VP7 serotypes recovered from asymptomatic neonates)]; and serotype 3 (which included a strain with VP7 serotype 1 specificity) (166). These newly assigned serotypes correlated with the VP4 amino acid homology of these strains.

Analysis of the recombinant-expressed VP5* or VP8* subunit of VP4 of three human rotavirus strains demonstrated that VP8* possessed the major antigenic site(s) for serotype specificity, whereas VP5* contained sites responsible for cross-reactivity among different VP4s (292). The VP8* subunit was analyzed further by expressing three peptides and studying them by immunoblot assay (291). These studies demonstrated that peptide B (amino acids 84 to 180) contained VP4 serotype and subtype specificities, whereas peptides A (amino acids 1 to 102) and C [amino acids 150 to 246 (and 247 to 251 from VP5*)] exhibited cross-reactivity among VP4s. This suggested that serotype and subtype specificities were located in a region extending from residues 102 to 149 of VP8*.

A significant role for VP4 in protective immunity was demonstrated during a study in which infection of newborn gnotobiotic piglets with a reassortant bearing the VP4 of one of its virulent porcine rotavirus parents and the VP7 of the other virulent porcine rotavirus parent was shown to induce resistance to disease caused by either virulent parental virus (221). This indicated that the VP4 and VP7 outer capsid proteins function as independent protective antigens *in vivo*. In addition, VP4 stimulated the same high level of neutralizing antibodies as VP7. Also, passively acquired neutralizing antibodies to VP4, as well as to VP7, independently conferred resistance to disease in infant mice in an experimental model of rotavirus illness (368). A MAb directed against VP4 of the porcine OSU strain that neutralized OSU as well as heterotypic simian RRV and bovine UK strains, passively protected suckling mice against challenge by either homotypic or heterotypic strains, indicating that cross-reactive antibodies to VP4 can also be protective (375).

Sera from animals convalescent from rotavirus infection usually contain significantly higher levels of VP4-neutralizing antibodies than do hyperimmune antisera to the same virus. Thus, serotype differences established with hyperimmune sera tend to be less clear when infection sera are employed in neutralization assays (521). In primary responses of gnotobiotic calves infected with bovine rotaviruses, significant serum antibody responses to VP4 or VP7 were approximately equal as determined by neutralization assay and epitope-blocking assay (451). It should be noted that infants vaccinated orally with a live attenuated RRV vaccine developed antibodies to neutralization epitopes on both VP7 and VP4, although the frequency of response to the latter was higher (175,442).

A comparison of the deduced VP4 amino acid sequences of a wide variety of rotaviruses revealed nine areas of divergence, the most prominent being the region including residues 92 to 192 (Fig. 11) (215). However, analysis of the sequence of single-amino-acid-substitution escape mutants selected with neutralizing MAbs identified certain variable and conserved regions on the linear sequence of VP4 that are involved in neutralization (see Fig. 11). Serotype-specific VP4 MAbs selected mutations predominantly in the VP8* subunit of VP4, whereas cross-reactive MAbs selected mutations predominantly in the VP5* subunit (see Fig. 11). Although the sites of mutation in VP8* ranged from residues 72 through 217, some of these sites, such as residues 89, 100, and 150, may be in close proximity on the folded protein because some mutants selected with a MAb directed to one of these regions were also resistant to neutralization by a MAb that selected a mutation at one of the other sites. One of the major sites at which a mutation was selected by cross-reactive antibodies is of special interest because it is within a hydrophobic region of 18 amino acids (384,385,386,387,388,389,390,391,392,393,394,395,396,397,398,399,400 and 401) that exhibits 45% identity with the putative fusion site of the E1 glycoprotein of Sindbis virus (309). Recently, a bacterium-expressed truncated recombinant

RRV VP5* containing this putative fusion region was shown to permeabilize liposomes (105).

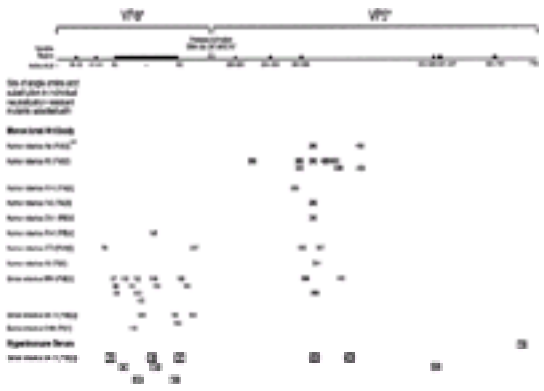

FIG. 11. Linear structure and antigenic organization of rotavirus outer capsid VP4. **VP4 serotype and genotype are shown in *parentheses. Boldface numbers* indicate amino acid substitutions in mutants selected with monoclonal antibody exhibiting cross-reactive (i.e., heterotypic) neutralizing activity; *numbers not in boldface and not in boxes* indicate amino acid substitutions in mutants selected with MAb with homotypic or limited heterotypic neutralizing activity. *Numbers in boxes* indicate amino acid substitutions in mutants selected with hyperimmune serum to SA11 virus. (Adapted from ref. 215, with additions from refs. 159,271,295,381, and 546, with permission.)

In addition to its other functions, VP4 appears to play a major role in virulence of rotaviruses (i.e., diarrhea, or loose, more frequent stools). When reassortant viruses derived from parental strains that varied in virulence for newborn mice were studied, it was observed that virulence segregated with the VP4 gene (371). Evidence for a role of VP4 in virulence has also been provided by RNA–RNA hybridization and sequence analysis of the VP4 gene of rotaviruses recovered from (a) infants and children with moderately severe to severe diarrhea, or (b) neonates infected in a nursery in which virus persisted for long periods of time and in which most affected newborns failed to develop significant symptoms (134,165). Virulence was not VP7 serotype specific in these instances, as each of the four major human rotavirus serotypes (1, 2, 3, and 4) was associated with both symptomatic and asymptomatic infections (224). In contrast, the VP4 gene of rotavirus strains from asymptomatic infections was highly conserved (95.5% to 97.5%) and was distinct from the VP4 gene of strains from symptomatic infections (25.4% to 27.1% divergence) and thus has now been classified as P2A [6] (165). In addition, the VP4 gene of strains of varying VP7 serotype that were recovered from symptomatic infections, exhibited significant conservation (87.4% to 97%). Thus far, long-term persistence of a uniform strain of rotavirus that does not cause significant symptoms has been documented in seven different nurseries in Africa, Europe, South America, and Australia (224,459). Each of these seven nursery strains possessed the conserved VP4 gene, suggesting that this gene is associated with reduced virulence (165). Furthermore, none of the other 10 rotavirus genes was conserved among the nursery strains. It should be noted, however, that in recent studies, rotavirus strains with a VP4 genotype [6] similar to that of strains from avirulent infections described previously, have been recovered from an increasing number of infants with diarrhea, some of which was severe (155,430). In addition, as noted later, the M37 nursery strain P2A [6] was evaluated as a vaccine candidate and found to induce a febrile response in 18% of infant vaccinees but was not associated with diarrhea (499). Thus, the presence of this genotype does not ensure an asymptomatic or attenuated rotavirus infection.

Further data regarding virulence were generated in the gnotobiotic porcine model, in which it was found that the VP3, VP4, VP7, and NSP4 encoding genes of a virulent porcine rotavirus each played an independent role in virulence: Substitution of any one of these genes by the corresponding gene from a human rotavirus avirulent for piglets resulted in an asymptomatic piglet infection (220). Moreover, all four genes in concert were required for the induction of illness in this model.

The NSP4 Protein

The NSP4 is a nonstructural, endoplasmic reticulum (ER)-specific glycoprotein encoded by genome segment 10 of group A rotavirus and has a MW of 28,000 (319,471). The NSP4 protein, which plays a unique role in rotavirus morphogenesis in infected cells, functions as an intracellular receptor by mediating the conversion of double-layered particles in the cytoplasm to triple-layered particles in the ER. Recently, the baculovirus-expressed recombinant NSP4 protein of the simian rotavirus SA11 strain was reported to act as an enterotoxin by inducing an age-dependent diarrhea in mice when administered by intraperitoneal or intraluminal routes but not when given intramuscularly (14,125). In addition, an SA11 synthetic peptide that contains amino acid residues 114 to 135 of NSP4 was also capable of inducing diarrhea in suckling but not adult mice. Furthermore, tyrosine at residue 131 of the protein was reported to be a key amino acid that was associated with the toxigenic activity of NSP4. It is hypothesized that NSP4 interacts with a putative cellular receptor of the gut epithelium and stimulates a calcium-dependent signal transduction pathway that increases plasma membrane chloride permeability and potentiates chloride secretion, thereby inducing a secretory diarrhea. The potential of antibodies to the NSP4 protein to protect against virus-induced diarrhea was examined by challenging mouse pups born to dams that were immunized with the SA11 NSP4 114-to-135 peptide or a control peptide. Pups born to dams immunized with the key NSP4 peptide had less severe diarrhea of shorter duration than controls. In an homologous system, an *Escherichia coli*-expressed NSP4 of murine rotavirus EW had similar toxigenic activity in mouse pups (213).

The nucleotide and deduced amino acid sequence of NSP4 from pairs of virulent and attenuated rotaviruses were compared in an attempt to further define the potential role of NSP4. Such sequence comparisons of the virus pairs yielded varying results. For example, comparison of the NSP4 sequences from two pairs of porcine rotavirus (strains OSU and Gottfried) as well as from symptomatic and asymptomatic human rotavirus strains suggested that mutations in NSP4, particularly those between amino acids 131 and 140, were associated with altered virus virulence of the

attenuated strain (272,542). However, comparison of the NSP4 amino acid sequence of human rotavirus strains Wa, M, and 89-12 as well as murine rotavirus strains EW, EC, and EHP that had been attenuated by tissue culture passage, with that of their respective virulent strains failed to identify any consistent or significant change (9,68,510).

Sequence analysis of over 90 NSP4 genes from strains from humans and nine different animal species indicated that there are four genetic NSP4 groups or alleles: NSP4A (genetic group I or DS-1 allele), which includes human DS-1 genogroup rotaviruses, bovine and equine rotaviruses, and simian SA11; NSP4B (genetic group II or Wa allele), which includes human Wa genogroup rotaviruses and porcine rotaviruses; NSP4C (genetic group III or AU-1 allele), which includes human AU-1 genogroup rotaviruses as well as rhesus, feline, canine, and lapine rotaviruses; and NSP4D (genetic group IV or EW allele), which includes murine rotaviruses (75,95,212,213,273,275). However, the relevance of such genetic diversity has not been determined.

Serum and intestinal humoral immune responses of mice to the NSP4 protein were measured by an immunocytochemistry assay that employed recombinant baculovirus-expressed SA11 NSP4 (NSP4A or DS-1 allele) as antigen. The mice that were studied were infected with a homologous murine rotavirus [EHP strain, (NSP4D or EW allele)], or a heterologous simian rotavirus [RRV, (NSP4C or AU-1 allele)] (234). Titers to NSP4 were low in both groups during the 28 weeks of observation, with no significant difference in titer between the two groups. Recently, humoral and cellular immune responses of naturally infected and/or vaccinated children and/or adults were evaluated by IgG and IgA enzyme-linked immunosorbent assay (ELISA) using recombinant baculovirus-expressed SA11 NSP4 and/or a synthetic peptide corresponding to residues 114 to 135 of SA11 NSP4. Most of the children and adults developed a low or modest immune response to the NSP4 protein and/or peptide after infection or vaccination, and 8 of 10 adults developed a cellular immune response (238). The role of the NSP4 enterotoxin in the natural history and pathogenesis of rotavirus infection in humans needs further clarification to assess its application to human disease.

INFECTION OF EXPERIMENTAL ANIMALS AND HOST RANGE

Group A rotaviruses have a wide host range, as indicated by their recovery from the newborn of almost all animal species that have been studied, except the guinea pig and rat (425). Many of these strains were detected in newborn animals with diarrhea. In contrast to human rotaviruses, most animal rotaviruses are not as fastidious in their requirements for cultivation *in vitro* (425). Under experimental conditions, some human rotavirus strains induce a diarrheal illness or subclinical infection in newborn animals such as gnotobiotic calves, gnotobiotic or conventional piglets, rhesus or cynomolgus monkeys, gnotobiotic lambs, puppy dogs, and newborn mice (24,330,340,427,453,479,530).

The gnotobiotic piglet has been particularly useful as an animal model, offering several advantages over other animal model systems (427): (a) prolonged susceptibility to infection and illness caused by certain strains of human rotavirus, (b) a close resemblance to humans in gastrointestinal physiology and development of mucosal immune system, (c) no influence of maternally derived antibodies in colostrum-deprived gnotobiotic pigs, (d) a relatively large litter size (average, five to eight piglets per litter), and (e) studied under gnotobiotic conditions to eliminate certain confounding variable factors.

In China, a human rotavirus was shown to induce a severe diarrheal illness in *Tupaia belangeri yunalis*, a nonhuman primate, following administration by the alimentary route (384). In limited studies, the ability of human rotaviruses to spread to animals has not been demonstrated. Movement of rotaviruses in the opposite direction has been investigated more extensively, and hybridization and sequence analyses indicate that certain naturally occurring animal rotavirus strains can infect humans on rare occasion (355). Moreover, the use of certain animal rotavirus strains as human vaccine candidates has been evaluated extensively under experimental conditions, as described later.

PATHOGENESIS AND PATHOLOGY

The following lesions have been identified in the jejunal mucosa of infants and young children hospitalized with rotavirus disease: shortening and atrophy of the villi, mononuclear cell infiltration in the lamina propria, distended cisternae of the ER, mitochondrial swelling, and sparse, irregular microvilli (210,345,463). Denudation of microvilli was also noted. Virus particles were visualized in dilated cisternae of ER and in lysosomes of columnar epithelial cells. Virus particles were also detected in goblet cells and phagocytes in the lamina propria. Occasionally, tubular structures were visualized in dilated cisternae of the ER. Impaired *d*-xylose absorption has also been observed (321), as well as abnormal gastric motor function, as indicated by a delay in emptying of a liquid meal (16). In addition, some patients have depressed levels of disaccharidases (maltase, sucrase, and lactase) (38).

Direct information concerning the pathogenesis of rotavirus infection has been obtained from experimentally infected animals that developed diarrheal illness following administration of human rotavirus (345). In one study, the pathogenesis of human rotavirus strain D (VP7 serotype 1) was studied in newborn, gnotobiotic, colostrum-deprived calves that developed illness following intraduodenal administration of virus (329). Morphologic changes proceeded in a cephalocaudad direction in the small intestine. Within half an hour of experimentally induced diarrhea, morphologic changes such as denuding of villi and flattening of epithelial cells were observed in the upper small intestine, but rotaviral antigens were not detected by immunofluorescence (IF). At this time, the lower small intestine was intact, but rotavirus antigens were abundant in swollen epithelial cells. Seven hours after onset of diarrhea, the lower small intestine showed morphologic changes similar to those seen earlier in the upper small intestine; however, rotavirus antigens were not detectable by IF. Forty hours after onset of diarrhea, the intestine appeared relatively normal. Examples of some of these changes are shown in scanning electron micrographs in Figure 12.

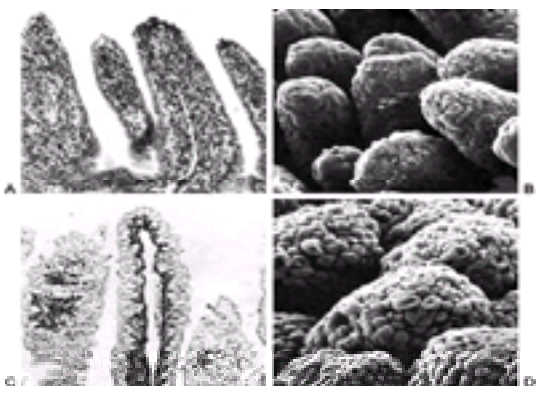

FIG. 12. Scanning electron and light micrographs of intestinal tissues from a gnotobiotic calf sacrificed 0.5 hr after onset of diarrhea induced by human rotavirus. **A:** Proximal small intestine with shortened villi and a denuded villus tip (second from right) (H&E, ×85)**. B:** Appearance of the same level of intestine shown in (A), depicting denuded villi by scanning electron microscopy (SEM) (H&E, ×125). **C:** Distal small intestine with normal vacuolated epithelial cells and normal villi (H&E, ×50). **D:** Same area as in (C), seen by SEM. Epithelial cells appear round and protruding (H&E, ×85). (Adapted from ref. 329, with permission.)

Piglets that developed rotavirus diarrhea following administration of human rotavirus demonstrated functional alterations in small intestinal villous epithelial cells (101,151,501). Glucose-coupled sodium transport was impaired, sucrase activity was decreased, and thymidine kinase activity was increased. However, adenylate cyclase and cyclic AMP were not altered. Absorption of the macromolecule human a-lactalbumin was found to be increased during rotavirus acute gastroenteritis in young children (207). In addition, studies in malnourished or well-nourished suckling mice infected with a murine rotavirus, or piglets infected with porcine rotavirus indicated that malnutrition increased the severity of symptoms and mucosal damage (177,411,482,548).

Although maladsorption is a generally accepted mechanism of rotavirus-induced diarrhea, which is characterized by viral replication in villus enterocytes in the small intestine with subsequent cell lysis and attendant villus blunting, depressed levels of mucosal disaccharidases, watery diarrhea, and dehydration, it may not be the sole explanation of rotavirus-induced diarrhea. For example, watery diarrhea was observed in homologous and heterologous piglet models before the detection of extensive intestinal histopathologic damage (322,470,501). Also, in a homologous piglet model, diarrhea subsided by 9 days after infection in nourished but not in malnourished piglets, whereas the degree of intestinal structural damage was comparable between these nutritional groups at that time after infection (547). In addition, in a heterologous mouse model, inactivated RRV induced diarrhea in the absence of viral replication (444). Diarrhea prior to obvious intestinal cell damage has also been reported in humans. In Germany, small intestinal mucosal biopsies were taken for histopathologic examination from 40 children aged less than 18 months during the acute phase (between days 2 and 10) of rotavirus diarrhea. Only two biopsies (5%) showed histopathologic evidence of damage (279). Thus, a clear distinction between intestinal mucosal damage and diarrhea exists in some cases. A secretory type of diarrhea similar to bacterial enterotoxin-induced diarrhea was observed recently in a homologous piglet model; it was characterized by inflammatory responses in the small intestine, including local T-lymphocyte expansion, enhanced intestinal major histocompatibility complex (MHC) class I and class II gene expression, and elevated tissue concentrations of prostaglandin E_2 (548). Intestinal inflammation induced by bacterial enterotoxin has been known to evoke fluid secretion by activation of the enteric nervous system (ENS). More recently, in a heterologous mouse model, four different drugs that inhibit ENS functions have been shown to attenuate the rotavirus (RRV)-induced secretory responses in the small intestine (307). This observation suggests that the ENS participates in the rotavirus-induced electrolyte and fluid secretion in the small intestine. Rotavirus nonstructural protein NSP4, which has recently been suggested to have a toxin-like function, may participate in inducing intestinal inflammation, activation of the ENS, and thereby a secretory-type diarrhea as discussed earlier.

The RRV strain MMU18006, which is present in a vaccine licensed for use in humans, can spread beyond the intestines in mice with severe combined immunodeficiency (SCID) and cause hepatitis (481). A similar response has been noted in malnourished mice or normal suckling mice (480). However, extensive clinical studies have failed to detect involvement of the liver during immunization of infants with RRV. Involvement of the liver has not been observed with a bovine (WC3) rotavirus strain that is currently a vaccine candidate. In addition, RRV, SA11, the canine CU-1, and the Ty1 turkey strains (and the UK bovine strain to a lesser degree) grow efficiently in HepG2 cells, a well-differentiated human cell line derived from a hepatoblastoma (276,440). The ability of SA11 to grow in these cells was assigned to the VP4 gene by segregation analysis (402). Most, but not all, human rotavirus strains grow poorly in these cells (276). However, most animal and human strains grow efficiently in MA104 cells (derived from monkey kidney) and CaCo-2 and HT29 cells (derived from a human colon carcinoma) (276). Additional data regarding pathogenesis were previously reviewed under individual viral proteins (e.g., VP4, VP7, NSP4).

EPIDEMIOLOGY

Morbidity and Mortality

Until the discovery of the rotaviruses, only a small proportion of severe diarrheal illnesses of infants and young children could be linked to an etiologic agent (240,539). However, as data from epidemiologic studies in the developed and developing countries have accumulated, it has become clear that rotaviruses are the major etiologic agents of serious diarrheal illness in infants and children under 2 years of age throughout the world (see Fig. 2) (34).

Although rotavirus diarrhea occurs with high frequency in the developed countries, mortality is low. In the United States, rotaviruses cause about 5% to 10% of all diarrheal episodes in infants and children under 5 years old; however, these

viruses account for 30% to 50% of severe diarrheal episodes (66). In this age group, it is estimated that rotaviruses are responsible annually for approximately 2.7 million episodes of diarrheal illness, 410,000 visits to a physician, 160,000 emergency room visits, 50,000 hospitalizations, and 20 deaths. Thus, during the first 5 years of life in the United States, approximately 4 of 5 children will develop rotavirus diarrhea, 1 of 7 will require a visit to a clinic or emergency room, 1 of 78 will be hospitalized, and 1 in 195,000 will die from rotavirus diarrhea (66,478). In addition, rotavirus diarrhea results in over $264 million in direct medical costs (primarily for hospitalization) and over $1 billion in total societal costs (primarily for loss of work time of parents or caregivers) (478). A high morbidity but low mortality rate can be attributed to the development during the 1940s of effective means for replacement of fluid and electrolytes lost during disease and their routine use in developed countries (116). This improvement in therapy has brought about a marked decrease in mortality from all forms of infantile diarrhea.

In developing countries, rotaviruses are the leading cause of life-threatening diarrhea in infants and young children. The burden of rotavirus diarrheal disease in infants and children under 5 years of age in developing countries has been estimated to be 130 million cases; over 18 million of these were considered moderately severe or severe (231). In addition, it has been estimated that 873,000 infants and children under 5 years old die from rotavirus diarrheal illness each year in developing countries (231). Thus, during the first 5 years of life in the developing countries, as in the developed countries, almost every child will experience an episode of rotavirus diarrhea but the consequences will be quite different in the developing countries: 1 of 8 will develop moderately severe illness and 1 in 160 will die (162).

In developed countries, the widespread distribution of rotaviruses in the community is indicated by the universal acquisition of serum antibodies to these viruses at an early age. For example, in the Washington, D.C., area, over 90% of infants and young children acquire rotavirus antibodies by the end of the third year of life, a pattern similar to that observed for respiratory syncytial and parainfluenza type 3 viruses (258,269,386). The high prevalence of rotavirus antibodies is maintained into adult life, suggesting that subclinical rotavirus reinfection occurs. A similar pattern of acquisition and maintenance of rotavirus antibody has also been observed in many other parts of the world (25).

Cross-sectional studies of hospitalized infants and young children with diarrheal illnesses have yielded the most compelling evidence for the importance of rotaviruses as etiologic agents of severe diarrhea of early life. For example, during a period of over 8 years, 34.5% of 1,537 infants and young children admitted with diarrhea to a Washington, D.C., hospital were shedding rotavirus in their feces on admission (Fig. 13) (47). Moreover, in a similar study in Japan of over 6 years' duration, 45% of 1,910 pediatric patients with diarrhea were rotavirus positive (281). In two similar shorter-term studies (1 year), one in Australia and the other in the United Kingdom, 52% of the infants and young children admitted with diarrhea were rotavirus positive (100,297). Also, in a 1-year study of hospitalized infants with diarrhea in Finland, 49% of the illnesses were associated with rotavirus infection (494).

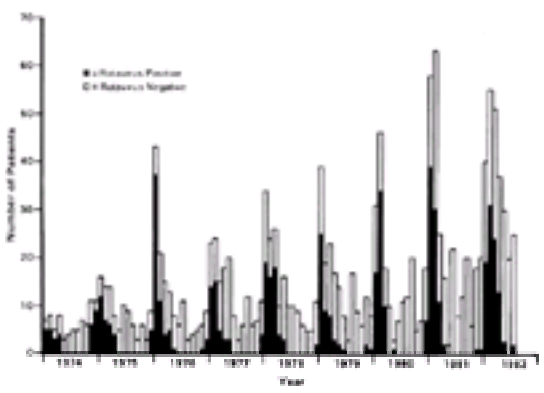

FIG. 13. Rotavirus infections in patients hospitalized with gastroenteritis at Children's Hospital National Medical Center, Washington, D.C., January 1974 to July 1982, as demonstrated by EM, IEM, and rotavirus confirmatory ELISA. (From ref. 47, with permission.)

The largest and longest cross-sectional study of hospitalized children with gastroenteritis was reported more recently from Australia (20). During a survey covering a period of 13 years, 39.6% of 3,785 children were shedding rotavirus in feces on admission. Notably, 55% of children (12 to 23 months old) with gastroenteritis were rotavirus positive. Rotavirus gastroenteritis was also often observed in the under 6-month age group (18.7% of cases) as well as the 5- to 13-year age group (16% of cases).

Rotaviruses have also been documented consistently as the most important etiologic agents of diarrheal illnesses in developing countries (25). For example, in a comprehensive study of the etiology of diarrheal illnesses for which treatment was sought, which included 6,352 patients treated at the Matlab Treatment Center in Bangladesh over a 1-year period, rotaviruses were the most frequently detected pathogen in children under 2 years of age, as 46% of the study group were rotavirus positive (43). The next most important agent was enterotoxigenic *E. coli*, detected in 28%. In the over-2-year age group, bacterial agents were recovered more frequently than rotavirus. The importance of rotaviruses in severe dehydrating diarrheal illnesses was demonstrated in another cross-sectional analysis in a hospital in Cairo, Egypt, in which 145 infants and young children under 18 months of age with fatal or potentially fatal diarrheal illness were studied (447). Rotaviruses were the pathogen most frequently detected, accounting for 34% of the cases. Enterotoxigenic *E. coli* ranked second (27% for LT and ST strains combined).

Prospective studies in developing areas of the world have demonstrated the magnitude of the problem of diarrheal diseases in general, and most studies have highlighted the unique capacity of rotaviruses to induce dehydrating illness with unusually high frequency. In a 30-month village-based study in northeastern Brazil, early childhood mortality exceeded 14% during the first 5 years of life. Furthermore, in over 52% of recorded deaths, diarrhea was listed as either

the primary or an associated cause of death (189). A sample of specimens from diarrheal episodes was tested for enteric pathogens, and 53% yielded a recognized etiologic agent. The most commonly detected pathogens were enterotoxigenic *E. coli* and rotaviruses, 21% and 19%, respectively. The poorest families had the highest diarrhea attack rates, which reached almost 10 per child per year in the 6- to 11-month age group. When a cohort of 45 children was studied prospectively over a 3-year period in Santa Maria Cauque, Guatemala, the incidence of diarrhea was 7.9 per child per year, and rotavirus was associated with 10% of such episodes (314,315). Significantly, dehydration was 14 times more frequent among children with rotavirus diarrhea than among individuals with diarrhea of bacterial, acute parasitic, or unknown etiology (531).

Rotavirus Serotypes

The development of MAbs that identify the VP7 of most clinical isolates and the widespread application of molecular biologic techniques have helped refine our understanding of the epidemiology of rotavirus serotypes with regard to infection and disease (155,217). Previously, the serotype of a rotavirus strain could be identified only by techniques, such as virus neutralization assays, not readily adaptable to large-scale epidemiologic surveys (13). Importantly, there has been complete concordance between serotype determined by ELISA using MAbs and by neutralization with hyperimmune antiserum (216).

MAb-based ELISA has been used to determine the distribution of VP7 serotypes of rotavirus isolates from children with acute gastroenteritis over a 6-year period in various countries of Europe, North and South America, Africa, and Asia. This analysis indicated that (a) 94.9% of 907 rotavirus isolates belonged to G serotypes 1, 2, 3, or 4 (5.1% were VP7 positive but could not be typed with MAbs to serotypes 1 through 4); (b) rotavirus serotype 1 was detected most often (54%), followed by serotype 2 (18%), serotype 3 (12%), and serotype 4 (11%); (c) each of the four serotypes had a worldwide distribution, with no single serotype being found exclusively in one location; (d) differences in the distribution of serotypes were observed year by year and in different countries during the same years; and (e) differences were not observed in the distribution of serotypes detected in developed and developing countries (23).

Information derived from 28 studies that included 5,419 rotavirus isolates obtained between 1979 and 1989 from North and South America, Europe, Asia, and Africa confirmed the results of earlier investigations: Serotype 1 was the most prevalent (61%), whereas serotypes 2, 3, and 4 were evenly distributed (10% to 16%), except that serotype 4 was not detected in Africa (522). A consistent difference in virulence of rotaviruses of varying VP7 serotype has not been observed (19,27). Serotype G 1 through 4 strains were also predominant in a long-term, 16-year study of children hospitalized with acute rotavirus diarrhea in Australia (40). In another large serotyping study, 91.5% of 3,756 rotavirus-positive stool specimens collected in seven regions of Japan from 1984 to 1997 were found to belong to serotype 1 (70.5%), 2 (9.6%), 3 (6.2%), or 4 (5.2%) (545). The need for continued surveillance is evidenced by the emergence of strains with VP7:5, 8, 9, or 10 specificity in several selected locations (85,94,98,155,171,217,358,383).

Serotype analysis of clinical isolates for their VP4 specificity has proceeded more slowly because of the scarcity of suitable reagents. In various parts of the world, P1A [8] strains appear to predominate in frequency. This was anticipated because VP7 serotype 1, the most frequently detected VP7 serotype, shares VP4 P1A specificity with two other epidemiologically important VP7 serotypes (i.e., 3 and 4) (216). As noted earlier in Table 1, an extensive VP4 genotyping classification has been developed (216).

Rotavirus Infections in Adults

Adults appear to undergo rotavirus reinfections quite commonly but characteristically with minimal or no clinical manifestations. For example, 22 (55%) of 40 adult household contacts of children hospitalized with rotavirus gastroenteritis developed serologic evidence of rotavirus infection, predominantly subclinical, at or about the time of their child's admission to the hospital (270). Although subclinical rotavirus infection is the most common outcome in adults, rotavirus gastroenteritis in adults has been described in army recruits in Finland as well as in patients (some geriatric) and staff in hospitals in various countries (34,226). Several outbreaks in geriatric groups had a high attack rate, and there were some fatalities (34). Nonetheless, these outbreaks are unusual because of the high level of rotavirus immunity that most adults have acquired from previous infections.

An unusual outbreak of rotavirus gastroenteritis was reported involving adults associated with children in a play group (414). Nine children 15 months to 5 years of age, three of five mothers who participated in play-group activities, four of five fathers, and each of two grandparents developed gastroenteric illness that could be traced to the play group. Overall, 18 of 21 individuals developed gastroenteritis, and 10 of 11 persons tested demonstrated evidence of rotavirus infection. Other sharp outbreaks of rotavirus-associated acute diarrheal illness have been described in which individuals of all ages were affected (140,300). During an extensive outbreak in an isolated South American Indian community in northern Brazil, the attack rate in adults over 41 years of age was 80% (300). However, these must be considered unusual, isolated events.

Rotavirus infections have also been associated with traveler's diarrhea in certain settings (41). However, these viruses are not considered to be major etiologic agents of this disease.

Group B rotaviruses have been implicated in several large outbreaks of severe gastroenteritis in adults in various parts of China involving 12,000 to 20,000 individuals. Affected individuals developed cholera-like, severe, watery diarrhea, and a few elderly patients died (468).

Nosocomial Infections

Nosocomial rotavirus infections occur frequently, as demonstrated in several studies (34). For example, 10 (17%) of 60 children hospitalized for nondiarrheal disease during a period of rotavirus prevalence developed a diarrheal illness associated with a rotavirus infection (420). Also, in another hospital study, about one of every five rotavirus infections

appeared to be hospital acquired (334).

Nosocomial infections have been described in various neonatal nurseries around the world (34). These are usually subclinical, although recently a nosocomial outbreak of rotavirus gastroenteritis was described in newborn nurseries in Italy (158).

Transmission

Rotaviruses are transmitted by the fecal-oral route. Oral administration of rotavirus-positive stool material induces diarrheal illness in volunteers (263,506). Nevertheless, speculation continues as to whether rotaviruses are transmitted also by the respiratory route (83,164,190). Evidence for this is circumstantial and rests on the following: (a) the rapid acquisition of rotavirus antibodies in the first few years of life in all settings, regardless of hygienic standards (385); (b) a few large outbreaks in which a fecal-oral spread could not be documented (140); and (c) the occurrence of respiratory symptoms in a proportion of patients with rotavirus gastroenteritis (190). There have been scattered reports of detection of rotavirus in the upper respiratory tract; however, the predominance of data from other studies suggests that this is not the usual mode of transmission (464,500,543,544).

The source of infection for the young infant who is normally not in contact with other infants and young children with gastroenteritis is not well documented. Most likely, infection is acquired from an older sibling or parent with subclinical infection (121,182). Shedding of rotavirus from the intestinal tract prior to onset of diarrhea or following cessation of diarrhea has been well documented (395).

Resistance to physical inactivation (along with the large number of viral particles shed in feces) may contribute to the efficient transmission of the human rotaviruses. This inference is drawn from the observed stability of various human and animal rotaviruses at ambient temperatures (10,124,267,341). For example, calf rotavirus present in feces retained infectivity for 7 months when kept at room temperature (347). Other observations that also suggest environmental contamination as a source of infection include (a) the persistence of rotavirus infection in certain newborn nurseries and (b) the high frequency of nosocomial rotavirus infection in hospitals (as described earlier). The ability of rotaviruses to survive on various surfaces under different conditions may contribute to the rapid spread of these agents (516). Although rotaviruses have been detected in raw or treated sewage, it is unlikely that contaminated water plays an important role in transmission of group A rotaviruses (449). High relative humidity (about 80%) results in a rapid loss in human rotavirus infectivity (10). Effective disinfection of contaminated material and careful handwashing constitute important measures to contain rotavirus infection, especially in a hospital or institutional setting (42,285,428,452,465,485,516).

Rotavirus has been detected on moist surfaces in day care centers, and in one controlled study rotavirus transmission was prevented in volunteers if a surface contaminated with rotavirus had been sprayed with a disinfectant (60,503). This approach may have applicability in such centers or in hospitals in an attempt to reduce the high rate of nosocomial infection, but it would not obviate the need for the development of immunoprophylaxis (301).

There has been speculation on the role of animals as a source of rotavirus infection of humans. This speculation has been intensified by the following observations: (a) certain animal rotaviruses share a neutralization antigen with human rotaviruses (see Table 1), and (b) certain naturally occurring animal rotavirus strains may infect humans or form reassortants with human rotaviruses (355). Nonetheless, this type of interspecies transmission appears to be a rare event in most parts of the world. However, it should be noted that human–bovine reassortant strain I321 or a human–porcine reassortant strain appears to be endemic in selected areas in India and Brazil, respectively (98,171).

Incubation Period

The incubation period of rotavirus diarrheal illness has been estimated to be less than 48 hours (100). The onset of experimentally induced rotavirus diarrhea in adult volunteers occurred 2 to 4 days after challenge (263,264). One of the volunteers who developed diarrhea 3 days after virus administration developed a fever and vomited on the first day after challenge, indicating that the incubation period of the illness under experimental conditions was 1 to 4 days.

Distribution

Geographic Distribution

Rotaviruses have been detected throughout the world wherever they have been sought (34,385). Furthermore, these viruses consistently constitute major etiologic agents of severe infantile diarrhea in every country where this disease has been studied by appropriate techniques.

Seasonal Patterns

Rotaviruses display a seasonal pattern of infection in developed countries, with epidemic peaks occurring in the cooler months of each year (34,385). This recurring pattern was clearly documented in the Children's Hospital National Medical Center (Washington, D.C.) study of infants and young children admitted with diarrheal diseases over an 8-year period (see Fig. 13) (47). The absence of rotavirus infections from July through October (1974 to 1982) was a consistent finding. In contrast, during January, 67% of 250 hospitalized diarrhea patients shed rotavirus, and during February, 58% of 219 patients were rotavirus positive. Outpatients with diarrhea exhibited a similar pattern. In a Japanese study extending from December 1974 through June 1981, rotaviruses were detected in the feces of 66% of 785 patients hospitalized with diarrhea during the cooler months of December, January, and February and in the feces of 56% of 549 children admitted in the spring (March, April, and May) (281). In contrast, only 5.6% of 576 pediatric patients admitted during the summer and autumn months were rotavirus positive. Recently, in a 13-year Australian study of children hospitalized with gastroenteritis, an annual winter admission peak was attributed to the increase in total incidence of rotavirus

gastroenteritis during this season, although rotaviruses were detected in 135 of the 156 months studied (20).

The cause for this striking seasonal pattern is not known, but the influence of low relative humidity in the home has been suggested as a factor facilitating the survival of rotaviruses on surfaces (46). However, when this factor was studied, a correlation with the temporal pattern of infection was not observed in every epidemiologic setting (281,341). A recent analysis of hospitalizations for diarrhea in the postneonatal period and the temporal distribution of rotavirus isolations from various centers suggests that rotavirus diarrhea spreads from the west to the east in the United States, appearing in the fall in the southwest and spreading progressively across the country, so that by late winter and spring it has reached the northeast (205,294). The usual seasonal pattern of rotavirus infection observed in the temperate climates does not occur uniformly in other settings (83,201).

Age, Sex, Race, and Socioeconomic Status

Rotavirus gastroenteritis severe enough to require hospitalization characteristically occurs most frequently in infants and young children from approximately 6 months to 2 years of age (25,35). Infants under 6 months of age experience the next highest frequency of such illness. In certain studies, this age group had the highest frequency (92,121,349,396,460,483). In one U.S. study, the age distribution of patients admitted to the hospital with gastroenteritis of any etiology was different for black and nonblack patients; 59% of all black patients admitted for gastroenteritis were younger than 6 months of age (45). This difference was also reflected in admissions for rotavirus diarrhea. Since the black children were predominantly from less affluent, inner-city areas, these differences probably reflect the effects of crowded living conditions, which may have allowed earlier and more efficient transmission of the virus.

An Australian study, which extended over a 13-year period, of hospitalized children with gastroenteritis deviated somewhat from this pattern (20). Although the peak incidence of rotavirus gastroenteritis was in the 12- to 23-month age group, in which 55% had rotavirus infection, rotaviruses were a frequent cause of gastroenteritis (18.7%) in children under 6 months of age. These viruses were also associated with 16% of the gastroenteric illnesses in the 5- to 13-year age group and were identified as the sole pathogen in 45 of 282 patients in this age group.

The low frequency of clinical illness in most (but not all) normal neonates who shed rotavirus remains an intriguing paradox that is being actively investigated because of its implications for immunoprophylaxis (34). As noted earlier, the gene encoding the outer capsid protein VP4 of strains recovered from asymptomatic neonatal infections is highly conserved and differs from the corresponding viral protein of strains from symptomatic infections (134,165). Further study is required to determine whether the highly conserved VP4 of strains from asymptomatic neonatal infections plays an important role in the ability of these viruses to persist over a long period of time in newborn nurseries without causing significant disease. As noted earlier, strains with a VP4 similar to that of strains recovered from asymptomatic (P2A [6]) infections have also now been observed in a small proportion of ill infants, indicating that the presence of this genotype does not ensure a silent infection (155,430,459).

Malnutrition is thought to play an important role in increasing the severity of clinical manifestations of human rotavirus infection (52,96,313). This phenomenon has been reproduced in an experimental mouse and piglet model (411,482,547). It has also been suggested that repeated diarrheal infections may be a precipitating factor in the development of malnutrition by damaging intestinal mucosa so that absorptive cells are compromised over an extended period (313,314).

Molecular Epidemiology

Initial investigations of the molecular epidemiology of human rotaviruses utilized gel electrophoresis of segmented genomic dsRNAs for strain identification (electropherotype) and comparison (123,209). For example, analysis of rotaviruses derived from 116 children hospitalized with gastroenteritis in Melbourne, Australia, between 1973 and 1979 identified 17 different electropherotypes (412). Distribution of electropherotypes was not random during the 7-year study period but showed, instead, a sequential pattern of appearance and prevalence. Only a limited number of electropherotypes was detected at any one time. Characteristically, a single electropherotype was predominant, often accompanied by less common types. In contrast, only two closely related electropherotypes could be identified among rotaviruses from 72 newborn babies studied in seven different hospitals from 1975 to 1979. It was remarkable that these two electropherotypes had similar RNA patterns and that neither was ever identified in viruses from children hospitalized for acute gastroenteritis. One of these electropherotypes was detected in nurseries in five different hospitals and persisted in one nursery for 4 years. This adds to the mystery of neonatal rotavirus infection, because the year-round occurrence of rotavirus infection in the nurseries by viruses of a single distinctive electropherotype differed from the seasonal pattern involving multiple electropherotypes in the general population.

Similarly, in France, an epidemiologic survey over a 16-month period in a maternity unit revealed that all 184 rotavirus fecal samples obtained from 3- and 6-day-old newborns exhibited the same electropherotype. This pattern was in sharp contrast to the variable electropherotypes found in postneonatal infections (152). In a similar study in Venezuela, 62 (57%) of 108 children shed rotavirus within the first few days of life; furthermore, a similar gel migration pattern was observed for each of the 52 samples examined. Six of the 62 children had diarrhea, but only one required oral rehydration therapy (390).

In addition to providing evidence for genetic diversity of human rotaviruses as well as heterogeneity of circulating rotaviruses, analysis of electropherotypes has also provided a method for tracing the spread of rotavirus through a population group (123). However, the electropherotype cannot be used to predict virulence (11,12,22,157).

Early RNA–RNA hybridization studies employing labeled ssRNA viral transcripts as probes for genomic RNA identified two major families of human rotaviruses (135,138). The 11 genes of most human rotaviruses exhibit significant homology to the corresponding genes of either Wa (VP7 serotype 1) virus or DS-1 (VP7 serotype 2) virus. On several occasions, human rotaviruses were identified that had a mixed genotype, with some genes being DS-1-like while others were Wa-like (135,138). This was interpreted as evidence for gene reassortment during co-infection *in vivo*. Hybridization

analysis also indicated that the corresponding genes of most animal viruses and human viruses lacked substantial homology. However, human rotavirus strains have been detected that possess certain gene segments with a high degree of homology with various animal rotavirus genes, indicating the likelihood of genetic reassortment between human and animal rotaviruses, but there is no evidence that this is of clinical or epidemiologic importance (355). In this regard, however, a third family of human rotavirus was described when a human rotavirus strain (AU-228 or AU-1) failed to hybridize to either Wa or a DS-1-like virus (KUN) (see Fig. 6) but did have a high degree of homology with a feline rotavirus (355). It was proposed that the term *genogroup* be adopted in lieu of *family* to conform to taxonomic hierarchy (355).

IMMUNITY

The mechanisms responsible for immunity to rotavirus infections and illness are not completely understood, especially in humans, in whom studies of the importance of rotavirus serum antibodies have yielded conflicting results. Animal models, however, have been particularly instructive in elucidating the role of antibodies and in dissecting the relative importance of systemic and local immunity (369,425,502). Initially, it was observed that newborn calves frequently developed rotavirus diarrhea despite a moderately high level of circulating rotavirus antibodies derived from colostrum (520). This observation was confirmed in a later experimental study in calves (51,520).

Subsequently, the relative roles of local and systemic rotavirus antibodies were examined in newborn gnotobiotic lambs (450). Two lambs were fed colostrum that contained rotavirus antibodies on day 1; two other lambs were fed the same preparation of colostrum containing rotavirus antibodies on days 1 through 4; and an additional 2 lambs were fed serum containing rotavirus antibodies on days 2 through 4. Following challenge with lamb rotavirus at 2 days of age, the 2 lambs that were fed colostrum only on day 1 developed diarrhea despite the acquisition of serum antibodies to rotavirus from the colostrum, whereas, the other 4 lambs did not become ill. These observations suggested that antibodies in the lumen of the small intestine were the primary determinant of resistance to rotavirus illness, whereas circulating serum antibodies failed to protect. Support for this interpretation was provided during a study of experimental heterologous rotavirus disease in newborn mice (373). It is also of interest that systemic rotavirus antibodies are present in the lumen of the gastrointestinal tract of neonatal calves if the level of circulating antibodies is sufficiently high. Such serum-derived mucosal antibodies can provide protection against experimentally induced infection and diarrhea (32).

In later studies of immunity in experimental animals, additional evidence for a role of rotavirus antibodies was obtained, but the antigenic determinants of resistance have not been clarified completely. Although serotype-specific immunity has been demonstrated convincingly in several experimental animal models, this could not be confirmed in other studies (369,425). For example, two avirulent bovine strains were evaluated in gnotobiotic calves for their ability to protect against disease caused by a virulent strain (50). Protection was conferred by prior infection with either avirulent strain, although one of these strains did not exhibit a significant antigenic relationship to the virulent challenge virus in cross-neutralization tests.

Information regarding correlates of rotavirus immunity was obtained during a volunteer study in which human rotavirus VP7 serotype 1 (D strain) was administered to 18 individuals by the oral route (263,264). Five of the 18 volunteers shed rotavirus, and four of those five developed diarrheal illness. A critical preexisting level of serum neutralizing antibodies to the homotypic virus or to a heterotypic VP7 serotype 2 human rotavirus correlated with resistance to diarrheal illness. The relationship of neutralizing activity in intestinal fluid to resistance was less clear. Volunteers with a high level (>1:100) of neutralizing activity in intestinal fluid to the homotypic virus tended to develop fewer diarrheal illnesses than those with lower levels (<1:100), but the difference was not statistically significant. The five volunteers who shed rotavirus developed an increase in intestinal fluid-neutralizing activity for the homotypic virus that ranged from 1.9- to 13.9-fold or greater. Each of the ill volunteers also developed a serum neutralizing antibody response to the challenge strain and also to heterotypic human rotavirus DS-1 (serotype 2), as well as to bovine rotavirus NCDV (serotype 6). More recently, the prechallenge sera from this study were reexamined by a competitive binding immunoassay (epitope-blocking assay) for antibody levels against several well-defined VP7 and VP4 neutralization epitopes (173). Volunteers who possessed prechallenge serum antibodies that blocked binding of a serotype 1 VP7-specific MAb (that mapped to residue 97) at a titer of more than 1:20 were resistant to infection and illness. A similar protective effect was observed for serum antibodies that blocked binding of a corresponding serotype 3 VP7-specific MAb that mapped to residue 94 on the serotype 3 VP7. This study not only confirmed the association of serum antibodies with resistance but also identified a specific protective epitope on VP7. Confirmation of the importance of antibodies was provided during a later series of challenge and rechallenge studies in which serum rotavirus IgG or jejunal neutralizing antibodies were observed to correlate with protection against infection and/or illness, whereas in a third series of studies, serum and jejunal rotavirus antibodies did not appear to correlate with resistance (504,505 and 506,509).

In related studies, salivary IgA antibodies as measured by ELISA were proposed as a surrogate for the level of intestinal rotavirus antibodies (512). Rotavirus serum IgA levels were also shown to be correlated with resistance to severe rotavirus illness (204). However, during a study of 1- to 24-month-old infants and young children residing in an orphanage, a firm correlation was observed between homotypic serum neutralizing antibodies and resistance to disease (70). A serum neutralizing antibody titer of 1:128 or greater to human VP7 serotype 3 was associated with resistance to gastroenteritis due to that serotype, whereas serum antibody levels of 1:64 or less were not associated with significant homotypic protection. The protective role of serum neutralizing antibodies in calves was also recently described (278). Nonetheless, serum antibodies may correlate only with, and hence reflect, local intestinal antibodies that are produced locally and/or enter the lumen of the intestinal tract by transudation (475).

The association between fecal (IgA) and serum (IgG) anti–rotavirus antibody titers and protection against infection and illness was also investigated in 100 children under 18 months of age attending day care centers in the United States for one or two rotavirus seasons (317,366). During the two seasons, seven outbreaks of G1 serotype and one of G3 serotype were detected. These studies concluded that (a) a rotavirus-specific fecal IgA titer of at least 1:80 or at least 1:20 correlated with protection against infection or illness, respectively; (b) preexisting serum anti–rotavirus IgA titer of greater than 1:200 or IgG titer of greater than 1:800 was associated with protection against infection; and (c) a high level of preexisting G type-specific blocking antibody was associated with protection against infection. Similarly, in Australia, a

direct correlation between high levels of anti–rotavirus intestinal IgA antibody and a significant degree of protection of children against natural rotavirus infection and illness was observed (86). Similar observations were made in animals; in a heterologous gnotobiotic piglet model, a direct association between the degree of protection and the level of intestinal IgA antibody-secreting cell response as well as serum IgA, intestinal IgA, and intestinal IgG titers was observed (473,540). In addition, in mice, a significant correlation was observed between anti–rotavirus intestinal and/or serum IgA and protection against homologous or heterologous rotavirus infection (126,324).

It should be noted, however, that in a recent study in a mouse model involving challenge with virulent murine rotavirus and IgA normal and IgA knockout mice, the correlation of protection with serum and intestinal immunoglobulin isotypes was investigated (365). This study showed that in the absence of IgA, other compensatory antibody isotypes, IgG in particular, were able to mediate protection against homologous rotavirus challenge (365).

The protective effect of prior rotavirus infection against severe rotavirus diarrhea was demonstrated in an Australian study (36). In a study of 81 neonates, 44 were rotavirus positive and 37 were rotavirus negative during the first 14 days of life; all were kept under clinical and serologic surveillance for 3 years. The frequencies of subsequent postnatal rotavirus infection were similar for the two groups. However, when postnatal rotavirus infection occurred, the children in the neonatal rotavirus-positive group developed significantly fewer rotavirus diarrheal illnesses when compared to the neonatal rotavirus-negative group (20% versus 46%). However, the protective efficacy of neonatal rotavirus infection was 100% against severe rotavirus diarrhea. Thus, neonatal rotavirus infection did not protect against reinfection but induced partial resistance against any rotavirus diarrheal illness and complete protection against severe rotavirus diarrhea during reinfection. The rotavirus strains responsible for neonatal infection in this study were of particular interest because these viruses exhibited the same electropherotype. One of the 20 neonatal strains was identified as serotype 3. The unusual electropherotype of the neonatal strains was not encountered among the strains that induced illness in the study group during the postneonatal period. Thus, infection at birth with a rotavirus strain that persisted in a newborn nursery without detectable modification, conferred partial protection against disease during reinfection with other rotavirus strains that most likely included a variety of serotypes. This finding, as described later, has been applied to the development of a candidate vaccine. Recently, neonatal infection with another unique rotavirus strain 116E, which shares VP7 specificity with the human WI61 (G9) strain and VP4 genotype with the bovine rotavirus B223 strain P [11], induced significant partial protection (46%) against subsequent rotavirus diarrhea during the first year of life (33). Also, rotavirus diarrhea in the neonatally infected group tended to be less severe.

Although there is a paucity of information from human studies, it appears that predominantly homotypic immunity is induced following the first naturally occurring or vaccine-induced rotavirus infection (502). This immunity is mediated by antibodies to VP7 and VP4 (221,244,475). Although in challenge studies the neutralizing antibody response to primary human rotavirus infection in piglets is primarily homotypic, a lower-level heterotypic response commonly occurs involving VP4 serotypes 1, 3, and 4 (223). Subsequently, in both infants and experimental animals, the predominantly serotype-specific response is expanded to include other serotypes following subsequent natural or vaccine-induced reinfection with the same or another serotype (55,56 and 57,175,451,454,467,513). For example, following vaccination with live RRV (VP7 serotype 3), adults develop a significantly greater number of heterotypic responses than do infants less than 6 months of age (59% versus 1.2%), as determined by an epitope-specific serum-blocking assay (175). It should be noted that one or more neutralization epitopes on VP4 or VP7 are shared among viruses of serotype 1, 3, or 4 (see Fig. 10 and Fig. 11). Thus it is not surprising that reinfection with a virus of the same serotype amplifies the cross-reactive neutralizing antibody response. Serotype-specific immunity has been demonstrated under experimental conditions in lambs and rabbits (82,454). Furthermore, immunization of cows with a single rotavirus serotype induced neutralizing antibodies to that strain and to heterotypic strains against which these animals had preexisting neutralizing antibodies but not to strains the animals had not encountered previously (454). In other studies, immunization of cows with a single rotavirus serotype induced a marked antibody response to numerous serotypes (56).

As noted earlier, the VP4 and VP7 proteins independently induce neutralizing antibodies, and as a consequence each outer capsid protein plays a role in resistance to disease (221,368,509). In a recent study employing an epitope-blocking assay, it was observed that a majority of infants and young children fed the live RRV vaccine developed antibodies to the major serotype-specific neutralization epitope on RRV VP7, and almost half of the vaccinees also responded to a major neutralization epitope on VP4 (442). This indicates that infection with an attenuated vaccine strain that is restricted in its capacity to replicate in the intestine can induce antibodies to neutralization epitopes on each of these protective antigens. In another study comparing serum antibody responses to VP4 or VP7 following oral administration of bovine rotavirus WC3 vaccine to infants not previously infected with rotavirus, VP7 appeared to be more efficient than VP4 for the induction of neutralizing antibodies by vaccination (507). However, the reverse was found in adults who possessed rotavirus antibodies and who were challenged with a wild-type human rotavirus (509). It is currently unclear which surface protein and which region of that surface protein is most efficient for the induction of protective immunity.

Although serotype-specific antibodies have been demonstrated in breast milk, the effect of breast-feeding on the occurrence of infantile gastroenteritis requires additional study (78,163,361). In any event, if breast-feeding does transfer immunity to newborns and young infants, its lasting protective effect appears to be modest.

External factors are being investigated for their influence on the immune response. For example, vitamin A deficiency impaired the serum antibody and the cell-mediated immunity responses in infant mice that were given the murine rotavirus strain EDIM orally (4).

The role of cell-mediated immunity in the immune response to rotavirus infection is also under investigation in humans and in animal models (367,415,475,502). Mice are susceptible to rotavirus-induced illness only during their first 15 days of life, a period too short to evaluate the active immune mechanisms involved in rotavirus-induced diarrhea. However, because mice of all ages are susceptible to infection with selected strains of murine rotavirus, an adult mouse model has been extensively used to study the factors and mechanisms involved in protective immunity (127,142,502). Such studies have shown that (a) rotavirus-specific antibodies are of primary importance in protection from rotavirus reinfection; (b) in general, homologous rotavirus strains are far more potent than heterologous rotavirus strains in inducing protective local humoral immune responses; (c) MHC class I–restricted CD8+ abT cells play a major role in resolution of primary rotavirus

infection, but rotavirus-specific antibodies, CD4+ T cells, and uncharacterized mouse strain–specific innate mechanisms are also involved in this role; (d) after primary infection, CD8+ T cells mediate almost complete protection (up to 2 weeks) or partial protection (3 months or less) from reinfection, however, this protection diminishes 8 months after primary infection; (e) perforin, Fas, or interferon-g are not essential in an anti-rotavirus activity mediated by CD8+ T cells; and (f) CD8+ T cells expressing a_4b_7 marker (an intestinal mucosal homing receptor integrin) are more efficient in mediating rotavirus clearance than the a_4b_7 negative cells (110,126,141,143,146,147 and 148,323,324,325 and 326,348,416). A central role played by CD8+ T cells in the control of primary rotavirus infection was also demonstrated in a homologous gnotobiotic calf model (378). In the same study, the importance of CD4+ T cells in the development of mucosal as well as systemic antibody responses was also shown. The relevance of these findings to understanding immune responses to rotavirus in humans remains to be established.

CLINICAL FEATURES

Rotavirus infection produces a spectrum of responses that vary from subclinical infection to mild diarrhea to a severe and occasionally fatal dehydrating illness. In one study, a comparison was made between (a) the clinical manifestations of 78 patients hospitalized with rotavirus diarrhea and (b) 72 patients hospitalized with a diarrheal illness that could not be associated with rotavirus (Table 2) (413). The majority of both rotavirus and nonrotavirus patients had a temperature of 37.9°C or above. However, the rotavirus group vomited and became dehydrated significantly more often than the rotavirus-negative group. The mean duration of vomiting as determined from history and hospital records was longer in the rotavirus group than in the rotavirus-negative group (2.6 days versus 0.9 days). Rotavirus diarrhea started later than vomiting but lasted longer (mean duration, 5 days versus 2.6 days). After infants and children were hospitalized, diarrhea continued for a mean of 2.6 days (range, 1 to 9 days) in the rotavirus group and 3.8 days (range, 1 to 16 days) in the rotavirus-negative group. The duration of hospitalization ranged from 2 to 14 days, with a mean of 4 days for the rotavirus group. It is of interest that in Japan, rotavirus infection has been associated in some instances with severe diarrhea characterized by a milky white stool (Hakuri) (346,354).

Clinical finding	Percent having each clinical finding	
	Rotavirus infection detected (72 patients)	Rotavirus infection not detected (78 patients)
Vomiting	90*	58*
Fever		
37.8–39°C	46	29
>39°C	31	33
Total	77	61
Dehydration	83*	40*
Hypertonic	5	16
Isotonic	95	77
Hypotonic	0	6
Irritability	47	40
Lethargy	36	27
Pharyngeal erythema	49	32
Tonsillar exudate	3	3
Rhinitis	26	22
Red tympanic membrane with loss of landmarks	19	9
Rhonchi or wheezing	8	8
Palpable cervical lymph nodes	18	9

TABLE 2. *Clinical characteristics of 150 children hospitalized with acute gastroenteritis*

Laboratory findings reflect the high frequency of vomiting and dehydration associated with rotaviral illness (413). A BUN value of greater than 18 mg/dL was observed in 58% of the rotavirus-positive group, and a urine specific gravity of 1.025 or greater was noted in 71%. These rates were significantly higher than in the nonrotavirus group. The frequency of acidosis and electrolyte imbalance did not differ in the two groups.

Over a 5-year period in a Toronto hospital, rotavirus gastroenteritis was responsible for the death of 21 infants and young children between 4 and 30 months of age (62). On arrival at the hospital, ten of these children were dead, and 10 were moribund and could not be resuscitated. One of the children was already hospitalized when he acquired the disease; this patient had been hospitalized with congestive cardiomyopathy, which also contributed to his death. With the exception of this patient and one other child, each of the children who died had been healthy previously. Death occurred within 1 to 3 days of onset of symptoms. The major factor causing death was believed to be dehydration and electrolyte imbalance in 16 individuals and aspiration of vomitus in three. In the remaining two patients, seizures were a contributing factor. Each of the 16 patients tested had a sodium level (serum or vitreous humor) in excess of 150 mEq/L, and sodium was in excess of 160 mEq/L in 11 of this group. The rapidly fatal course of untreated severe rotavirus gastroenteritis was underscored by the fact that the parents of 16 of the 20 children who were brought to the hospital had had some contact with a physician during the course of the illness.

Rotaviruses can produce a chronic symptomatic infection or serious illness in immunodeficient children (236,376,438,518). For example, chronic diarrhea associated with prolonged shedding of rotavirus was described in children with primary immunodeficiency, T-cell immunodeficiency, or SCID. An unusual aspect of illness in certain individuals in the former group was the occurrence of rotavirus antigenemia. In addition, a child with SCID developed a transient hepatitis during rotavirus infection (376). Also, in four 4- to 8-month-old infants with laboratory-proven rotavirus infection who had severe immunodeficiency disease, rotavirus antigen was detected in sections of the liver and kidney examined after death (161). During chronic infection in immunocompromised children, rotavirus can undergo marked changes in its genome, as indicated by abnormal electrophoretic migration patterns of rotavirus RNAs (see Fig. 3., A64 strain) (106,228).

Rotaviruses pose a special threat to individuals who are immunosuppressed for bone marrow transplantation. In one study of gastroenteritis in a bone marrow transplant unit, 8 of 78 patients (average age, 20 to 21 years) shed rotavirus as the sole pathogen, and five of these individuals died (536). Also, rotavirus infections acquired nosocomially have been associated with severe diarrhea in adult renal transplant recipients (387). Rotaviruses do not appear to play an important

role in diarrhea occurring in adults infected with human immunodeficiency virus (HIV) (184).

A temporal association of rotavirus infection with a variety of other disease conditions, both isolated illnesses and single outbreaks, has been described (191,196,248,255,266,448,514). Because the occurrence of these conditions is extremely rare in comparison to the very high incidence of rotavirus infection, it appears that with the exception of severe disease manifestations in immunocompromised patients, necrotizing enterocolitis and hemorrhagic gastroenteritis in neonates, and pneumatosis intestinalis in infancy, the association of rotavirus infection with most of the reported conditions is most likely temporal and not etiologic (61,104,417,418,533).

However, because of the recent reports of intussusception after oral administration of a quadrivalent rhesus rotavirus–based vaccine in infants (see later), the significance of the temporal association of wild-type rotavirus infection with intussusception deserves further attention (198). Rotavirus was detected in the stools of 11 (37%) of 30 infants and young children in Japan with intussusception; 5 of 7 of the rotavirus-positive group developed a serologic response, suggesting that wild-type rotavirus might have been the cause of intussusception (283,284,357). Furthermore, expansion of this study indicated that 20 (33%) of 61 cases of intussusception (including the 30 patients just mentioned) had evidence of rotavirus infection (265). Three later studies in Australia, France, and Germany failed to find a significant association of intussusception with rotavirus infection (350,362,457).

Rotavirus genomic RNA has been detected by polymerase chain reaction (PCR) in serum and/or spinal fluid of certain patients with rotavirus gastroenteritis and convulsions (364). Further studies are needed to determine the significance of these findings.

DIAGNOSIS

The clinical manifestations of rotavirus illnesses are not sufficiently distinctive to permit diagnosis on this basis alone. Therefore, diagnosis requires detection of virus or viral antigen and/or demonstration of a serologic response. The epidemiologic pattern of rotavirus disease at any one time may suggest this diagnosis, but laboratory confirmation is required.

Many assays have been developed for the detection of rotavirus in stools (535). Specimens from the 1st to the 4th day of illness are optimal for virus detection; however, shedding may continue for up to 3 weeks, depending on the duration of symptoms. Viral shedding usually coincides with the duration of diarrhea, but diarrhea can continue for an additional 2 to 3 days (410). Initially, direct visualization of stool material by EM was employed for rotavirus detection (39,45,130). It had the advantage of high specificity because rotaviruses have a distinctive morphologic appearance. The EM continues to be important in the diagnosis of rotaviral diseases and is frequently used to resolve discrepancies in results from other techniques. When only a few specimens are to be examined for rotavirus, EM is the most rapid diagnostic method because fecal specimens can be stained with phosphotungstic acid and examined directly within a few minutes of collection. Direct EM examination of stools permits detection of rotavirus in 80% to 90% of the virus-positive specimens (45). IEM is not necessary for the detection of rotaviruses because the particle has such a distinct morphologic appearance that it can be readily identified without the use of an immune serum. However, modified methods have been developed that may prove useful under selected conditions (359,462,525).

Various automated methods are available for the detection of rotaviruses in stool specimens (535). The method of choice in many laboratories is the confirmatory ELISA, because it is highly sensitive, does not require specialized equipment, and has a built-in control for nonspecific reactions (535). For example, a preimmunization or postimmunization animal serum is employed as the solid-phase precoat; the preimmunization serum acts as the control because a fecal specimen must exhibit a significantly greater reactivity in the well that is coated with the postimmunization animal serum in order to be considered positive. Some laboratories have routinely employed other methods for virus detection, such as counterimmunoelectroosmophoresis, gel electrophoresis of rotavirus RNA, reverse passive hemagglutination assay (RPHA), latex agglutination, or an ELISA in which polyclonal and/or MAbs are used (535). Commercial kits are available for ELISA, latex agglutination, RPHA, and immunoblot enzyme assay, but assays that do not include confirmatory reagents may yield false-positive results. An enzyme immunoassay has also been developed for detection of group B or group C rotavirus and for measurement of antibodies directed against these viruses (150,308,534).

A dot hybridization assay for detection of rotaviruses has been developed based on *in situ* hybridization of labeled rotavirus ssRNA transcripts to heat-denatured rotavirus RNA immobilized on a nitrocellulose membrane (128,132). The method is highly specific, yielding results that are concordant with those obtained with other tests such as EM, RNA analysis, and ELISA (118,132). In a comparative study of ELISA and dot hybridization for the detection of rotavirus in various dilutions of fecal specimens, the dot hybridization method was 10- to 100-fold more sensitive than the confirmatory ELISA (132). The limit of detection for purified viral RNA by the dot hybridization procedure was 8 pg in a homologous reaction. A variety of other research laboratory techniques are now used for the detection of group A rotaviruses (535). The most promising is PCR, which is 100,000 times more sensitive than the standard electropherotype method and 5,000 times more sensitive than hybridization (517,532,535). For example, using a PCR-based assay, virus shedding was detected from 4 to 57 days after diarrhea onset, and 30% of the children shed virus detectable by the assay for 25 to 57 days (409). PCR has also been applied to the detection of group B and C rotaviruses (119,169). Flow cytometry is described as another sensitive method for rotavirus detection (15).

It is also possible to recover human rotaviruses from stool specimens directly in cell culture with reasonable efficiency. This method appears to be approximately 75% as efficient as antigen detection test procedures (195). The efficiency of recovery of virus from rectal swabs using cell culture is considerably less. Growth of rotavirus in tissue culture makes possible the determination of virus serotype by neutralization assay; however, serotype is most often determined by ELISA (for which commercial kits are available) and less often by solid-phase IEM using absorbed antisera or serotype-specific (VP7) MAbs for each of the four major serotypes (535). It may be necessary to use several MAbs directed at different epitopes of the same serotype because of epitope polymorphism within a serotype (88,511). Serotype-specific MAbs are employed in a sandwich procedure together with one or more polyclonal antisera. Rotavirus

serotype can also be predicted with considerable accuracy by nucleotide sequence analysis of the VP7 gene because there is a high degree of conservation of sequence in variable regions among rotaviruses belonging to the same serotype (174). VP7 serotype can also be predicted by a variety of other methods, including PCR, hybridization with single gene substitution (VP7) reassortants used as probes, and hybridization with oligonucleotide probes prepared from the VP7 sequence of human rotavirus serotype 1, 2, 3, or 4 or additional strains (170,215,233). The use of PCR has enabled the genotyping of rotavirus-positive specimens that could not be typed by ELISA. Also, VP4 genotype can be identified by PCR or PCR-derived probes, and VP4 serotype can be determined by neutralization or ELISA using monoclonal or other serotype specific antibodies (84,154,215,216).

There are a variety of techniques for measuring a serologic response to rotavirus infection, such as IEM, complement fixation (CF), IF, immune adherence hemagglutination assay, ELISA, neutralization, hemagglutination inhibition, inhibition of reverse passive hemagglutination, ELISPOT assay, and immunocytochemical staining (234,246,443). The CF method is about as efficient as the other methods for detecting an antibody response in patients between 6 and 24 months of age, but it is not as efficient in adults or in infants under 6 months of age. In these age groups, IF, ELISA IgG, ELISA IgM, and ELISA IgA are more efficient. Because IgA does not cross the placenta, a rotavirus IgA ELISA has been particularly effective in demonstrating serologic responses in young infants who possess passively acquired maternal IgG antibodies (304,305). This assay can also be used for measuring antibodies in saliva, duodenal fluids, and stools (305). Fecal rotavirus IgA antibody levels exhibit a direct relationship with duodenal IgA antibody levels (183). In addition, a rise in fecal rotavirus IgA antibodies measured by ELISA reflects an intestinal neutralizing antibody response (91). It has been suggested that copro-IgA conversion in feces obtained weekly would be a more sensitive indicator of rotavirus reinfection than seroconversion or detection of virus (37,87). Based on observations from a clinical study in infants and children, it was suggested that rotavirus IgA in serum reflects the immunologic status of the intestinal lumen with respect to this virus (102,203,204). Early diagnosis can also be made by ELISA, which can detect a specific serum IgM response as early as 5 or 6 days after onset of illness.

Neutralizing antibodies are detected by plaque reduction, neutralization of IF foci, neutralization of virus as determined by quantitation of viral antigen by ELISA, or inhibition of cytopathic effect in roller-tube cultures (246). Neutralization assays yield the most meaningful information about the identity of the infecting rotavirus and the development of a serotype-specific antibody response. The plaque reduction neutralization assay is more sensitive than tube neutralization for detection of antibody, although the latter is slightly more efficient for detecting a seroresponse (248). A competition-solid-phase immunoassay that measures epitope-specific immune responses to individual rotavirus serotypes has proven to be especially useful in evaluating immune responses at the level of individual epitopes. This technique employs the test serum as the blocking reagent and uses individual MAbs as the detecting reagent (442).

Detection of rotavirus and/or the demonstration of a serologic response to rotavirus in an individual patient does not necessarily establish an etiologic association of rotavirus with that patient's illness. This is important in all age groups but especially in newborns and adults, who commonly undergo inapparent infection.

TREATMENT

The primary aim of treatment of rotaviral gastroenteritis is the replacement of fluids and electrolytes lost by vomiting and diarrhea. Intravenous fluid administration has been used successfully for many years in treating dehydration from diarrhea. Because facilities for parenteral administration of fluids and electrolytes are not readily available in many parts of the world, intensive efforts have been made to evaluate the efficacy of oral fluid replacement therapy (3,268,421,423,433,439). Various formulations of oral rehydration salts (ORS) solutions have been shown to be effective in the treatment of dehydration caused by rotavirus diarrhea, with some minor variations in their efficacy. For example, in a double-blind study, oral rehydration therapy with electrolyte solutions containing either glucose or sucrose has been shown to be highly effective for rotavirus gastroenteritis (422). In another study of oral rehydration of infantile diarrhea of mixed etiology, all of the patients who were fed glucose electrolyte solution and 92% of those fed sucrose electrolyte solution were treated successfully (360). The sucrose group experienced a slower correction of electrolyte abnormalities, and a larger proportion of patients required more than 24 hours of therapy. It was concluded that sucrose could be employed as a substitute for glucose, but that glucose electrolyte solutions were preferable.

The standard World Health Organization (WHO) oral glucose electrolyte formula is composed of the following: sodium, 90 mmol/L; chloride, 80 mmol/L; potassium, 20 mmol/L; citrate, 10 mmol/L; and glucose, 111 mmol/L, resulting in an overall osmolarity of 310 mOsm/L (5,6,423). Bicarbonate, 30 mmol/L, may be substituted for citrate, 10 mmol/L (6). Recently, an ORS solution containing a reduced sodium concentration has been found to be more effective than the standard WHO solution. Thus, a solution containing sodium, 75 mmol/L; chloride, 65 mmol/L; potassium, 20 mmol/L; citrate, 10 mmol/L; and glucose, 75 mmol/L, resulting in an overall osmolarity of 245 mOsm/L (reduced osmolarity ORS solution), was compared to the standard WHO ORS solution in infants with noncholera diarrhea in a mulicenter trial (71). The proportion of infants who required unscheduled intravenous therapy was significantly lower in the group receiving the reduced osmolarity ORS (required in 10%) than among those receiving the WHO ORS solution (required in 15%). After correction of the initial calculated fluid loss by oral rehydration solution, either water or fluids without added electrolytes (such as breast milk or some other form of low-solute feeding) should be administered orally in addition to the oral rehydration solution. When this regimen is used, both continued diarrheal fluid and electrolyte losses will be replaced and normal daily fluid requirements will be maintained (432,433).

Rice-based solutions have been compared with glucose-based oral rehydration solutions in infants and young children hospitalized with mild to moderately dehydrating diarrheal illnesses associated with various pathogens, including rotavirus (63,397). Each was found to be effective, but the rice-based solution was more effective in decreasing total stool output and increasing absorption and retention of fluid and electrolytes. Later, glucose-based and rice-based oral rehydration solutions were each found to be effective in treating mild to moderate dehydration caused by various pathogens, including rotavirus (342). Although a rice-based solution was associated with less stool output during the first 6-hour period, this effect did not persist after the initial 12 hours of therapy, and it was concluded that this difference was

of minor clinical importance (63,139,342,397).

If oral rehydration does not correct the fluid and electrolyte loss, or if the patient is severely dehydrated or in shock, intravenous fluids must be given immediately. Oral rehydration therapy should not be given to patients with depressed consciousness because of the possibility of fluid aspiration.

With regard to the use of various medications for symptomatic treatment of the acute diarrhea in children 1 month to 5 years of age, the American Academy of Pediatrics (AAP) does not recommend the use of loperamide, anticholinergic agents, bismuth subsalicylate, adsorbents, or lactobacillus-containing compounds and, in addition, the use of opiates as well as opiate and atropine combination drugs for treatment is contraindicated (6).

Human milk, containing rotavirus antibodies, has been used successfully for treatment of immunodeficient children with chronic rotavirus infection and illness (99,303,438). In contrast, colostrum or milk concentrate from cows immunized with human rotavirus was not effective for the treatment of children with acute rotavirus gastroenteritis, although a decrease in the duration of virus shedding was observed (115,202). However, daily oral administration of rotavirus antibody–containing bovine colostrum appeared to exert a protective effect during an orphanage outbreak of rotavirus diarrhea (115). The effect of a single oral dose (300 mg/kg body weight) of gammaglobulin in infants hospitalized for gastroenteritis (70% rotavirus associated) was evaluated in a double-blind placebo-controlled trial. The treatment group had a significantly shorter duration of diarrhea, viral excretion, and hospital stay (185). In addition, in another study, the administration of human serum immunoglobulins by the alimentary route to two infants with prolonged rotavirus diarrhea of 4 or 7 months duration was effective in clearing the virus and the associated diarrhea (186). More recently, bovine colostrum prepared by immunization of pregnant cows with human rotavirus strains of G1, 2, 3, or 4 specificity was given orally to rotavirus diarrhea patients 4 to 24 months of age and was found to significantly reduce the duration and frequency of diarrhea as well as the consumption of oral rehydration solution (193,436)

The efficacies of several broad-spectrum antiviral agents have been examined as inhibitors of rotavirus replication *in vitro*. In this survey, various adenosine analogs were found to have antirotavirus activity, and it was suggested that this activity resulted from inhibition of S-adenosylhomocysteine hydrolase, an enzyme involved in regulating methylation required for maturation of viral mRNA (277).

Bismuth subsalicylate (BSS) (20 mg/kg) given orally five times a day for 5 days as an adjunct to rehydration therapy shortened the course of disease in children 4 to 28 months of age hospitalized with acute rotavirus diarrhea in a prospective double-blind placebo-controlled treatment trial (455,456). Because of the association between the use of salicylates and Reye's syndrome, the authors reviewed the possibility of such an association with BSS or other nonacetylsalicylic acid salicylates and could find none. In addition, blood salicylate and bismuth levels attained in the treatment group were well below those considered toxic. However, as noted before in considering the use of various medications for symptomatic treatment of acute diarrhea in children 1 month to 5 years of age, the AAP does not recommend the use of bismuth subsalicylate (6).

PREVENTION AND CONTROL

General Principles

Observations made during epidemiologic and hospital-based studies worldwide clearly indicate the need for prevention of rotavirus disease (25,244). The aim of a rotavirus vaccine should be to prevent severe rotavirus gastroenteritis during the first 2 years of life, the period when rotavirus disease is most serious and takes its greatest toll (34,244). This is a realistic goal because natural infection does not provide complete protection against a subsequent reinfection or mild disease (36,316,486). Considerable evidence from studies in animals indicates that local intestinal immunity plays the most important role in resistance to rotavirus disease. These observations suggest that the effectiveness of a rotavirus vaccine will depend, in large part, on its ability to stimulate intestinal IgA antibodies and other forms of local immunity. The most effective means of stimulating local immunity is thought to be infection involving the local site. For this reason, most current efforts in experimental rotavirus immunoprophylaxis are directed toward the development of live attenuated vaccines. Although progress has been made during the past few years in developing various live virus vaccine candidates, a number of important issues have been raised concerning the most effective strategy to be pursued.

Longitudinal studies have shed some light on the resistance to disease induced by prior, naturally acquired rotavirus infection. Reinfection within the first few years of life appears to be a common event in certain settings, but in most circumstances an infant who has had a severe bout of rotavirus diarrhea usually experiences a milder illness during reinfection (30,36,486). However, in most instances, in these studies it was not ascertained whether reinfection involved the same or a different serotype. In one study it was possible to demonstrate the effectiveness of homotypic antibodies. Residents of an orphanage who had a preoutbreak serum homotypic neutralizing antibody titer of greater than 1:128 were resistant to rotavirus disease (70). In another study, neonates who were infected in a newborn nursery during the first 14 days of life with what appeared to be a single strain of rotavirus experienced almost 50% fewer rotavirus diarrheal episodes during the next 3 years than did a cohort of infants who had not been infected with rotavirus when they resided in the nursery (38% versus 85%) (36). In addition, none of the 24 children infected neonatally developed severe diarrheal illness on reinfection, whereas 8 of the 20 who had not been infected neonatally developed severe diarrheal illness associated with rotavirus infection. During the 3-year surveillance period, participants in the study were infected with rotavirus strains that exhibited at least two different electropherotypes, neither of which corresponded to that of the strain responsible for neonatal infection.

Finally, in a cohort study in Mexico in which 200 infants were followed from birth to 24 months of age, 96%, 69%, 42%, 22%, and 13% of them experienced 1, 2, 3, 4, or 5 rotavirus infections, respectively. Although seemingly discouraging from a vaccinology perspective, the good news was that no child developed a moderate-to-severe diarrheal illness after the second infection. This suggests that a controlled vaccine-induced infection might have the same protective effect

(486). With regard to serotype, second infections tended to be caused by a different G serotype (p = 0.054).

If homotypic immunity proves to be relatively effective against severe diarrheal illness, the next issue that must be resolved involves the protective efficacy of attenuated rotaviruses. Rotavirus produces a superficial infection that primarily involves the epithelium of the small intestine. Experience with mutants of other viruses that cause a mucosal infection, such as influenza A virus and respiratory syncytial virus, indicates that in many instances attenuation is a reflection of decreased viral replication in the target organ, which is also the site at which infection is initiated (69). Experience with attenuated mutants of mucosal viruses also indicates that decreased viral replication is associated with a diminished immune response. This means that a delicate balance must be achieved between satisfactory attenuation and satisfactory immunogenicity.

Again, observations made during the longitudinal surveillance of children infected during the neonatal period are instructive (36). These neonatal infections were attenuated, primarily asymptomatic or associated, at most, with mild diarrhea. Nonetheless, neonatal infection induced immunity to severe rotavirus diarrhea for at least 3 years. This suggests that a naturally occurring attenuated rotavirus infection can induce significant resistance.

It is clear from epidemiologic studies worldwide that a highly effective vaccine is needed to produce protection against each of the four most prevalent serotypes that account for more than 95% of rotavirus illnesses (522). This means that effective coverage against disease could be provided most efficiently by a quadrivalent vaccine (VP7 serotypes 1, 2, 3, and 4), unless sufficient heterotypic immunity to protect against severe rotavirus disease could be induced by one or two VP7 serotypes. Epidemiologic studies have not yielded conclusive information in regard to this question.

In gnotobiotic calves and piglets, heterotypic immunity has been demonstrated between an animal rotavirus (bovine, VP7 serotype 6) and a human rotavirus (VP7 serotype 1) (528,529,549). Calves infected *in utero* with bovine rotavirus resisted challenge with human rotavirus at birth. However, in other studies in piglets and calves, only homotypic immunity was demonstrated, although in certain instances the severity of diarrhea was reduced following heterotypic challenge (44,153,351,519,521). Whether effective heterotypic immunity to each of the four major serotypes of human rotavirus could be induced in humans by infection with a single rotavirus was one of the early issues that needed to be addressed, because generally, heterotypic immunity to viruses is more transient than homotypic immunity, and this could limit the usefulness of monotypic rotavirus immunoprophylaxis, as described later in this section (253).

Current Strategies

Current strategies for development of a rotavirus vaccine range from cell culture cultivation of strains obtained from humans or animals to the application of recently developed molecular biologic techniques. The most extensively evaluated approach is based on the method first reported by Edward Jenner in 1798 for vaccination of humans against smallpox (290). Jenner used a live, antigenically related animal virus, cowpox, to immunize humans against variola virus, the etiologic agent of smallpox. The usefulness of this strategy for human rotavirus vaccination was suggested by the early observation that human and animal rotaviruses shared a major common antigen (250,251,520). Thus, infants and young children who developed illness following rotavirus infection developed a serologic response detectable by CF not only to the infecting human rotavirus strain but also to various animal strains (250). The feasibility of this approach was shown during animal studies in which calves administered a bovine rotavirus (serotype 6) *in utero* were protected from illness following challenge at birth with a human rotavirus of VP7 serotype 1 specificity (529).

Initially, a high tissue-culture passaged, cold-adapted, serotype 6 bovine rotavirus [strain NCDV (RIT 4237)] vaccine was developed and was studied extensively for reactogenicity, antigenicity, dose-requirement, and protective efficacy (487,488,491). This nonreactogenic, orally administered vaccine virus induced over 80% resistance to clinically significant diarrhea in infants and young children in two separate efficacy trials in Finland (489,490). In addition, vaccination of neonates appeared to modify the severity of rotavirus diarrhea during the 16-month follow-up period (496). Following two doses—one in the neonatal period and a second dose 7 months later—the vaccine had a protective efficacy of 43% against any rotavirus diarrhea and 89% against severe diarrhea (497). However, it failed to induce protection against rotavirus diarrhea in trials in several developing and developed countries and, as a consequence, further evaluation of the candidate vaccine was not pursued (48,103,107,194,338,434,441).

A related VP7 serotype 6 bovine rotavirus strain, designated WC3, has also demonstrated variable protective efficacy in various studies in the United States and overseas (48,76,77,107,338). For example, in 3- to 12-month-old infants in Philadelphia, its protective efficacy (when serotype 1 strains were predominant) was 76% against any rotavirus diarrhea and 100% against moderate-to-severe rotavirus diarrhea (76,77). In contrast, during later studies in Cincinnati and the Central African Republic, the vaccine exhibited a protective efficacy against moderate-to-severe rotavirus diarrhea of 35% to 41%, and in China, 50% against any rotavirus diarrhea (31,77,156,492). Because of the perceived low level of protection, the vaccine was withdrawn from further study in its monovalent formulation.

Another animal rotavirus strain, RRV strain MMU 18006, which is antigenically similar to human rotavirus VP7 serotype 3 by neutralization, has been studied intensively (48,107,241,259,260,338). The RRV vaccine has been evaluated in both developed and developing countries. Although in some settings it induces a mild, transient, febrile response in about one third of the target population of infant vaccinees under 6 months of age, it appeared to be more antigenic than the NCDV (RIT 4237) bovine rotavirus attenuated strain, as determined by the frequency of serum antibody responses following vaccination (304,493). However, the RRV vaccine has been nonreactogenic in neonates (133). This may be of some importance because vaccination soon after birth may be necessary in developing countries, where immunization is needed most. In these locations, 10% to 40% of neonates do not have contact with a health care provider beyond the newborn period (192). The vaccine is taken orally, usually following ingestion of buffered formula, or buffer alone, to protect the virus from partial or total inactivation by stomach acid (394). In addition, breast-feeding is usually withheld prior to immunization because of the possibility of virus inhibitors in the milk (393,394).

In a field trial in 1- to 10-month-old infants in Venezuela, the vaccine's overall protective efficacy rate was 64% against

any rotavirus diarrhea (137,391). Moreover, in the 1- to 4-month age group, vaccine efficacy was 82% against any rotavirus diarrhea, whereas its efficacy was 90% against the most severe illnesses encountered in the entire study group. Results of efficacy trials were also encouraging in Maryland, Sweden, and Finland, but the vaccine failed to protect young infants in Rochester, NY or Arizona; furthermore, it induced only a low level of protection (29%) in 2- to 5-month-old infants in Maryland (72,168,252,256,257,405,434,495). The basis for protective efficacy in these studies became apparent after the strains recovered during various trials were serotyped. The predominant strains responsible for disease in the Venezuelan study were serotype 3, the same serotype as the vaccine strain; whereas, in the Rochester and Maryland studies, almost all the strains recovered from ill infants were serotype 1. Moreover, in the Arizona study almost all typed strains belonged to serotypes other than serotype 3. These observations suggested that serotype-specific immunity was required for protection against rotavirus diarrhea in young infants not primed by previous rotavirus infection (304). Protection against heterotypic strains in Finland and Sweden was observed in older infants and young children who may have been primed by previous rotavirus infection (168,495). Nonetheless, the effectiveness of a rotavirus vaccine must ultimately be judged by its ability to induce protective antibodies to all of the epidemiologically important rotaviruses in very young infants.

Failure of the RRV vaccine to induce protection in young infants against heterotypic rotavirus strains suggested that the initial strategy for development of a rotavirus vaccine required modification. As a consequence, the Jennerian approach to rotavirus immunoprophylaxis was altered to include the use of a quadrivalent vaccine that incorporated the VP7 specificity of each of the four epidemiologically important VP7 serotypes coupled to the attenuation phenotype of RRV (241,243,254,256,257,259,335,337). This approach took advantage of the segmented genome of rotaviruses and the ability of these viruses to undergo gene reassortment with high efficiency during co-infection (181). Virus reassortants were isolated from tissue cultures co-infected with a cultivatable, wild-type animal virus (RRV or bovine UK rotavirus) and a poorly cultivatable human rotavirus (335,337). Monospecific antiserum directed against the animal rotavirus parent, or a set of MAbs directed against the VP7 of the animal rotavirus parent, was used to select for virus reassortants with human rotavirus VP7 neutralization specificity. With this selective pressure, it was possible to isolate reassortants that derived only the gene segment coding for VP7 from the human rotavirus parent, whereas the remaining 10 genes were derived from the animal rotavirus parent. In this manner, single human rotavirus gene substitution reassortants were isolated that possessed the human rotavirus gene for VP7 of serotypes 1, 2, 3, or 4 on a background of 10 animal rotavirus genes. As expected, these reassortants exhibited the neutralization specificity of the human rotavirus parent (335,337). Because RRV belongs to serotype 3, it was not necessary to prepare an RRV-human rotavirus serotype 3 reassortant. Phase I studies indicated that each of the RRV-human rotavirus reassortants was similar to its RRV parent with respect to attenuation and immunogenicity (259). Subsequently, a quadrivalent rotavirus vaccine formulation, which contained single VP7 gene substitution human-RRV reassortants with serotype 1, 2, or 4 specificity and RRV itself as the serotype 3 representative, was shown to be as safe and as attenuated as RRV alone (388,389). Simultaneous administration of monovalent or quadrivalent RRV vaccine and trivalent oral poliovirus vaccine did not appear to influence the “take” rate of either vaccine (66,230,235,339,407).

Individual reassortants or the quadrivalent vaccine were evaluated for efficacy in over 10,000 infants and young children worldwide (243). The individual reassortants, DxRRV (serotype 1) or DS-1xRRV (serotype 2), each induced 67% protection against VP7 serotype 1 diarrhea in Finland (498). In Rochester, the DxRRV vaccine induced 77% protection and the RRV vaccine 66%, both against predominantly VP7 serotype 1 diarrhea (310). Protection against serotype 1 induced by RRV or the serotype 2 reassortant suggested that heterotypic immunity can be effective in some circumstances. Also, a reanalysis of two efficacy trials, one in Peru and one in Brazil, yielded promise that the quadrivalent vaccine may be effective in developing countries if the end point is the prevention of severe diarrheal illness (289,298,299).

In a large study of the quadrivalent vaccine and a monovalent DxRRV vaccine in the United States, the protective efficacies during the first rotavirus season against predominantly VP7 serotype 1 rotavirus diarrhea were 64% and 69%, respectively (28). During the second season, when only about two thirds of the strains had VP7 serotype 1 specificity, the monovalent vaccine provided only 7% protection, whereas the quadrivalent vaccine achieved a protective efficacy of 48%, but the number of infections were too few to achieve statistical significance. However, the trend was consistent with the importance of serotype-specific immunity. In a large-scale follow-up efficacy study of these same vaccines (but at a 10-fold higher dose of each component), a protective efficacy of 49% and 54% was observed for the quadrivalent and monovalent vaccines, respectively, over a single season when the most common serotype was serotype 1 (71%) (404). However, when efficacy was evaluated according to severity score, the quadrivalent vaccine achieved a protective efficacy against severe diarrhea of 80% (100% against dehydration), while the monovalent vaccine had an efficacy of 69% (85% against dehydration) against this form of diarrheal disease. Moreover, the quadrivalent vaccine tended to protect more effectively against the diarrhea caused by G3 serotypes when compared to the monovalent vaccine (77% versus 45%) (404).

In three additional large-scale efficacy trials with the higher dose of vaccine in Finland, Native Americans in the United States and a poor population in Venezuela, vaccine efficacy ranged from 48% to 68% against any rotavirus diarrhea. However, against severe rotavirus diarrhea, it reached 91% in Finland (97% against dehydration and 100% against hospitalization), 88% in Venezuela (75% against dehydration), and 69% in Native Americans (too few cases of dehydration to evaluate) (237,237a,392,435). In the Native American study also, the quadrivalent vaccine induced a higher level of protection than did the monovalent G1 vaccine against a non–serotype 1 strain that was predominant (53% versus 20%). A transient low-grade fever of greater than 38°C (rectally) was observed in up to 29% of the vaccinees in these large clinical trials within the first 5 days of the first dose of vaccine.

Progression Toward Licensure of RRV-based Vaccine

From the evidence presented in June 1998, the Advisory Committee on Immunization Practices (ACIP) recommended routine immunization with three oral doses of the RRV-based vaccine at 2, 4, and 6 months of age for all full-term infants (66). Shortly thereafter, the U.S. Food and Drug Administration granted a biologics license to Wyeth Laboratories for the manufacture and distribution of the rotavirus vaccine (RotaShield) for the immunization of infants at 2, 4, and 6 months of

age. Later, in 1998, the AAP also recommended the vaccine (7).

Withdrawal of ACIP Recommendation for Rotavirus Vaccine

In July 1999, the Centers for Disease Control (CDC) reported that between September 1, 1998, and July 7, 1999, 15 cases of intussusception had been reported to the Vaccine Adverse Events Reporting System (VAERS) following administration of rotavirus vaccine to almost 1 million infants (65). Although this was consistent with the expected number of cases of intussusception per week (background rate, 51/100,000/yr in the first year of life), there was concern that because VAERS is a passive reporting system, there were likely to be additional cases; also, the observation that 11 of the 15 cases occurred during the first week after the first dose was of further concern. Thus, the CDC and the AAP recommended that administration of rotavirus vaccine be postponed pending availability of more data (8,65).

In a follow-up meeting in October 1999, the CDC reported to the ACIP that 102 confirmed or presumptive cases of intussusception had been reported to VAERS, 46 of them with onset within 7 days of receipt of the first dose of vaccine and, in addition, that case-series and case-control studies supported the observation that the highest risk was during the first week (3 to 7 days) after the first dose of vaccine. They estimated an attributable risk of intussusception following vaccination to be 1 in 2,500 to 1 in 5,000 infants. [These attributable risk estimates were recently revised in April 2000 by the CDC to be 1 case in 12,274 infants who were vaccinated, or 1 case in 20,100 doses, from expanded cohort studies (286).]

With the initial data, the ACIP “concluded that intussusception occurs with significantly increased frequency in the first one-to-two weeks following vaccination with RRV-TV, particularly following the first dose” and withdrew its recommendation that rotavirus vaccine be given at 2, 4, and 6 months of age (67).

It should be noted that in pre-licensure studies of RotaShield (as later licensed), 2 of 8,240 infants developed intussusception, one case on day 51 after the second dose, and one case on day 7 after the third dose (406).

Other Vaccine Approaches That Have Been in Clinical Trials

A bovine rotavirus WC3 strain–based reassortant vaccine designated WI79-9, which contains the gene-encoding VP7 of a human serotype 1 strain and the remaining 10 genes from WC3, was nonreactogenic and had 64% protective efficacy against any rotavirus diarrhea and 87% against severe rotavirus diarrhea following three doses given to infants and young children (474). Furthermore, a four-component WC3-based vaccine containing a single gene from a human rotavirus of G1, 2, or 3 or P1A specificity and the remaining genes from the bovine strain was shown to induce about 70% protection against all disease and against moderate to severe disease (77). A double-gene substitution reassortant, WI79 (4 and 9) with P1A [8] and G1 specificity in a background of nine WC3 genes was found to have a low immunogenicity (77). However, a mixture of each single gene reassortant, WI79-4 and WI79-9, was highly immunogenic.

The UK strain of bovine rotavirus has also been evaluated in clinical trials sequentially in adults, older children, and infants, using the individual strains of human–bovine rotavirus reassortants with VP7 specificity for serotype 1, 2, 3, or 4 in a background of 10 bovine rotavirus genes (80). Each component was nonreactogenic, and immunogenic in phase I trials. The four strains were combined into a quadrivalent formulation and administered sequentially as described previously and proved to be safe and immunogenic in phase I trials (79).

In addition, (a) a single gene substitution reassortant, WaxUK, with a single human rotavirus gene from the Wa strain that coded for VP4 P1A in a background of 10 bovine rotavirus genes, and (b) a double-gene substitution reassortant, WaxDS-1xUK, with a gene from the Wa strain as earlier and a VP7 gene from the human rotavirus strain DS-1 that encoded G2 specificity in a background of nine bovine rotavirus UK genes, have been evaluated sequentially as described (214). Each candidate vaccine has been shown to be safe and immunogenic in phase I trials (117).

Another approach to rotavirus immunoprophylaxis involves the use of a live, orally administered, neonatal human rotavirus strain that appears to be naturally attenuated. The impetus for evaluating this strain came from the observation that neonates who experienced a subclinical rotavirus infection in an Australian nursery during the first 14 days of life were protected against clinically significant rotavirus diarrhea for up to 3 years (36). The neonatal rotavirus strain M37 (G1, P2A), derived from a Venezuelan neonate, appeared to be satisfactorily attenuated and immunogenic during a phase I trial in infants (136,336,499). However, in an efficacy trial in Finland, the M37 strain failed to induce protection against VP7 serotype 1 illness (388,499).

Phase I studies with another neonatal strain, RV3 (G3, P2A), which was obtained from the Australian nursery noted before, have also been initiated (18). This strain was attenuated and induced an antibody response in certain vaccinees after a single dose. A cold-adapted strain of human rotavirus D (G1, P1A) has also undergone early clinical studies and needs further evaluation (218; and Treanor, unpublished studies).

A live, orally administered, human rotavirus strain (89-12) with VP7:1, VP4:1A [8] specificity, which was attenuated by 33 passages in monkey kidney cells, has recently been evaluated in a clinical trial of efficacy in infants enrolled at 10 to 16 weeks of age. The vaccine was safe, inducing a low grade fever (38.1°C or greater, rectal) in about 15% of the vaccinees, and immunogenic. It had a protective efficacy of 89% against any rotavirus diarrhea and approximately 83% against severe or very severe diarrhea over a single season during which a VP7:1 strain was predominant (29).

Another candidate vaccine undergoing early clinical trials is a live oral vaccine in which a lamb rotavirus (G10, P [12]) is the immunogen (48).

Other Approaches to Vaccination

Other strategies to immunization are also being explored. Among these is the use of molecular biologic approaches

including (a) synthetic viral proteins, (b) viral proteins expressed by cloned rotavirus cDNA, (c) empty capsids expressed by a baculovirus recombinant, (d) synthetic peptides, (e) DNA vaccines, and (f) an inactivated G1, P [4] strain (AU64) for parenteral administration (48,81,199,229,338).

Passive Immunization

Finally, passive immunization has been shown to be effective in preventing or modifying rotavirus illness in animals (113,193,436). Similar studies have now been carried out in infants and young children, with promising results in most, but not all, instances (17,54,55,99,114,115). Various sources of passively administered rotavirus antibodies (such as eggs from immunized hens, or milk formula containing bovine milk immunoglobulin from cows hyperimmunized with human rotaviruses) have been considered (99,537,538). However, except for special circumstances such as in immunocompromised individuals, passive immunization is not practical for protection against rotavirus illness in humans, because it requires repeated administration of antibodies.

THE FUTURE

It is apparent that major advances made in the quest for a rotavirus vaccine have yielded encouraging signals that severe rotavirus disease can be prevented or modified. Although there are numerous questions regarding future rotavirus vaccines (e.g., formulation, nature of antigens, need for VP4 component, need for additional serotypes, role of enterotoxin), they all appear minor when compared to the issue of the risk of intussusception following administration of any vaccine candidate. Can any rotavirus vaccine in pre-licensure studies be ensured to be free of the risk of inducing intussusception? How large must studies be before proposing licensure? What are the ethical implications of withholding the use or development of a rotavirus vaccine for a developing country where mortality from rotavirus diarrhea is up to 870,000 per year in infants and young children (120,247,296,331,515,524a)? How does one weigh risk versus benefits of rotavirus vaccine?

CHAPTER 56 Orbiviruses

Polly Roy

Orbiviruses constitute a genus within the *Reoviridae* family. They are transmitted between their vertebrate hosts by hematophagous arthropods (ticks, *Culicoides* species flies, or mosquitoes, depending on the viral species), and replicate in both vertebrates and arthropods. No orbivirus is considered an important human pathogen. However, orbiviruses can cause infections and diseases of economic importance in ruminants in many parts of the world, including Africa, Australia, Southeastern Asia, South and Central America, and the United States. Although orbiviruses were recognized as early as 1900, and the initial morphologic and biochemical characterizations were reported in 1969, detailed studies of the molecular biology, genome structure, and encoded products have been obtained only recently. Because of its economic importance, most analyses have focused on the prototype virus of the genus, bluetongue virus (BTV). Significant advances have been made in understanding the structure–function relationships of BTV proteins, their roles in virus replication and assembly processes, and the three-dimensional (3D) x-ray–resolved structure of BTV proteins and virus particles. Because BTV is the best studied member of the *Orbivirus* genus, this chapter predominantly discusses BTV, and other viruses are mentioned only if they demonstrate important differences or have unique features. However, for certain sections, such as Classification, Genetics and Orbivirus Evolution, and Pathogenesis and Disease, all members are discussed. Coltiviruses are considered as a separate genus at the end of the chapter, although many of the principles of their structure and replication strategies appear to be quite similar to those of Orbiviruses.

CLASSIFICATION

The *Orbivirus* genus is one of at present nine genera within the *Reoviridae* family. The *Reoviridae* family includes vertebrate, arthropod, and plant pathogens. Despite their basic similarity with certain other members of the family (e.g., reoviruses and rotaviruses), orbiviruses differ greatly in details of their structure, physicochemical properties, replication cycle, pathogenesis, and epidemiology. The members of the *Orbivirus* genus, unlike the reoviruses and rotaviruses, are arthropod borne. Based on serologic cross-reactivities, 19 groups of orbiviruses are distinguished; in addition, there are several unclassified isolates (134). Within each serogroup, multiple serotypes are distinguished by neutralization tests. The orbivirus serogroups, serotypes, principal vectors, and main hosts are listed in Table 1 with their assigned abbreviations. The BTV group, which consists of at least 24 different serotypes (BTV-1, -2, etc.), infects *Culicoides* species and a number of wild and domestic ruminants (e.g., sheep, cattle), occasionally causing high morbidity and mortality, but often with no apparent clinical symptoms (38). Other orbiviruses that can cause disease in animals include African horse sickness virus (AHSV; nine serotypes, AHSV-1, -2, etc.) and epizootic hemorrhagic disease virus of deer (EHDV; nine serotypes, EHDV-1, -2, etc.).

TABLE 1. *Orbiviruses: Serogroups, serotypes, vectors and vertebrate hosts*

VIRION STRUCTURE

Like all members (reoviruses and rotaviruses) of the *Reoviridae* family, orbiviruses are nonenveloped viruses with two protein shells and a genome consisting of double-stranded RNA (dsRNA) segments (Fig. 1**A**, Fig. 1**B**, Fig. 1**C**, Fig. 1**D**, Fig. 1**E**, Fig. 1**F**). The inner shell of BTV, termed the *core,* is composed of two major proteins: VP3 and VP7. The inner shell in turn encloses three minor proteins, VP1, VP4 and VP6, and the genome of 10 segments of dsRNA. The outer shell, termed the *outer capsid,* consists of two other major proteins: VP2 and VP5 (225).

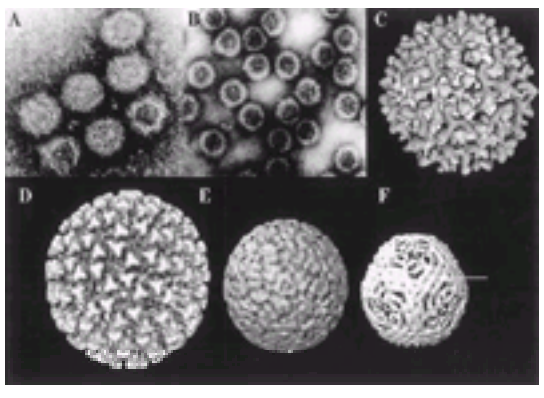

FIG. 1. A: Electron micrographs of negatively stained bluetongue virus (BTV) particles and core. **B:** Surface representations of the 3D cryoelectron microscopy structures of BTV virion (40 Å resolution) (**C**), showing sail-shaped VP2 spikes (trimers) and globular VP5 trimers; and the core of BTV viewed along the icosahedral threefold axis, showing the whole core (**D**), the middle layer of VP3 (210 to 290 Å) molecules cut away from the core structure (**E**), and the innermost density of three minor proteins in association with genome (**F**). Ordered strands of genomic RNA *arrow*) are visible at 2.3 Å resolution. Only the upper hemisphere is displayed for clarity. (Courtesy of B.V.V. Prasad, Baylor College, Houston, TX; from ref. 71, with permission.)

The morphologic features of unstained and unfixed, complete virus particles and the cores have been determined by 3D analysis at 23 to 40 Å resolution using cryoelectron microscopy and computer image reconstruction methods (63,71,167). More recently, the atomic structure of the core particle has also been resolved by x-ray crystallography at a resolution of 3.6 Å (62).

The 3D structure of the BTV core (sedimenting at 470 S), with a diameter of 69 nm (radius, 34.5 nm), has an icosahedral symmetry with a triangulation number of 13 (T=13) in a left-handed configuration. The core consists of two concentric layers of density surrounding a central density (see Fig. 1). The outer layer of the core is made up of clusters of VP7 trimers, which exist as prominent triangular protrusions, and are located at all the local and strict threefold axes (see Fig. 1D). These trimers are about 40 Å in length and 40 Å in diameter at the surface of the core and are arranged as six-membered rings, with five-membered rings at the vertices of the icosahedron. These ring structures are alluded to in the genus name *Orbis* (ring or circle). There are a total of 780 VP7 molecules per particle, forming 260 trimers, or triangular capsomers, that are arranged around distinctive 132 channels, which are present at all 5- and 6-coordinated positions of the T=13 lattice (see Fig. 1D). The VP7 trimers extend 8 nm outward from an inner density (at a radius of 28 nm), and the protruding capsomers give a bristly appearance to cores when examined by cryoelectron microscopy. The aqueous channels that are surrounded by these trimers are about 8 nm wide at the outer surface and 8 nm deep. Some of these channels extend inward, penetrating through to the inner layer. These channels probably provide pathways for transportation of metabolites and messenger RNA (mRNA) species during the transcription processes of core particles. The inner layer, which is made up of the second major protein, VP3 (see discussion VP3 structures, later), is relatively featureless and exhibits a smooth bed of density, with almost spherical shape (see Fig. 1E), but it has an angular appearance owing to variations in thickness of the protein shell. The density in the central portion of the core structure is within a radius of less than 21 nm (see Fig. 1F). It represents the structures involving the VP1, VP4, and VP6 proteins and the genomic RNA (see later).

The 3D reconstruction of BTV double-capsid particles by cryoelectron microscopy has shown a well-ordered morphology of the complete virion (71). This is in contrast to the morphology deduced by negative-staining methods, which gives a fuzzy appearance to the outer capsid (225). The outer capsid has an icosahedral configuration, and the two proteins of the capsid have distinctive shapes, one globular and almost spherical, the other sail-shaped (see Fig. 1C). The globular

structures, 120 in number, sit neatly in the spaces formed by each of the six-membered rings of VP7 trimers. The sail-shaped spikes, which project 4 nm beyond the globular proteins, are located above 180 of the VP7 trimers and form 60 triskelion-type motifs that cover nearly all the VP7 molecules. These spikes are believed to be the hemagglutinating protein VP2 that also contains the neutralizing epitopes. The underlying globular proteins are probably composed of VP5. The two proteins form a continuous layer around the core, except for the holes at the fivefold axes. A similar well-ordered morphology has also been obtained by cryoelectron microscopy reconstruction analysis of the tick-borne Broadhaven virus (BRDV) outer capsid, indicating that indeed orbiviruses are icosahedral particles (197). Moreover, since the two outer capsid proteins, VP4 and VP5, of BRDV differ in their sizes from BTV VP2 and VP5, it was possible to confirm the identity of the triskelion shape as trimers of VP4 of BRDV (equivalent to VP2 of BTV). The shape of the BRDV VP5 (VP5 of BTV) indicates that VP5 is also a trimer, thus implying that there are 360 copies of VP5 or 120 trimers. The current understanding of the topography of the seven structural proteins in virions is illustrated in a schematic diagram (Fig. 2).

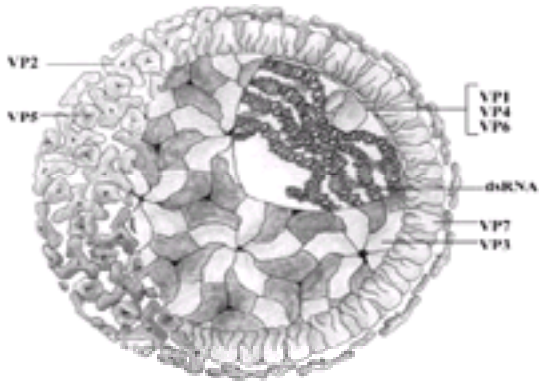

FIG. 2. Schematic diagram of the bluetongue virus (BTV) particle showing the positions and structures of BTV components. The diagram is based on data obtained from cryoelectron microscopic and x-ray crystallographic analyses and on data obtained from baculovirus recombinant expression systems.

GENOME STRUCTURE AND ORGANIZATION

The orbivirus genome is composed of 10 dsRNA segments, ranging in size from 0.56×10^6 to 2.7×10^6 daltons (48). The segments can be separated by polyacrylamide gel electrophoresis (PAGE) into patterns distinctive for each group and within groups between serotypes. For some isolates, certain segments co-migrate.

The RNA, when extracted under acidic conditions (pH 4.0) with sodium docecyl sulfate (SDS) and phenol, occasionally appears as an unfragmented continuous structure. Under the electron microscope, this structure has a rosette configuration with 10 varying-length loops that emanate from a central region resembling a doughnut. The relative size of each of the 10 loops is about equivalent to the sizes of the individual gene segments. The RNA segments are numbered 1 to 10 in order of migration (Fig. 3) and also may be referred to as large, medium, and small segments (i.e., L1 to L3, M4 to M6, and S7 to S10) (206). Their relative order of mobility may vary according to the electrophoretic conditions used. The dsRNA profiles of members representing each orbivirus serogroup are generally distinctive by PAGE and also differ from those of other members of the *Reoviridae* family (105).

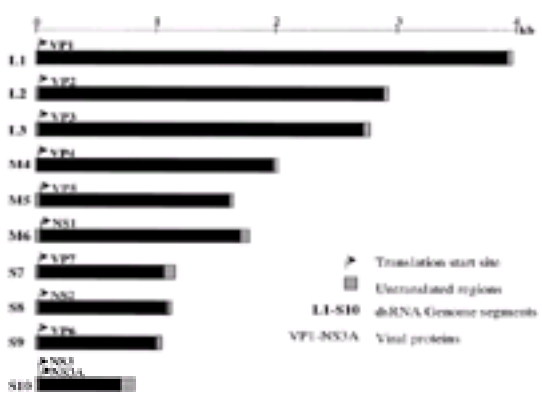

FIG. 3. Schematic diagrams of the 10 RNA segments of BTV-10 and their relative lengths and other features revealed by sequence analysis.

The complete sequences of all 10 dsRNA segments have been determined initially of BTV-10 (48) but subsequently for a number of other BTV serotypes as well as for EHDV, AHSV, the tick-transmitted BRDV, and more recently the Chuzan virus of the Palyam serogroup (134,143,144,189,241,244).

The 10 dsRNA segments of BTV have conserved terminal sequences (Table 2; see Fig. 3). Both strands of each of the 10 dsRNA segments are entirely complementary, forming complete duplexes. However, the 5' terminus of the coding strand of each duplex is capped and methylated, as are the BTV mRNA transcripts (84). The opposing, noncoding strands in the virion dsRNA species are neither capped nor methylated. For the mRNA sense strand of all segments, the conserved terminal sequences involve eight nucleotides at the 5' ends and six nucleotides at the 3' ends (175). For BTV-10, the total genome is 19,220 base pairs (bp) in length, representing a molecular weight ratio (M_r) of a 13×10^6

daltons (Table 3; see Fig. 3). The sizes of the BTV-10 RNAs range from 3,954 bp (L1, $M_r \sim 2.7 \times 10^6$) to 822 bp (S10, $M_r \sim 5 \times 10^5$). The base distribution total of the genome is 28.1% A, 28.1% U, 21.9% C, and 21.9% G. The base ratios of the individual segments are similar (i.e., A or U range from 29.3% to 25.4%, G or C from 24.6% to 20.7%). The 5'-noncoding regions vary in length from eight (segment M4) to 34 (M6) nucleotides. The 3'-noncoding sequences are generally longer, varying from 31 (M5) to 116 (S10) nucleotides (see Table 2).

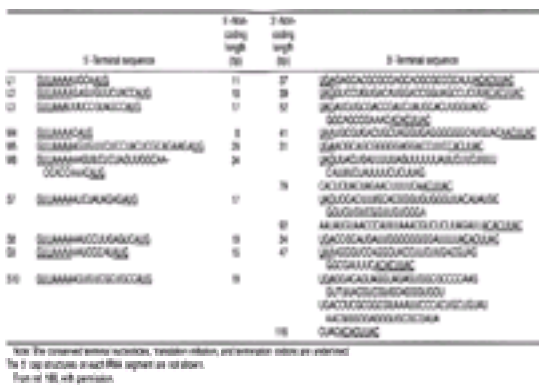

TABLE 2. *Noncoding terminal sequences of the bluetongue virus viral RNA segments*

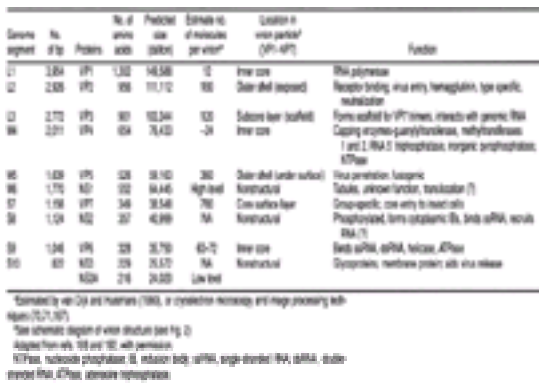

TABLE 3. *Bluetongue Virus (BTV-10) coding assignments*

The 5'- and 3'-terminal sequences of the 10 mRNA strands of BTV, EHDV, and AHSV have partial inverted complementarity and are thus capable of forming secondary end-to-end (panhandle) structures and exhibiting some common features (e.g., a looped-out sequence proximal to the 3'-terminus) (21,95). Overall, each mRNA appears to have the possibility to form a complex secondary structure involving stem-loop configurations that are similar not only between corresponding segments of various BTV serotypes but also to those of EHDV and AHSV (21,187). Although this attribute may be of particular relevance to mRNA stability (on the premise that secondary structure limits degradation by endonucleases, or exonucleases), it is potentially also relevant for mRNA recognition by the viral polymerase and for the association of RNA segments. Interestingly, whatever the intrastrand complementary sequence arrangement may be, parts of the conserved 5'- and 3'-hexanucleotides remain unpaired and, by virtue of their actual sequence as well as the presence of a capped, methylated structure, provide a means to distinguish the ends of the coding from the noncoding strands. Thus, both the sequences and lengths of the BTV noncoding regions may be relevant for mRNA packaging into precursor particles, for strand selection for mRNA synthesis, and for determining translation efficiencies of different mRNAs.

Apart from the BTV-10 L1 segment, the first AUG initiation codon in the mRNA strand of each segment initiates a single open reading frame (ORF) and product characteristic of that mRNA. For L1, the second AUG (positions 12 to 14) codon but not the first (positions 7 to 9) is the initiation codon (see Table 2). There are two methionine codons in the same reading frame in the S10 RNA sequence, one at residues 20 to 22, the other at residues 59 to 61 (48,115). These are used to synthesize the NS3 and NS3A products of S10 (see Fig. 3).

Extensive data on the genome sequences of the different BTV serotypes and of other orbiviruses are discussed in the section on Genetics and Orbivirus Evolution. The data demonstrate that, apart from RNA segments L2 and M5, the other RNA segments are highly conserved within each serogroup.

GENE CODING ASSIGNMENTS AND VIRUS PROTEINS

Each genome segment of BTV codes for the synthesis of one major protein, except segment S10, which codes for two related proteins: NS3 and NS3A (43,130). The structural proteins are numbered VP1 to VP7 in order of their decreasing sizes on SDS-PAGE. In addition to the seven structural proteins, four nonstructural proteins (NS1, NS2, NS3, and NS3A) are also synthesized in infected cells (188). The coding assignments, sizes, and locations of the gene products are summarized in Table 3. When individual gene products are compared with these values, several striking variations are evident. These variations are discussed later, with other data, for each gene product.

The Two Outer Capsid Proteins

The outercapsid proteins VP2 and VP5 are encoded by RNA segments L2 and M5, respectively (130) and exhibit the least conservation between virus serotypes (188).

The BTV-10 VP2 protein consists of 956 amino acids (M_r 111,000; see Table 3), rich in cysteines and residues, which may indicate that it has a highly ordered, disulfide-bonded structure (46,47,49,56,169,240,241). Comparisons of BTV-10 VP2 sequence with VP2 sequences of other BTV serotypes and with that of EHDV and AHSV, the two other closely related Orbiviruses (Table 4) indicate that it is the most variable of BTV proteins. Nevertheless, some BTV serotypes are more closely related than others (e.g., BTV-10 and -17 than BTV-10 and BTV-1, -2, and -13). In general, the differences in amino acids among the seven serotypes that have been sequenced to date are distributed evenly throughout the protein (243), although there are a number of highly variable regions that can be identified (Fig. 4). Conversely, there are a number of highly conserved regions that are evident. The C-terminus and the middle region of VP2 are relatively well conserved, with the absolute conservation of an octapeptide (see Fig. 4) among all seven serotypes (NPYPCLRG; amino acids 360 to 367 in BTV-10), which may reflect a functionally important region of the protein. The common phylogenetic origin of all these viruses is shown by other conserved features, such as six conserved cysteine residues, similar hydropathic profiles, the formation of perfect diagonal lines when the BTV VP2 proteins are aligned, and the indicated secondary structures, such as a-helices, b-strand, and turns (188).

Serotype	BTV-10A	BTV-2	BTV-3	BTV-10	BTV-11	BTV-13	BTV-17	BTV-20Au	EHDV-1	AHSV-3	AHSV-4	AHSV-6

TABLE 4. *Homologies among nine bluetongue virus (BTV), one epizootic hemorrhagic disease virus (EHDV), and three African horse sickness (AHSV) VP2 proteins*

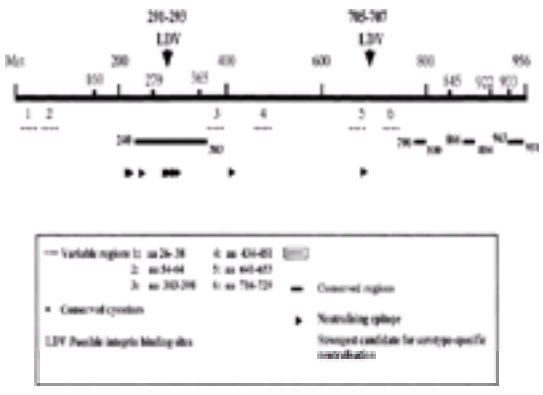

FIG. 4. Schematic diagram of VP2 protein. Structural and antigenic properties of VP2 based on the analyses of amino acid sequences of different bluetongue virus serotypes.

The VP2 protein of BTV is a hemagglutinin and is directly involved in the attachment of virus to cells (30,67,75). When VP2 is removed, the hemagglutinin, infectivity, and binding of the derived particles are significantly reduced for vertebrate cells (20,44,135,162). However, *in vitro*–generated intermediate subviral particles (ISVP) of BTV that still contain the chymotrypsin cleavage products of VP2 are fully infectious (135). The VP2 protein is the principal antigen that determines serotype specificity (79,102,191), and VP2 elicits serotype-specific neutralizing antibodies that confer protection against homologous virus infection in vertebrate hosts (80,94,191). The neutralizing epitopes of VP2 are predominantly conformation dependent, and VP2 purified from SDS-PAGE fails to induce neutralizing antibodies (87,116,180,236). VP2-specific monoclonal antibodies neutralize virus infectivity and provide passive protection against homologous virus challenge. Antisera raised in rabbits and mice after immunization with insect cell lysates expressing recombinant VP2 proteins of different serotypes efficiently neutralized the infectivities of homologous and, to a lesser extent, certain other heterologous BTV serotypes (94,217). These data suggest that not all BTV serotypes are equally distinct.

A number of conformationally dependent neutralization epitopes on VP2 have been identified (27,56,57,69,116,236) (see Fig. 4). Five epitopes for BTV-1 (amino acids 211, 267, 328 to 335, 491, and 539) and for BTV-10 (amino acids 208, 211, 327, 402, and 654) at similar positions and an additional one for BTV-13 (amino acids 642 to 651) have been mapped. These neutralizing epitopes of BTV are probably not unique to each serotype (166,178,180). Some data for AHSV VP2 neutralization sites have also been generated recently that are similar to those of BTV (127).

The second outer capsid protein, VP5, of BTV-10 has 526 amino acids (M_r 59,163) (53,139,170). The protein is variable to a certain extent, but not as variable as the VP2 protein (74,162,246). The protein also shares strong sequence homology with the VP5 proteins of EHDV-1, AHSV-4, and Chuzan virus but not with the VP5 of tick-borne BRDV VP5

(95,96,143,242,244). It is noteworthy that after the initiating methionine at the N-terminus, a glycine residue is present that is conserved in the VP5 proteins of all BTV and EHDV analyzed so far (95). However, the protein is not myristoylated (P. Roy, unpublished data). VP5 may be glycosylated containing short and unbranched N-linked carbohydrate moieties and possibly O-linked sugars (246). It has recently been shown that VP5 has a role in virus penetration of endosomal membrane and is responsible for the release of virus core into cell cytoplasm (68).

Based on the amino acid sequence, VP5 is divided into an aminoterminal coiled-coil domain and a carboxyl-terminal globular domain with a flexible hinge region in between (Fig. 5). The aminoterminus of VP5 could also potentially form two amphipathic helices (helix 1 and helix 2), each with about equal separation of hydrophobic and hydrophilic faces followed by a putative fusion peptide (see Fig. 5). Such structural features support the concept that VP5 is capable of inducing membrane destabilization and permeabilization (68).

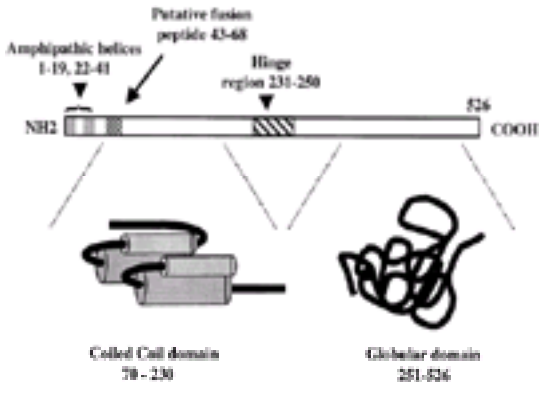

FIG. 5. Schematic organization of VP5 protein showing the putative fusogenic coiled-coil domain and the globular domain that are linked by a hinged region.

Clearly, the two outer capsid proteins VP2 and VP5 are responsible for virus entry and penetration processes. The predicted structures of these proteins correlate with such functions. Like VP5 of BTV, both rotavirus and reovirus have similar structural organization in the outer capsid protein (Fig. 6). It is interesting that in rotavirus and reovirus, a coiled-coil structure is present in the VP4 and s1 proteins, which are the hemagglutinin proteins and the viral attachment proteins to cellular receptors, unlike the situation in BTV, in which it is the VP5 protein that has the coiled-coil structure and not VP2. The positions of the domains within the rotavirus VP4 are inverted in relation to the BTV VP5 protein. The function of virus attachment and the penetration for orbiviruses are therefore performed by two different proteins.

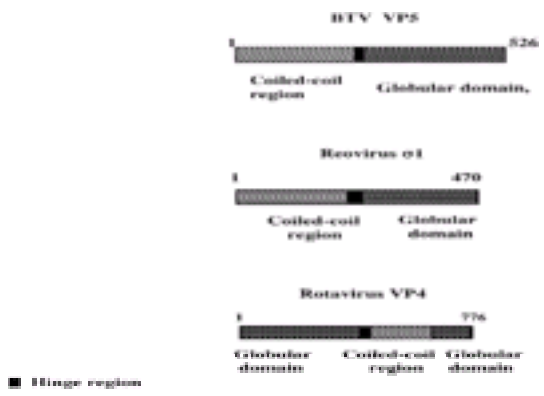

FIG. 6. The overall organization of VP5 primary structure shows the similar organization with rotavirus outercapsid protein, VP4, and reovirus outer capsid protein, s1. Note that all three proteins consist of coiled-coil and globular domains.

VP5 may also play a role in virus neutralization activity. In BTV, VP5 appears to enhance the protective neutralizing activity of VP2 (191), whereas in AHSV and the Kemerovo serogroup, VP5 appears to carry neutralization epitopes itself (128,154).

The Five Core Proteins

In virus-infected cells, parental BTV virions (550S) are converted to core particles (470S) containing VP1, VP3, VP4, VP6, and VP7 and exhibiting RNA-dependent RNA polymerase activity. This enzymatic activity allows the virus to synthesize mRNA from virion RNA templates (83). Recently, much progress has been made in dissecting enzymatic functions provided by the core proteins. This has been possible owing to the availability of highly purified recombinant baculovirus-expressed functional proteins and of subvirion structures.

The three minor proteins VP1, VP4 and VP6, together with 10 dsRNAs, form the innermost part of the core. All three proteins are highly conserved across the different BTV serotypes that have been analyzed to date. The largest viral protein, VP1, with an M_r of 149,588, is encoded by the dsRNA segment 1, or L1 (184). The molecule is a highly basic protein and is present in a low molar ratio in the virion (see Table 3). Based on its size, location, molar ratio in the core, and predicted amino acid sequence, this protein is the prime candidate for the virion RNA-dependent RNA polymerase (184). The primary sequence of VP1 contains a GDD motif (positions 287 to 289), characteristic of other RNA

polymerases. In addition, VP1 exhibits some sequence homology with a number of other RNA and DNA polymerases (184). Indeed, extracts of cells that were infected with a recombinant baculovirus expressing VP1 protein showed a poly(A) polymerase activity in an *in vitro* assay (218). Recent data have shown directly that indeed VP1 is the viral polymerase protein and has the capability to synthesize *in vitro* complementary BTV RNA on a BTV single-stranded (ssRNA) template, generating RNase-resistant dsRNA duplexes (172).

The second minor protein of the core, VP4 (M_r 76,433), is encoded by M4 RNA (250). The protein has a high content of charged amino acids and exists as a dimer in solution and within the core. A leucine zipper in the center of the molecule is responsible for the dimerization of VP4 (173). The dimeric form of VP4 is essential for encapsidation of the protein within the core. Highly purified recombinant VP4 has been demonstrated to possess various enzyme activities (nucleotide triphosphatase, RNA 5'-triphosphatase, inorganic pyrophosphatase, guanylyltransferase, methyltransferase 1 and 2) that are necessary for the modification (capping) of 5'-termini of positive stranded RNA species (18,111,171,174). Thus, complete BTV RNA capping appears to be associated with this one viral protein alone (171).

The third minor protein, VP6, is encoded by S9 RNA. VP6 has an M_r of 35,750 and is very rich in basic amino acids (Arg, Lys, and His), suggesting that VP6 may bind to nucleic acids (181). Baculovirus-expressed and BTV-derived VP6 have both been shown to have a strong affinity for binding ssRNA and dsRNA species, even in the presence of SDS, indicating that its nucleic acid–binding ability is independent of its tertiary structure and suggesting its close association with the viral genome in virions (181). Subsequent studies demonstrated that VP6 protein is highly active as a helicase enzyme (199). VP6 hydrolyzes adenosine triphosphate (ATP) in the presence of divalent cations. Both ssRNA and dsRNA stimulate the ATPase activity of VP6. Like most helicases, in the presence of ATP, the VP6 enzyme unwinds dsRNA substrates with 3' overhangs. Interestingly, it also unwinds substrates with 5' overhangs, which has been reported for only a few other helicases, and, as expected, it unwinds blunt-ended dsRNA (Fig. 7). Like other helicase proteins, VP6 appears to form hexameric oligomers in the presence of RNA. Oligomer formation can be monitored by size-exclusion chromatography after chemical cross-linking. The nucleic acid–binding and helicase capabilities might allow VP6 to participate in mRNA transcription, but also in virus assembly by interacting with the 10 mRNA species and assisting the process of rendering them into dsRNA segments. The fact that VP6 binds dsRNA (as well as ssRNA) may be relevant to the encapsidation process and sequestering of dsRNA species into precursor cores and virions (194,195).

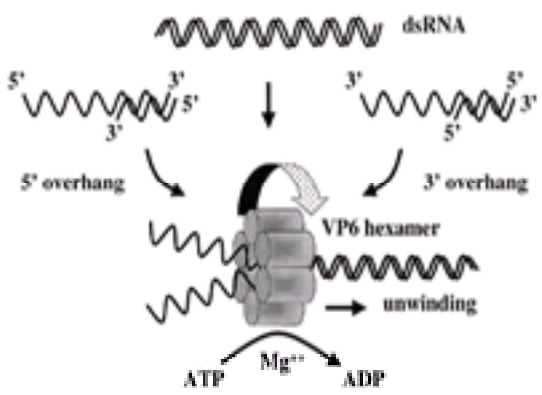

FIG. 7. Schematic of helicase activity of hexameric VP6 on various duplex RNA templates.

The VP6 protein is abundant in basic residues, particularly in two regions of the carboxy half of the molecule. A series of aminoterminal and carboxy-terminal deletion mutants when transiently expressed revealed that VP6 has nuclear transport signals that may be correlated with positively charged domains of the molecule (247). In the intact molecule, though, these signals are masked, and the protein is retained in the cytoplasm. The sequences near the amino acids (33 to 80) of the 328–amino acid protein are required for the retention of VP6 within the cell cytoplasm, whereas a region rich in basic residue (amino acids 303 to 308) near the carboxy terminus appears to possess nuclear localization signals (247).

The VP3 and VP7 proteins are the two major proteins of the core; VP7 is the more abundant (see Table 3). The larger protein, VP3, forms an inner scaffold for the deposition of the surface layer of VP7 in the core. VP3 also interacts with the three minor proteins. The L3 RNA encodes the VP3 protein (M_r 103,344) (50,168). The protein is hydrophobic and for BTV-10 consists of 901 amino acids. As far as analyzed to date, VP3 is highly conserved among BTV serotypes and other orbiviruses (e.g., EHDV and AHSV). For example, only nine amino acids are different in the VP3 proteins of U.S. serotypes BTV-10 and BTV-17 (50). A similar conservation is seen by comparing the VP3 sequences of other U.S. and Australian BTV serotypes (60). The protein is also remarkably similar to that of EHDV-1 and AHSV-4 (59,110), reflecting its very specific role in determination of virus capsid morphology and in the organization of the virus genome (Table 5). Recombinant VP3 protein is recognized by all anti-BTV antisera and reacts weakly with anti-AHSV and anti-EHDV antisera (93,110), suggesting that there are conserved functions in VP3 as well as conserved amino acid sequences.

BTV-10	VP2		VP7

TABLE 5. *Comparisons of the two core proteins of three orbiviruses*

The second major protein, VP7, has an M_r of 38,548 and is highly conserved among the various BTV serotypes (106,107,229,249). The VP7 protein of BTV is also closely related to those of EHDV and AHSV (up to 80%; see Table 5) (108,221,279) but is only distantly related to the equivalent protein of the tick-borne BRDV, only 21% amino acids being identical in type and position (144). The BTV-10 VP7 protein is deficient in charged but rich in hydrophobic amino acids. VP7 has only one lysine, which is remarkable because all the other BTV gene products are lysine rich.

The recombinant BTV-10 VP7 protein reacts with antibodies raised to different BTV serotypes and, to a much lower level, with antibodies raised to AHSV and EHDV, indicating that, like VP3, it possesses group-specific determinants (161). Similarly, recombinant VP7 of AHSV-4 reacts with antisera raised to nine different AHSV serotypes and, at a much lower level, with BTV antisera (15). The high-level synthesis of BTV VP7 has facilitated the purification and crystallization of the protein (5). Three different crystal forms (I through III) suitable for x-ray diffraction analyses were generated. Type I crystals are hexagonal rods, whereas type II and III crystals are monoclinic. From x-ray and light-scattering studies, it was deduced that VP7 forms trimers in crystal forms and in solution. These crystals diffracted at up to 2 Å resolution (further details given later).

The Nonstructural Proteins

Four different nonstructural proteins have been identified in BTV-infected cells. The two major nonstructural proteins, NS1 and NS2, are synthesized abundantly, whereas the two minor, closely related proteins, NS3 and NS3A, are barely detectable (31,43,85). The sequences of each NS protein are highly conserved (96%) among BTV serotypes (reviewed in 188). The synthesis of NS1 and NS2 in BTV-infected cells coincides with that of two virus-specific structures, tubules, and the granular inclusion bodies (IBs), that are characteristic for orbivirus-infected cells (31,85). IBs can be both granular and fibrillar and are found throughout an infected cell, but predominantly near the nucleus (31). Virus tubules are present in large numbers, mostly in perinuclear locations. So far, no function has been ascribed to BTV tubules, although they may be involved in the translocation of virus particles to the cell plasma membrane, whereas the NS3 proteins facilitate their egress (see Release of Virions). NS1-specific monoclonal antibodies have been shown to react with virus particles that are either in close proximity to IBs or leaving infected cells.

Tubules are composed of the M_r 64,445 NS1 protein, the product of RNA M6 (219) (see Table 3). This protein is synthesized more abundantly than any other BTV protein (78). The protein may be used as a group-specific diagnostic reagent (179). The BTV-10 NS1 protein has a low content of charged amino acids but is rich in cysteines (114,188), suggesting a highly ordered structure. Interestingly, six of the BTV-10 NS1 cysteines are clustered in pairs, with two or five amino acids in between; they may form disulfide bridges. When the NS1 gene is expressed in insect cells by a recombinant baculovirus, tubules similar to those found in BTV-infected mammalian cells are formed, confirming that the tubules are multimeric forms of the NS1 protein (219). Cryoelectron microscopy analyses have shown that the BTV tubules are on average 52.3 nm in diameter and up to 1,000 nm long with a helical configuration (73). The NS1 protein, which is about 5.5 nm in diameter, forms a dimer. The tubular structure consists of a helically coiled ribbon of NS1 dimers, with about 21 or 22 dimers per turn. A ribbon of dimers may be seen unwinding from the ends of tubules under certain conditions.

The nature of the NS1 interactions involved in tubule formation have been analyzed using a series of N- and C-terminal deletion and site-directed mutagenesis targeting cysteine residues (139). When expressed by recombinant baculoviruses, the data demonstrated that both the N- and C-termini and only one pair of cysteines, at amino acid positions 337 and 340, are essential for tubule formation. Using a panel of monoclonal antibodies, together with a series of NS1 mutants containing deletions and substitutions, an antigenic site has been identified at the carboxy end of the molecule (139). Interestingly, extension of the C-terminus with a peptide of at least 250 amino acids had no effect on the assembly of the tubules and on their morphology (137). Recombinant chimeric NS1 tubules are highly immunogenic, eliciting protective B- and T-cell responses (185).

The second nonstructural protein, NS2, with an M_r of 41,000 (215) (see Table 3), is the only virus-specific phosphoprotein that is present in BTV-infected cells (28,85). NS2 is encoded by RNA segment S8 and is rich in charged amino acids (48,130). The BTV-10 NS2 protein has seven cysteine residues, four of which are located near the carboxy terminus (48). The protein is generally hydrophilic, with pairs of positively charged amino acid (K, R) domains located near both ends of the protein. NS2 is synthesized to a high level and is mostly present in cytoplasmic IBs (90,215). NS2 expressed by baculovirus vectors forms multimeric IBs in insect cells in the absence of other BTV gene products, and the morphology is similar to that found in BTV-infected cells (215).

NS2 protein has been shown to bind ssRNA (82,212,215), but not dsRNA. This property is similar to that of the rotavirus NS3 protein, which also forms oligomeric structures, binds ssRNA, and exists in complexes with viral RNA species in

infected cells (104). The phosphorylation of NS2, which involves specific serine residues, does not appear to be important in RNA-binding activity (213,215). Similarly, the C-terminus (including the last 130 amino acids) is not required for ssRNA binding or for oligomerization (251). The N-terminus of NS2 was not required for oligomerization (up to residue 92) either, but was found to be essential for ssRNA binding. In particular, the arginines at amino acid positions 6 and 7 and a lysine at position 4, but not a glutamic acid at position 2, are required for ssRNA binding (251). Similarly, for NS2 of EHDV, a short N-terminal region (amino acids 75 to 83) have also shown to be essential for RNA-binding activity (212). It is believed that NS2 is involved in recruiting mRNA species into IBs during assembly of virus components.

Unlike the NS1 and NS2 proteins, the two smallest nonstructural proteins, NS3 and NS3A, are synthesized in low abundance in BTV-infected BHK cells (43,85). However, in contrast to vertebrate cells, high-level expression of these proteins can be detected in invertebrate cells in which virus release is nonlytic (65). This suggests that NS3 or NS3A may have a significant functional role in invertebrate cells. Both NS3 and NS3A proteins are encoded by BTV RNA S10 (43,130,221). Biochemical and immunologic analyses on expressed S10 gene products have shown that NS3 and NS3A are related and derived from alternative translation initiation sites (43,115). Deletion of the first AUG abolishes synthesis of NS3 but not that of NS3A (238).

The NS3 proteins of all BTV serotypes have two conserved hydrophobic domains (amino acids 118 to 141 and 162 to 182) (115). In addition, there are two potential glycosylation sites (amino acids 63 and 150). Using a transient expression system, NS3 and NS3A proteins made in mammalian cells are glycosylated and converted into heterologous polylactosaminoglycans (238). In contrast to BTV NS3 sequences, NS3 of different AHSV serotypes are not highly conserved, and the variation in the NS3 sequence has been shown to influence the virulence characteristics of the progeny virus strain (126). Based on mutational analysis of NS3, it appears that like rotavirus NSP4 (a nonstructural glycoprotein), both hydrophobic domains span the cell membrane, with both termini being cytoplasmic (Fig. 8). Only the site at amino acid position 150 but not at position 63 may have the potential for modification by N-linked glycosylation (2). The NS3 proteins are transported through the Golgi apparatus to the cell plasma membrane in the presence or absence of tunicamycin, suggesting that carbohydrate chains are not required for transportation (238). These proteins are found to be associated with intracellular, smooth-surfaced vesicles as well as the plasma membrane (91). The data strongly suggest that the NS3 proteins are integral membrane glycoproteins. By using recombinant baculoviruses, it has been shown that NS3 or NS3A facilitates the release of virus-like particles (VLPs; as surrogates of virions) from host cells, and that these proteins are present at the site of the membrane from which VLPs are released (92). This indicates that the integration of NS3 or NS3A into the plasma membrane probably helps the release of mature virions. The function is similar to that of NSP4 of rotaviruses, which interacts with viral bilayered particles to facilitate their transport across the rough endoplasmic reticulum of infected cells (1,136).

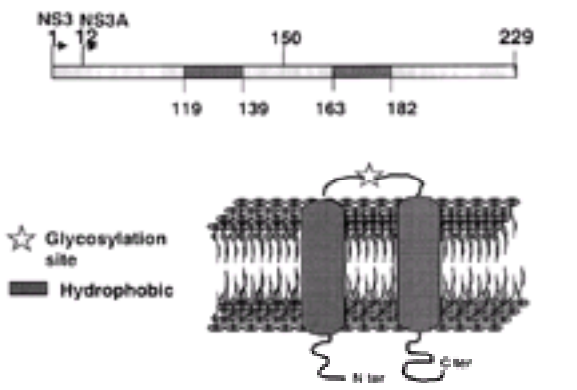

FIG. 8. Diagram of NS3 protein (*top*) and its organization in membrane (*bottom*). Note the positions of the two hydrophobic domains (amino acids 119 to 139 and 163 to 182) and the single glycosylation site (amino acid 150). The two start codons (amino acids 1 and 12) are indicated at the top schematic.

From recent studies, it appears that the release of mature virions aided by NS3 takes advantage of cellular exocytic pathway. NS3 forms a complex with cellular protein p11, which is the smaller component of the p36/p11 heterotetrameric calpactin II complex (22). Further, although the first 13 residues of NS3 interact with this p11, the carboxy end of NS3 interacts with VP2 of mature virions. Because calpactin II complex is involved in cellular exocytosis, it is assumed that p11 binding by NS3 provides a mechanism for the virus to use the cellular exocytic pathway for nonlytic virus release (7).

X-RAY CRYSTALLOGRAPHIC STRUCTURES AND THREE-DIMENSIONAL RECONSTRUCTION OF PROTEINS AND PARTICLES

The Atomic Structure of VP7

BTV-10 VP7 is the first capsid protein of members of the *Reoviridae* family that has been crystallized, and the structure has been solved at atomic level. The data show some striking features in comparison to the protein structure of other viruses. The VP7 structure revealed a unique molecular architecture of trimeric nature (61). Each monomer consists of two distinct domains, the upper and lower, which are twisted such that the top domain of one monomer rests on the lower domain of a threefold-related subunit in a clockwise direction (Fig. 9). The interactions between subunits are extensive both between the top and bottom domains, involving both hydrophobic and specific hydrogen bond interactions. The smaller upper domain of VP7 forms the “head region” of the trimer, which appears as a knobby projection on the outer surface of the core by cryoelectron microscopy and contains the central one third of the polypeptide chain of the molecule (amino acids 121 to 249). In the trimer, the three upper domain subunits, each of which is folded into an antiparallel b-sandwich, are intimately associated through two extended loops from each subunit, both with each other and with all possible threefold related subunits. The x-ray structure of the upper domain of AHSV-4 VP7, which was

solved subsequently, also revealed similar structural arrangement, indicating that it is likely that the VP7 of all orbiviruses may have similar structures (6). The characteristic feature of the upper domains of both molecules is the presence of an Arg-Gly-Asp (RGD) motif (although for AHSV, the RGD site is located at a slightly different position), which may be responsible for binding of the orbivirus core to a cellular integrin receptor. The lower domain of the VP7 trimer is composed of nine a-helices and long extended loops and is formed by both the N-terminus (amino acids 1 to 120) and the C-terminus (amino acids 250 to 349) of the molecule (see Fig. 9). The interjunction region between the two domains is exposed and is easily accessible to proteolysis. The single lysine residue of BTV-10 VP7 is situated at this junction between the two domains, which explains why mutation at this site had deleterious effect on core assembly (112). The helices in the bottom domain pack together tightly. The mutational studies obtained indicate that the interactions between VP7–VP7 monomers are rigid and that the compact nature of VP7 trimer could easily be destabilized by a single point mutation at the key positions (112,117).

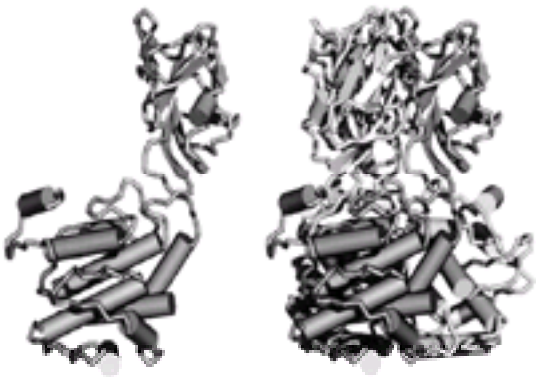

FIG. 9. The structure of a monomer (*lower*) and trimer (*upper*) of VP7. Note the aminoterminus in the *right foreground* and the carboxyl terminus in the *left* on the monomer. The view is shown from the side, and the extensive rather flat base of the molecule lies in a horizontal plane in this view (61,62). (Drawn by J. Diprose, J. Grimes, and D, Stuart, using Bobscript [40], POV-ray and Photoshop.)

Core Particle

X-ray crystallographic structures at 3.5 Å resolution for core particles of two different BTV serotypes (BTV-1 and BTV-10) have been determined (55,62,63). Combining the atomic data with high-resolution (23 Å) cryoelectron microscopy of BTV core, an atomic model has been constructed for the structure and organization of VP7 and VP3 within the core particle.

The organization of 260 VP7 trimers follows precisely a T=13 icosahedral lattice, in accordance with the theory of quasi-equivalence (63). The threefold axis of the trimer (85 Å long) is perpendicular to the core surface, and the broader base of the trimer (65 Å) contacts the internal network of the VP3 of the subcore (see Fig. 9A and Fig. 9B). The VP7 layer occupies between 295 and 365 Å from the center of the core. As shown in Figure 10A, five VP7 trimers at different distances from the fivefold axis form a protomeric unit (labeled P to T). These trimers show relatively little variation in their structure throughout the core surface layer (see Fig. 10B). The 260 trimers of VP7 adhere to a scaffold that is made up of only 120 VP3 molecules, indicating a symmetry mismatch in the interactions and that these trimers interact in 13 different relative positions. The interactions between the different trimers are facilitated by a thin band of hydrophobic patch on the contacting surfaces, which leads to some small deviations between the 13 copies in the contact patches. The interface between VP7 and VP3 trimer layer is principally formed by the side-to-side packing of short hydrophobic side chains from helix 4 and its twofold or quasi-twofold partner in the neighboring trimers. The interaction between various VP7 (T13) trimers and underneath VP3 (T2) layer is extensive and relatively well filling; the shape of the various VP7 trimers remains essentially the same. The T trimers appear to be the most tightly attached to the VP3 subcore and are likely to act as nucleation points, and the P trimers probably constitute the last series of trimers that attach to the VP3 subcores.

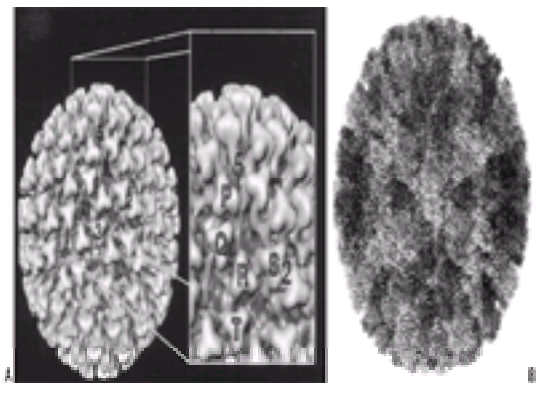

FIG. 10. Surface representation of the bluetongue virus (BTV) core. **A:** The cryoelectron microscopic three-dimensional (3D) reconstruction of BTV-10 core showing the trimers of VP7, with an enlarged portion highlighting the protomeric unit of the viral capsid. The 260 trimers of VP7 are arranged in laevo T = 13 lattice on the VP3 shell. The icosahedral axes are marked, as are channels II and III in the layer of VP7. In the enlarged section, the five quasi-equivalent trimers are marked P (closest to the fivefold axis) and S (closest to the twofold axis) through to T (the trimer on the icosahedral threefold axis. (From ref. 63, with permission.) **B:** The structure of the BTV-1 (*SA*) core (62). The structurally equivalent trimers have been given the same color (shade of *gray*). The trimers cover most of the pores through the VP3 layer, leaving a single pore on the icosahedral fivefold axes as the likely site of exit of nascent mRNA (for details, see text).

(Drawn by J. Diprose, J. Grimes, and D. Stuart, using Bobscript [40], POV-ray, and Photoshop.

The inner protein shell, known as the subcore, is composed entirely of 120 copies of the VP3 protein, which are organized as an icosahedral lattice with T=2 symmetry (62). The VP3 subcore shell has a maximal diameter of 59 nm, forming a central space with an internal diameter of 38 nm, that contains both the genome and the minor core proteins. The 120 copies of VP3 that are arranged as two sets (A and B) of 60 subunits form the subcore layer (Fig. 11A). Five of the A-group molecules are arranged as a five-pointed star around each fivefold axis. Five additional B-group molecules are positioned one between each of the points of the star, but at a further distance from the fivefold axis. Thus, the VP3 molecules form convex disk-shaped decamers. Twelve decamers, positioned one at each of the fivefold axes, are arranged end to end, forming the complete VP3 shell.

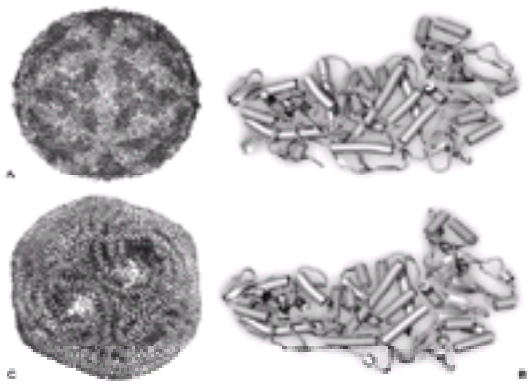

FIG. 11. A: The structure of the VP3 layer showing the arrangement of 120 copies of two types of VP3 molecules. **A** is shown in *light gray* and *B* is shown in *dark gray*, as seen in bluetongue virus serotype 1 (BTV-1). Sixty copies of each of the two molecules (A and B) pack together to form a thin closed shell of protein that encapsulates the viral genome. An analysis of the interactions between the molecules suggests that the A–B (and to a lesser extent the A–A) interactions forming a flower-shaped decamer around each fivefold axis are the strongest, with weaker A–B pseudo-twofold and B–B pseudo-threefold interactions connecting the decamers (62). **B:** The structure of two types of VP3 molecule, *A* (*left*) and *B* (*right*), as observed in the BTV-1 core. The molecules are similar in overall shape of thin triangular plates, with slight differences in conformation. Note some curling up of the B molecule, which facilitates it packing around the icosahedral threefold axes. The details of the fold within the two molecules differ at several places. Note the differences at the top of the molecules (closest to the icosahedral fivefold axes), where a compact structure is seen in *A* and a more extended structure in *B* (62). **C:** The ordered genomic dsRNA in the core of BTV. The diagram shows the model that has been built into the four layers of electron density, accounting for about 80% of the genome. The empty volume close to the icosahedral fivefold axes is the putative location for transcription complex (*TC*) (55). (Drawn by J. Diprose, J. Grimes, and D. Stuart, University of Oxford, UK, using Bobscript [40], POV-ray, and Photoshop.)

Both the A and B VP3 subunits have similar overall shape, and the individual VP3 molecule forms a flat, elongated triangular wedge shape (13 to 35 Å thick × 75 Å wide × 130 Å long) which contains many a-helices as well as b-strands and is made up of three distinct domains (see Fig. 11B). The three domains have quite different folds from each other. The *apical* domain (amino acids 298 to 587) is situated closest to the fivefold axes in the intact particle. The *carapace domain* (amino acids 7 to 297, 588 to 698, and 855 to 901) forms a rigid plate that represents most of the surface of the subcore shell. The *dimerization domain* (amino acids 699 to 854), which forms quasi-twofold interactions between individual A-group molecules, is situated farthest away from the fivefold axes (62). The dimerization domain is also responsible for interactions of A and B subunits between different decamers.

The inner surface of the VP3 shell interacts directly with the minor protein components (VP1, VP4, and VP6) of the transcriptase complexes (TCs), which are located at the fivefold axes, within the central space. The inner surface of the VP3 subcore shell has relatively few charged residues and has a series of shallow grooves. These features may be essential to organize the dsRNA molecules of the genome and to allow them to be transported rapidly and simultaneously through the active sites of the TCs. The TCs (probably 12 in total) appear to be present as a single complex at the vertices of the icosahedral particle and therefore do not have strict icosahedral symmetry. It has not yet been possible to resolve their structure or their interactions with the dsRNA in atomic detail. It is clear, however, that activation of the core associated enzymes in the presence of magnesium ions and nucleoside triphosphate (NTP) substrates causes conformational changes around the fivefold axis of the core and results in outward movement of VP3 and VP7, which allows opening of a pore in the VP3 layer at the fivefold axes (55). The mRNAs synthesized by the core-associated TCs are extruded through this pore, then pass out through the central space in the pentameric rings of VP7 trimers. There are also pores in the VP3 layer at the threefold axes, but in the intact core particle, these are completely blocked by the T trimer of VP7.

Much of the genomic RNA can also be detected by x-ray crystallography as electron density within the central core space. The dsRNA is highly ordered, and about 80% of the entire genome can be modeled as four distinct concentric layers that have center-to-center spacing between RNA strands of 26 to 30 Å (see Fig. 11C). As a consequence of the spacing of the A and B forms of VP3, the grooves in the inner surface of the subcore shell form a spiral around the fivefold axis. The outer dsRNA layer appears to interact with these grooves and can also be modeled as a spiral extending outward from the TC. It is uncertain how the RNA molecules pass inward to the next and subsequent concentric shells. The density detected in the inner layers of RNA gets progressively weaker, suggesting that its organization and icosahedral symmetry is progressively less rigid, although each layer maintains an overall spiral

organization (55).

REPLICATION

The replication cycle of orbiviruses has not been studied in detail. It is presumed that the basic features, including the transcription processes and the conservative mode of genome replication, are similar to those of reoviruses. Unlike reoviruses or rotaviruses, however, orbiviruses multiply in arthropods as well as in vertebrates. They are also structurally different, with protein components that bear little or no primary sequence similarities to those of the reoviruses or rotaviruses. In view of this, it is likely that some stages of the orbivirus multiplication and morphogenesis processes are unique. The overall information available on the BTV replication cycle and assembly has been generated primarily from immunoelectron microscopic studies and the use of baculovirus expression systems and is summarized in a schematic diagram (31,194) (Fig. 12). In the following subsections, the various steps of replication cycle of BTV and distinct features of the viral multiplication and assembly processes are reviewed and discussed.

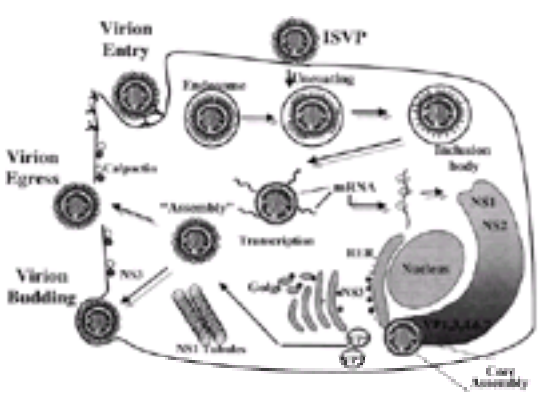

FIG. 12. Schematic diagram of an orbivirus replication cycle (deduced from bluetongue virus data).

Adsorption

Field isolates of orbiviruses often replicate poorly in cultured cells; however, most adapt readily to growth *in vitro* as reported by passage in embryonated chicken eggs or in varieties of cultured cells of mammalian and insect origins, including BHK-21, Vero, MDBK, HeLa, *Aedes* species, and *Culicoides* species cell lines (129,233).

BTV adsorbs rapidly to susceptible cells at both 4°C and 37°C, with the maximal adsorption occurring within 20 minutes (83). The cell receptors involved in orbivirus infection have not been identified, although some information is available suggesting their nature. In early studies, analysis of BTV–erythrocyte interactions indicated that the virus binds to a sialoglycoprotein, the glycophorin component of human and a number of animal erythrocytes (30). The binding to erythrocytes and vertebrate cells appears to be mediated by the BTV outer capsid protein VP2. Virion particles lacking VP2 but retaining the second outer capsid protein, VP5, exhibit a reduced capacity to bind to vertebrate cells (81). Using reassortants of BTV-20 (which agglutinates sheep erythrocytes only) and BTV-21 (which agglutinates sheep, bovine, human, or goose erythrocytes), it has been demonstrated that hemagglutinating ability segregates with VP2. ISVPs of BTV, from which the outer capsid has been modified by digestion with trypsin or chymotrypsin but not completely removed, also bind cells (131). In a recent study using a purified recombinant VP2 protein, it was demonstrated that VP2 alone is responsible for virus entry into mammalian cells and indeed is the viral hemagglutinin (67). Purified VP2 also had a strong affinity for binding to glycophorin A, confirming that VP2 is responsible for BTV transmission by the *Culicoides* species vector to vertebrate hosts during blood feeding. Further, by various enzymatic treatments of BTV-permissive mammalian cells, it has been shown that the BTV receptor molecule is likely a protein component of the glycoprotein; alternatively, a second protein molecule could also serve as a co-receptor for BTV infection of mammalian cells (67). In contrast, BTV-derived core particles bind efficiently to invertebrate cells (e.g., *Culicoides* species), but only at a low level to mammalian cells (133,239). BTV cores are highly infectious for invertebrate cells. The available data suggest that the RGD motif of VP7 is involved in the core entry mechanism for *Culicoides* species cell culture (148,200).

Entry and Uncoating

Like some reoviruses, BTV is subject to endocytosis after binding to a receptor on a cell plasma membrane through VP2 of the outer capsid (67). After invagination and detachment from the cell surface, a coated vesicle containing the virus is formed (31). The clathrin coat of this vesicle is rapidly lost, leading to the formation of a large translucent, endocytic vesicle (see Fig. 12). Shortly after infection, virions are found in vesicles in the vicinity of the nucleus. During these initial events, the morphology of BTV is probably drastically altered owing to degradation of VP2 and to an altered conformation of VP5. It seems likely that the C-terminal globular domain of VP5 molecule somehow attaches to endosomal membranes, allowing the extension of N-terminal coiled-coil domain, which is likely to destabilize the endosomal membrane (68). ithin 1 hour of infection, BTV is converted to core particles that appear to lack all the VP2 and most of the VP5 of the outer capsid layer (83). Removal of both outer capsid proteins appears to be required to activate the virion transcriptase, analogous to rotavirus transcription mechanism. In the cytoplasm, the partially or completely uncoated particles bind to the cell cytoskeleton (specifically the intermediate filaments) and initiate transcription of viral mRNA species (221).

Electron microscopy using a variety of detection procedures indicates that soon after the initiation of transcription, a matrix structure (similar to IBs) accumulates near the core and eventually spreads to surround it (81,90). These structures are probably formed by condensation of viral mRNA and newly synthesized viral proteins. Particles with bi-shelled morphology are often observed at the periphery of these matrix bodies beginning 6 hours after infection (88,89). It is

suggested that such progeny virus particles are assembled within or in juxtaposition to the IBs.

Transcription and Replication

In vitro, BTV mRNA synthesis can be activated by proteolytic digestion of the outer capsid of the virus (131,221,222 and 223). This facilitates access of NTPs to the genome within the core and the extrusion of the newly synthesized mRNA to the cytoplasm through the channels along the fivefold symmetry axes. The BTV transcriptase has a low *in vitro* temperature optimum of 28°C, lower than the 47° to 52°C optimum reported for reovirus transcriptase (103,225). However, BTV mRNA synthesis is efficient at 37°C, particularly at low core concentrations (223). The structural integrity of the core particle appears to be essential for maintaining an efficient transcriptional activity. Intracellular core particles eventually lose their surface VP7 layer to generate subcores that, at least *in vitro,* fail to transcribe RNA (83). It is noteworthy that the *in vitro* transcription activity of the core could be completely blocked by certain VP7 monoclonal antibodies (P.P.C. Mertens unpublished observation). Recent studies using individual recombinant proteins in *in vitro* assay systems have allowed delineation of specific roles of the proteins of the transcription complex within the core and the tentative cascade of RNA synthesis as shown in Figure 13. It appears that VP6 helicase unwinds the genomic duplex RNA molecules, whereas VP1 polymerase initiates the synthesis of positive-stranded RNA species from the 3' end of each negative-stranded RNA segment of the dsRNA molecule (172,199). It is not known, however, whether all the *de novo* RNA molecules are synthesized simultaneously or consecutively, or whether VP1 alone is sufficient for synthesis of positive-stranded RNA species on the newly generated negative strands. It is most likely that dsRNA templates are required for the synthesis of positive-stranded RNA species, and the RNA synthesis is more efficient when VP1 and VP6 are present as TC complex within the subcore. Nevertheless, it is accepted that the negative-stranded RNA species are synthesized from the 3' end of the positive-stranded RNA molecule, and VP1 alone is able to initiate the replicase activity. Once the positive-stranded RNA molecules are synthesized, the 5'-termini of these molecules are modified by the enzymatic activities of VP4. The class I methylated cap structure is formed solely by VP4, and thus both genomic positive-stranded RNAs and the 10 mRNAs possess the 5'-methylated cap structure (18,132,171). Various stages of RNA synthesis are depicted in Figure 13.

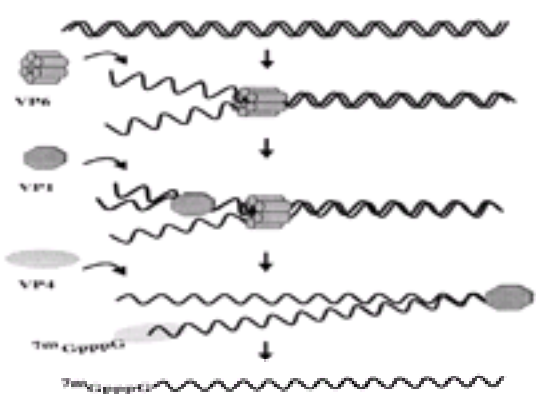

FIG. 13. Mechanisms of viral RNA synthesis and the role of each of the three minor proteins in RNA synthesis.

It is presumed that the overall strategy of orbivirus mRNA transcription is similar to that of reoviruses and rotaviruses. The mRNA species are capped and methylated during the transcription process. They are extruded from subviral particles into the cytoplasm and program the synthesis of virus proteins. The secondary structures of the mRNAs may facilitate mRNA egress from particles and may also contribute to the overall stability of the mRNA species within the cytoplasm of infected cells as well as to their interactions with ribosomal components for the purpose of translation.

The relative frequency of transcription of the respective genome segments remains unaltered during the course of infection (84). The transcripts are not produced at equimolar amounts for all 10 segments of BTV (84). The smaller genome segments are generally the most frequently transcribed, although M6 RNA (encoding NS1) is synthesized more abundantly than the smallest segment, S10 RNA (encoding NS3). The molar ratios of the 10 different BTV mRNAs appear to remain the same throughout the infection cycle. The ratios of mRNAs synthesized *in vivo* and *in vitro* are similar. Equivalent data have been obtained for other orbiviruses (76).

Nothing is known about the *in vivo* RNA replication mechanisms of orbiviruses. It is believed that like reoviruses and rotaviruses, the packaged positive strand serves as a template for synthesis of a negative strand, and once the negative strand is synthesized, it remains within the nascent progeny particle. As discussed previously, VP1 acts as the replicase enzymes, but the roles of other proteins in negative strand synthesis remain undefined.

Protein Synthesis

Infection of cells with BTV leads to a rapid inhibition of cellular macromolecular synthesis. Components of the infecting virion or its interaction with cellular structures may be involved in producing a cytotoxic effect. The first virus-specific polypeptides are detected 2 to 4 hours after infection, and the rate of protein synthesis increases rapidly until 11 to 13 hours after infection, after which it slows down but continues until cell death (84). Most proteins are synthesized throughout the infection cycle and accumulate during infection until cell lysis. In infected cells, VP6 is often resolved into two closely migrating bands in PAGE, one of which may be a modified form of the other (85,130). Recent data have shown that the two proteins are derived from initiation of protein synthesis at two distinct initiation codons in the S9 mRNA and not by posttranslation modification (226). The properties of the viral proteins were discussed previously (see Gene Coding Assignments and Virus Proteins).

Cytoskeleton in Bluetongue Virus–Infected Cells

During BTV infection of cells, a reduction in the number of microtubules occurs with some fragmentation of the microtubule network near the cell membrane. Microfilaments also change during infection (31).

The involvement of the cytoskeleton in BTV multiplication has been indicated by its close association with BTV antigens and virus-specific structures, including IBs, tubules, and 55-nm diameter, virus-derived particles (32). The 10-nm diameter filaments, rather than the 25-nm filaments, are involved. Analyses indicate that intermediate filaments probably provide sites for particle binding (32). Also, although most of the IBs are cytoskeleton associated, only some tubules are associated with the cytoskeleton (32,88).

Assembly

During infection, a fibrillar network develops around the infecting core particle in the cytoplasm. This resembles the IBs that are so pronounced later during the infection course. IBs are rich in mRNA and the phosphorylated NS2 protein (10,215). In addition, viral capsid proteins, such as core proteins VP3 and VP7, are also present in the IB matrix, indicating that this may be the assembly site of core particles either within or at the periphery of the IBs (88,90). By contrast, outer capsid proteins VP2 and VP5 are present either at the periphery of the IBs or at other locations (90). The presence of electron-dense virus-derived immature particles inside IBs has led to the belief that core particles may be synthesized within IBs and that the further stages of mature virion development occur either in the cytosol or after binding of the particles to the cytoskeleton. A hallmark of orbivirus infections is the presence of tubules throughout the cytoplasm (113). These tubules are of indeterminate length, contain no RNA, and appear to be empty. The tubules of each orbivirus appear to have distinct width and morphology, implying that they may have some specific role for each type of virus (78). NS1, which forms these tubules, is also found associated with corelike structures within IBs, implying that NS1 before multimerization may have certain roles in virus assembly. In BTV-infected cells, IBs, tubules, and intracellular particles are associated with vimetin-rich, intermediate filament networks of the cell cytoskeleton (31). The components requirements and temporal order of assembly of cores and virus particles have mostly been generated using baculovirus expression system in which VLPs and subviral corelike particles (CLPs) are produced by coexpression of certain BTV proteins (Fig. 14). The formation of CLPs and VLPs was neither dependent on the presence of the IBs or tubules nor on the other nonstructural proteins (NS3 proteins), the three minor proteins, or the dsRNA genome. The results from a series of studies could be summarized as follows: coexpression of VP3 and VP7 yields CLPs that are visually identical to authentic core morphology (see Fig. 14) (45,70). Generation of CLPs, combined with cryoelectron microscopy studies, revealed that of the 260 trimers, some 200 are tightly bound, with the remaining 60 trimers more loosely attached. In the absence of VP3, VP7 forms trimers, but these trimers do not assemble as particles. However, VP7 of certain orbiviruses (e.g., AHSV) can self-assemble to flat sheets of hexagonal rings (13). These rings are similar to the six-membered rings of VP7 trimers seen in the core surface layer. Similar assembled structures were seen in insect cells when AHSV VP7 was expressed by recombinant baculoviruses (15). In contrast, VP3 alone does assemble as icosahedral subcore-like structures (see Fig. 14, *lower panel*), but such subcores are relatively unstable, unlike the subcore structure formed by equivalent protein of the tick-borne BRDV orbivirus or of rotaviruses (146). Nevertheless, by low-resolution cryoelectron microscopy analysis, VP3 subcore exhibits similar organization of VP3 molecules (see Fig. 14), as seen by subsequent atomic structures of authentic VP3 within the core, indicating that VP3 is probably assembled first, and it serves a primary role in formation of the virus capsid (reviewed in 194). The VP7 layer not only provides increased rigidity and stability to the core particle but also can play a role in cell entry by the core and initiation of infection, particularly in insect cell systems (vector), as well as in protection against virus infection (227).

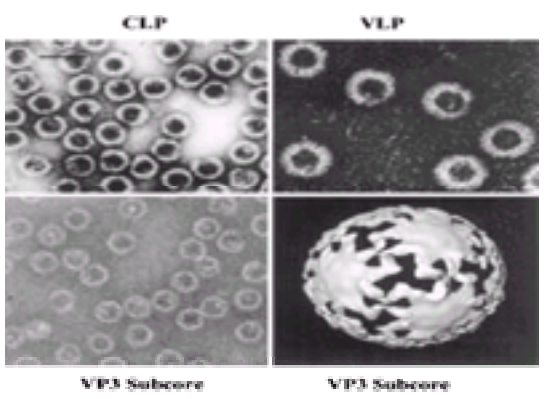

FIG. 14. Electron micrographs of baculovirus-expressed corelike particles (CLPs) and virus-like particles (VLPs) (*upper panel*). The appearance of expressed CLPs composed of VP3 and VP7 (*left*). The double-shelled VLPs containing VP2, VP3, VP5, and VP7 (*right*) (44,45). The *lower panel* shows images of spherical subcores (VP3 alone) in amorphous ice (*left*) and reconstructed inner shell only, with a cutoff radius of 28.2 nm (subcores), viewed down a twofold axis (*right*) (From ref. 70, with permission.)

Expression of BTV VP3 and VP7 in the presence of VP1, VP4, or VP6, or any combination of these, leads to the encapsidation of these minor proteins. After dialysis, they remain with the subcore, indicating that they interact specifically with VP3 (110,120). Further, high-resolution cryoelectron microscopy analysis (Fig. 15) indicates that the localization of TC within the core is highly specific.

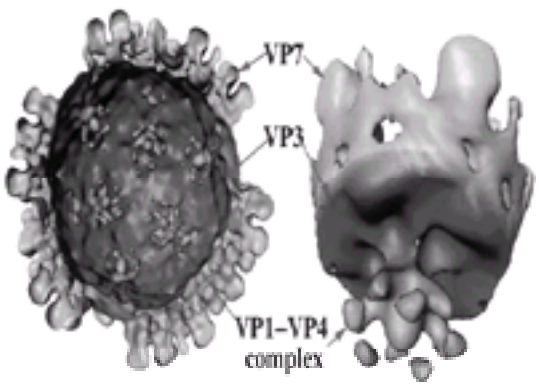

FIG. 15. High-resolution cryoelectron microscopy of corelike particles (CLPs) showing the localization of VP1 and VP4 within the CLPs. (Courtesy of B.V.V. Prasad, Baylor College, Houston, Texas.)

The combination of CLP assay and site-directed mutagenesis has allowed mapping of the domains within VP3 and VP7 that are essential for core assembly even before availability of x-ray structure (110,211). For example, specific VP3 residues (methionine at amino acid 500, arginine at amino acid 502) have been shown to be crucial to core assembly. Similarly, the C-terminus, but not the N-terminus, of VP7 is essential for assembly of VP7 trimers onto the VP3 subcore. Other internal residues on VP7 are also identified that are either dispensable or essential for protein–protein interactions during core assembly (110). In addition, by making domain-switched chimeric VP7 molecules using BTV and AHSV, the regions and residues responsible for protein folding and oligomerization have been mapped, confirming the role of these residues on overall structure of the VP7 molecules and their role in virus capsid assembly (140).

Further, based on subsequent x-ray structure of VP7, an extensive range of targeted VP7 mutations have been generated that not only precisely identify the critical residue responsible for core assembly but also revealed that core assembly depends on the trimer formation and the overall precise shape of the trimers, which eventually generate tight lattice of 260 VP7 trimers within the core. The data also indicate that there is a clear sequential order of trimer attachment on VP3 scaffold. The T trimers, which are at the threefold axis of the icosahedron, act as nucleation, whereas P trimers that are farther from the threefold axis and near to the fivefold axis, are the last to attach (117).

In contrast to assembly of VP7 trimers on VP3 subcore, nothing is known about how and in what order the viral genome and the three minor proteins interact with each other to form the innermost core structure in association with VP3.

Once the stable core is assembled, the two outercapsid proteins VP2 and VP5 are acquired by interaction with the core surface, both proteins being attached to the VP7 layer of the core. The assembly of VP3, VP7, or VP5 and VP2 is easily mimicked both by baculovirus expression systems and by the *in vitro* transcription-translation system (see Fig. 14) (44,110,118,120). The 3D reconstruction of these VLPs showed an icosahedral structure of 86-nm diameter with essentially the same features as for the native BTV virus particles (72). After VP2 and VP5 are attached, the particles are no longer transcriptionally active. Instead, they are available for release from the infected cell.

VLP technology has also given an opportunity to determine the structural compatibilities of VP2 and VP5 of various BTV serotypes (119). When assembled particles were examined, it was clear that despite the high level of sequence variation among the different serotypes, the VP2 and VP5 proteins of different BTV serotypes formed VLPs with the VP3 and VP7 of another source (119). Some combinations (e.g., the VP2 of BTV-2 and the VP5 of BTV-10) did not form VLPs, suggesting that VP2 may require the VP5 of the same or a closely related serotyping (e.g., BTV-10 or BTV-17) but may not form VLPs efficiently with the VP5 proteins of a more distant serotype.

Although the viral proteins have an intrinsic ability to self-assemble, a specific mechanism must exist for the recognition and incorporation of mRNA species and their use to generate dsRNA. This may involve the virus-induced nonstructural proteins (e.g., NS2), the core proteins, and particular sequences and structures of the viral RNA species themselves. It is hypothesized that the viral mRNA species are selectively assembled so that particles each acquire all 10 mRNA species. The role of the NS2 protein, which binds ssRNA but not dsRNA, may be crucial to the success of encapsidation. The conservation of the terminal regions of the mRNAs may be of relevance to the question of their recruitment to the sites of particle morphogenesis and encapsidation into cores and eventually virions.

Release of Virions

The mechanism whereby BTV is released from infected cells has been the subject of some speculation and appears to depend on the cell type. In most vertebrate cell cultures, a high proportion of virus remains cell associated, although some may appear in the culture medium after cell death and subsequent lysis. However, other mechanisms are operative for virus release as shown by infection of MDBK cells with BTV-8. In this system, by 4 to 5 hours after infection, progeny virions are released, well before cell (23). Such a process is more pronounced in insect cell cultures, such as *Culicoides* species or *Aedes aegypti*–derived C6/36 cells.

Virus particles have been observed to leave infected cells in either of two ways. First, particularly early in infection, particles can be seen to bud through the cell membrane and acquire, at least temporarily, an envelope (10,31,34). However, no virus antigen has been detected so far at the surface of such enveloped particles. Second, egress of virus particles from infected cells is accomplished by a process of extrusion in which individual or groups of virus particles move through a locally disrupted plasma membrane (89). This appears to happen without a significant effect on host cell viability. Both types of particles have been observed to be released at least from certain cell surfaces infected with BTV as discussed previously (89). The nonstructural, NS3 protein has been identified at the sites of the plasma membrane where virus particles leave, suggesting a role for this protein in this process (89). In contrast to mammalian cells, in

Culicoides species or C6/36 cells, where NS3 is synthesized at a significant level (in comparison to the mammalian cells), more than 90% of particles are released in the culture medium (13,65) (Fig. 16). Released particles and those remaining on the cell surface often appear to retain an association with an underlying cortical layer of the cell cytoskeleton (89).

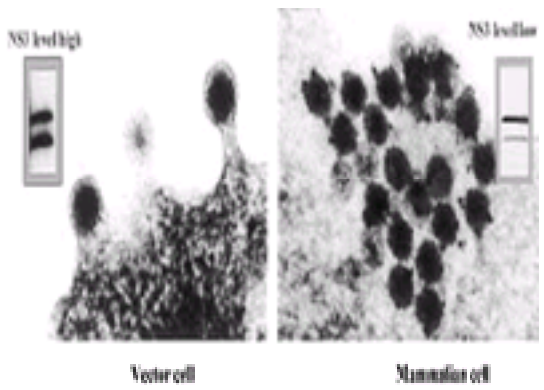

FIG. 16. Electron micrograph of two types of cells infected with bluetongue virus and expression level of NS3 and NS3A in these cells.

The involvement of NS3 in virus release had been further substantiated by an elegant study using recombinant baculoviruses expressing VLPs and NS3. The data demonstrated that VLPs are generally associated with the cell cytoskeleton upon ssembly. However, assembled particles were released from infected cells in the presence of the recombinant NS3 proteins (92). Thus, clearly, NS3 proteins are required for budding and subsequent release of VLPs and BTV particles from infected cells. The current hypothesis is that NS3 mediates virus release through the cellular exocytic pathway.

GENETICS AND ORBIVIRUS EVOLUTION

Because of their segmented genomes, and depending on genetic compatibility, orbiviruses may reassort their genes during co-infection. This has been analyzed using both wild-type and temperature-sensitive (ts) mutant viruses, although unlike with reoviruses and rotaviruses, only limited studies have been carried out with orbivirus ts mutants. Reassortants have been widely used to define the gene coding assignments and the biologic functions of the viral proteins (19,20,102,145,156). The opportunities for virus evolution by a step-wise process of reassortment as opposed to a process of drift through the accumulation of point mutations, deletions, and duplications are well known for a number of viruses with segmented genome (e.g., arenaviruses, bunyaviruses, orthomyxoviruses, certain plant viruses, and members of the *Reoviridae* family).

Reassortment Capability and Genetic Diversity of Genome Segments

High-frequency genome segment reassortment between different but compatible orbiviruses has been demonstrated not only in the natural vertebrate and invertebrate hosts but also in tissue culture systems (16,52,102,124,151,153,154 and 155,158,176,177,196,203,206). For BTV, experimentally generated reassortment in insect vectors (e.g., *Culicoides variipennis*) is reportedly higher (42%) than in a vertebrate host (e.g., 5% in sheep) (196). Genome segment reassortment may be an important factor in the generation of genetic diversity in orbivirus populations in nature.

It is believed that many field isolates of orbiviruses consist of mixtures of RNA segments from populations of virus strains. When virus was recovered from a BTV outbreak in Washington State and fingerprinted, it exhibited a mixed population of RNA segments, representing both BTV-10 and BTV-11 serotypes, the two circulating viruses of that region (17). Similarly, BTV isolates from *Culicoides* species vectors have been shown to have mixed populations of genome segments from two BTV serotypes (176). Another feature of natural orbivirus infections is that multiple serotypes of the same serogroup or different serogroups (e.g., BTV and EHDV) have been recovered from individual hosts (152,157,204), indicating that antigenically distinct viruses can be present in a single host. Under optimized conditions in tissue culture systems, reassortment between compatible serotypes occurs at such a high frequency that the parental viral genotypes are present as only a minority of the progeny virus population.

The coding assignment for certain genome segments of BTV and Kemerovo serogroup viruses were initially determined using reassortant viruses (64,102,130,142,165). In addition, reassortant analysis has been used to study genes that affect virus virulence in the Kemerovo serogroup and the genes involved in virus neutralization (151,153,155). Similar studies involving BTV and AHSV serotypes have also been reported (14,156).

Although reassortment has been demonstrated within orbivirus serogroups (e.g., Wallal, Kemerovo, and BTV, as discussed previously), no evidence has been obtained for reassortment between members belonging to different orbivirus serogroups.

Studies of the genetic diversity and variation in RNA segment sequences within a serotype have been determined, initially by using RNA oligonucleotide fingerprint analyses of BTV field samples and more recently by using cDNA cloning or polymerase chain reaction (PCR) (reviewed in 188,192, and 193). For example, genotypic variation of BTV-11 isolates obtained in the same year (1973) and from different regions of the United States, or from the same region (e.g., Colorado) but in different years (1963 to 1975), have been reported. The results indicated that although all the BTV-11 isolates were related, albeit to various extents, to the United States prototype BTV-11 strain, all showed some sequence differences, indicating that considerable evolution of the BTV-11 genome has occurred in the United States (207). In

summary, both genetic drift and genetic shift contribute in orbivirus evolution.

Genetic Relationships Within Serogroups

P>In early studies, hybridization techniques were applied to determine the genetic relationship of the dsRNA genome segments between different orbivirus serotypes, in particular for BTV (77,179,190). The results of such studies showed that the L2 and M5 segments (encoding the two outer capsid proteins) exhibited little or no cross-hybridization between serotypes, whereas studies of the other eight RNA segments, which gave strong hybridization signals, indicated that they were more conserved. Of these eight segments, some segments gave stronger cross-hybridization signals than did others. For example, cross-hybridization with M6 and S8 that code for two nonstructural proteins (NS1 and NS2, respectively) were usually the strongest, indicating that these two genes are highly conserved across the serotypes. The S7 segment appears to be less well conserved among BTV serotypes than were the remaining segments that code for core proteins. Apart from the S10 segment of AHSV, which appears to be more variable than that of BTV (25,224), similar results have been obtained for AHSV.

Although the available data suggest that the BTV serotypes evolved from a common ancestor, the gene pools of viruses on different continents may have diverged significantly (reviewed in 52 and 192). This may reflect the accumulation of mutations and reassortment and coevolution of gene pools at different locations, such as the Far East, Australia, Africa, or North America. It has been proposed that the term *topotype* should be applied to each distinct group (58). Cross-comparisons using PCR and RNA sequence data indicate that BTV isolates can be grouped within a single topotype if their L3 segments show less than 8% sequence difference. For BTV or EHDV strains that contain greater than 11% but less than 23%, variants can be grouped within different topotypes (58).

Phylogenetic Relationships Between Different Serogroups Based on Sequence Analyses

Although relationships between viruses from different serogroups cannot be assessed by cross-hybridization techniques, phylogenetic relationships can be assessed by cDNA and protein sequence analyses of corresponding genes of different orbiviruses. By such means, a close genetic relationship has been demonstrated among BTV, EHDV, and AHSV (Fig. 17). Sequence comparisons indicate that VP3 is the most conserved protein, whereas VP2 is the most variable (see Table 4 and Table 5). Some 57% to 58% of the aligned BTV-10 and EHDV-1 VP3 amino acids are identical to those of AHSV-4 VP3. This compares with an identity of 79% between the BTV and EHDV VP3 sequences. For the VP7 proteins, 64% of the aligned amino acids of BTV-10 and EHDV-1 are identical, whereas 44% to 46% of amino acid residues are identical to the aligned AHSV-4 sequence (95,96,187,193). As expected, the VP2 proteins of the three viruses are only 17% to 23% identical. However, various other comparative analyses of the proteins indicate that the VP2 species of the three orbiviruses are similar. Unlike VP2, the other outer capsid protein VP5 is more conserved among the three viruses. On alignment, the AHSV-4 VP5 is 42% to 45% identical in amino acid sequence to VP5 proteins of BTV-10 and EHDV-1 (193,237). The identity between BTV and EHDV VP5 is 62% (95,96). Clearly, these viruses share strong phylogenetic relationships.

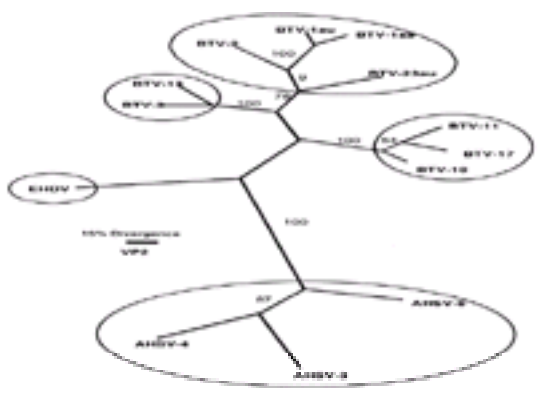

FIG. 17. Phylogenetic relationships of gnat-transmitted orbiviruses based on the VP2 sequences of different African horse sickness virus (AHSV), bluetongue virus (BTV), and epizootic hemorrhagic disease virus (EHDV) serotypes. An unrooted maximal likelihood tree for the VP2 protein data is shown, with branch lengths proportional to the number of amino acid changes. The BTV serogroup is illustrated as a monophyletic group of viruses with 100% bootstrap support and maximum parsimony branches as indicated by values above branches. (Modified from ref. 141, with permission.)

PATHOGENESIS AND DISEASE

Orbiviruses produce a spectrum of consequences from infection, reaching from severe and fatal disease to subclinical infection, depending on virus or host strain. Virus is transmitted to vertebrate hosts through blood-feeding insect vectors, and infectious particles migrate to lymph nodes where they initially replicate and subsequently spread to spleen, thymus, and other lymph nodes, becoming associated with circulating blood cells, where virus may persist for weeks or months (reviewed in 4 and 122). A distinct feature of orbivirus infections is their capacity to induce prolonged cell-associated viremias in vertebrate hosts, including both the species involved in virus transmission cycles and clinical hosts (122,138,205).

Prolonged bluetongue viremias are particularly notable in cattle, which thus serve as virus reservoirs. After experimental inoculation of calves, infectious virus can be detected for up to 8 weeks, and viral nucleic acid can be detected in erythrocytes for up to 20 weeks (122). BTV has been shown to bind to glycophorins on the surface of bovine and ovine erythrocytes (30), where it may remain as invaginations of the erythrocyte cell membrane in an infectious state for prolonged periods, possibly for the life time of the red blood cell (11). The location of orbiviruses in erythrocyte

membrane invaginations precludes contact with antibody and T cells and protects against immune elimination, thus providing multiple opportunities for infection of blood-sucking midges over an extended time period.

The role of leukocytes in cell-associated viremias is less certain. BTV has been recovered from bovine mononuclear cells during the early stage of infection (4,205,234). However, active replication of virus in these cells appears to be restricted to proliferating cells. *In vitro* studies of bovine lymphocytes have shown multiple subpopulations to be susceptible to infection (201). Helper T-cell subsets replicate BTV to high titer and undergo cytopathic infection, whereas T-cytotoxic suppressor and null cells become persistently infected without lysis. Monocyte-macrophages appear to be targets for infection with AHSV.

Most orbiviruses are neurovirulent in infant mice or hamsters inoculated intracerebrally, and some viruses are neuroinvasive and neurovirulent after parenteral inoculation. Susceptibility decreases with advancing age, and fetal animals are the most sensitive to infection. Neurovirulence of BTV strains for bovine fetuses correlated with neuroinvasiveness in mice (230). Kemerovo complex viruses occasionally produce meningoencephalitis in humans (141).

Another feature of orbivirus pathogenesis appears to be the ability of viruses to replicate in and to damage endothelial cells, with tropisms for cells representing distinct anatomic sites. This phenomenon has been demonstrated in animals infected with BTV, EHDV, and AHSV (109,123,216). Infection of endothelial cells is followed by infection of vascular smooth muscle cells and pericytes, which undergo lytic infections, resulting in virus-induced vascular injury and a cascade of pathophysiologic events characterized by capillary leakage, hemorrhage, and disseminated intravascular coagulation. Clinically, these events are manifested by mucosal edema, hemoconcentration, pulmonary edema, hydrothorax, hydropericardium, serosal hemorrhages, other hemorrhagic and thrombotic phenomena, hypotension, and shock (reviewed in 163 and 164). A curious feature of BTV infections in sheep is hemorrhage at the base of the pulmonary artery. The differential susceptibility of endothelial cells to BTV infection also may explain markedly distinct features of pathogenesis in sheep and in cattle. Generally, sheep develop potentially fatal hemorrhagic disease and have extensive endothelial cell infections, whereas cattle typically develop subclinical infections and have only minimal endothelial infections (38,122,163,164). Thus, BTV and other related orbiviruses such as AHSV and EHDV in their respective large animal hosts have pathophysiologic features resembling other viral hemorrhagic fevers.

Congenital infection is a feature of orbiviruses in ruminant species. Infection of pregnant cattle and sheep with BTV or EHDV can result in fetal infection, abortion, or congenital anomalies (99,121,122,159,163,164,248). A variety of anomalies have been reported, including runting, blindness, deafness, hydranencephaly, arthrogryposis, campylognathia, and prognathia. Although wild-type BTV infection of pregnant ewes can lead to maternal death, abortion, and fetal death, a number of studies have implicated live attenuated BTV vaccines as a principal cause of teratogenesis (99,163,248). Congenital BTV infection occurring in late gestation usually does not result in congenital anomalies, although newborn animals may circulate low levels of virus in their blood and have delayed immune responses. The interval between maternal infection and last detectable viremia in offspring has been as long as 20 weeks, suggesting a mechanism for long-term survival of BTV. However, such congenitally infected animals eventually clear the infection and are not immunologically tolerant or persistently infected (122). Congenital infection of calves with Kasba (Chuzan) virus, a Palyam group virus, results in a syndrome of hydranencephaly and cerebellar hypoplasia, distinct from BTV disease (54). Palyam group viruses also cause arthrogryposis and other malformations in the animal model, such as chicken embryos, similar to those seen in BTV-infected ovines (235).

As for other viral infections, orbivirus pathogenesis is influenced by a variety of host factors, including age, genetics, immunologic function, and other underlying diseases (38,39,109). Some of the key features (Table 6) of orbivirus disease are summarized later. For detailed information, see other reviews (3,38,231).

Genus	Serogroup	Disease hosts	Syndrome	Geographic distribution
Orbivirus	African horse sickness	Equidae, zebra, dog	Cardiopulmonary disease, hemorrhagic fever	Africa, Middle East, Asia, Europe
	Bluetongue virus	Sheep, cow, goat, deer	Rhinitis, stomatitis, coronitis	Africa, Asia, Australia, Americas
	Changuinola	Human	Febrile illness	Panama
	Epizootic hemorrhagic disease	Deer	Similar to bluetongue	Americas, Australia, Africa
	Equine encephalosis	Cow, horse	Similar to bluetongue, encephalitis	Asia, Australia, Japan, South Africa
	Kemerovo	Human	Febrile illness, encephalitis	Russia
	Lebombo	Human	Febrile illness	Africa
	Palyam	Cow	Abortion, congenital anomalies	Japan, South Africa
	Orungo	Human	Febrile illness	Africa
Coltivirus	Colorado tick fever	Human	Febrile illness (encephalitis, hemorrhagic fever)	China, Europe, North America

TABLE 6. *Orbiviruses and coltiviruses that cause disease in humans and domesticated animals*

African Horse Sickness

African horse sickness (AHS) differentially affects members of the Equidae family; horses are the most susceptible, and donkeys and mules show mild symptoms. Laboratory adopted AHSV may cause disease in dogs and humans (141). Zebras, which are thought to be the only indigenous animal known to act as a natural reservoir for the virus, exhibit viremia but do not manifest clinical signs of infection. The disease caused by AHSV was first recognized as a distinct entity after the introduction of horses into Central Africa in 1569 (39). In South Africa, AHSV caused outbreaks as early as 1719 and gradually was introduced to other areas of sub-Saharan Africa, demonstrating its wide geographic distribution (39). From time to time, AHS has spread beyond its usual distribution, causing devastating epizootics in many countries, including the Middle East, Pakistan, Afghanistan, India, North Africa, and the Iberian Peninsula, due to

importation of infected animals (e.g., zebra into Spain in 1987).

There are four recognized forms of the disease in horses, reaching from a 100% mortality rate to mild symptoms. The *pulmonary form* is characterized by a short incubation time of 3 days with death occurring (100% mortality rate) 2 to 4 days after the initial symptoms. A body temperature of up to 41°C, dyspnea, paroxysms of coughing, and discharge of frothy fluid from the nostrils are the main clinical signs. Edema of the head and neck and bulging of the supraorbital fossae can also be seen. This form of the disease is most common in outbreaks in susceptible animals. In the *cardiac* or *subacute edematous form*, initial symptoms include fever and edema of the neck, supraorbital fossae, eyelids, lips, cervical and sternal regions, and ventral abdomen. The incubation period is 7 to 8 days with 63%. The cardiac form of AHS is usually common in horses in enzootic areas. The *mixed form* is an intermediate form of the pulmonary and cardiac disease. *African horse sickness fever*, the mildest form of disease, is characterized by a 10-day incubation period, with high temperature (40.5°C for 1 to 3 days), but 100% recovery. This form of the disease is typical within enzootic areas.

Bluetongue

Bluetongue disease was first detected in South Africa as early as 1900 and subsequently spread to all parts of sub-Saharan Africa where nonindigenous breeds of sheep were introduced (38). In the 1940s, the disease was recognized to occur outside of Africa (in Cyprus and in North America), and in the 1950s, it appeared in Israel, the Iberian peninsula, and the Indian subcontinent (38). It is now clear that BTV is present on all continents, except for Europe, where it has been periodically introduced but has not persisted. Sheep, white-tailed deer, and pronghorn antelopes infected with BTV may develop severe disease as discussed previously, whereas cattle generally experience asymptomatic or only mild infection (38). Cattle sustain prolonged viremias and thus serve as silent hosts. The expression of clinical signs in sheep depends on the strain of virus, breed of sheep, and possibly other factors; attack rates have been as high as 80%, with mortality rates as high as 50%.

Epizootic Hemorrhagic Disease of Deer and Ibaraki Virus Disease

Epizootic hemorrhagic disease of deer was recognized clinically in North America in the 19th century. In 1955, a virus was recovered from white-tailed deer during an epizootic in New Jersey, and the following year a distinct virus (EHDV serotype 2) was isolated during an outbreak in South Dakota. In 1974, EHDV was recovered from *Culicoides* species in Nigeria. EHDV causes disease in white-tailed deer in North America but is not pathogenic for cattle or sheep. However, a subtype of EHDV, named Kawanabe virus (138), was recovered from the brain of a calf with central nervous system signs in Japan in 1984. In 1959, an epidemic of a BTV-like disease affecting cattle in Japan was shown to be due to Ibaraki virus, a close relative of EHDV. Ibaraki virus also occurs in other Southeast Asian countries and in the Philippines (141).

Equine Encephalosis

This virus was first isolated in 1967 from South African horses with fatal peracute illness resembling AHSV (36). Outbreaks have been recognized in South Africa and are associated with infection by four of the seven serotypes known.

Palyam Group Virus Disease

Two orbivirus strains isolated from sentinel calves and *Culicoides oxystoma* in Japan in 1984 and 1985 were provisionally named Chuzan and Kagoshima virus respectively (138) but were later shown to be the same virus. Chuzan virus was subsequently implicated in an epizootic of congenital anomalies (hydranencephaly–cerebellar hypoplasia) in cattle in Japan in 1985 and 1986 (138). An inactivated, whole-virus vaccine is marketed in Japan against Chuzan virus disease. Recently, Chuzan virus was shown to be antigenically indistinguishable from Kasba virus, a Palyam group agent recovered from *Culex vishnui* mosquitoes in India in 1956 (101). Another member of Palyam virus group, Nyabira virus was recovered repeatedly from aborted cattle fetuses in Zimbabwe in the 1970s (208). The medical importance of this agent is presently uncertain.

IMMUNITY AND VACCINE

Orbivirus infection is followed by the appearance of neutralizing antibodies within 8 to 14 days (41). Antibodies also play a central role in protection against reinfection. There is a good correlation between the induction of neutralizing antibodies against the major outer capsid protein VP2 and protection of sheep against homologous challenge (80,191). Orbivirus infection also results in the production of antibodies to other structural and nonstructural viral proteins.

Infection of sheep and cattle with two distinct serotypes confers protection against other serotypes that had not been included in inoculum (205). Similarly, antibodies raised with a mixture of recombinant VP2 proteins of various serotypes not only neutralized the infectivity of the homologous strains but also cross-neutralized certain heterologous viruses (217). It is possible that cross-reactive epitopes exist on VP2, but other mechanisms may help to protect as well (see later).

In addition to neutralizing antibodies, cell-mediated immunity (CMI) also plays an important role in recovery from infection and protection against reinfection. Cytotoxic (CD8+) cells responsive to BTV antigen *in vitro* were demonstrated in blood of cattle and sheep during the first week of infection and peaked at 2 weeks (34). The role of CMI in protection against BTV infection was demonstrated in sheep that conferred protection on challenge with live virus (205). Lymphocyte stimulation by *in vitro* BTV antigens correlated with protection in these animals. Immunity was major histocompatibility complex (MHC) restricted and thus host specific. Further evidence for CMI in sheep was obtained by demonstrating cytotoxic T-lymphocyte (CTL) responses and protection of recipient twins by passive transfer of immune lymphocytes depleted of B cells (205). These data are also supported by *in vitro* studies. BTV antigen-specific ovine T-cell lines have been shown to become stimulated by a number of different BTV serotypes (210). Also, sheep vaccinated with recombinant BTV CLPs containing only VP3 and VP7 (without neutralizing determinants) were shown to cross-protect

against virulent virus challenge (98). However, the specificity and location of antigenic sites for T cells are still poorly understood. Studies of BTV in mice identified CTL responses that were principally cross-reactive, but other studies suggest that serotype-specific CTL responses may occur as well (202,205). Ovine T-cell lines established from sheep immune to BTV-1 showed serotype specificity and were directed against antigenic sites on the VP2 outer capsid protein (209), but other T-cell lines reacted with antigens localized on VP5 and inner core proteins. Antibody-dependent cell-mediated cytotoxicity may also play a role in protective immunity (202).

Using vaccinia virus recombinants that individually express each of the 10 BTV gene products, it has been shown that both the structural and nonstructural proteins are capable of inducing CTL responses (100). Further, CTL response mediated by NS2 appears to confer protective immunity in mice against challenged virus (100).

Despite the high morbidity and mortality associated with BTV and other orbiviruses, little attention has been given to developing efficacious vaccines for these viruses. The only vaccines that are currently used to protect against BTV and AHSV are live attenuated vaccines. Attenuated BTV vaccines have been developed by serial passage in embryonated chicken eggs; because of the plurality of serotypes (24 serotypes), multivalent vaccination has generally been used. Similarly, live virus vaccine for nine serotypes of AHSV has been developed in South Africa. Polyvalent live attenuated vaccines are presently produced in South Africa (37) and administered as two quadravalent vaccines consisting of serotypes 1, 3, 4, and 5 and serotypes 2, 6, 7, and 8. These vaccines are considered to induce cross-protective immunity to AHSV-9. Optimal immunity and protection from disease, however, is best provided by a serotype monospecific vaccine (109). This was recently demonstrated in an AHSV outbreak in Spain, where polyvalent vaccines failed to give protective immunity against AHSV-4, the serotype responsible for the disease (109). A commercial live attenuated virus vaccine against Ibaraki disease is also available in Japan. Problems associated with these live virus vaccine use include teratogenicity, insect transmission, interference by maternal antibody, and the potential for reversion and gene reassortment with wild-type viruses (232,248). Various whole-virus inactivated vaccines have been tested but are not yet available commercially.

Considerable clinical trials have been carried out in recent years with baculovirus-generated recombinant BTV proteins, CLPs, and VLPs (183,191). Initial studies involving unpurified VP2 and VP5 proteins of BTV-10 have demonstrated that VP2 alone at high doses (>100 µg/dose) could afford protection in sheep against virulent virus challenges, whereas much less VP2 was needed for complete protection when mixed with a low amount of VP5 (~20 µg/dose), suggesting that the two proteins are probably sufficient for vaccine development. Subsequently, baculovirus-synthesized VLPs consisting of VP2, VP3, VP5, and VP7 were used in vaccination trials with the rationale that VLPs are biologically and immunologically similar to virions and elicit high titers of neutralizing activity against the homologous and also heterologous BTV serotypes. The protective activities of VLP vaccination have been assessed in a number of vaccination trials in large numbers of susceptible Merino sheep. The data demonstrated that long-lasting protection against homologous BTV challenge could be achieved by vaccination with VLPs. Some cross-protection was also achieved depending on the challenge virus and the amounts of antigen used for vaccination (183).

VLPs are highly immunogenic, even at low doses. Sheep given only 10 µg of VLPs actually received only 1–2 µg of VP2 (10% to 20% of the VLP mass). This compared well with the much higher amounts required for VP2 alone or VP2 and VP5 mixtures in protection studies. There are several possible explanations. First, when assembled into VLP, the conformational presentations of the relevant epitopes on VP2 probably mimic those on the authentic virus. Second, both VP2 and VP5 are present. Third, any of the four BTV proteins might have a direct role in eliciting cell-mediated immunity induced by the BTV VLP.

The question of whether CLPs, containing only the two conserved proteins VP3 and VP7 would provide a measure of homologous and heterologous BTV protection was also investigated (98). The data obtained from clinical trails in sheep indicated that either partial protection (with only slight fever) or complete protection (depending on dose) against homologous and heterologous virus challenge was achieved by CLP vaccination. Animals showed strong group-specific antibody response but no neutralizing antibodies. Since CLPs are conserved across the various serotypes, CLPs could have potential for candidate vaccine, which may at least mitigate the bluetongue disease and inhibit the virus spread.

BTV CLPs and VLPs offer particular advantages as potential vaccines over more conventional systems. Large quantities of CLPs and VLPs can be produced as a result of the high-expression capabilities of baculovirus vectors (produced in serum-free medium) and can be purified using a one-step generic protocol based on the physical properties of the particle. More importantly, these particles are devoid of any detectable amount of insect or baculovirus proteins or nucleic acids and thus pose no potential adverse effects.

Baculovirus expressed subunit vaccines have also been generated for AHSV-4 in response to the recent outbreak of AHSV-4 in Europe (182). Insect cells infected with recombinant baculovirus expressing VP2 and VP5 were used for the vaccination of horses. These studies demonstrated that complete protection against AHSV infection occurred when horses were vaccinated with as little as 5 µg of recombinant AHSV-4 VP2. These trials have shown that vaccines based on synthesized recombinant proteins can give high immunogenicity while providing a safer alternative to modified live vaccines.

The immunodominant group-specific protein VP7, in the absence of other AHSV proteins, has also demonstrated its potential for use as a subunit vaccine. In a mouse model, T-cell immunity was shown to play an important role in the development of a protective immune response to AHSV in the absence of neutralizing antibodies. The results also demonstrated that a single inoculation of purified VP7 generated significant protection against a heterologous virus serotype (227).

In conclusion, both mixtures of recombinant proteins and multicomponent empty particles, such as CLPs and VLPs, have potential for development of efficacious and safe vaccines against orbivirus infections and disease.

COLTIVIRUSES

Coltiviruses, which have been isolated from ticks, mosquitoes, rodents, and humans, had previously been classified with the orbiviruses (42). However, viruses of this group have many distinctive features and have recently been recognized as a separate genus in the *Reoviridae* family (134). Only a brief account is presented here. To date, only three coltivirus serotypes are recognized. The type-specific virus, Colorado tick fever virus (CTFV), can cause a fatal human disease. It was originally isolated from ticks in North America. The other two serotypes, Eyach and S6-14-03 viruses, are not associated with human disease and show little, if any, cross-reaction in neutralization tests with CTFV. Published information concerning the molecular and genetic features of these viruses is limited.

The negatively stained coltivirus particles are about 80 nm in diameter with two capsids. The surface of the core has an icosahedral symmetry, although the overall structure appears to be slightly different from orbivirus cores by conventional electron microscopic analysis (147). Neither the capsid organization nor the protein components have been fully characterized. Unlike the genomes of orbiviruses, coltivirus genomes consist of 12 dsRNA segments with estimated sizes ranging from 2.53×10^6 to 0.24×10^6 daltons (total genome size about 18×10^6 daltons). All isolates of CTFV have similar dsRNA PAGE profiles. Their similarities have been substantiated by data obtained from hybridization studies (8,12). By such analyses, RNA segments 4 and 6 appear to be more variable than other segments, with RNA segment 6 exhibiting the highest degree of variation. By analogy with other members of the *Reoviridae* family, RNA segments 4 and 6, therefore, probably code for the outer capsid proteins of virions. Coltiviruses exhibit high frequency of RNA segment reassortment both in tissue culture and in tick vectors (12).

The coltivirus multiplication cycle and replication processes in cell culture have not been studied in detail. It is possible that they are similar to those of members of the *Orbivirus* genus because CTFV-infected cells are characterized by a large number of striated filaments equivalent to the orbivirus NS1 tubules as well as the presence of large numbers of inclusion bodies.

CONCLUDING REMARKS

Since the early 1990s, significant advances have been made in orbivirus research. The ability to synthesize CLPs and VLPs representing distinct stages in the virus life cycle in eukaryotic cells by the use of expression systems has opened up a novel approach for defining the mechanisms and steps involved in the intracellular protein–protein interactions that lead to virus assembly. The recent data on x-ray crystallographic structures of BTV core have revealed how a complex particle with multiple proteins at different molar ratio can be assembled. There is little doubt that expression systems, together with crystallographic data of various orbivirus proteins and the corelike structures that are now being prepared, will eventually allow a complete understanding of the virus capsid assembly process. The function of most of the structural and nonstructural proteins have also been defined, in relation to the replication cycle and virus particle assembly. These have been possible mainly due to the availability of highly purified individual proteins. However, some of the most intriguing questions, specifically, the packaging mechanism that encapsidates the exact number of 10 discrete RNA molecules into the newly synthesized viral capsid, remains elusive and a challenging problem, but this area too may yield to experimental systems in the near future. A reverse genetics system involving exact-copy BTV RNA transcript vectors and BTV protein expression vectors is under investigation. It is likely that such systems, in combination with assembled protein components in eukaryotic cells, will allow the dissection of the mechanism by which viral RNA species are incorporated into cores to serve as the viral genome. The opportunity then to build infectious BTV *de novo* from its component parts becomes very real and should allow a comprehensive analysis of many biologic properties of the orbiviruses.

CHAPTER 57 *Retroviridae*: The Retroviruses and Their Replication

Stephen P. Goff

The retrovirus family, the *Retroviridae*, consists of a large and diverse group of viruses found in all vertebrates. These viruses replicate through an extraordinary and unique life cycle, differentiating them sharply from other viruses. The virion particles generally contain a genomic RNA, but upon entry into the host cell, this RNA is reverse transcribed into a DNA form of the genome that is integrated into the host chromosomal DNA. The integrated form of the viral DNA, the provirus, then serves as the template for the formation of viral RNAs and proteins that assemble progeny virions. These features of life cycle—especially the reverse flow of genetic information from RNA to DNA, and the establishment of the DNA in an integrated form in the host genome—are the defining hallmarks of the retroviruses. This life cycle also accounts for many of their diverse biologic activities. The creation of the proviral DNA confers on the viruses a powerful ability to (a) maintain a persistent infection despite a host immune response, and (b) enter the germ line, permitting the vertical transmission of virus.

The retroviruses have played a unique role in the history of molecular biology. They have attracted attention on several grounds.

- Biochemistry: The viral replication enzymes, including the reverse transcriptase (RT) and integrase (IN), are extraordinarily useful tools in manipulating nucleic acids *in vitro* and *in vivo*. Through the preparation of cDNAs, RT has been crucial for studies of mRNA synthesis and gene regulation.
- Pathogenicity: Retroviruses are known as major pathogens affecting nearly all vertebrates. Human immunodeficiency virus type 1 (HIV-1), the agent of the acquired immunodeficiency disease syndrome (AIDS) pandemic, will probably cause more human death and suffering than all but a handful of pathogens in recorded history.
- Markers of evolutionary history: The insertion of a provirus into the germ line provides a Mendelian tag that marks an event at a particular time in evolution. The inheritance of that tag can then be used to follow speciation, migrations, and divergence of species.
- Insertional activation of oncogenes: The integration of retroviral DNA is inherently mutagenic, and retrovirus replication thus causes gross alterations of host genes. When insertions lead to tumor formation, the locations serve to identify new oncogenes.
- Transduction: Retroviruses can acquire host sequences in the formation of acutely transforming genomes. The identity, structure, and expression of these genes has provided much of our current knowledge of the routes by which normal growth control can be subverted by genetic alterations.
- Gene delivery vectors: The structure of transforming viruses provided a model for the use of retroviruses to deliver therapeutic genes efficiently and cleanly into cells. Retroviruses now serve as major tools in the medical black bag of gene therapists.

This chapter will describe the replication and molecular biology of the retroviruses, concentrating on the most broadly conserved aspects of the life cycle. Because of the magnitude of the retroviral literature, citations here cannot be comprehensive, and referencing has been selective and concentrated on more recent publications. The distinctive features of the human retroviruses, especially the lentiviruses and spumaviruses, will be addressed in much more detail in later chapters. A comprehensive review of retroviral biology [*Retroviruses* (130)] has recently been published and should be consulted for additional details of almost all aspects of their replication.

TAXONOMIC CLASSIFICATION

The retroviruses were originally classified by the morphology of the virion core as visualized in the electron microscope. Examples of the appearance of the virions in these micrographs are presented in Figure 1. The virion particles are spherical and surrounded by an envelope consisting of a lipid membrane bilayer. The surface is studded by projections of an envelope glycoprotein. There is a spherical layer of protein under the membrane, and an internal nucleocapsid (or nucleoid) whose shape varies from virus to virus. The shape and position of the nucleocapsid core was historically used as the major classifying feature of the retroviral genera. A-type viruses were defined as those forming intracellular structures with a characteristic morphology, a thick shell with a hollow, electron-lucent center. These particles are now appreciated as representing an immature capsid on route toward the formation of other structures. This term is thus no longer in use to denote a virus classification, although it is used to describe the structures formed by some virus-related intracellular retrotransposons (the intracisternal A-type particles, or IAPs) (400,444). B-type viruses show a round but eccentrically positioned inner core. C-type viruses assemble at the plasma membrane and contain a central, symmetrically placed, spherical inner core. The D-type viruses assemble in the cytoplasm, via an A-type intermediate, and on budding they exhibit a distinctive cylindrical core.

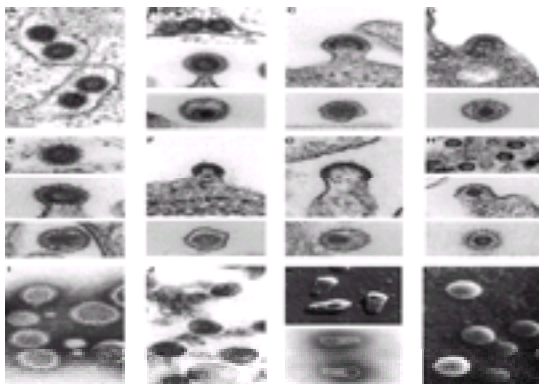

FIG. 1. Electron micrographs of representative virion particles. The diameters of all the particles are approximately 100 nm. **Panel A:** Type A particles. These older classifications have been useful in partially defining the various genera of the family *Retroviridae*, but the number of genera has now been increased on the basis of new criteria. The genera have recently been formalized and given new names by the International Committee on Taxonomy of Viruses. The alpharetroviruses, betaretroviruses, and gammaretroviruses are considered “simple” retroviruses, whereas the deltaretroviruses, epsilonretroviruses, lentiviruses, and spumaviruses are considered “complex.” The simple viruses encode only the Gag, Pro, Pol, and Env gene products; the complex viruses encode these same gene products but also an array of small regulatory proteins with a range of functions. The properties of the viruses belonging to each of these genera will be summarized briefly here. Representative members of each genus are listed in Table 1.

New name	Examples	Morphology
Alpharetrovirus	Avian leukosis virus (ALV) Rous sarcoma virus (RSV)	C-type
Betaretrovirus	Mouse mammary tumor virus (MMTV) Mason-Pfizer monkey virus (MPMV) Jaagsiekte sheep retrovirus (JSRV)	B-, D-type
Gammaretrovirus	Murine leukemia viruses (MuLV) Feline leukemia virus (FeLV) Gibbon ape leukemia virus (GaLV) Reticuloendotheliosis virus (RetV)	C-type
Deltaretrovirus	Human T-lymphotropic virus (HTLV)-1, -2 Bovine leukemia virus (BLV) Simian T-lymphotropic virus (STLV)-1, -2, -3	–
Epsilonretrovirus	Walleye dermal sarcoma virus Walleye epidermal hyperplasia virus 1	–
Lentivirus	Human immunodeficiency virus type 1 (HIV-1) HIV-2 Simian immunodeficiency virus (SIV) Equine infectious anemia virus (EIAV) Feline immunodeficiency virus (FIV) Caprine arthritis encephalitis virus (CAEV) Visna/maedi virus	Fullerene core
Spumavirus	Human foamy virus (HFV)	Immature

TABLE 1. *Retrovirus genera*

Alpharetroviruses

The alpharetroviruses are simple retroviruses characterized by a C-type morphology, and are typified by the avian leukemia viruses (ALV). The genome contains *gag*, *pro*, *pol*, and *env* genes, with no additional known genes; *pro* is at the 3' end of *gag* and in the ame reading frame. The tRNA primer is tRNATrp. The viruses are widespread in many avian host species. The ALV members are classified into 10 subgroups (termed A through J) by their distinct receptor utilization. The first four subgroups represent exogenous viruses of chickens; the subgroup E includes a family of endogenous chicken viruses; and subgroups F and G include endogenous viruses of pheasants.

Betaretroviruses

The betaretroviruses are simple retroviruses characterized by either a B-type morphology, with a round eccentric core, or a D-type morphology, with a cylindrical core. The best-known examples are the mouse mammary tumor virus (MMTV) and the Mason-Pfizer monkey virus (MPMV). Assembly occurs in the cytoplasm via an A-type intermediate, and the completed immature particle is then transported to the plasma membrane and budded. The genomes contain *gag*, *pro*, *pol*, and *env* genes, and the *gag*, *pro*, and *pol* genes are all in different reading frames. The genome of MMTV contains an additional gene termed the *sag* gene, for superantigen. The viruses also contain a dUTPase region as part of the *pro* open reading frame (ORF) (204). The tRNA primer is tRNALys-3 or tRNALys-1,2. There are both exogenous and

endogenous viruses in this genus. Examples are found in mice, primates, and sheep.

Gammaretroviruses

The gammaretroviruses are simple viruses characterized by a C-type morphology. This genus has the largest number of members known, including the murine leukemia viruses (MuLVs), the feline leukemia viruses (FeLVs), and the gibbon ape leukemia virus (GALV). The genome contains only *gag*, *pro*, *pol*, and *env* genes; the *gag*, *pro*, and *pol* sequences are in the same reading frame, and the Gag-Pro-Pol protein is expressed by translational readthrough of a stop codon at the end of *gag*. The genome primer is tRNAPro or tRNAGlu (132,514). The murine viruses are divided into subgroups by their distinct receptor utilization. Many exogenous and endogenous viruses are found in diverse mammals, and examples have been isolated from reptiles and birds.

Deltaretroviruses

The deltaretroviruses are complex viruses characterized by a C-type morphology. The most famous examples are the human T-lymphotropic viruses (HTLVs) and the bovine leukemia virus (BLV). The genome contains *gag*, *pro*, *pol*, and *env* genes; the *gag*, *pro*, and *pol* genes are present in three different reading frames, and expression of the Gag-Pro-Pol protein requires two successive frameshifts. In addition, the genomes contain regulatory genes termed *rex* and *tax* that are expressed from an alternatively spliced mRNA. These gene products control the synthesis and processing of the viral RNAs. The tRNA primer is tRNAPro. No closely related endogenous viruses are known, and the exogenous viruses are only rarely found in a few mammals.

Epsilonretroviruses

The epsilonretroviruses are complex viruses characterized by a C-type morphology. The prototype is the walleye dermal sarcoma virus (469). The genomes contain *gag*, *pro*, *pol*, and *env* genes; the *gag*, *pro*, and *pol* genes are in the same reading frame. They also contain one to three additional genes termed *orfs A, B,* and *C*. The *orfA*gene is a viral homolog of the host cyclin D gene and so may regulate the cell cycle (410). The viruses use tRNAHis or Arg as the primer. The only known examples are exogenous viruses in fish and reptiles.

Lentiviruses

The lentiviruses are complex viruses characterized by a unique virion morphology, with cylindrical or conical cores. The most important example is HIV-1, but nonprimate viruses in the genus include the caprine arthritis encephalitis virus (CAEV) and visna virus. The genomes express *gag*, *pro*, *pol*, and *env* genes; *gag* is in one reading frame, and *pro-pol* in another. A single frameshift is used to express Gag-Pro-Pol. The Pol region of the nonprimate lentiviruses includes a domain for deoxyuridine triphosphatase (dUTPase). A number of accessory genes are also expressed. In HIV-1, these genes are *vif*, *vpr*, *vpu*, *tat*, *rev*, and *nef*; these genes control transcription, RNA processing, virion assembly, host gene expression, and a number of other replication functions (150). The tRNA primer is tRNALys1,2. A large number of exogenous viruses in this genus have been found in diverse mammals, but the only endogenous sequences are relatively distant from these viruses.

Spumaviruses

The spumaviruses are complex viruses with a unique virion morphology, containing prominent spikes on the surface and a central but uncondensed core. The prototype example is the human foamy virus (HFV). The virion is assembled in the cytoplasm and budded into the endoplasmic reticulum (ER) and the plasma membrane. There is probably only a single cleavage of the Gag protein near the C-terminus (797), and no major change in morphology during maturation. The genomes express *gag*, *pro*, *pol*, and *env* genes, and also at least two accessory genes known as *tas*/*bel-1*, and *bet* (242,483). The *tas* gene encodes a transcriptional transactivator. Unique features are the separate expression of the Pol protein from a spliced mRNA and the presence of large amounts of reverse transcribed DNA in the virion (493). The genome contains a second transcriptional start site near the 3' end of the *env* gene. The tRNA primer is tRNALys1,2. A number of exogenous viruses have been found in diverse mammals, and distantly related sequences are present as endogenous elements in the human genome (141).

Evolutionary Relationships

The sequences of the various retroviral genomes have been compared and used to determine the relatedness of any pair (475). A number of phylogenetic trees can be constructed using *gag*, *pro*, *pol*, or *env* genes, and in most aspects these trees are similar. A tree based on comparisons of the *pol* gene (Fig. 2) shows the clustering of viruses within each of the main genera. However, it is important to realize that a phylogenetic tree is not necessarily identical to an evolutionary history, and that the history that led to the formation of the known genera is not necessarily simple. It is noteworthy that there is no obvious clustering of all the simple viruses into a group apart from all the complex viruses. Thus, complex viruses probably arose from the simple ones more than once, with many evolving through the independent acquisition of separate genes.

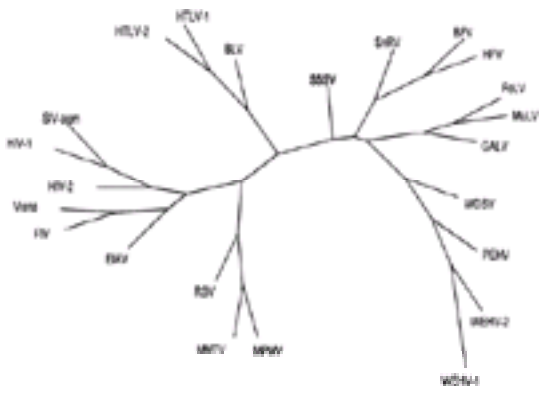

FIG. 2. Phylogenetic relationships within the retrovirus family. An unrooted neighbor-joining phylogenetic tree, constructed with the PHYLIP package based on an alignment of the amino acid residues of reverse transcriptase genes of several retroviruses (777). (Provided courtesy of S. Quackenbush and J. Casey.)

The retroviruses are related to viruses of other families. The retroviral RTs show close sequence similarity to the polymerases of the hepadnaviruses and the caulimoviruses, which also replicate by reverse transcription. The retroviruses also show extensive similarity in both *gag* and *pol* gene sequences to the retrotransposons, endogenous mobile elements with long terminal repeats (LTRs), and to retroposons, elements without LTRs. Retroviral RTs show more distant similarity to the group II mitochondrial introns; to the retrons, elements in myxobacteria and rare isolates of *Escherichia coli*; and to telomerase, an RT responsible for maintenance of the chromosomal termini in eukaryotes; and they show a slight similarity to the DNA polymerases of viruses and hosts (474).

Transforming Viruses

During the replication of any retrovirus, replication-defective variants can arise through deletion or recombination events. Such mutants or variants can be propagated as a mixed virus culture along with the wild-type parent. In these mixtures of two genomes, the replication-competent parent acts as a helper virus to provide the missing replication functions in *trans* for the replication-defective transforming virus. In extremely rare events, the genomes of a replication-competent virus can acquire novel host sequences that provide significant new biologic activities to the virus. If the new gene product is mitogenic or antiapoptotic for the host cell, or in more subtle ways alters the growth of the cell, the recombinant may become a potent oncogenic virus. A large number of such transducing viruses have been isolated and characterized as derivatives of one or another of the replication-competent parent viruses. In each case, the morphology and host range of the virus is determined by the helper virus that provides the replication functions to the defective genome. A partial listing of the most intensively studied of these viruses is presented in Table 2.

Parental virus	Transforming virus	Transduced gene
Avian leukosis virus (ALV)	Rous sarcoma virus	v-*src*
	Avian myelocytomatosis virus	v-*myc*
	Avian erythroblastosis virus	v-*erbA,B*
	Avian myelocytomatosis virus 29	v-*myc*

Simian sarcoma-associated virus	Woolly monkey sarcoma virus	v-*sis*

TABLE 2. *Examples of acute transforming retroviruses*

VIRION STRUCTURE

Retrovirus virions are initially assembled and released from infected cells as immature particles containing unprocessed Gag and Gag-Pol precursors of the proteins that eventually make up the mature virus. The immature virion morphology is spherical, with a characteristic electron-lucent center. The virions have been described as a protein vesicle, to suggest some fluidity in the interactions between the individual Gag proteins that make up the particle. At maturation, the precursor proteins are cleaved, and the structure and morphology of the virion changes drastically (784). The mature retrovirus particle is a spherical structure, roughly 100 nm in diameter. The size of the virions in a given preparation is not highly homogeneous but rather varies over a fairly wide range, suggesting that a discrete, highly ordered structure may not exist. After processing of the Gag precursor during virion maturation, the capsid (CA) protein collapses to form a more ordered paracrystalline core, but even then the overall diameter of the virion is heterogeneous and suggestive of considerable disorder. The virions exhibit a buoyant density in sucrose in the range of 1.16 to 1.18 g/mL. The sedimentation rate of the particles is typically about 600 S. The virions are sensitive to heat, detergent, and formaldehyde.

Virion Proteins

The stoichiometry of the various viral gene products in the virion are not very firmly established, but estimates suggest that about 1,500 to perhaps 2,000 Gag precursors are present per particle. After processing, all cleavage products are

thought to be retained, suggesting equimolar presence of these proteins in the mature virions. The levels of the Pol proteins are typically about 1/10 to 1/20 of the Gag proteins, corresponding to about 100 to 200 molecules per virion. The levels of the Env proteins are quite variable among the viruses. For the gammaretroviruses, the levels of Env are close to that of Gag; perhaps 1,200 monomers, or 400 trimers, are present per virion. For the lentiviruses, the levels of Env per virion are much lower, possibly as low as 10 trimers per virion.

Nomenclature

The cleavage of Gag, Pol, and Env precursors forms the products in the mature infectious virions. These proteins are named by convention by a two-letter code: MA for matrix or membrane-associated protein, CA for capsid, NC for nucleocapsid, PR for protease, DU for dUTPase, RT for reverse transcriptase, IN for integrase, SU for surface protein, and TM for transmembrane protein (416). The localization of these proteins in the mature virion is not known with great precision, but a highly schematic version of the generic retrovirion can be drawn (Fig. 3).

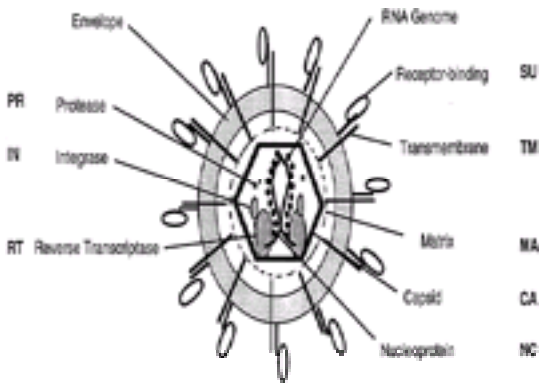

FIG. 3. Generalized retrovirion structure and components. A highly schematic view of the arrangement of viral gene products within the virion particle. The two-letter nomenclature for each protein is indicated.

Arrangement of Virion Components

The genomic RNA is highly condensed in the virion by its association with the nucleocapsid protein, NC. The complex is contained within a protein core largely composed of the CA protein, another *gag* gene product. The shape of the core differs among the various retroviral genera, and indeed it is a distinguishing feature of each genus. In most of the viruses, the core is roughly spherical, but in some cases it is either conical or cylindrical. In all the viruses, the core is surrounded by a roughly spherical shell consisting of MA, which in turn is surrounded by the lipid bilayer of the virion envelope. The virion membrane contains the envelope glycoprotein, with the TM subunit present as a single-pass transmembrane protein anchor, and the SU subunit as an entirely extravirion protein bound to TM. The envelope proteins for those viruses examined closely have been found to reside in the membrane as trimers.

ORGANIZATION OF THE RNA GENOME

The viral genome is a dimer of linear, positive-sense, single-stranded RNA, with each monomer 7 to 13 kilobases (kb) in size. The viral genomic RNA is present as a homodimer of two identical sequences, and thus the virions are functionally diploid. The dimer is maintained by interactions between the two 5' ends of the RNAs in a self-complementary region termed the dimer linkage structure (DLS). The RNA genome is generated by normal host transcriptional machinery and thus exhibits many of the features of normal mRNA. The RNA is capped at the 5' end, using the common $_{m7}$G5'ppp5'G$_{m}$p structure; and it contains a string of poly(A) sequences, about 200 long, at the 3' end.

A number of sequence blocks are so important that they have been named to facilitate descriptions of their functions in the life cycle (Fig. 4). These key sequences are clustered at the termini of the RNA. A short sequence, the R (for repeated) region, is so called because it is present twice in the RNA: once immediately after the cap at the 5' end and again at the 3' end, just before the poly(A) tail. Downstream of the 5' R lies another sequence, termed U5 for unique 5' sequence, which includes one of the *att* sites required for proviral integration. The U5 region is followed by the primer binding site (pbs), an 18-nt sequence at which a host tRNA is hybridized to the genome and the site of initiation of minus-strand DNA synthesis.

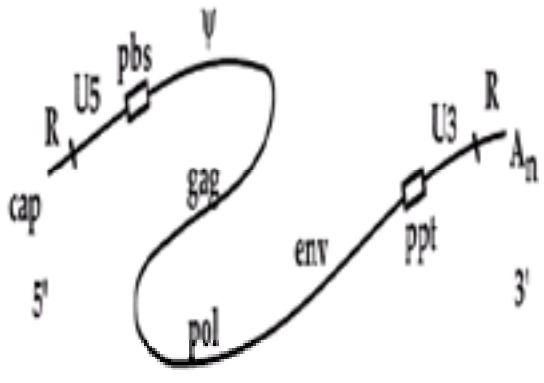

FIG. 4. The organization of the retroviral RNA genome. The single-stranded RNA genome is depicted as a *curved line.* From 5' to 3' along the RNA, the features include a 5' cap structure; *R*, a sequence block repeated at both 5' and 3' ends; *U5*, a unique 5' sequence block; *pbs*, the primer binding site and site of initiation of minus-strand DNA synthesis; *Y*, the

major recognition site for the packaging of the viral RNA into the virion particle; the *gag*, *pol*, and *env* genes; *ppt*, the polypurine tract and site of initiation of the plus-strand DNA synthesis; *U3*, a unique 3' sequence block; the second copy of the R sequence; and finally, a 3' poly(A) sequence.

The region downstream from the pbs often contains the major signals for the encapsidation of the viral RNA into the virion particle, in sequences called the Psi element. The region also often contains a major splice donor site for the formation of subgenomic mRNAs. The bulk of the RNA sequences that follow are coding regions for the viral proteins. The genomes of all the replication-competent retroviruses contain at a minimum three large genes, or ORFs: from 5' to 3' along the genome, the genes are termed *gag*, for group-specific antigen; *pol*, for polymerase; and *env*, for envelope. The three genes in the simple retroviruses occupy nearly all the available space in the center of the genome.

Downstream of the genes lies a short polypurine tract (ppt), a run of at least nine A and G residues. The ppt is the site of initiation of the plus-strand DNA. The ppt is followed by a sequence block termed U3 for unique 3' sequence; this region contains a number of key cis-acting elements for viral gene expression, and one of the *att* sites required for DNA integration. The U3 abuts the 3' copy of the R region, which is followed by the poly(A) tail. As we shall see, the R, U5, U3, pbs, and ppt sequences all play important roles in reverse transcription. The lengths of these sequence blocks in various retroviruses are summarized in Table 3.

Virus (example)	U3	R	U5
Alpharetrovirus (ALV)	150–250	18–21	80
Betaretrovirus (MMTV)	1200	15	120
Gammaretrovirus (MLV)	450	60	75
Deltaretrovirus (HTLV)	250–350	120–240	100–200
Lentivirus (HIV-1)	450	100	60–80
Spumavirus (HFV)	800	200	150

TABLE 3. *Size of sequence blocks in various retroviral RNAs (nt)*

OVERVIEW OF THE LIFE CYCLE

The retroviruses replicate through a complex life cycle. A short summary of the steps of the cycle is as follows (a schematic view is shown in Fig. 5):

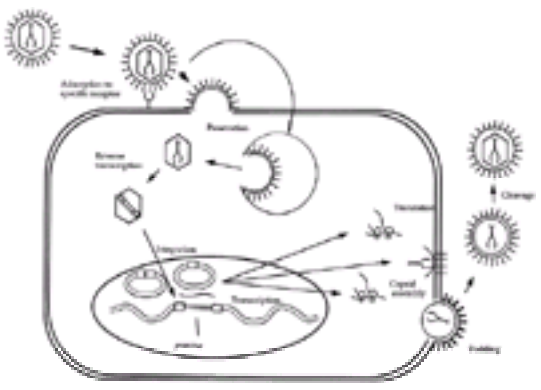

FIG. 5. A schematic view of the retrovirus life cycle. The major steps in the replication of a typical retrovirus are indicated, including those in the early phase of the life cycle, extending from the infecting virion (*top left*) to the formation of the integrated provirus, and those in the late phase of the life cycle, extending from the provirus to the formation of mature progeny virus (*right*).

- Receptor binding and membrane fusion
- Internalization and uncoating
- Reverse transcription of the RNA genome to form double-stranded linear DNA
- Nuclear entry of the DNA
- Integration of the linear DNA to form the provirus
- Transcription of the provirus to form viral RNAs
- Splicing and nuclear export of the RNAs
- Translation of the RNAs to form precursor proteins
- Assembly of the virion and packaging of the viral RNA genome
- Budding and release of the virions
- Proteolytic processing of the precursors and maturation of the virions

Changes in the Viral Genome

A quick perusal of this list reveals that the life cycle begins with an RNA genome, passes through an intracellular DNA intermediate, and is completed with a return to an RNA form in the progeny virus particle. An overview of the structures of the genome at various times in this cycle is presented in Figure 6. The RNA genome of the virion contains short terminal repeats (the R region) at its termini. During reverse transcription, as we shall see later, sequence blocks termed U5 and U3 are duplicated, so that the resulting double-stranded DNA is longer at both ends than the RNA template. This DNA thus contains LTRs (consisting of sequence blocks U3, R, and U5) at both ends. The next step is the integration of the DNA to form the provirus; the integrated provirus is collinear with the preintegrative DNA, and it retains the LTRs [except for one or two base pairs (bps) lost during the course of integration]. Finally, the DNA is forward transcribed by the RNA polymerase II system to produce the progeny RNA genome. Transcription is initiated at the U3-R boundary of the 5' LTR, and the transcripts are processed and polyadenylated at the R-U5 boundary of the 3' LTR, recreating the exact structure of the input RNA, complete with its short terminal repeats. This RNA is packaged and exported in virion particles. Each step will be described in more detail later.

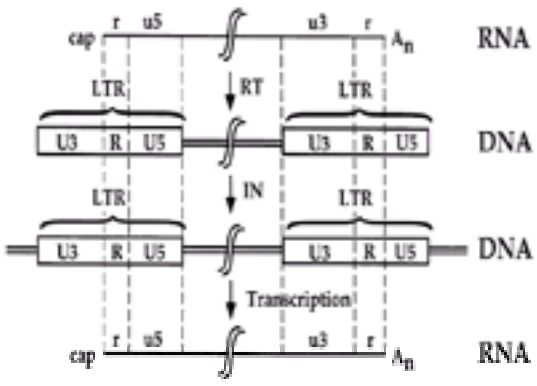

FIG. 6. Structures of the termini of the viral RNA and DNA genomes at various stages of the viral life cycle. Sequence blocks in RNA are indicated by lower case, and those in DNA by upper case. The structure of the RNA genome in the virion particle is indicated at the top. Reverse transcription of the RNA soon after infection involves the duplication and translocation of u5 and u3 sequence blocks, and it results in the formation of a double-stranded DNA molecule containing two terminal LTRs. The integration of the DNA genome occurs at the terminal sequences, establishing a provirus that is collinear with the preintegrative DNA. The forward transcription of the provirus is initiated at the U3/R border in the provirus; the resulting RNAs are cleaved and polyadenylated at the r/u5 border, recreating a viral RNA genome (*bottom*) identical to the infecting RNA.

THE VIRUS RECEPTORS

To enter a cell and initiate infection, all retroviruses require an interaction between a cell surface molecule—a receptor—and the envelope protein on the virion surface. The interactions are complex, involving an initial binding, drastic conformational changes in the envelope protein, an induced fusion of the viral and cellular membranes, and the internalization of the virion core into the cytoplasm. The SU subunit of Env is thought to make the major initial contacts with the receptor, and the TM subunit is thought to be most important for membrane fusion. The reorganization of the two lipid bilayers—one on the virion and one on the cell—to join them and evert the core into the cell is a remarkable process. The details of these complex processes are not understood for any retrovirus, and the whole Env protein is likely to be involved in efficient entry. However, there is a great deal of information about the identity and structures of the receptors used by various retroviruses. It is apparent that these viruses utilize an extraordinarily diverse set of cell surface molecules as receptors (see refs. 60 and 754 for reviews).

An important tool in the analysis of receptor utilization is the phenomenon of virus interference, or superinfection resistance. Cells chronically infected by a particular virus can be challenged for their susceptibility to infection by the same or different viruses. Such cells cannot be infected by any virus that must enter by the same receptor as used by the first virus, but they are readily infected by viruses that utilize a distinct receptor from that utilized by the first. The reason is that the expression of the Env protein by the first virus binds to the receptor intracellularly, preventing its export to the cell surface or its function as a receptor for newly applied virus (148,369). The phenomenon allows for the rapid classification of those viruses that use a common receptor.

The properties of the receptors of the major retroviral genera will be summarized later.

Alpharetrovirus Receptors

Three genes that encode functional receptors for various members of the ASLV family have been characterized. The receptor for the A subgroup was identified by selecting for the transfer of susceptibility to resistant mouse cells by genomic DNA fragments (787). The active gene was identified as encoding a membrane-anchored glycoprotein with sequence similarity to the ligand-binding repeat of the low-density lipoprotein receptor (LDLR) (50), and its identity as the true receptor has been confirmed by correlating its genetic map position with the *tv-a* locus (49). A soluble form of the receptor binds virus and blocks its infectivity (135). Functional versions of the protein can be anchored into the membrane either by a transmembrane segment or by a glycosylphosphaticlylinositol (GPI) anchor, and the receptor can even be fused to a foreign membrane protein, the epidermal growth factor (EGF) receptor, to permit efficient virus entry (667). The key determinants of the receptor for virus recognition and utilization have been identified (627).

The *tv-b* locus, encoding the receptor for both the B and D subgroups of the ALV, was similarly cloned and shown to encode a protein termed CAR1, unrelated to *tv-a* but with sequence similarity to the receptors for tumor necrosis factor (TNF) and the Fas death receptors (95). The intracellular portion of the molecule contains the sequence of a “death domain,” present on other cytotoxic receptors, and can trigger the apoptotic death of the cell upon ligand binding. This response is likely to mediate the toxic effects of the cytopathic ASLVs. However, noncytopathic viruses seem also able to bind and trigger the same receptors, and so the basis for the distinct effects of the two virus classes remains uncertain.

The *tv-e* locus is present in turkey but not chicken, and it allows infection by the subgroup E viruses. The gene was cloned by its sequence similarity to the chicken *tv-b* locus (5). The cloned gene product was shown to confer susceptibility to subgroup E but not B viruses, and to allow binding of subgroup E envelopes to the cell surface.

Betaretrovirus Receptors

A receptor for MMTV has been identified by gene transfer of cDNA libraries (278). The gene product allows cells to bind virus, and it allows infection by pseudotypes carrying the MMTV envelope. A second receptor for the betaretroviruses was also recently identified. The type D simian viruses, including MPMV and SRV-1, -2, -4, and -5, show cross-interference with three type C viruses: feline endogenous virus (RD114), baboon endogenous virus (BaEV), and avian reticuloendotheliosis virus (REV), suggesting that they all utilize a common cell surface receptor. Gene transfer of a human cDNA library into nonpermissive mouse cells was used to identify a gene that conferred susceptibility to infection by RD114 (694). The cDNA encoded a protein of 541 amino acids nearly identical to the previously cloned human Na^+-dependent neutral-amino-acid transporter named Bo (371,596). Consistent with this similarity, expression of the RD114 receptor in NIH 3T3 cells resulted in enhanced cellular uptake of L-^{3}H-alanine and L-^{3}H-glutamine.

Gammaretrovirus Receptors

A total of four receptors have been characterized for various subgroups of the MuLVs and their relatives, although there are others not yet identified (488). The ecotropic murine viruses are the most studied of this group, including the Moloney MuLV (MMLV), Friend MuLV, and Rauscher MuLV, as well as endogenous viruses from the AKR mouse, the AKR MuLV (AKV). The ecotropic receptor used by all these viruses is expressed on all strains of laboratory and wild mice of the species *Mus musculus*, mapping to the Rec1 locus on chromosome 5; a functional receptor is also expressed by rats. The ecotropic receptor was identified by gene transfer to nonpermissive human cells, selecting for susceptibility to MuLV infection (13). The gene encodes a membrane glycoprotein of 67 kd containing a total of 14 membrane-spanning domains; critical portions have been identified by mutational analyses. The corresponding human gene is highly homologous, but it cannot serve as a functional receptor by virtue of a small number of amino acid changes in the third extracellular loop of the protein. Other subtle mutations in this region of the receptor of other strains of mouse and of other rodents can cause varying changes in the susceptibility of the cell to infection by different ecotropic viruses (12,197). The SU subunit of the envelope protein binds to the receptor *in vitro* using a relatively small pocket region (162). The normal function of the protein has been identified as a transporter or permease for cationic, basic amino acids (379). The receptor, termed mCAT-1, was shown to be identical to y+, the previously characterized transporter in mammalian cells. The gene for mCAT-1 is now known as *Atrc1.* There is no strong evidence for a coreceptor or for any additional molecules besides the receptor being required; however, it has been noted that the infectivity of various cell lines does not correlate with the levels of receptor (747). Thus, it is possible that other molecules may modulate virus utilization of the receptor.

The amphotropic receptor is utilized by a group of MuLVs derived from wild mice and able to infect a wide range of mammalian species, including humans. The receptor was cloned by selection for susceptibility to virus infection after transfection of cDNA libraries into nonpermissive Chinese hamster ovary (CHO) cells (195,490), and by its homology to the gene for the previously identified GALV receptor (734). The gene, known variously as *Ram1* or GLVR2 or rPiT-2, encodes a 652-amino-acid protein that functions as a sodium-dependent phosphate symporter (368). The protein is predicted to contain 10 membrane-spanning domains, and residues in extracellular loops 2 and 4 have been shown important for virus entry (418,446). The synthesis and stability of the receptor is regulated by phosphate levels, and its down-regulation by virus infection results in substantial reduction in phosphate uptake by cells.

The receptor utilized in common by the GALV, the simian sarcoma–associated helper virus, and the FeLV subgroup B (698) is widely expressed in many mammals, including primates, cat, dog, mink, rabbit, and rat (but not mouse), as well as in some avian species. The human receptor, termed GLVR1 or hPiT-1, was cloned by gene transfer into nonpermissive mouse cells (346,517). The sequence of the gene predicts the existence of 10 membrane-spanning segments, and a large third intracellular loop. The protein shows similarity to that of a *Neurospora* phosphate permease gene, pho4+, and has been shown directly to serve as a sodium-dependent phosphate symporter (368,521). Specific amino acid changes introduced into the fourth extracellular loop can block FeLV-B and simian sarcoma–associated virus (SSAV) infection without affecting GALV, suggesting that these various viruses interact in slightly different ways with the receptor. GALV cannot use the human amphotropic receptor GLVR2, but a single amino acid change in the receptor will permit its use (198).
