The genome of HCV was sequenced and characterized long before virus-like particles were described. It was shown early on that HCV is inactivated by chloroform (98), indicating that particles are enveloped, and it was shown through filtration that the diameter is between 30 and 60 nm (126). Low levels of virus in plasma samples and problems of *in vitro* cultivation have made visualization of this virus difficult; however, virus-like particles have been identified using electron microscopy (292). Figure 3 shows spherical particles about 50 nm in diameter that specifically reacted to HCV

antibodies, observed in thin-section electron microscopy of an *in vitro* infected cell line (292).

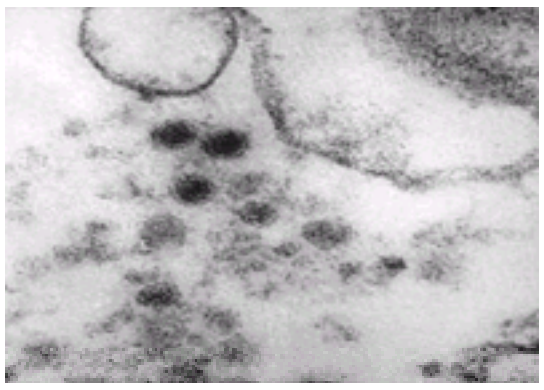

FIG. 3. Standard thin-section electron microscopy of *in vitro* infected HPBALL cells harvested on day 25 postinoculation showing hepatitis C virus–like particles. (From ref. 292, with permission.)

Sucrose gradient analyses of HCV-positive sera and plasma have isolated both low-density (1.06 to 1.13 g/mL) and high-density (1.17 to 1.25 g/mL) fractions containing HCV RNA (133,152,317). It has yet to be established whether these fractions represent intact virions or forms of subviral HCV RNA–containing material. It is probable that association with low-density lipoproteins (LDL) is responsible for the low-density fraction. A density of 1.06 g/mL is unusually low, even for an enveloped RNA virus such as HCV, and is close to that of plasma LDL (133), whereas the higher-density fractions (1.1 to 1.18 g/mL) possibly represent free virus or particles complexed with immunoglobulin (Ig) (66,133). Association with LDL could confer two advantages to the virus: (a) particles may be protected from antibody-mediated neutralization, and (b) virions may gain entry into cells through the cellular LDL receptor. These data argue in favor of a protective association between HCV virions and LDL, and recent reports suggest that the LDL receptor can mediate uptake of HCV, but it is unclear whether this leads to productive infection (3,227).

Replication

One of the major hurdles in testing both neutralizing antibodies and antiviral drugs to combat HCV infection is the lack of an effective cell culture system for the virus. The data regarding the functions of HCV genes and replication of the virus have been derived using established mammalian cell expression systems or the chimpanzee animal model. Infectious RNA transcripts used in chimpanzees have demonstrated requirements for 3'-UTR elements and functional enzymatic activities in HCV replication (172,340). This model, however, is too expensive for extensive analyses such as these. Unfortunately, a tissue culture system reliable enough to support HCV growth to the extent that experiments on replication can be carried out is yet to be developed.

Tissue Culture

There have been several reports of mammalian cells able to support the growth of HCV. The cell lines used include MT2, peripheral blood mononuclear cells, lymphocyte cell lines, and hepatocytes from humans and chimpanzees (reviewed in 213). An enhancement of HCV replication in MT2 cells by Epstein-Barr virus was recently reported; in particular, the *EBNA1* gene was thought to be involved (305). These systems rely on the use of reverse transcription–polymerase chain reaction (RT-PCR) for the detection of virus and, in particular, strand-specific RT-PCR as evidence of virus replication. Data indicating the presence of negative-stranded RNA need to be interpreted with care because specificity and sensitivity can vary depending on the choice of primers and reaction conditions (187,194). Data indicate, however, that there exist limited cell culture systems for HCV; with further development, these may provide an effective *in vitro* study system for the virus.

Alternative approaches to studying virus assembly or the role of viral antigens in replication have involved the production of virus-like particles (34) or pseudotype vesicular stomatitis virus (VSV) particles containing E1 or E2 (183). These systems provide a potential means of studying envelope glycoprotein interactions, essential elements required for particle assembly, and neutralizing antibody activity. A subgenomic replicon containing most of the nonstructural proteins of HCV was shown to replicate to high levels in a hepatoma cell line (206); radiolabeling of viral RNA and proteins was possible. Systems such as this may provide the basis for defining functional HCV replication units and testing of antiviral drugs.

Experimental Animal Models

Chimpanzee

The chimpanzee (*Pan troglodyte*) is genetically more than 98.5% identical to humans and is the only proven animal model for HCV infection and disease. Chimpanzee studies provided the first evidence of HCV transmission (137), a means of measuring infectivity, and material for cloning and characterizing the HCV genome (45,64). Evidence of a lack of protective immunity against HCV, understanding of the role of HVR1, and insights into possible vaccine strategies have also been gained from chimpanzee studies. Finally, this model has provided the only reliable means of testing the infectivity of transcribed RNAs from molecularly cloned, putative full-length HCV cDNA (169,338).

In most aspects, the virologic and clinical presentation of acute HCV infection is similar in humans and chimpanzees. This includes onset of disease, level of viremia, and timing of serologic response and liver damage, as indicated by alanine aminotransferase (ALT) elevation. There are, however, some differences. Only about 30% to 50% of

chimpanzees develop persistent HCV infections (31), compared with as many as 70% to 80% of humans.

The onset of hepatitis C in chimpanzees is typically mild. Although about 25% of patients with transfusion-associated hepatitis C become jaundiced, there are no reports of jaundice in a chimpanzee due to HCV infection. This milder disease in chimpanzees is also reflected in lesser degrees of hepatic injury measured by ALT levels or histopathology. Chimpanzees rarely develop significant chronic liver disease, although both chronic hepatitis and hepatocellular carcinoma have been reported (326). This low incidence may be biased, however, by the young age at which many animals are infected and the short observation period.

Humoral immune responses to HCV structural proteins are observed less frequently and are found to be significantly weaker in chimpanzees than in humans (4,54,63). Even in the absence of strong humoral immune responses, however, the cellular immune response has been described to be quite vigorous in chimpanzees with acute, self-limited hepatitis C (77). Termination of HCV infection correlates precisely with the onset of a multispecific intrahepatic cytotoxic T-lymphocyte (CTL) response that can persist for more than 1 year after resolution of infection (75).

The development of infectious RNA transcripts from a functional molecular clone allowed infection and pathogenesis studies with a single, well-defined viral polyprotein sequence. This greatly simplified the study of HCV evolution during acute and chronic infection and the analysis of HCV-specific immune responses (169,214,338,339).

After intrahepatic injection of transcribed full-length uncapped RNAs, circulating HCV RNA was generally detectable in the serum by 1 week after inoculation and increased during the first 10 to 12 weeks (169). ALT levels peaked at weeks 10 to 14 after infection, and in most animals, seroconversion was observed after 2 to 3 months (169). The severity of intrahepatic histologic changes, especially portal inflammation and focal necrosis, was typical for hepatitis C in chimpanzees and paralleled ALT elevations. These pathogenic profiles are strikingly reminiscent of those obtained in chimpanzees inoculated with the infectious HCV-containing samples. These experiments proved that circulating RNA is indeed due to authentic virus replication, rather than release of inoculated nucleic acid, and defined the elements of a functional HCV genome. In addition, the demonstration that RNA transcribed from cloned HCV cDNA could initiate infection and cause hepatitis in chimpanzees provided the formal proof that HCV alone is the causative agent of this disease.

Mouse

Although HCV does not infect mice, several mouse models have proved valuable in hepatitis C research. Mice that are transgenic for human major histocompatibility complex (MHC) molecules, for example, have been used efficiently to identify HCV epitopes and to test vaccination strategies. By immunization with peptides, DNA vaccines, or vaccinia viruses expressing HCV sequences, multiple human leukocyte antigen (HLA)-A2–restricted T-cell epitopes of the hepatitis C virus have been defined (248,294,330). These epitopes were endogenously processed and also recognized by HCV-infected humans. Thus, mice transgenic for human MHC molecules represent an excellent model system to develop immunotherapeutic vaccines that may be used in humans. For example, a multiepitope vaccine has been shown to induce simultaneous CTL responses to a pool of five different epitopes (248).

Transgenic mice that express individual or several HCV proteins have been used to analyze the biosynthesis of HCV proteins and their pathogenic role. Liver-specific expression of HCV core and E2 proteins resulted in the predominantly cytoplasmic presence of core protein with occasional nuclear staining and both cytoplasmic and membrane expression of the E2 protein. Importantly, the liver of two independent mouse lineages remained histologically normal for the entire observation period, that is, until 6 months and 18 months of age, respectively (156,250). In contrast, transgenic mice expressing HCV core under the control of a regulatory region from HBV developed progressive hepatic steatosis (229), and one fourth of the male transgenic mice developed hepatocellular carcinoma (238). This effect was specific for the expression of HCV core as a transgene because transgenic mice that carried HCV E1 and E2 under the same transcription control region did not have neoplastic lesions in the liver (168).

Finally, immunodeficient mice have been used to test the hypothesis that HCV persists in peripheral blood mononuclear cells (PBMC). Specifically, severe combined immunodeficiency (SCID) mice have been intraperitoneally inoculated with hematopoietic cells from HCV-infected subjects (43), and HCV-infected human liver fragments have been transplanted under the kidney capsule of immunodeficient mice (108). The studies suggest that HCV persists in mononuclear cells at a low rate of multiplication.

Tree Shrew

Tree shrews, tupaia belangeri chinensis, have been shown to be susceptible to HCV inoculation. So far, these animals have been experimentally infected with HCV genotypes 1a, 1b, and 3, but viremia was only transient or intermittent, with a low rate of anti-HCV seroconversion (335).

PATHOGENESIS

Immunobiology of Infection

Viral Entry into the Host

Although the primary source of HCV infection has not been determined in up to 40% of cases, HCV infection is generally thought to occur through parenteral routes. HCV virions spread through the bloodstream, and as early as 2 days after intravenous infection of chimpanzees, HCV RNA becomes detectable in the liver, the primary site of HCV replication.

A candidate protein for the cellular HCV receptor is human CD81, a transmembrane molecule that is expressed on most

human cells except red blood cells and platelets. Binding of CD81 coated on beads to the HCV E2 domain and to HCV RNA–containing particles in chimpanzee infectious plasma is species specific and can be inhibited by anti-E2 antibodies and by serum from chimpanzees vaccinated with E2 protein (253).

Another candidate receptor is the low-density lipoprotein receptor (LDLR) (3,227). Endocytosis of the HCV receptor complex, as well as its inhibition by anti-LDLR antibody, has recently been demonstrated *in vitro.* It has yet to be shown whether either of these receptors provides a route of entry that leads to productive infection in cells.

Cell and Tissue Tropism

As the primary site for HCV replication, the liver contains the highest levels of HCV RNA, ranging from 10^{8} to 10^{11} copies per gram of tissue (304). However, only a small percentage of hepatocytes (5% to 19%) are HCV RNA positive by *in situ* hybridization. Accordingly, expression of HCV antigens is rather low (1% to 10%). In addition, only 1% to 5% of mononuclear cells, and an even smaller proportion of biliary epithelial or sinusoidal lining cells, express HCV antigens (237). Most infected cells display little or no hepatocellular damage, which may suggest weak stimulation of the immune system due to low antigen expression (23) (see later).

RT-PCR techniques with a high specificity for the negative-stranded HCV RNA also commonly detected RNA in lymph nodes and pancreas and less frequently in adrenal glands, bone marrow, thyroid tissue, and spleen (189). Whether HCV also replicates in PBMC is controversial. Indirect evidence for extrahepatic replication of HCV in PBMC is derived from the observation that HCV HVR1 sequences isolated from PBMC of HCV-infected patients displayed considerable differences in the complexity of quasi-species as compared with HVR1 sequences isolated from serum and liver of the same individuals. The predominant sequences from each source were mutually different in 23% of patients (245).

Immune Responses

Humoral Immune Response

Although individuals vary in both specificity and timing of anti-HCV seroconversion, HCV-specific antibodies are generally detectable 7 to 31 weeks after infection (62). The humoral immune response is usually multispecific and targeted against epitopes within the HCV core, envelope, NS3, and NS4 proteins (4,146,299).

A major problem in assessing the relevance of these antibody responses is the lack of a convenient neutralization assay for HCV. As in other viral infections, antibody binding could interfere with HCV entry into host cells or viral replication, and it could opsonize virions for elimination by macrophages.

Evidence for a protective role of antibodies stems from limited studies in which chimpanzee or tissue culture infectious HCV was neutralized *in vitro* by incubation with antibody (95,293,344). Thus far, the HVR1 of the HCV E2 protein has been identified as the major target for neutralizing antibodies (95,293). This N-terminal sequence of 30 amino acids exhibits high sequence variability (130,155). Sequence variability in HVR1, however, does not appear to evolve by random drift, because virologic data from a single-source infection showed that amino acid replacements either are limited to particular sets of amino acids with shared biochemical properties or are completely conserved (218). Thus, amino acid substitutions appear to be influenced by both negative and positive selection, presumably by the immune response of the host.

Neutralizing antibodies appear to be targeted to sequences within the envelope glycoproteins in addition to the HVR1 sequence. Vaccination with recombinant envelope proteins expressed in mammalian cells elicited high titers of glycoprotein-specific antibodies that protected chimpanzees from low-dose homologous HCV challenge (63). In this experiment, the strongest correlate of protection was the level of specific antibodies that were capable of inhibiting binding of the HCV E2 to the candidate HCV receptor CD81 expressed by the cell line Molt-4 (253,275). This neutralization of binding (NOB) assay was also employed to detect high titers of antibodies that interfered with binding to the HCV E2 protein in the serum of patients who resolved chronic but not acute hepatitis C (147). The data suggest that the epitopes responsible for priming of NOB antibody responses are conserved in differing viral genotypes.

Despite these observations, however, the role of antibodies targeted to the envelope proteins, especially the HVR1, remains less clear. Several studies have suggested that neutralizing antibodies target the envelope proteins (63,94,95,275), that an early antibody response to the HVR1 is associated with viral clearance (9,347), and that more complex initial quasi-species distribution and viral complexity of the HVR1 correlate with HCV persistence (266). A recent study, however, reported that clearance of HCV in 28 chimpanzees was not associated with an antibody response to E1 and E2 (32). In addition, in 12 chimpanzees with persistent infections analyzed from two different studies, there was no evidence that the persistence was related to the development of immune escape of variants in the E1, E2, and specifically, HVR1 region (32,214). These results suggest that additional mechanisms are involved in maintaining viral persistence (see later).

Cellular Immune Response

The cellular immune response is thought to play a particularly important role in the host's defense against infections with noncytopathic viruses such as HCV because of its ability to recognize viral antigens in and to eliminate virus from infected cells. Although it is known that the liver is significantly enriched for cells of the innate immune response, such as natural killer cells, as well as for T-cell receptor-g– and d–positive cells and Va24-positive T cells, the role of the innate and antigen-nonspecific immune response to HCV has not yet been sufficiently studied. Most analyses have concentrated on the induction, effector function, and maintenance of HCV-specific CD4+ helper T cells and CD8+ cytotoxic T cells.

CD4+ Helper T Cells

Recent studies suggest that the HLA class II restricted T-cell response is particularly important to the outcome of acute HCV infection (84,111,185,224). Specifically, it has been demonstrated that patients with acute self-limited HCV mount an early as well as vigorous and multispecific helper T-cell response that is readily detectable in the peripheral blood (84,185). If, in contrast, this immune response is weak, less efficient, or not maintained for a sufficient length of time, patients proceed to persistent infection and chronic hepatitis (111). Thus, the intensity, epitope specificity, and cytokine profile of the T-cell response during the early stages of HCV infection appear to be predictive of viral clearance and recovery. Interestingly, these findings correlate well with the clinical observation that recovery from hepatitis C usually occurs within 3 months of clinical onset and that it is more common in patients with clinically evident than with asymptomatic disease (112).

A list of HCV sequences and epitopes targeted by CD4+ helper T cells is presented in Table 3. The most frequently recognized epitopes are contained within HCV core 21 to 40, NS4 1767 to 1786, NS4 1909 to 1929, and NS3 1251 to 1272, with the putative minimal optimal epitope within the NS3 sequence located at amino acids 1251 to 1259. Remarkably, these epitopes not only are highly immunogenic and immunodominant but also are conserved among HCV genotypes, indicating that mutations in these sequences may not be compatible with the HCV life cycle. Moreover, all of these T-cell epitopes bind promiscuously to a large variety of different HLA class II molecules with high affinity, suggesting that they can be efficiently presented and recognized by patients with many different HLA haplotypes. Thus, they are ideal candidates to be included in prophylactic or therapeutic T-cell–based vaccines against HCV.

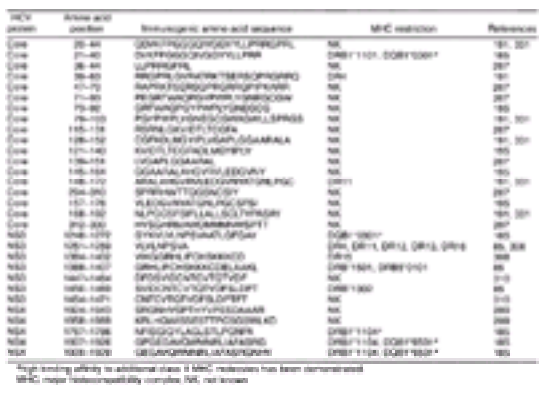

TABLE 3. *HCV peptides recognized by human class II MHC restricted CD4$^+$ T cells*

Helper T cells mediating this HCV-specific immune response have been shown to display a helper T-cell subtype 1 (T_H1) or T_H0 cytokine profile, whereas a T_H2 profile is associated with a chronic course of infection (322). In another study, the levels of circulating interleukin-2 (IL-2), IL-4, IL-10, and IFN-g were significantly higher in patients with chronic hepatitis C than in uninfected controls (50).

After recovery from acute hepatitis C, the HCV-specific helper T-cell response has been observed to persist. Whether this HCV-specific memory T-cell response is able to protect against reinfection with homologous or heterologous virus is not yet known and can only be analyzed in chimpanzees. Similarly, a frequently discussed, controversial question is whether maintenance of a virus-specific memory response requires persisting antigen or even low levels of replicating virus for periodic de novo induction of virus specific T cells. Although trace amounts of persisting, replicating virus have been detected in patients who have clinically and serologically recovered from hepatitis B virus (272), this question cannot yet be answered for HCV.

CD8+ Cytotoxic T Cells

Only three recent studies analyze the role of the CTL response in acute hepatitis C of humans and chimpanzees (56,75,192). In all three studies, an early, vigorous, multispecific CTL response was associated with a self-limited outcome of infection. In the chimpanzee model, the onset of this multispecific intrahepatic CTL response correlated precisely with termination of infection (75).

To identify potentially protective CTL responses, several other studies have analyzed the CTL response of HCV-seronegative, healthy people with frequent exposure to HCV. Interestingly, individuals who were repetitively exposed to HCV either occupationally (178) or by HCV-infected spouses (284) mounted peripheral blood HCV-specific helper and CTL responses in the absence of either a humoral immune response or viremia. This observation is compatible with the hypothesis that T-cell memory may be induced by periodic reintroduction of viral antigen by recurring, subclinical viral exposure.

Similar to helper T-cell epitopes, CTL epitopes have been identified in all viral proteins (33,55,89,175,176 and 177) (Table 4). As in other viral infections, with influenza and human immunodeficiency virus (HIV), HCV-specific CTLs have been shown to be broadly cross-reactive and able to recognize different viral subtypes. Several epitopes have also been demonstrated in the context of several HLA haplotypes, which have been grouped to HLA supertype families. To date, nine HLA class I supertypes are defined according to the A2-like, B7-like, B44-like, A1-like, A24-like, B27-like, B58-like, B62-like, or A3-like binding motif that a given viral peptide needs to contain in order to bind to a specific HLA allele. In total, more than 95% of the world population displays at least one of these HLA supertypes, an important consideration

for the potential applicability of a CD8+ T-cell–based vaccine.

TABLE 4. *HCV epitopes recognized by class I MHC restricted CD8+ T cells*

Because repetitive *in vitro* stimulation with HCV-derived peptides is required to expand CTL from the peripheral blood, the frequency of progenitor CTL in the circulation is assumed to be rather low (55,271). This has been confirmed by the recently developed technique of staining peptide-specific T cells with MHC peptide tetramers, a technique that does not require *in vitro* expansion of T cells. In the peripheral blood, 0.01% to 1.2% of circulating CD8+ T cells have been shown to be specific for two analyzed HCV NS3 epitopes, whereas at the site of inflammation, the infected liver, the frequency of epitope-specific CD8+ T cells was at least 30-fold higher (127). All of the intrahepatic NS3-specific CD8+ T cells were CD69+, suggesting that they were activated and presumably contribute to immune-mediated liver injury. Notably, however, this virus-specific intrahepatic response is not sufficient to induce viral clearance in most chronically infected patients presumably because the frequency of intrahepatic HCV-specific T cells in chronic hepatitis C is still significantly lower than that for other self-limiting infections (212).

The apparent weakness of the HCV-specific CTL response is not due to generalized immunosuppression because the CTL response against influenza virus (273) and Epstein-Barr virus (135) is normal in HCV-infected patients. The HCV-specific CTL response may therefore be too weak to achieve viral clearance but may exert some control over viral load during chronic infection. Indeed, a stronger polyclonal CTL response in the peripheral blood (270) and the liver (233) is associated with lower levels of HCV viremia. It appears, however, that this occurs at the expense of an inflammatory liver disease, which after many years to decades, may lead to irreversible liver cirrhosis and hepatocellular carcinoma.

Mechanisms of Immune-Mediated Liver Injury

Several histologic features allow a clear differentiation between hepatitis C and other types of inflammatory liver disease. Specifically, the triad of steatosis, bile duct damage, and lymphoid follicles within the portal tracts is characteristic for hepatitis C (21,282).

Steatosis manifests as large droplets of fat vacuoles in the cytoplasm of hepatocytes (193). Importantly, transgenic mice that expressed the HCV core protein intrahepatically also developed progressive hepatic steatosis (239). Bile duct damage is a frequent finding in hepatitis C but is uncommon in other forms of chronic viral hepatitis (21,193). Finally, eosinophilic material (Mallory-like bodies) in the cytoplasm of periportal hepatocytes is found in about 20% of chronic cases of HCV hepatitis (193).

The level of necroinflammatory activity, fibrosis, and cirrhosis can vary widely and is not necessarily associated with an increased serum alanine aminotransferase activity. Disease progression to liver cirrhosis is promoted by various cofactors, such as co-infection with other hepatotropic viruses (e.g., HBV [73,100]) and alcohol intake (220,249). HCV infection also appears to increase the susceptibility to liver injury after iron loading in chimpanzees (31).

Primary hepatocellular carcinoma (HCC) is a frequent complication of longstanding chronic active hepatitis. The mean intervals between infection and onset of cirrhosis and of HCC are relatively long and are estimated to be 21 and 29 years, respectively (164). As recently shown in hepatitis B virus infection, HCC is assumed to be induced by chronic immune-mediated hepatocellular injury and regeneration. Indeed, in regions of active inflammation, CD8+ T cells can be found surrounding hepatocytes expressing Fas antigen, and the generation of acidophil Councilman's bodies is interpreted as CTL-induced hepatocyte apoptosis (134).

Immune-mediated liver disease is initiated by HCV-specific liver-infiltrating T cells. These cells, which are estimated to represent about 1% of the total body lymphocytes, are continuously recruited from the peripheral blood (238) and do not undergo clonal expansion in the liver. With recruitment of T cells from the blood, a certain local and functional compartmentalization has been observed. Although CD4+ helper T cells are found in the portal areas, CD8+ lymphocytes infiltrate the hepatic lobules. B cells, on the other hand, are predominantly seen in germinal centers of lymphoid follicles located in the portal tracts (246). Studies of the effector function of intrahepatic T cells revealed that the intrahepatic helper T-cell response is focused on the HCV NS4 protein and mediated by T cells that express a selective T-cell receptor not found in the peripheral blood compartment (223). The predominant use of Vb5.1 by intrahepatic T cells (154) also indicates oligoclonal expansion and a restricted specificity for a common immunodominant HCV antigen.

Presentation of HCV antigens on infected hepatocytes, recognition by CTL, and induction of liver injury appear to be enhanced by HCV-induced expression of HLA-A, -B, and -C and by intracellular adhesion molecule 1 (23). In more aggressive forms of HCV infection, even CD68+ macrophages and monocytes are found. These activated cells are

thought to mediate and enhance antigen presentation and hence the inflammatory process as a whole (215). As a result, most cases of circulating HCV are thought to be produced through continuous rounds of *de novo* infection and rapid turnover of cells, not through release from chronically infected cells (103).

The mechanisms that regulate T-cell–induced viral clearance versus T-cell–induced liver injury are not completely understood. Liver-infiltrating HCV-specific T cells are T_H1 dominant and have been shown to produce IFN-g and tumor necrosis factor-a (TNF-a). These cytokines can suppress replication and gene expression of other viruses, such as HBV, without provoking liver disease. Thus, it is possible that HCV is less susceptible to these cytokines and that destruction of infected hepatocytes plays the predominant role and promotes chronic inflammatory liver disease.

Destruction of infected hepatocytes may occur in several ways: HCV-infected hepatocytes can be killed by HCV-specific CTL clones by means of Fas ligand, TNF-a, or perforin-based mechanisms. Fas ligand–induced apoptosis of hepatocytes is especially feasible because expression of Fas, a mediator of apoptosis, is upregulated in HCV-infected hepatocytes as well as in uninfected bystander cells in response to inflammatory cytokines (225) and because Fas (CD95) is expressed on activated, liver-infiltrating T cells (204). TNF-a is predominantly produced by macrophages (324) but is also released by (176) and expressed on the surface of (161) CTL. Finally, perforin-mediated mechanisms may contribute to lysis of antigen presenting, anti-Fas and TNF-a–resistant cells (18).

After exerting their effector functions, most of these liver-infiltrating T cells undergo programmed cell death themselves. T_H1 cells are preferentially attracted into HCV-infected livers and are especially sensitive to Fas- and FasL-induced apoptosis. Nuti and colleagues estimated a loss through apoptosis of 2×10^8 cells, with is 0.1% of the total body lymphocytes, per day (238).

Mechanisms of Persistence

The mechanisms whereby HCV circumvents the immune response, persists, and causes chronic inflammatory liver disease are currently undefined. One hypothesis is that the HCV-specific immune response is too weak to clear HCV from all infected hepatocytes once a persistent infection is established. Hypothetically, this may be due either to an insufficient induction of the primary immune response during acute infection (75) or to the inability to maintain the T-cell response at high levels during chronic hepatitis C (111). Generally, the intensity of the initial immune response depends on antigenic load, co-stimulatory signals, the type of the antigen-presenting cell, and differentiation and cytokine profile of helper T cells. Each of these factors may not be optimal in acute HCV infection because, for example, display of HCV antigens is relatively low and co-stimulatory molecules are predominantly expressed on professional antigen-presenting cells in the lymph nodes and not on hepatocytes, the preferred cell type for HCV replication. It has also been shown that dendritic cells (DC) from HCV-infected individuals exhibited an impaired stimulatory potential against allogeneic CD4 T cells (153). Exogenous IL-2 or IL-12 restored such defective DC capacity, which offers promise for the modulation of DC functions that are presumably due to the observed lower expression of IFN-g levels, lower CD86 expression, and IL-12 p35 and p40 transcripts (153).

Second, recent reports indicate that individual HCV proteins may actively suppress the immune response of the host. For example, expression of HCV core by recombinant vaccinia viruses suppresses the generation of vaccinia virus-specific cytotoxic T cells in mice (188). Although the mechanisms by which this inhibitory effect of HCV core is mediated have not been identified, numerous regulatory roles of HCV core that affect signal transduction, expression of viral and cellular genes, and cell growth and proliferation are known and can potentially mediate these effects (60,217,264,265,290,343).

In addition, two separate proteins of the hepatitis C virus have been shown to interfere with the antiviral actions of IFN. IFN induces antiviral genes, such as double-stranded RNA-activated protein kinase (PKR) at the transcriptional level. PKR inhibits protein synthesis by phosphorylation of the translation initiation factor eIF2a. Strikingly, an E2 sequence of the IFN-resistant HCV genotypes 1a and 1b, but not the IFN-sensitive HCV genotypes 2a, 2b, and 3a, exhibits homology with the phosphorylation sites of the IFN-inducible protein kinase PKR and the translation initiation factor eIF2a (316). These E2 sequences of the HCV genotype 1a and 1b are able to bind to and inhibit the kinase activity of PKR.

Particular sequences in NS5A between amino acids 2209 and 2248, termed the *interferon sensitivity-determining region* (ISDR), appear to correlate with the sensitivity of HCV to IFN treatment. This function is highly controversial, and many groups have found no association between NS5A sequences and IFN resistance or sensitivity in infected patients (70,251,252). This HCV nonstructural protein has been shown, however, to bind and inhibit the IFN-induced protein kinase PKR (105,106,312), an immediate-early effector of the cellular antiviral response induced by IFN. Interestingly, the interaction of NS5A with PKR is modulated by mutations within the ISDR, which has also been shown to be the PKR-binding domain (107). Therefore, the observations that HCV antigens interact with an IFN-induced protein may in part explain the mechanism of relative IFN resistance observed with some genotypes.

A third hypothetical explanation for HCV persistence could be the high genetic variability of the virus due to a lack of proofreading activity of the viral RNA polymerase. Recent studies suggest that circulating HCV has a half-life of only about 3 hours, indicating relatively efficient virus replication and release, at least in patients with high levels of viral load (234). This dynamic process, capable of continuously generating viral variants, allows genetic variation to be an important strategy for the establishment and maintenance of persistent infection in order to adapt quickly to humoral or cellular immune selection pressure. Weiner and associates reported the emergence of an HCV mutant that was able to escape the HCV-specific CTL response in a chimpanzee with chronic evolution of HCV infection (328). Sequence variations in T-cell epitopes have also been found in patients with acute and chronic hepatitis C (57,151,321), although at a low frequency. Evidence of selection pressure exerted by the humoral immune response has been obtained from several clinical studies (reviewed in 101). More complex initial quasi-species with sequence changes in E1 and HVR1 of E2 have been reported more often in patients who develop persistent infection than in patients who clear HCV (266). In immunocompromised patients, the viral nucleotide sequence variability in the HVR1 of HCV was markedly lower than in immunocompetent HCV-positive patients, suggesting that immune selection, primarily by HVR1-specific antibodies,

influences sequence variation in this region (239).

EPIDEMIOLOGY

Hepatitis C is a disease with a worldwide distribution, although the prevalence varies broadly among geographic areas. It is estimated that there are 170 million chronic carriers of HCV in the world, and reported prevalence rates range between about 0.1% in countries like Iceland and Norway to the 18.1% reported in Egypt (129). Because most infections with HCV become persistent, spread is primarily by parenteral exposure to the blood of chronically infected individuals. Therefore, factors such as social and cultural customs, medical practices, available medical technology, and individual behaviors that lead to exchange of blood between individuals all contribute to the infection rates in a specific area or country.

Prevalence and Incidence

The Centers for Disease Control and Prevention (CDC) has estimated that there were about 28,000 new infections with HCV in the United States in 1995. This compared with an incidence of about 180,000 new cases per year in the mid-1980s (14) (Fig. 4). This dramatic drop off in new infections is partially due to screening blood donors for antibody to HCV. More important, however, this decline likely reflects changes in drug use and other behavior patterns possibly associated with the AIDS epidemic. The Third National Health and Nutrition Survey, a large-scale serologic survey, was conducted between 1988 and 1994 by the CDC. Serum samples were tested for anti-HCV and for HCV RNA from 21,241 people 6 to 89 years of age (17). The prevalence of anti-HCV in this population was 1.8%, which extrapolates to about 3.9 million Americans infected by HCV. HCV RNA was detected in 73.9% of the HCV-positive subjects. Thus, it is estimated that at least 2.7 million Americans are chronically infected with HCV. The age-stratified prevalence rates are shown in Figure 5. It is clear that HCV infections in the United States are most common in the middle adult years, peaking in the fourth decade, with 65% of all infections occurring among people 30 to 49 years of age. Because drug use is the most important risk factor, the age distribution may represent a cohort effect of the rapid increase in use of illicit drugs among young adults around the time of the Vietnam War. In other parts of the world, the epidemiology may be different. In Italy, it was found that the prevalence of anti-HCV in the population increased with age. It is believed that there was a lot of HCV transmission before the Second World War due to the use of unsterilized injection equipment (120). Demographic factors associated with increased prevalence of HCV infections, including race, economic status, and marital status, are shown in Table 5. Behavioral factors that most strongly correlated with HCV infections were illegal drug use and high-risk sexual behavior. The adjusted odds ratio for any cocaine use was 5.16 compared with people who denied ever using cocaine and was 2.99 for those who admitted to using marijuana more than 100 times compared with those who denied ever using it. The use of injection drugs was not determined in this survey, and it is assumed that the use of marijuana was a surrogate marker for other high-risk behavior. The number of sexual partners and the age at first sexual intercourse also correlated with HCV. The adjusted odds ratio for greater than 50 sexual partners was 5.16 compared with people with no partners or one partner (17).

Modes of Transmission

Most hepatitis C infections become chronic, with a resulting persistent viremia. Transmission of the virus from person to person by parenteral exposure to blood from a persistently infected individual is believed to be the most common means of infection. However, nonparenteral or nonapparent parenteral exposure probably is also likely to occur (17). Although it appears that HCV can be transmitted by mucosal exposure, compared with HBV infection, this route is very inefficient. The low titers of HCV in the blood relative to hepatitis B likely accounts for the difference in mucosal transmission, although other virologic factors could also be important. Although HCV is a member of the Flaviviridae family, there is no epidemiologic or experimental evidence for transmission by an insect vector, although it remains theoretically possible.

The single most important mode of transmission of HCV in the United States and probably most Western countries is the illicit use of injectable drugs. At this time, HCV has been virtually eliminated from the blood supply, but studies from before the HCV-screening era indicated that even then, drug use was the most common identifiable exposure found in patients with chronic HCV infections (16). Sexual transmission of HCV is not as common as it is with hepatitis B virus, but it seems to occur. It is difficult to control for other behavior-related risk factors when studying spousal transmission, rates among sex workers, or rates observed in sexually transmitted disease clinics. However, very low rates (2.7% to 2.9%) of HCV positivity have been observed in sexual partners of HCV-positive hemophiliac patients, and the few positive partners had alternative risk factors (42,124). In a study of household contacts of 60 women who had been infected with HCV by a contaminated batch of anti-D Ig, there were no male partners positive and only one of 170 children positive. However, several studies correlate HCV positivity with number of sexual partners, employment in the sex industry, or sexually transmitted diseases (22,210,278). Male homosexuals also tend to have higher rates of HCV, but transmission by male homosexual practices occurs less frequently than that of HBV, and several studies have found that male homosexual sexual practices appear to play a minor role, if any, in transmission (39,247). An analysis of asymptomatic blood donors who were found to be anti-HCV positive found an association between admitted cocaine snorting and HCV infection (10). It is possible that this represents transmission by trauma to the mucous membranes with a shared cocaine straw. It is also possible that admitted cocaine use correlates with intravenous drug use that was not admitted (17).

Risk Factors

Any behavior, occupation, or medical condition that results in frequent percutaneous exposure to blood presents the most important risk for acquiring hepatitis C. Figure 6 shows the changing importance of several selected risk factors associated with acute HCV infection from 1983 through 1996. In studies performed before specific screening tests for HCV infections were available, there was a significant association of acute NANBH and a history of transfusion within the 6 months preceding the transfusion (15). With the understanding that HIV could be transmitted by blood transfusion, blood donors began to be screened by a rigorous interview that included lifestyle questions. Many of the behaviors that relate to increased risk for HIV are also related to HCV risk. In addition to the enhanced interview, donor blood was screened by two nonspecific tests that could identify some high-risk donors. A test for antibody to HBcAg identified individuals who had been exposed to HBV. It is presumed that people who had been exposed to HBV would be at increased risk for HCV infections as well. In one retrospective analysis, it was found that 11.9% of people receiving blood transfusions including at least one unit that was anti-HBc positive, compared with 4.2% of recipients of all anti-HBc–negative blood, developed NANBH (179). It was calculated from this study that if the blood had been screened for anti-HBc, 43% of the posttransfusion NANBH cases would have been prevented.

The second nonspecific screening assay to reduce posttransfusion hepatitis was the measurement of the ALT level in the donor blood. A French study found that the risk from HCV infection from blood transfusion dropped from 4.1 per 1000 transfused units to 3.4 per 1000 units in recipients of ALT-screened blood and to 1.4 per 1000 units in recipients of ALT plus anti-HBc–screened blood (150). Surrogate testing was instituted in 1986 in the United States, and with the addition of specific tests for anti-HCV in 1991, it has been estimated that the risk for acquiring HCV from a blood transfusion is now about 1 in 103,000 transfusions (283).

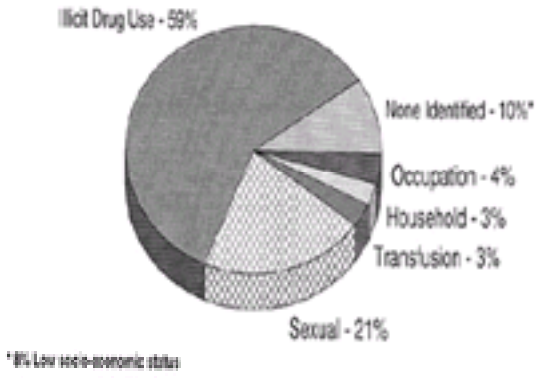

FIG. 6. Proportion of acute hepatitis C cases related to selected risk factors in the United States between 1983 and 1996. Before testing, transfusion accounted for about 20% of acute non-A, non-B hepatitis C cases. At present, transfusion associated hepatitis C has been virtually eliminated. (Data from the Centers for Disease Control and Prevention.)

In addition to blood transfusion, the use of many plasma products was associated with HCV infections. Before the use of screened and treated clotting factor concentrates, more than 90% of hemophiliac patients treated with these products were infected with HCV. At present, screening of source plasma, as well as specific viral inactivation steps added to the manufacturing process, has eliminated HCV from clotting factors as well as other plasma products.

Because source plasma is now screened for anti-HCV, it was thought that a potential paradoxical effect on HCV transmission might occur in the use of Ig for hepatitis A prophylaxis and to treat patients with hypogammaglobulinemia. This product had never been reported to transmit HCV or NANBH. However, because the screening assay did not eliminate all HCV-positive plasma units and the plasma pools often included more than 10,000 units, the previously safe Ig might now contain infectious HCV because it would no longer be neutralized by specific antibody previously present in the pool. Recently, that prediction was realized when transmissions of HCV by a preparation of intravenous Ig were observed (41). At this time, all Ig preparations for either intramuscular or intravenous use are screened for HCV RNA by a sensitive PCR assay or undergo viral inactivation steps during manufacture, and it is believed that no infectious HCV remains in any Ig preparations.

The majority of acute cases of HCV now occur in injection drug users (IDUs) (Fig. 7). Between 1991 and 1996, surveillance studies performed by the CDC found that 59% of adults with acute HCV infections had a history of drug use. A study of IDUs in Baltimore revealed that 76.9% were positive for antibody to HCV, compared with 65.7% for HBV, 20.5% for HIV, and 1.8% for human T-cell lymphotropic virus. In addition, it was found that 64.7% of these IDUs were already HCV seropositive within 1 year of initiating injection drug use (110). It was also found that seroprevalence was independently associated with reusing syringes, injecting the first time with someone more than 5 years older, and injecting cocaine (109). Among similar studies from around the world, HCV-seropositive rates among IDUs were reported to be 60% to 70% in Victoria, Australia (76), 60% to 70% in Iceland (208), 95.7% in Switzerland (82), and 74.6% in Saudi Arabia (236). The use of drugs and sharing of syringes, needles, or other drug paraphernalia is an extremely efficient means of transmission of HCV. The other major risk factors include sexual exposure (see Mode of Transmission, earlier), occupation, and household contact. At least 10% of acute HCV cases have no epidemiologic factors identified. In a study of the risk factors associated with chronic hepatitis among blood donors who tested positive for anti-HCV, a history of drug use, including cocaine snorting, was the most common risk factor, followed by sexual promiscuity, transfusion, imprisonment, tattooing, needle stick, and acupuncture. Only sexual promiscuity would not be considered a parenteral exposure (74).

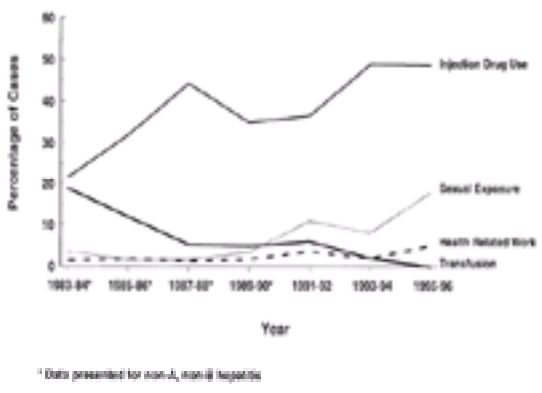

FIG. 7. Exposure risks associated with acquiring hepatitis C among adults in the United States between 1991 and 1996. (Data from the Centers for Disease Control and Prevention.)

CLINICAL FEATURES

Acute Hepatitis

The incubation period for hepatitis C averages about 7 weeks, with a range of 2 to 26 weeks, after exposure as measured by prospective studies of transfusion-associated hepatitis and needle sticks (285,288). The clinical picture of acute hepatitis C (illustrated in Fig. 8**A**) resembles other forms of acute viral hepatitis. However, symptoms of malaise, nausea, and right upper quadrant pain followed by dark urine and jaundice appear in only about one third of patients.

Biochemical evidence of hepatitis, such as elevated levels of serum ALT, are observed in more than 80% of cases, with levels typically 10 times normal or higher. ALT elevations usually coincide with symptoms, and both tend to resolve in 2 to 12 weeks. Hepatitis C RNA can be detected in the serum early after exposure, usually within the first 3 weeks (93). In acute resolved cases, the RNA disappears as the disease resolves (see Fig. 8**A**). HCV is rarely associated with fulminant hepatitis, but it has been reported (92,333). There are no recognized sequelae in patients who resolve hepatitis C infections. However, patients in whom HCV resolves do not in general appear to be protected from reinfection. Multiple bouts of hepatitis C have been reported in patients repeatedly treated with blood or plasma products (184). Liver biopsy is not recommended for the diagnosis of acute viral hepatitis, but in cases in which it has been performed, the histologic changes in addition to lymphocytic infiltrates include distinctive eosinophilic clumping of hepatocyte cytoplasm, acidophilic bodies, microvesicular steatosis, and activation of the sinusoidal cells (83).

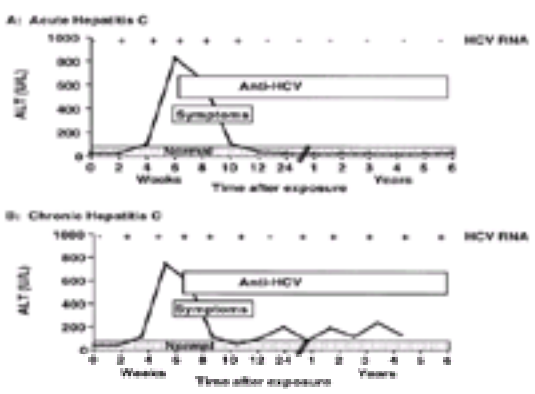

FIG. 8. Representation of clinical responses in patients after infection in acute (**A**) and chronic (**B**) hepatitis C. ALT, alanine aminotransferase.

Chronic Hepatitis

The clinical responses observed in chronic hepatitis C are illustrated in Figure 8**B**. The single most important feature of HCV infection is the propensity of the virus to cause persistent infection. About 85% of patients infected remain so for more than 6 months, most for the remainder of their lives. These chronically infected patients are the source of almost all new infections and themselves are at increased risk for the development of significant chronic liver disease, cirrhosis, and HCC. Many chronically infected patients do not have symptoms and would not be detected unless tested by their physicians or if they donate blood. Others may develop severe chronic liver disease over only a few years or, more commonly, over several decades. Figure 9 shows typical histologic features observed in chronic hepatitis C infection. Patients with chronic HCV infection may experience increased fatigue as their only symptom. Others may have overt symptomatic liver disease with anorexia, nausea, right upper quadrant pain, dark urine, and pruritus. ALT levels frequently fluctuate over time and may be normal or significantly elevated in the same patient measured at different times, whereas others have persistently normal or persistently elevated ALT levels. A summary was published of 10 reports in which 233 patients with chronic HCV infection but with normal ALT levels were studied by liver biopsy; it revealed that 12% had normal liver biopsies, 25% had only nonspecific changes, 41% had histologic findings of chronic persistent hepatitis, 22% had chronic active hepatitis, and only 0.5% had cirrhosis (143). Therefore, normal ALT levels do not always correlate perfectly with benign disease.

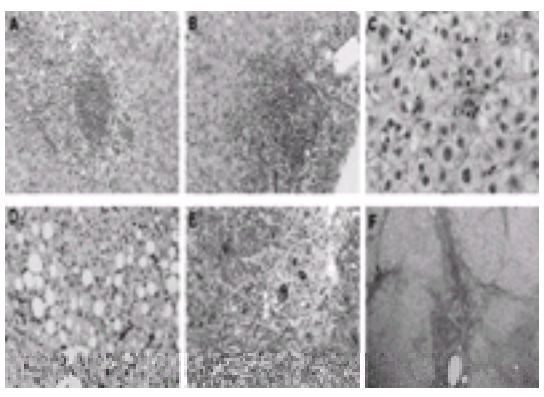

FIG. 9. Typical histologic features of chronic hepatitis C. **A:** Portal area with a lymphoid aggregate. Lymphoid aggregates in hepatitis C have an organization similar to primary lymphoid follicles in lymph nodes (H&E, ×200). **B:** Portal area showing piecemeal necrosis and Poulsen lesion. The edge of the portal area is disrupted by lymphocytic infiltration. Within the portal area is a lymphoid aggregate surrounding a duct that shows reactive epithelial changes. This “duct injury” is termed a *Poulsen lesion.* It is not associated with chronic cholestasis or duct loss (H&E, ×100). **C:** Lobular inflammation. Small foci of inflammation are seen within the hepatic parenchyma in chronic hepatitis C. Hepatocellular apoptosis can sometimes be observed. **D:** Steatosis. Accumulation of intracellular lipid within hepatocytes is a common feature in chronic hepatitis C and is seen more often in hepatitis C than in hepatitis B. Severe steatosis is uncommon. **E:** Periportal fibrosis. The earliest fibrotic change in hepatitis C is an expansion of the portal area by fibrosis. This is seen as thin collagen fibers extending out from the portal area to separate hepatocytes. This gives the portal area a stellate appearance. **F:** Advanced fibrosis. As the disease progresses, more scarring takes place. Fibrous bridges form between adjacent portal areas and between portal areas and central veins. The change shown here falls short of a diagnosis of cirrhosis. (Courtesy of Dr. David Kleiner, Laboratory of Pathology, National Cancer Institute, National Institutes of Health, Bethesda, MD.)

Outcomes of chronic hepatitis C infections in individual patients are difficult to predict. Hepatitis C patients presenting with significant chronic liver disease develop serious sequelae. For instance, of 100 Japanese patients presenting with chronic hepatitis C and liver disease and followed an average of 11 years earlier, 42 developed cirrhosis and 19 HCC (310). When patients are followed prospectively from infection, however, the picture is quite different (286). The National Heart Lung and Blood Institute conducted a series of five studies on posttransfusion hepatitis between 1968 and 1980 in which 8% to 18% of blood recipients developed hepatitis; about 90% of these cases were designated NANBH, almost all due to HCV (287). Follow-up studies of the 568 cases of NANBH an average of 18 years after transfusion as well as of 984 matched controls who were transfused but did not develop hepatitis revealed that death from all causes occurred in 51% in the hepatitis group and 52% in the controls. The mortality rate from liver disease was 3.2% among the hepatitis patients and 1.5% among controls, which was a small but significant difference. About one third of the patients who underwent liver biopsy after 18 to 20 years had cirrhosis, but presumably only the sicker patients had biopsies.

A group of children in Germany who had undergone cardiac surgery before 1991 when HCV screening of blood donors was begun were studied a mean of 19.8 years after their first surgery (325). Sixty-seven of 458 (14.6%) patients studied had anti-HCV, but only 37 of these (55%) had detectable HCV RNA. Only one HCV RNA–positive patient had elevated ALT levels, and this patient had right-sided heart failure. Seventeen HCV RNA–positive patients underwent liver biopsy. There was periportal fibrosis in two patients, both of whom had congestive heart failure, and micronodular cirrhosis in another. The remaining 14 patients had minimal lymphocytic periportal infiltrates. Therefore, in this group of patients infected as children and evaluated nearly 20 years later, the infection had cleared in 45% and was following a relatively benign course in the others. It is possible that in subsequent decades, these patients will begin to develop significant liver disease.

In contrast to the prospective studies reviewed previously, studies of patients with hepatitis C referred for evaluation of chronic liver disease show a rather different picture (320). Liver biopsies were performed in 101 patients in the United States with transfusion-associated chronic liver disease due to HCV. An additional 30 patients were studied but did not undergo biopsy because of abnormal coagulation tests. The mean interval from transfusion to diagnosis in this group was 19.5 years. This study showed the progressive nature of HCV-associated chronic liver disease. The mean interval from transfusion to diagnosis for patients with chronic hepatitis was 13.7 years, for chronic active hepatitis was 18.4 years, for cirrhosis was 20.6 years, and for HCC was 28.3 years. During the follow-up, which averaged about 4 years, 8 patients died from cirrhosis, and 11 died from HCC. These results were very similar to those reported earlier from Japan, in which the mean intervals to chronic hepatitis, cirrhosis, and HCC were 10.0, 21.2, and 29 years, respectively (16,165). Thus, chronic liver disease due to HCV infection generally follows an indolent but progressive course.

Hepatocellular Carcinoma

The most serious late outcome of chronic HCV infection is HCC. Soon after specific tests became available to detect patients with HCV infection, the association of chronic HCV infections with HCC was made. Worldwide, most HCC cases are related to either chronic HBV or HCV infection, and the prevalence of HCC and the proportion of cases related to either virus is directly reflected by the prevalence of each virus in that population (Fig. 10). Chronic infection with either virus results in chronic inflammation, necrosis, regeneration, and cirrhosis, which are all related to increased risk for oncogenesis. Cirrhosis of almost any cause carries an increased risk for HCC, and about 80% of patients with HCC have cirrhosis (281). HBV is a DNA virus that can integrate into the host genome, and it expresses the X protein, which is a transactivator, interacts with p53, and has other properties that may contribute to tumorigenesis. On the other hand, HCV is a typical RNA virus without the potential for its genome to be reverse-transcribed by a viral polymerase into DNA. The question of whether any of the HCV gene products have an effect on cellular metabolism that could lead to oncogenic transformation is under investigation. For instance, studies have shown that the HCV core protein can enter the nucleus and protect the cells from apoptosis mediated by anti-Fas or TNF-a, probably through activation of nuclear factor kappa B (216,346). In addition, NS3 has been reported to transform 3T3 cells in which it is expressed, and NS5A contains a potential transcriptional transactivator domain near its C terminus (69,277). In addition, transgenic mice expressing the core protein developed primary liver cancer resembling HCC after 16 months of age (228). Either of these phenomena could be related to carcinogenesis. Interaction of HCV proteins with cell regulatory factors may exert only small effects on the cell. However, because it typically takes 20 to 30 years for tumors to appear in persistently infected patients, it is possible that even such a small effect when exerted over a long time could be responsible for hepatocarcinogenesis.

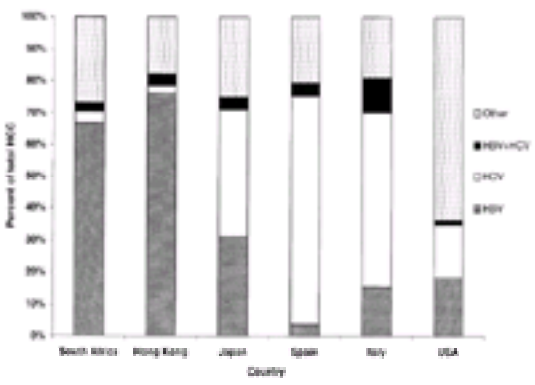

FIG. 10. The relative proportion of hepatocellular carcinoma cases associated with chronic hepatitis B virus (HBV) or hepatitis C virus (HCV) infections in different countries. Some parts of the world still have relatively high numbers of HBV carriers, resulting in a high proportion of hepatocellular carcinoma HCC cases due to HBV. In other countries such as Japan, HBV is coming under control resulting in a higher proportion of HCC cases related to HCV. (From ref. 81, with permission.)

Extrahepatic Manifestations of Infection

A variety of clinical syndromes that may be either autoimmune or mediated by immune complexes have been associated with chronic HCV infections. The diseases most closely associated with chronic HCV infections are essential mixed cryoglobulinemia, membranoproliferative glomerulonephritis, and porphyria cutanea tarda (122). Other diseases that have been related to HCV include keratoconjunctivitis sicca, lichen planus, autoimmune thyroiditis, Mooren corneal ulcers, idiopathic pulmonary fibrosis, and diabetes mellitus (122). Type II or essential mixed cryoglobulinemia (MC) is characterized by vasculitis with palpable purpura, arthralgias, and weakness and may involve the kidneys or central nervous system. This association has been reported from many areas of the world but appears to be particularly strong in Italy. A prospective study of MC in patients with chronic liver disease revealed that 46% of patients with chronic HCV infections and only 5% of patients with HBV infections had cryoglobulinemia, and about half of these patients had the clinical syndrome (1). The cryoglobulins have been shown to be composed of HCV, anti-HCV Ig, rheumatoid factor, and complement, and the cutaneous vascular lesions contain HCV, rheumatoid factor, and IgG (2). Successful treatment of HCV with IFN generally improves the MC (53). There is an additional association among HCV, MC, and lymphoproliferative disorders. Among 25 patients with MC, 7 had B-cell non-Hodgkins lymphoma. Serum anti-HCV was detected in 88% of the patients with MC and in all the patients with lymphoma (348). It is possible that the putative replication of HCV in lymphoid cells contributes to the pathogenesis of MC and the associated lymphoproliferative disorders. Membranous or membranoproliferative glomerulonephritis has also been linked to HCV infection and is most often seen together with MC (276). However, immune complex deposition, including HCV core protein, in the absence of cryoglobulins has also been reported (241).

Porphyria cutanea tarda also has a strong association with chronic HCV infection, although there appears to be a marked geographic variation in the rate of HCV positivity in patients with porphyria. A recent study in the United States found that 16 of 17 porphyria patients tested positive for anti-HCV, whereas only 17% in Northern Europe, 20% in Australia and New Zealand, and 65% in Southern Europe tested positive (68). Iron overload is often associated with this form of porphyria, and patients are often improved by frequent phlebotomies to deplete the excess iron stores; antiviral therapy also appears to have a beneficial effect (243,257).

DIAGNOSIS

The common tests used for diagnosis of HCV infection were designed primarily for screening of blood donors. These assays are based on detection of serum antibody to various HCV antigens because these antibodies are nearly universally present in patients who are chronically infected with HCV. Acute HCV infections are relatively rare among blood donors, but the antibody tests often fail to detect these patients in the window period between the time of infection and the time of appearance of antibody detectable by the assay. Therefore, the antibody assays also have limited utility for diagnosis of patients with acute HCV infections. Tests for HCV RNA genome detection based on the PCR or other highly sensitive RNA detection systems have been used for the diagnosis of acute hepatitis. Although these tests are available for clinical testing and are being used in blood banking, they have not yet achieved final approval for these uses by the U.S. Food and Drug Administration.

Serologic (Antibody) Assays

The components of the different diagnostic assays that have been developed are shown in Table 6. The locations of the antigens and peptides on the HCV polyprotein are shown in Figure 11.

Diagnostic test	Components
ORTHO HCV ELISA Test System	c100-3
ORTHO HCV 2.0 ELISA Test System	c100-3 c22-3 c200
ORTHO HCV Version 3.0 ELISA Test System	c22-3 c200 NS5
RIBA HCV 3.0 Strip Immunoblot Assay (SIA)	c22 Peptide 5-1-1 Peptide c100 Peptide c33c Antigen NS5 Antigen

[a]Locations of antigens and peptides on the HCV polyprotein are shown in Figure 11.
ELISA, enzyme-linked immunosorbent assay.

TABLE 6. *Components of previous and current commercial anti-HCV antibody test systems licensed in the United States*[a]

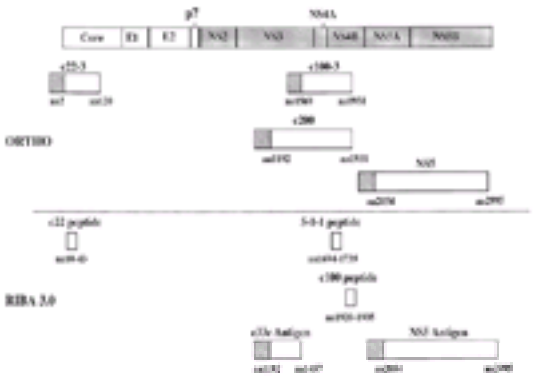

FIG. 11. Location on the HCV polyprotein of recombinant antigens and peptides used in the Ortho enzyme-linked immunosorbent assay (ELISA) (Ortho-Clinical Diagnostics, Rochester, NY) and the Chiron recombinant immunoblot assay (RIBA) antibody test systems (Chiron Corporation, Emeryville, CA). Recombinant antigens are expressed in yeast as fusion proteins with superoxide dismutase; this protein tag is represented by the *hatched area.* The antigens and peptides used in individual test systems are shown in Table 6.

The first diagnostic assay for HCV infection was developed as part of the studies that led to the initial detection of the agent. The first clone identified, 5-1-1, was used in hybridization assays to identify three overlapping clones that together constituted a 363–amino acid peptide termed *C100-3,* which was then expressed at high levels in yeast (181) and used in the first-generation enzyme-linked immunosorbent assay (ELISA). Other antigens were added later to make the second-generation commercial ELISA. The newest approved system, the Ortho HCV version 3.0 ELISA test system (Ortho-Chemical Diagnostics, Rochester, NY), includes three recombinant antigens, c22-3, c200, and NS5. Each of these polypeptides is expressed in yeast as a fusion protein with superoxide dismutase. At present, there are two licensed anti-HCV ELISA systems available in the United States, and several other systems are available in other countries. The latest test kit, version 3.0, may shorten the interval between infection and the first detection of serum antibody. Nevertheless, studies of patients with a defined exposure, such as transfusion, have shown that antibodies are not generally detectable for at least 6 weeks and may not appear for several months (118). HCV RNA may often be found in the patient's serum within the first week after exposure; therefore, the patient is probably infectious during this period before antibodies can be detected, but these patients with acute hepatitis C usually have not yet developed detectable antibody, making positive diagnosis difficult.

Supplemental tests have been developed to help exclude false-positive ELISA results. The most commonly used supplemental assay is the recombinant immunoblot assay RIBA (Chiron Corporation, Emeryville, CA). In this assay, several recombinant peptide antigens (locations are shown in lower half of Fig. 11 are applied on a strip, which is then probed with the patient's serum. In this way, the response to individual antigens can be recognized, and some false-positive ELISA results can be eliminated.

Virologic Assays

Sensitive tests for HCV RNA based on RT-PCR or other nucleic acid amplification techniques can be used during the window period. Although some of these tests are available commercially, the assays are not yet licensed as diagnostic tests in the United States, and the performance, sensitivity, specificity, and reproducibility of any given assay may not be well established. Until these tests are licensed, the user must rely on published results or reputation to judge the quality of the assay. Quantitative assays of HCV RNA can be performed by end-point dilutions of RT-PCR assays, competitive RT-PCR assays, or one of the commercial tests, such as the AMPLICOR Monitor (Roche Diagnostics, Nutly, NJ) or the QUANTIPLEX or bDNA assay (Chiron Corporation, Emeryville, CA). These quantitative tests may have utility in monitoring viral load in patients undergoing antiviral therapy (119).

Immunoassays using monoclonal antibodies for the detection of the core antigen of HCV (HCVcAg) have been developed with the claim of sensitivities comparable to nucleic acid amplification systems (19). In this assay, the viral envelope and the preexisting anti-core antibodies are stripped off the HCVcAg by detergents; the core antigen is then detected by a standard immunoassay. Although the HCVcAg was detected in 94.5% of 59 patients who had detectable HCV RNA, it was not shown that the assay actually had similar sensitivity to detect virus at a very low level. More studies are needed to determine whether such an assay can have the necessary sensitivity to close the serologic window between the time of the first appearance of viremia and the development of serum antibody.

Assays to determine the HCV genotype have recently become useful in clinical decision making. It has been know for some time that patients with genotype 1 infections are relatively resistant to IFN therapy. With combination therapy of IFN plus ribavirin, it has been found that patients with genotype 2 and 3 HCV infections may need only 6 months of therapy, whereas those with type 1 infections must be treated for a full year (see later). Many systems for determining genotypes have been published (see Nomenclature and Genotypes, earlier), and at least one system (LIPA assay) is available commercially, although not licensed (303).

TREATMENT AND PREVENTION

HCV presents a nearly perfect target for an antiviral drug approach to therapy. Hepatitis C is a chronic disease that progresses slowly over many years. Therefore, there is a long period of time in which antiviral therapy could be initiated as well as a long treatment window when therapy might be effective. The viral genome codes for several enzymatic activities that are vital to replication and quite distinct from human analogs. These include proteases, a helicase, and the RNA-dependent RNA polymerase, which all could be targeted by inhibitors.

One of the most promising approaches to anti-HCV drug discovery is the development of inhibitors of the virally encoded protease NS3. This chymotrypsin-like serine protease is essential for the maturation of the viral polyprotein, and efficient enzymatic activity requires complex formation between NS3 and its cofactor, NS4A. Targets for inhibition could include the NS3–NS4A interaction, zinc binding in the NS3 domain, and direct protease inhibitors. Of these, inhibitors of protease activity appear the most realistic (reviewed in 26 and 182).

Licensed Therapeutics

Two drugs have been approved for the treatment of chronic HCV infections. IFN-a has been approved for the treatment of compensated chronic NANBH (hepatitis C) since 1991, and recently ribavirin, a guanosine analog, has been approved

for use in combination with IFN-a. There are now several IFNs available, including IFN-a $_{2a}$; IFN-a$_{2b}$; IFN-a$_{n1}$, which is a combination of nine IFNs; and consensus sequence IFN, in which a consensus sequence of a variety of IFNs was synthesized. All these forms of IFN are produced by recombinant DNA technology and therefore are consistent and free of potential contamination by human pathogens. Clinical trials have not indicated major differences in the response rates among these products. Pegylated forms of IFN (bound to polyethylene glycol) are under development that may offer advantages over the presently available IFNs (235).

IFNa$_{2b}$ was the first approved form of IFN. It was originally used in a dose of 3 million units administered subcutaneously three times a week for 6 months. Later, it was found that improved virologic responses were obtained if therapy were extended to 1 or even 2 years, and it is now approved for treatment for that period. A meta-analysis of 32 clinical trials revealed that the biochemical (normalization of ALT) end of treatment response (ETR) rate was 47% of treated patients compared with 4% of controls. Virologic ETR rates (no detectable HCV RNA by RT-PCR) was 29% of treated patients, compared with 5% of controls (52). However, 5 months after the cessation of therapy, the sustained biochemical and virologic response rates had fallen to 23% and 8%, respectively. Although the ETR rates for patients treated for 6 months or 12 to 24 months were not different (45% versus 47%), the sustained response rate was 27% in those receiving longer-term therapy, compared with 14% for those receiving 6 months of treatment. Therefore, the present recommendation is for at least 12 months of therapy. Because the first IFN treatment trials occurred in the mid-1980s, few treated patients have been followed for long periods of time. The data that are emerging, however, are encouraging. Ten patients who were treated with IFN-a $_{2b}$ between 1984 and 1987 were followed 6 to 13 years after therapy. All 5 patients who had a sustained responses 6 months after the cessation of therapy remained HCV RNA negative, and only one had a minimally elevated ALT level (190). All 5 patients had improved scores for inflammation and fibrosis in their liver biopsies. The 5 patients who did not have responses at 6 months continued to have HCV RNA detectable in their blood, elevated ALT levels, and progressive disease on biopsy.

Patients who never respond or who relapse may be retreated with the same or a different form of IFN, at the same or a higher dose, and for a longer period of time. Only about 2% to 3% of nonresponders treated with higher doses and for longer periods had sustained responses after retreatment (5,51); however, sustained responses were achieved in about 15% of relapsers treated for an additional 6 months at the same dose, in 29% treated 6 more months at a higher dose, and in about 43% of patients retreated for 12 months.

Ribavirin is a nucleoside analog of guanosine that is absorbed orally and has been extensively studied as an antiviral agent for more than 20 years. Monotherapy of hepatitis C with ribavirin resulted in a nonsustained reduction of ALT levels without significant effects on HCV replication (38). However, combination therapy of ribavirin with IFNa $_{2b}$ resulted in a sustained response rate of 49%, compared with only 5% observed in matched patients treated with IFN alone (78). Figure 12 represents a sustained response to IFN-a and ribavirin treatment in chronic hepatitis C. In addition, as many as 50% of patients who relapse after an initial response to IFN alone have had sustained responses to the combination therapy (77). The combination of IFN-a$_{2b}$ and ribavirin has now been approved for both the initial treatment of patients with chronic HCV infections and for patients who have relapsed after initially responding to IFN alone. The utility of the combination therapy in treating individuals who never responded to IFN monotherapy is not yet clear.

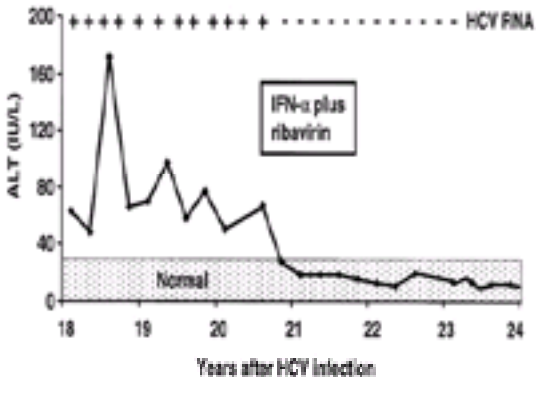

FIG. 12. Representation of spontaneous fluctuations in serum alanine aminotransferase (ALT) over time in chronic hepatitis C virus (HCV) infection and a sustained response to antiviral treatment. During treatment with interferon-ax, 3 million units weekly, and ribavirin, 1000 mg/d, ALT values decrease and remain within normal range, and serum HCV RNA remains undetectable by reverse transcription–polymerase chain reaction (RT-PCR).

Although all patients with chronic hepatitis C are candidates for therapy, at present, treatment is recommended for only a defined subset. These are patients with chronic hepatitis C who are at risk for progression to cirrhosis. These patients have persistently elevated ALT levels and liver biopsy findings of either portal or bridging fibrosis and at least moderate degrees of inflammation and necrosis (201). It is less clear whether patients with milder forms of liver disease are at significant risk for progression, and it is recommended that these patients be followed carefully, including repeat liver biopsies at 3- to 5-year intervals. Patients with more severe disease, such as established cirrhosis, probably would benefit from therapy, and patients with decompensated liver disease should be considered for transplantation. At present, treatment is not recommended for children younger than 18 years of age. Co-infection with HIV or HBV is not a contraindication to treatment, and HIV-infected patients with good CD4 levels have responded well to therapy (86). Treatment of drug or alcohol abusers should not be initiated without careful consideration. Contraindications to treatment include history of depressive illness, cytopenia, hyperthyroidism, and renal transplantation. Because markers of autoimmunity are common in chronic HCV infection, it is often difficult to determine the cause of the liver disease. A treatment decision between immunosuppression and antiviral therapy is often difficult and needs careful consideration because of the potentially negative effects of immunosuppressive therapy on hepatitis C.

Factors that influence treatment outcomes have been studied extensively. The NS5A region has been shown to interact with the protein kinase PKR, which is a known mediator of IFN-induced antiviral activity (see Mechanisms of Persistence, earlier). It is also known, however, that patients with genotype 1 viruses in general respond less well than patients infected with genotype 2 or 3 viruses (79). It has now been shown that patients with genotype 2 or 3 infections can be treated with IFN-a_{2b} plus ribavirin for only 6 months, whereas those with type 1 infections must be treated for at least 12 months (219,258). Thus, patients being evaluated for antiviral therapy should have their infecting virus genotyped. Poor treatment response rates have also been correlated with high pretreatment viral RNA levels. This may reflect the sensitivity of the virus to endogenous IFN.

Prevention

Prevention of hepatitis C at present is based on prevention of exposure to contaminated blood by screening of blood and plasma donors, identification of carriers by testing high-risk individuals, and public health measures designed to prevent spread. No effective vaccine has been developed to prevent HCV infection. In developed countries, screening of blood donors has virtually eliminated transmission of HCV by transfusion. Even before the specific screening tests were available, HCV transmission by blood had been significantly reduced by elimination of paid donors, ridged donor screening implemented to reduce HIV transmission, and possibly the use of surrogate tests for hepatitis C infection (see Modes of Transmission, earlier).

Source plasma for manufacture into various plasma products, such as clotting factors, is now all screened by the specific assays. Because these products are all made from pools containing plasma from thousands of donors, most of these pools continue to have low levels of HCV. Presently, these plasma-derived products all must undergo some specific process designed to eliminate or inactivate viruses, especially lipid-enveloped viruses that include HCV, HBV, and HIV. At the present time, plasma products are all considered to be free of infectious HCV.

Passive Immunization

Some recent studies indicate that the passive immunoprophylaxis of HCV infections may be possible. Pooled Ig with a high titer of anti-HCV was mixed with HCV *in vitro,* and this mixture was shown to be noninfectious when injected into a chimpanzee (344). Using the same Ig preparation, chimpanzees were inoculated with HCV and then given the Ig weekly for 13 weeks. Relative to the untreated control chimpanzees, the treated animals had a short, low-level viremia with minimal disease. When the treatment was stopped, however, the HCV viremia reappeared with acute disease (180). These two experiments show that antibody alone can have a profound effect on HCV infection and can neutralize the virus under limited conditions. The place for passive immunization with high titered Ig preparations in the prevention of HCV infection in humans has not been determined.

Active Immunization

HCV itself presents numerous problems that complicate the development of an effective vaccine. The lack of a suitable *in vitro* culture system makes production of vaccine quantities of whole virus impractical. The genetic diversity of the virus and the high level of mutability also complicate vaccine development. A vaccine based on the E1 and E2 glycoproteins was tested in chimpanzees (63). The vaccine produced an antibody response to E1 and E2, but it was short lived and required frequent boosting. Animals that were challenged intravenously with a very low dose of HCV were protected if the challenge virus was the same as the virus that was used to make the vaccine. Although protection against infection was not produced against other strains of HCV or higher levels of challenge virus, infections in the vaccinated chimps tended to be mild and short lasting. It is possible that a vaccine that only prevents chronic infections would be useful. Such a vaccine would prevent the most serious problems associated with chronic HCV and would greatly reduce the chance of transmitting the virus to others. Phase 1 clinical trials are in progress with a related vaccine based on the E2 glycoprotein only.

The challenges to the development of an effective HCV vaccine may require nonclassic approaches. A strong T-cell response, including both helper T cells and cytotoxic T lymphocytes, may be very important for both clearing and preventing infection. It has been suggested that specifically inducing CTL responses to well-conserved epitopes included in nonstructural proteins may be important for a prophylactic vaccine. Several laboratories are now studying this possibility in the chimpanzee model.

PERSPECTIVES

The etiologic agent of hepatitis C has been known for just over 10 years. Even without a cell culture system to study this virus carefully, progress in all aspects of hepatitis C has been remarkable. High-priority areas for future investigation include elucidating the mechanisms of persistence and carcinogenesis. Detailed understanding of viral replication and the development of efficient, high yield *in vitro* culture systems and small animal models remain important problems. The pharmaceutical industry currently has large efforts in antiviral therapy, which should begin to yield results soon. However, on a global basis, it is not likely that antiviral drugs that need to be taken over long periods of time will have a major impact owing to the expense, logistics, and compliance. Therefore, vaccines against hepatitis C designed to either prevent new infections or treat existing, chronic infections remain the highest priority for future research. HCV presents numerous problems that make the development of effective prophylactic or therapeutic vaccines immensely difficult. As some of the basic questions are answered, the path to a useful vaccine may become clearer.

CHAPTER 35 *Coronaviridae:* The Viruses and Their Replication

Michael M. C. Lai and Kathryn V. Holmes

CLASSIFICATION

Coronaviruses, a genus in the family *Coronaviridae*, are large, enveloped, positive-stranded RNA viruses that cause highly prevalent diseases in humans and domestic animals (Table 1). They have the largest genomes of all RNA viruses and replicate by a unique mechanism, which results in a high frequency of recombination. Virions mature by budding at intracellular membranes, and infection with some coronaviruses induces cell fusion.

[a]Other diseases caused by coronaviruses include infectious peritonitis, immunologic disorders, runting, nephritis, pancreatitis, paralysis, myocarditis, and sialodacryoadenitis.
HCoV-229E, human respiratory coronavirus; TGEV, porcine transmissible gastroenteritis virus; PRCoV, porcine respiratory coronavirus; CCoV, canine coronavirus; FECoV, feline enteric coronavirus; FIPV, feline infectious peritonitis virus; RbCoV, rabbit coronavirus; HCoV-OC43, human respiratory coronavirus; MHV, murine hepatitis virus; SDAV, sialodacryoadenitis virus; HEV, porcine hemagglutinating encephalomyelitis virus; BCoV, bovine coronavirus; IBV, avian infectious bronchitis virus; TCoV, turkey coronavirus.

TABLE 1. *Serotypes, natural hosts, and diseases of coronavirus*

Coronaviruses were first recognized as a distinct virus group by their characteristic virion morphology in negatively stained preparations (1,36) (Fig. 1). The viral envelopes are studded with long, petal-shaped spikes, giving coronaviruses the appearance of a crown (Latin, *corona*), and the nucleocapsids are long, flexible helices. Other characteristics that define Coronaviridae include the 3'-coterminal, nested-set structure of the mRNAs, unique RNA transcription strategy, genome organization, nucleotide sequence homology, and the properties of their structural proteins (36,138). The Coronaviridae family includes two genera, coronavirus and torovirus, which share many features of genome organization and replication strategy but have different virion morphology and genome lengths. The Coronaviridae, together with the Arteriviridae family, are classified in the order Nidovirales, whose member viruses share a unique feature: they all synthesize a nested set of multiple subgenomic mRNAs (34). Toroviruses and all members of the Arteriviridae family infect only animals. This chapter discusses coronaviruses exclusively.

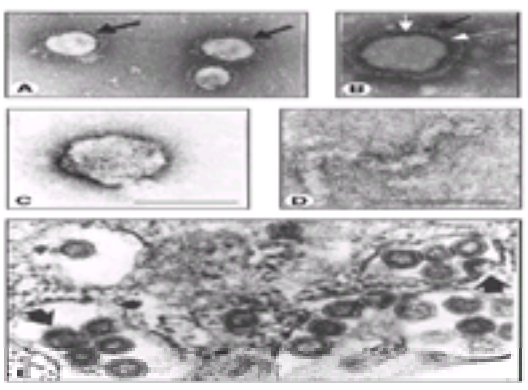

FIG. 1. Morphology of coronaviruses. Human respiratory coronavirus HCoV-OC43 (original magnification, ×90,000) **(A)** and turkey enteric coronavirus TCoV **(B)** in negatively stained preparations. The large, petal-shaped spikes (*black*

arrows), composed of the S glycoprotein, seen on the envelopes of both viruses distinguish coronaviruses from other enveloped viruses. Some coronaviruses also exhibit a fringe of shorter spikes composed of the hemagglutinin-esterase (HE) glycoprotein (*white arrows*). **C: I**nternal core of porcine transmissible gastroenteritis virus (TGEV). The core was obtained after removal of envelope by treatment with NP-40 and appears to have a spherical symmetry. **D:** Helical nucleocapsid released from the TGEV core structure by Triton X-100 treatment. *Bar*: 70 nm. **E:** Human cell infected with human respiratory coronavirus HCoV-229E. Spherical virions are seen budding at membranes of the ER and in smooth-walled vesicles (*arrows*). The electron-dense helical nucleocapsid is visible as slender, flexible tubules within the virions. The virus particles of some coronaviruses may mature further into electron-dense particles (215) (original magnification, ×60,000). (**B** courtesy of Peter Tijssen; **C and D** courtesy of Luis Enjuanes.)

Coronaviruses can be divided into three serologically distinct groups (see Table 1). Within each serogroup, the viruses are classified according to their natural hosts, nucleotide sequences, and serologic relationships. Most coronaviruses naturally infect only one animal species or, at most, a limited number of closely related species. Virus replication *in vivo* can be either disseminated, causing systemic infections, or restricted to a few cell types, often the epithelial cells of the respiratory or enteric tracts and macrophages, causing localized infections (see Table 1). Nucleotide sequences of the entire genomes of several coronaviruses, including avian infectious bronchitis virus (IBV), murine hepatitis virus (MHV), human coronavirus 229E (HCoV-229E), and porcine transmissible gastroenteritis virus (TGEV), confirm the similarity of the genome organization of these different coronaviruses (28,72,94,95,144).

VIRION MORPHOLOGY AND STRUCTURE

The structure of coronavirus virions is diagrammed in Figure 2. The virions are spherical enveloped particles about 100 to 120 nm in diameter. Inside the virion is a single-stranded, positive-sense genomic RNA 27 to 32 kb in size, the largest of all RNA virus genomes (28,72,94,138,144). The RNA genome associates with the N (nucleocapsid) phosphoprotein (50–60 kd) to form a long, flexible, helical nucleocapsid (175,254). When released from the virus particles, the nucleocapsids appear as extended tubular strands 14 to 16 nm in diameter (211,254) (see Fig. 1, panel **D**). Recent studies showed that in at least two coronaviruses (TGEV and MHV), the helical nucleocapsid is enclosed within an "internal core structure," 65 nm in diameter, that is spherical, and possibly icosahedral, in form. The core is composed of M (membrane) glycoprotein (and probably N protein as well). It can be released from virions by NP-40 treatment (211) (see Fig. 1, panel **C**). The virus core is enclosed by a lipoprotein envelope, which is formed during virus budding from intracellular membranes (91,201,264). Two types of prominent spikes line the outside of the virion. The long spikes (20 nm), which consist of the S (spike) glycoprotein, are present on all coronaviruses; the short spikes, which consist of the HE (hemagglutinin-esterase) glycoprotein, are present in only some coronaviruses (see Fig. 1, panels **A** and **B**). The envelope also contains the M glycoprotein, which spans the lipid bilayer three times (171,172 and 173); thus, the M protein is apparently a component of both the internal core structure and the envelope. The envelope also contains an E (envelope) protein, which is present in much smaller amounts than the other viral envelope proteins (87,271,295).

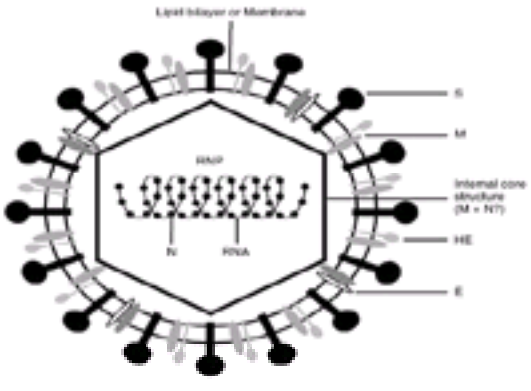

FIG. 2. Model of coronavirus structure: a schematic diagram of virion structure. S, spike glycoprotein; M, membrane glycoprotein; E, small envelope protein; HE, hemagglutinin-esterase glycoprotein; N, nucleocapsid phosphoprotein; ICS, internal core-shell composed of M glycoprotein; NC, nucleocapsid.

Structural Proteins

The S glycoprotein forms the large, petal-shaped spikes on the surface of the virion. This heavily glycosylated protein has a molecular mass of about 150 to 180 kd. S can be divided into three structural domains (from N- to C-terminus): a large external domain that is further divided into two subdomains, S1 and S2; a transmembrane domain; and a short carboxylterminal cytoplasmic domain. The S1 subdomain includes the N-terminal half of the molecule and forms the globular portion of the spikes. It contains sequences that are responsible for binding to specific receptors on the membranes of susceptible cells. S1 sequences are variable, containing various degrees of deletion and substitutions in different coronavirus strains or isolates. Mutations in S1 sequences have been associated with altered antigenicity and pathogenicity of the virus (74,99). In contrast, S2 sequences are more conserved. S2 is acylated and contains two heptad repeat motifs that suggest a coiled-coil structure (53,167). Indeed, evidence suggests that the mature S protein forms an oligomer, most likely a trimer (58). Thus, S2 subdomain probably constitutes the stalk of the viral spike. In most MHV strains and in bovine coronavirus (BCoV), the 180-kd S protein is cleaved during or after virus maturation by a cellular protease to yield the S1 and S2 proteins that remain noncovalently associated in the viral spikes. The extent of S cleavage varies among different coronaviruses and also depends on the host cell types (81,253). The cleavage of S into S1 and S2 may enhance the cell fusion activity or viral infectivity (89,255), but even uncleaved S protein can mediate

cell–cell fusion and fusion of the viral envelope with host cell membranes, though at a lower efficiency (26,245,259). The S proteins of coronaviruses in group I are not cleaved; even so, some of these viruses, such as feline infectious peritonitis virus (FIPV), can induce cell–cell fusion (54).

The S glycoprotein has several important biologic functions (Table 2). Monoclonal antibodies against S can neutralize virus infectivity (47,77), consistent with the observation that S protein binds to cellular receptors (86,128). The receptor-binding domain of the S protein of MHV is localized within the N-terminal 330 amino acids of the S1 domain (257). Consequently, the amino acid sequences of the S1 domain can determine the target cell specificity of coronaviruses in animals (99,219).

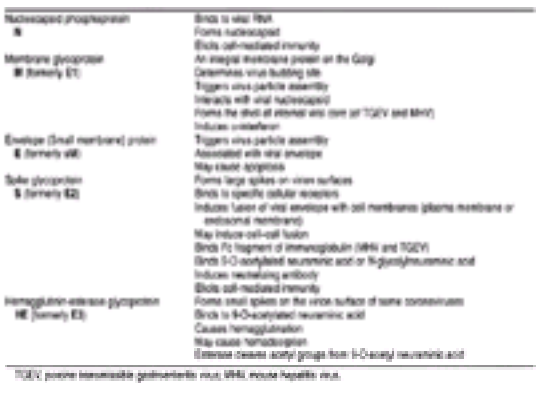

TABLE 2. *Properties and functions of coronavirus structural proteins*

S protein also induces fusion of the viral envelope with host cell membranes and, sometimes, cell–cell fusion. Expression of coronavirus S protein alone can induce fusion of receptor-bearing cells (54,259,294). The membrane fusion activity is most likely conferred by the internal hydrophobic sequences within the S2 (167). However, the fusion activity can be affected by sequences at multiple sites in the S2 as well as S1 (84,217).

Several other biologic activities have been associated with the S protein (see Table 2). The presence of MHV S protein on the plasma membrane of infected cells makes the cells susceptible to B-cell–mediated cytotoxicity (108,280), and the S glycoproteins of several coronaviruses share a similar sequence with the Fcg receptor for immunoglobulin (Ig), enabling the S protein to bind to the Fc fragment of IgG (198). This molecular mimicry may play a role in viral pathogenesis. The S proteins of BCoV and HCoV-OC43 can also bind 9- *O*-acetylated neuraminic acid-containing glycans and possess a hemagglutinating activity (227,228 and 229). This binding may be involved in the first step of virus infection for these viruses. Thus, S is a large, multifunctional protein that plays a central role in the biology and pathogenesis of coronavirus infections.

The HE glycoprotein is found on the virions of some group II coronaviruses and turkey coronavirus (TCoV) (group III) as a disulfide-linked dimer of a 65- to 70-kd protein that forms short spikes on the virions (see Fig. 1 and Fig. 2) (104,117,129,231). The presence or absence of this protein is highly variable even among group II coronaviruses, and its structure is frequently mutated or completely deleted during serial virus passaging in culture (288), suggesting that the HE protein is not essential for viral replication. Interestingly, the HE protein of coronavirus shares about 30% amino acid sequence similarity with the hemagglutinin protein of influenza C virus and may have been derived by a recombination between an HE mRNA of influenza C virus and the genomic RNA of an ancestral coronavirus (168). Like the S proteins of BCoV and HCoV-OC43, HE protein of various coronaviruses binds 9- *O*-acetylated neuraminic acid residues (229,231,274) and likely contributes to the hemagglutination and hemadsorption activities of coronaviruses. As the name implies, HE has an acetylesterase activity that cleaves acetyl groups from 9- *O*-acetylated neuraminic acid (274,290), thereby preventing or reversing the hemagglutination or hemadsorption induced by S or HE. These properties suggest that HE may be involved in either virus entry or virus release from infected cells. Indeed, some monoclonal antibodies against HE of BCoV can neutralize virus infectivity (64). In this virus, HE may mediate initial adsorption of the virus to cell membranes, but subsequent steps of virus entry most likely require the interaction of the S protein with a specific receptor, in a mechanism similar to that seen in other coronaviruses. This conclusion is supported by the finding that infection of murine cells by an HE-containing strain of MHV is inhibited by the monoclonal antibodies against the cellular receptor (83) or the viral S protein, despite the presence of HE protein in the virion (77). Thus, HE appears to be a “luxury” protein and is not absolutely necessary for virus infection in culture. Nevertheless, the presence of HE in a virus may alter its pathogenicity in animals (287).

The M glycoprotein differs from other coronavirus glycoproteins in that only a short aminoterminal domain of M is exposed on the exterior of the viral envelope. This domain is followed by a triple-membrane–spanning domain, an a-helical domain, and a large carboxylterminal domain inside the viral envelope (7,163,171,217). In some coronaviruses, such as TGEV, the carboxylterminus of the M protein is exposed on the virion surface (212). Glycosylation of the aminoterminal domain is O-linked for MHV and N-linked for IBV and TGEV (65,106,142,197). Monoclonal antibodies against the external domain of M neutralize viral infectivity, but only in the presence of complement (47). M proteins of some coronaviruses can induce interferon-a (43). The M proteins are targeted to the Golgi apparatus and not transported to the plasma membrane (172,173,258). In TGEV and MHV virions, the M glycoprotein is present not only in the viral envelope but also in the internal core structure (211).

An additional small envelope protein (E, formerly called sM), which is 9 to 12 kd, was recently shown to be associated with the viral envelope (87,159,295). Both E and M proteins are required for budding of virions (see Assembly and Release of Virions) (27,271). The topology and abundance of the E protein in the viral envelope have not been precisely

determined.

The nucleocapsid protein, N, is a phosphoprotein of 50 to 60 kd that interacts with viral genomic RNA to form the viral nucleocapsid. N has three relatively conserved structural domains, including an RNA-binding domain in the middle (187) that binds to the leader sequence of viral RNA (249). N protein in the viral nucleocapsid further interacts with M (254), leading to the formation of virus particles. N may also play a role in viral RNA synthesis, as suggested by a study in which an antibody directed against N inhibited an *in vitro* coronavirus RNA polymerase reaction (49). N protein also binds to cellular membranes and phospholipids (5), a property that may help to facilitate both virus assembly and formation of RNA replication complexes.

Coronaviruses, like other positive-stranded RNA viruses, do not incorporate RNA-dependent RNA polymerase into mature virions. Protein kinase activity is present in purified virions, but it is not yet clear whether it is a viral or cellular enzyme (240).

Viral Genome

The genomes of several coronaviruses are illustrated in Figure 3. Coronavirus genomic RNAs are capped, polyadenylated, positive-stranded RNAs of 27 to 32 kb in length. They can function as mRNAs, and the purified genomic RNA is infectious (164, 226). At the 5' end of the genome is a sequence of 65 to 98 nucleotides, termed the *leader RNA,* that is also present at the 5' ends of all subgenomic mRNAs (139, 238, 243). An untranslated region (UTR) of 200 to 400 nucleotides follows this leader sequence. At the 3' end of the RNA genome is another UTR of 200 to 500 nucleotides, followed by poly(A) of variable length. The sequences of both the 3'- and 5'-UTR are important for RNA replication and transcription. The remaining genomic sequence includes 7 to 10 open reading frames (ORFs). Gene 1, which comprises two thirds of the genome from the 5' end, is about 20 to 22 kb in length. It consists of two overlapping ORFs (1a and 1b). These ORFs are translated into a polyprotein, which is the precursor of viral polymerase. The order of the genes encoding the polymerase (*Pol*) and the four structural proteins that are present in all coronaviruses is 5'- *Pol*-S-E-M-N-3'. These genes are interspersed with several ORFs encoding various nonstructural proteins and the HE glycoprotein, which differ markedly among coronaviruses in number, nucleotide sequence, gene order, and method of expression (138) (see Fig. 3). The functions of most of the nonstructural protein gene products are unknown; some are absent in genomes of some coronaviruses (232, 291). The marked variability of coronavirus genome structure may be the result of RNA recombination.

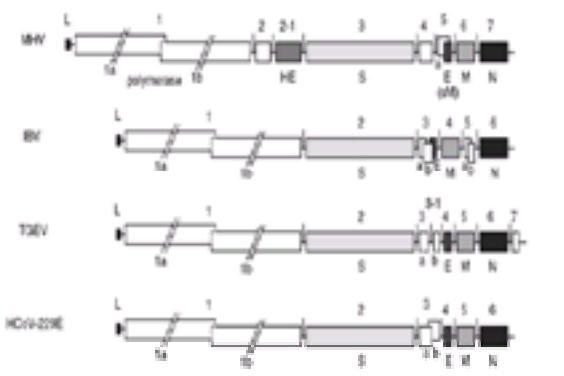

FIG. 3. Genomic organization of coronaviruses. The structures of four coronavirus genomic RNAs, for which complete sequences are available, are shown. The sizes of the genes are drawn about to scale, except for gene 1. The murine hepatitis virus (MHV) genome is 31.2 kb, and its gene 1 is 22 kb. The genomes for avian infectious bronchitis virus (IBV), porcine transmissible gastroenteritis virus (TGEV), and human respiratory coronavirus (HCoV)–229E are 27.6, 28.5, and 27.2 kb, respectively. The 5' end consists of a cap and a 65- to 98-base long leader sequence (L). *Shaded boxes* represent open reading frames (ORFs) encoding structural proteins; *unshaded boxes* encode nonstructural proteins. The *vertical lines* represent intergenic sequences (IG). The area between two IGs represents one gene; the separate ORFs within each gene are translated from a single mRNA species. Note the variations in the number, sequences, and locations of the ORFs encoding the nonstructural proteins. Coronavirus genomes are polyadenylated at the 3' end.

GROWTH OF CORONAVIRUSES

Most coronaviruses infect only the cells of their natural host species and a few closely related species. Some coronavirus strains may infect a wider range of cells under certain experimental conditions; for example, intracerebral inoculation of some MHV strains into owls and African green monkeys can result in central nervous system infection (33, 192). Primary isolation of human respiratory coronaviruses often requires human fetal tracheal organ cultures (see Chapter 36). Expansion of the viral host range can be achieved by serial passaging of the virus in a heterologous cell line or can occur spontaneously during persistent infection of cells of the natural host species. A variety of MHV variants capable of infecting hamster and human cells have been isolated by these processes (18, 19, 224). This expansion of host ranges often results from the ability of the virus to use an expanded repertoire of receptor molecules (18).

In their natural host species, coronaviruses exhibit marked tissue tropism; for example, TGEV causes mainly gastrointestinal diseases in pigs, whereas a closely related virus strain, porcine respiratory coronavirus (PRCoV), causes predominantly respiratory infections in pigs (51). The species and tissue specificity of the virus is at least partially determined by the nature and distribution of cellular receptor molecules and by sequence variations in the viral S glycoprotein (219).

Coronavirus replication takes place in the cytoplasm of infected cells and can occur in enucleated cells, although at a low

efficiency (29,281). However, actinomycin D has been reported to inhibit the replication of some coronaviruses in some cell lines (67,73,148). Thus, the possible role of the nucleus in coronavirus replication is still debatable. Infectious coronaviruses can be isolated from culture fluids and from infected cells disrupted by freezing and thawing. Infectivity of MHV virions is fairly stable at pH 6.0, but the virus is rapidly inactivated at a mildly alkaline pH (256). Coronaviruses can cause either cytocidal or persistent infections of cells in culture and in animal infections, depending on the virus strain and the host cell. In cytocidal coronavirus infections, cells may form multinucleated syncytia, lyse, or both. Plaques on infected cell cultures can be visualized by cell lysis, fusion, neutral red staining, or, in the case of BCoV, hemadsorption. Persistent HCoV-229E infection can be established in some human cell lines, producing virus for weeks without cytopathic effects or cell death (39). After an acute lytic infection, many coronaviruses establish persistently infected carrier cultures with minimal cytopathic effects; these cultures are resistant to superinfection by the wild-type virus (39,50,89,105).

Coronaviruses and their replication *in vitro* and *in vivo* can be detected by sensitive immunoassays with various monoclonal antibodies, nucleic acid hybridization, and reverse transcription–polymerase chain reaction (RT-PCR) as well as by plaque assay, immunofluorescence, and, in some cases, hemadsorption (34,48,193).

CORONAVIRUS REPLICATION

The major events in the coronavirus replicative cycle are summarized in Figure 4.

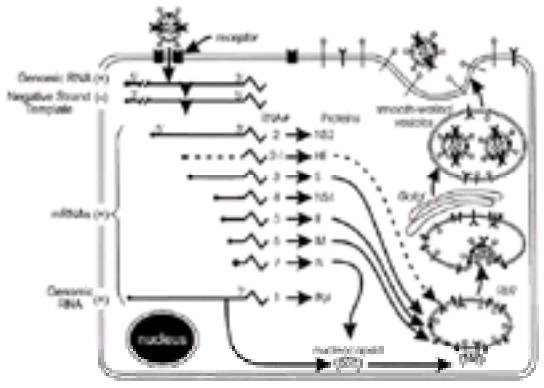

FIG. 4. Coronavirus replication cycle. Virions bind to the plasma membrane by interaction of the spikes with specific receptor glycoproteins or glycans. Penetration occurs by S protein–mediated fusion of the viral envelope with the plasma membrane or endosomal membranes. The gene 1 of viral genomic RNA is translated into a polyprotein, which is cotranslationally or posttranslationally processed to yield an RNA-dependent RNA polymerase (Pol) and other proteins involved in viral RNA synthesis. The Pol products use the genomic RNA as a template to synthesize negative-stranded RNAs, which are, in turn, used to synthesize genomic RNA and subgenomic mRNAs. The mRNAs in infected cells consist of an overlapping nested set of 3' coterminal RNAs containing a common leader RNA sequence at the 5' end. The mechanism of subgenomic mRNA synthesis has not been established (see Fig. 5). With a few exceptions, each mRNA is translated to yield only the protein encoded by the 5' most open reading frame of the mRNA. These proteins include structural proteins N, M, E, S, and HE and several nonstructural proteins. The N protein and newly synthesized genomic RNA assemble in the cytoplasm to form helical nucleocapsids. The membrane glycoprotein M is inserted in endoplasmic reticulum (ER) and anchored in the Golgi apparatus. Nucleocapsid (N plus genomic RNA) probably first binds to M protein at the budding compartment that lies between the RER and the Golgi. Similarly, E protein is also transported through the ER to the Golgi, where E and M proteins interact to trigger the budding of virions, enclosing the nucleocapsid. The S and HE glycoproteins are also translated on membrane-bound polysomes, inserted into the RER, and transported to the Golgi complex. These proteins are cotranslationally glycosylated, then trimerized and transported through the Golgi apparatus, where they undergo further modifications and, in some coronaviruses, are cleaved into two subunits, S1 and S2. During transport, some S and HE proteins associate with M protein and are incorporated into the maturing virus particles. Excess S and HE proteins that are not incorporated into virions are transported to the plasma membrane, where they may participate in cell–cell fusion or hemadsorption, respectively. Virions are apparently released by exocytosis-like fusion of smooth-walled, virion-containing vesicles with the plasma membrane. Virions may remain adsorbed to the plasma membranes of infected cells. The entire cycle of coronavirus replication takes place in the cytoplasm.

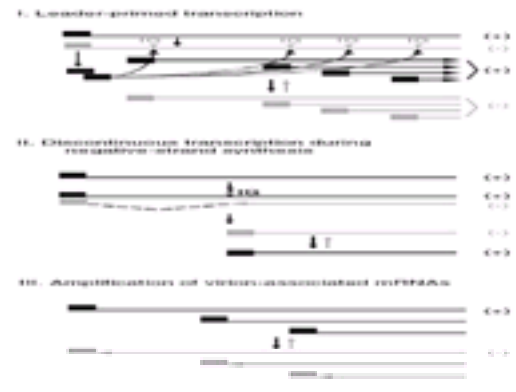

FIG. 5. Proposed models of coronavirus mRNA transcription (see text). *Solid lines* represent positive-stranded RNA; *dashed lines* represent negative-stranded RNA. *Boxes* represent the leader RNA or antileader. *Arrowheads* indicate the direction of transcription.

Attachment

The first step in the viral replication cycle is the binding of virions to the plasma membranes of target cells. Coronaviruses containing the HE glycoprotein (e.g., BCoV, HCoV-OC43) may bind to 9- *O*-acetylated neuraminic acid (sialic acid), a common moiety on membrane macromolecules (229,231,275). Enzymatic removal of the 9-*O*-acetylated neuraminic acid from cell membranes or treatment of virus with HE-specific monoclonal antibodies inhibits BCoV infection but does not completely block it (63,64,229), suggesting that the binding of HE to 9- *O*-acetylated neuraminic acid residues is necessary for, or at least can facilitate, virus infection. Inhibition by diisopropylfluorophosphate of the esterase activity of HE also markedly reduces BCoV infectivity (274); however, the esterase activity is likely involved in virus release rather than in virus entry because the newly synthesized virions may be trapped by the neuraminic acid residues on cell surface molecules and require esterase for virus release. In any case, virus binding to neuraminic acid residues may not be a crucial step for virus infection because many coronaviruses do not bind sialic acids. Furthermore, because sialic acid is a common cell surface carbohydrate and the tissue tropism of coronaviruses is restricted, this HE-sialic acid binding may not be sufficient to determine viral tropism. Recent studies have shown that the S protein of TGEV binds *N*-glycolyl neuraminic acid, whereas S protein of PRCoV, which is related to TGEV but causes primarily respiratory infections, does not, raising the possibility that this binding may contribute to the enterotropism of TGEV (230).

The main determinant of viral tropism is likely the binding of the S protein to a specific receptor glycoprotein on the cell surface. Receptors have been identified for several coronaviruses. The MHV receptor is a murine biliary glycoprotein belonging to the carcinoembryonic antigen (CEA) family in the Ig superfamily (69,283). It has an extracellular domain with four Ig-like loops, a transmembrane region, and a short intracytoplasmic domain. The viral S glycoprotein binds to the N-terminal Ig-like domain of MHV receptors (70). A monoclonal antibody against the receptor blocks MHV infection in murine cell culture and in infant mice (203,238). Subsequent studies have shown that other members of the murine CEA family and several human CEA-related glycoproteins can also serve as MHV receptors (44,45,68,194,292,293).

The MHV receptor is expressed predominantly in the liver, gastrointestinal tract, macrophages, and B cells, but not on thymic T cells (51,88), consistent with the target cell specificity of MHV. Surprisingly, the level of MHV receptor in the brain is very low, although many MHV strains can infect brain. Thus, MHV may use other receptors for central nervous system infections. A mouse strain SJL expresses a mutant MHV receptor that is functional when expressed at high levels in hamster or human cells, and yet SJL mice are highly resistant to MHV infection (68,293). Therefore, receptor expression is not the sole determinant of viral tropism. Several MHV variants can efficiently use human CEA as receptors for infection of human cells (18,19). The expression level of the MHV receptor may be a limiting factor for MHV infections under some conditions; increased levels of receptor expression can enhance the susceptibility of the cells to MHV infection (46,220). It is interesting to note that MHV infects polarized epithelial cells through only the apical, not the basolateral, surface (214), consistent with the MHV receptor expression pattern in respiratory and enteric epithelium in mice (88).

HCoV-229E, TGEV, FIPV, and probably canine coronaviruses (CCoV) use the cell membrane–bound metalloprotease, aminopeptidase N (APN), of their respective host species (23,57,285), rather than CEA-like molecules, as a receptor. APN is widely distributed on many cell types, including respiratory and enteric epithelial cells and neuronal and glial cells (131). Some monoclonal antibodies against porcine or human APN block the binding of TGEV or HCoV-229E virions to their target cells (57,285). However, the protease activity of APN is not necessary for the receptor function; inhibitors of APN and mutations of APN that abrogate the enzymatic activity do not block virus infection (57,283).

Penetration and Uncoating

After virus binds to a specific receptor, it enters the cell, a step that involves fusion of the viral envelope with either the plasma membrane or the endosomal membranes. MHV, BCoV, and IBV exhibit a neutral or slightly alkaline pH optimum for induction of cell–cell fusion (149,204,256,279), suggesting that these viruses may cause fusion of the viral envelope with the plasma membrane at the normal physiological pH of the extracellular environment. Therefore, these viruses probably enter cells by virus–cell fusion at the plasma membrane. In contrast, infectivity of some MHV strains is reduced, but not completely inhibited, by lysosomotropic drugs, suggesting that these viruses may enter cells through the endosomal pathway (84,127,190). Current experimental evidence indicates that different coronaviruses can enter cells either by acidic pH–dependent endocytosis or by pH-independent fusion at the plasma membrane (124).

The mechanism by which a virus uncoats and releases its genomic RNA into the cytoplasm is not yet clear. Cellular factors may be required for both virus penetration and uncoating. Some murine cell lines are resistant to MHV infection despite the presence of a functional MHV receptor; MHV infections in these cells are blocked at penetration, uncoating, or other steps of virus entry (8,79,286). These resistant mouse cells can be grouped into three complementation groups, suggesting that at least three cellular genes are involved in the processes of virus entry (8).

Transcription of Viral mRNA

Once viral RNA is released into the cytoplasm, it is used to synthesize a viral RNA-dependent RNA polymerase, which then initiates the transcription of viral mRNAs. Coronaviruses synthesize multiple subgenomic mRNAs, each of which translates one or, occasionally, more than one protein. There is a subgenomic mRNA for the expression of every viral gene except gene 1, which is expressed from the genomic RNA. Five to seven subgenomic mRNAs are synthesized in infected cells, depending on the coronavirus strain or isolate. These viral mRNAs are represented by numbers in order of decreasing size (138); mRNAs discovered after these numbers were assigned are denoted by a hyphen and a second number (e.g., mRNA 2-1) (37). The mRNAs form a nested set with a common 3' end and poly(A) (see Fig. 4). Although each mRNA, except the smallest, contains two or more ORFs, only the 5'-most ORF is translated, with minor exceptions, as noted later. Thus, these mRNAs are functionally monocistronic.

A characteristic feature of coronavirus subgenomic mRNAs is the presence at their 5' end of a leader sequence, 65 to 98 bases long, that is identical to the sequence at the 5' end of the genomic RNA (139,238,243). This leader sequence is not found elsewhere in the genome; however, the sequence between each gene, termed the *intergenic sequence* (16) (Fig. 5; see also Fig. 3), or transcription-associated sequence (TAS) (100) shares a sequence homology of 7 to 18 nucleotides with the 3' end of the leader (238). The core sequence of the intergenic sequence for MHV is UCUAAAC or a variant of it (112), whereas the 3' end of the leader consists of several tandem repeats of UCUAA. Sequence comparison of viral genomic and mRNAs suggests that subgenomic mRNAs are derived by juxtaposition of the leader sequence to the mRNAs through the UCUAA repeat sequence (238). The mechanism of joining these two RNA elements is discussed later in this section.

The viral genomic RNA is first transcribed into negative-stranded RNA, which is then used as the template for synthesis of mRNAs and genomic RNA. Studies have shown that both genomic- and subgenomic-sized negative-stranded RNAs are present in relative ratios comparable to those of the corresponding positive-stranded genomic and subgenomic mRNAs (222,235,236). All the negative-stranded RNAs were in double-stranded form; no free negative-stranded RNA was detected (210,221,222). The mechanism of synthesis and the functions of the subgenomic- and genomic-length negative-stranded RNAs are subjects of controversy. There are several models to explain how the subgenomic mRNAs are synthesized so that the leader RNA is fused to the mRNAs (see Fig. 5). Several pieces of experimental data are relevant to the formulation of these models: ultraviolet (UV) light transcriptional mapping studies (108,248,289) indicate that the UV target sizes of subgenomic mRNAs are roughly equivalent to the physical sizes of the individual mRNAs, suggesting that they are transcribed independently. Early in infection, the UV target sizes of the subgenomic mRNAs are equivalent to that of the genomic RNA (176,288), indicating that synthesis of a genomic-sized RNA is a prerequisite for subgenomic mRNA transcription. The difference in UV target size between the early and late stages of viral infection suggests that different mechanisms of RNA synthesis may operate at different stages of the viral replication cycle. Furthermore, in cells simultaneously infected with two different MHV strains, as much as half of the mRNAs may contain a leader sequence derived from one strain and coding sequences from the other strain (184), indicating that the leader sequence can be freely exchanged during transcription. This observation has been reproduced using a defective-interfering (DI) RNA vector system (see later), in which most of the DI-derived subgenomic mRNAs contain a leader sequence derived from the helper viral RNA molecule (109,297). Therefore, all models of coronavirus transcription include a discontinuous transcription process by which the leader sequence and mRNA sequences are derived from two different RNA molecules (109,297).

The first model for coronavirus mRNA synthesis involves *leader-primed transcription* (135) (see Fig. 5**I**). According to this model, discontinuous transcription occurs during positive-stranded RNA synthesis. The genomic RNA is first transcribed into a full-length negative-stranded RNA. Transcription of the leader RNA begins at the 3' end of the full-length, negative-stranded template RNA and terminates at the end of the leader sequence. The leader dissociates from the template, possibly with the polymerase, and subsequently binds to any intergenic sequence on the negative-stranded template and serves as the primer for mRNA transcription, resulting in an mRNA that contains a leader RNA fused to the mRNA. Several pieces of evidence are consistent with this model:

- MHV-infected cells contain free leader RNAs ranging in size from 50 to 90 nucleotides (16); however, free leader RNAs were not found in BCoV-infected cells (42).
- Leader RNAs transcribed from two different MHV strains in the same cell can be randomly joined to mRNAs from either strain (184).
- In an *in vitro* transcription system using lysates derived from MHV-infected cells, exogenously added leader RNA can be incorporated into subgenomic mRNAs (10).
- Studies using a DI RNA vector system showed that the appearance of full-length, genomic-sized negative-stranded RNA precedes the appearance of subgenomic negative-stranded RNA and subgenomic positive-strand mRNAs (4). Furthermore, the appearance of subgenomic mRNAs preceded the synthesis of subgenomic negative-stranded RNA, suggesting that the subgenomic mRNAs are most likely synthesized from the genomic-sized negative-stranded RNA template, at least early in infection. The subgenomic negative-stranded RNA could be generated from amplification of the subgenomic mRNA (4). However, the possible differences in the relative sensitivity for detection of the different RNA species in this study have not been rigorously excluded.

According to this transcription model, the IG or TAS sequences serve as promoters for mRNA transcription. In the case of MHV, these sequences include a minimal core promoter sequence of seven nucleotides (UCUAAAC) (111,178). When this seven-nucleotide sequence is inserted into the DI RNA and expressed in the MHV-infected cells, a subgenomic mRNA is transcribed from this intergenic sequence site (179). The transcribed MHV mRNA contains a leader sequence derived from the 5' end of the same RNA molecule (in *cis*) or a different RNA molecule (in *trans*) (297). Fusion of the leader RNA occurs within the UCUAAAC sequence. Additional sequences neighboring these seven nucleotides may also contribute to the joining of these two RNA regions (267).

The intergenic sequences preceding the various ORFs show some variability. Certain mRNAs, such as MHV mRNA 2-1, can be transcribed only when the leader RNA sequence (particularly its 3' end) and the intergenic sequence preceding the gene (i.e., HE gene) are compatible (133), suggesting that the interaction between the leader RNA and intergenic sequence regulates mRNA transcription. Deletion or mutation of the leader RNA abolishes or severely reduces mRNA transcription (152,297). According to this model, the subgenomic negative-stranded RNAs are synthesized from the subgenomic mRNA and may serve as the templates for transcription later in the viral replication cycle. This possibility would account for the UV target sizes observed later in infection.

An alternative model for coronavirus mRNA transcription is *discontinuous transcription during negative-stranded RNA synthesis* from the full-length genomic RNA template (222) (see Fig. 5**II**). According to this model, the polymerase pauses at one of the IG or TAS sequences and then jumps to the 3' end of the leader sequence in the genomic RNA template, generating a subgenomic negative-stranded RNA with an antisense leader sequence at its 3' end. This subgenomic negative-stranded RNA then serves as a template for synthesis of mRNAs. The positive-stranded intergenic sequence serves as the transcriptional termination sequence or the sequence that interacts with the leader RNA to facilitate

polymerase jumping during negative-stranded RNA synthesis. This model is compatible with the following experimental observations:

- Subgenomic negative-stranded RNAs have a poly(U) sequence at the 5' end and an antisense leader sequence at the 3' end (101,235); thus, they are exact complementary copies of the viral subgenomic mRNAs.
- The different subgenomic negative-stranded RNAs and their corresponding mRNAs are equally abundant in infected cells (236).
- Subgenomic replicative intermediate RNAs actively replicate in infected cells. When subgenomic RNAs were separated by size and then denatured, the smaller RIs generated smaller mRNAs, and the larger RIs generated only larger mRNAs. This finding suggests that each subgenomic mRNA may be transcribed from a corresponding subgenomic-sized, negative-stranded template (222). Furthermore, subgenomic negative-stranded RNAs were detected in the membrane-associated replication complexes (234).
- The UV target sizes for subgenomic mRNA synthesis at a later stage of viral replication correspond to the sizes of the individual subgenomic mRNAs (108,248,289). However, this model does not explain the kinetics of the appearance of various RNA species (4) or the UV target sizes of these mRNAs early in viral replication (176,289).

In this model, the IG or TAS sequences involved in the leader-mRNA fusion will operate during negative-strand RNA synthesis.

A third model (see Fig. 5**III**) is based on the finding that subgenomic mRNAs are incorporated into virions of some coronaviruses, including BCoV, TGEV, and IBV (103,236,298), along with the full-length genomic RNA. This model proposes that, after virus entry, the subgenomic mRNAs associated with the incoming virions are used directly as templates for the synthesis of subgenomic negative-stranded RNAs, which, in turn, serve as templates for the synthesis of additional subgenomic mRNAs (232,233). This model is not compatible with the discontinuous nature of coronavirus RNA synthesis. Furthermore, not all coronaviruses have been found to contain virion-associated subgenomic mRNAs. Coronavirus positive-stranded mRNAs cannot be amplified when transfected into infected cells (41,152). Nevertheless, it is possible that this model may operate at some stages of the viral replication cycle for some coronaviruses.

Data available at this time cannot unequivocally establish or exclude any of these models. The difficulty in differentiating these models is partially due to the fact that subgenomic negative-stranded RNAs can be copied from subgenomic mRNAs and vice versa because the subgenomic RNAs contain the complete cis-acting signals for negative-stranded RNA synthesis (155). So far, the synthesis of the subgenomic mRNAs and the synthesis of subgenomic negative-stranded RNAs have not been uncoupled in infected cells under any experimental conditions. Therefore, it is difficult to determine experimentally which subgenomic RNA species, positive- or negative-sense, comes first. Furthermore, most of the studies were performed late in infection when both positive- and negative-stranded subgenomic RNAs were already present and presumably could be further copied from each other. It is possible that elements from each of these models may operate at various stages of the viral life cycle. Comparative information about RNA transcription mechanisms in other related viruses, such as toroviruses and arteriviruses, may help to elucidate coronavirus RNA transcription because they have smaller RNA genomes and polymerase genes (59,242); furthermore, infectious viral complementary DNA (cDNA) or its transcripts are available for arteriviruses (269,270). However, there are no leader sequences on torovirus subgenomic mRNAs, and coronavirus replication has a high frequency of leader switching that is not seen in arterivirus replication.

Coronavirus RNA synthesis takes place on membranous structures associated with the endoplasmic reticulum (ER), Golgi complex, or late endosomes, depending on the cell types (61,237,265). Most of the gene 1 proteins are associated with the newly synthesized viral RNA. This observation is consistent with the finding that MHV temperature-sensitive mutants with defects in gene 1 can be classified into five complementation groups, all of which are defective in viral RNA synthesis (15). Anti-N antibody has been shown to inhibit MHV RNA synthesis *in vitro,* suggesting that N protein is involved in RNA transcription (49). Host components may also be involved in viral RNA synthesis (150,151).

In addition to the leader RNA and intergenic sequences, several other RNA elements, including the 3' end of the viral genome (155,156), are involved in the regulation of coronavirus mRNA transcription. About 55 nucleotides at the 3' end of the genomic RNA and the poly(A) sequence are required for the initiation of negative-stranded RNA synthesis (155); in contrast, the presence of the entire 3'-UTR region (305 nucleotides) is necessary for mRNA transcription (156). The difference in the lengths of the 3' end sequences required for negative-stranded RNA and mRNA synthesis suggests that most of the 3' end cis-acting sequence is involved in the synthesis of positive-stranded RNA. Thus, the 3' end of viral RNA (or 5' end of negative-stranded RNA) likely interacts with the leader or intergenic sequence to regulate mRNA transcription.

Replication of Genomic RNA

The viral genomic-sized RNA in the infected cell consists of two components: the mRNA encoding gene 1 products (5%) and the genomic RNA to be packaged into nucleocapsids and virions (95%) (210,244). Unlike the discontinuous synthesis of subgenomic mRNA, the production of genomic RNA presumably requires uninterrupted synthesis using a full-length, negative-stranded template. Therefore, the mechanism of genomic RNA replication conceivably differs from that of subgenomic mRNA transcription. It has been shown, however, that some genomic-sized RNAs of MHV may be synthesized by discontinuous transcription, that is, fusion of the leader sequence to a UUUAUAAAC sequence immediately downstream of the leader RNA, thereby creating a genomic-sized RNA with a small deletion (296). This mechanism has also been demonstrated in DI RNA replication. During MHV DI RNA replication, the leader sequence of the DI RNA can be rapidly replaced by that of the helper virus RNA (181), suggesting that MHV RNA replication involves a free leader RNA (of either positive or negative sense), similar to the discontinuous transcription of subgenomic mRNAs. In addition, the leader sequence of MHV RNA genome undergoes rapid evolution in the number of UCUAA repeats at the 3' end of the leader (180). These UCUAA sequences are also hot spots of RNA recombination, possibly as a result of discontinuous synthesis (116). Therefore, the replication of genomic RNA appears to occur by discontinuous synthesis

involving a leader RNA as well.

Studies of MHV DI RNA have also revealed information regarding the minimum cis-acting signals for coronavirus genomic RNA replication. Replication of the MHV DI RNA requires sequences of about 400 to 800 nucleotides at both the 3' and 5' ends of the genomic RNA and an internal replication signal of about 135 nucleotides (119,154). However, other DI RNAs of MHV and BCoV do not require this internal sequence for replication (41,169). This difference is likely due to differences in the secondary structure of the RNA genomes between different viral strains (120). The lengths of the cis-acting signals for RNA replication at both ends of the viral RNA differ slightly from those required for mRNA transcription (152,154,156). Additionally, the 3' end cis-acting signal for genomic RNA replication (154) is longer than that required for negative-stranded RNA synthesis (155), again suggesting long-range interactions between the two ends of the genomic RNA during RNA replication.

Translation of Viral Proteins

Although all but the smallest coronavirus mRNAs contain multiple ORFs, only the 5'-most ORF of each mRNA is generally translated by a cap-dependent ribosomal scanning mechanism (see Fig. 4). Most of the structural proteins, including S, M, N and HE, are translated from separate mRNAs by this mechanism. Because each of the coronavirus mRNAs contains a 5' leader sequence, which enhances translation in virus-infected cell lysates (260), virus-specific mRNAs may be preferentially translated in the face of translational shutoff in the infected cells. Other viral proteins are translated by other distinct mechanisms (see Fig. 3). First, the mRNA 1 of all coronaviruses contains two large overlapping ORFs that are translated into one polyprotein by a ribosomal frame-shifting mechanism (28,30,72,94,144). Translation of this gene, however, is initiated by the conventional cap-dependent translation mechanism. Second, in several coronavirus mRNAs, it is the second or third ORF that is most efficiently translated. For example, the E protein is translated from the second ORF of MHV mRNA 5 and the third ORF of IBV mRNA 3. These ORFs are preceded by an internal ribosomal entry site sequence that allows ribosomes to bypass the upstream ORFs and translate the downstream ORF by a cap-independent translation mechanism (161,262). Some of the upstream ORFs are also translated, but the translational efficiency and functional significance of these proteins are not clear. Third, several other mRNAs contain two overlapping ORFs, both of which are translated by unknown mechanisms. For example, mRNA 5 of IBV contains two ORFs that are both translated *in vitro* and *in vivo* (160), and an internal ORF (termed I) within the N genes of MHV and BCoV is translated *in vivo* (75,233).

Processing and Intracellular Transport of Viral Proteins

Polymerase Precursor Polyprotein 1a and 1b

Polyprotein 1a and 1b is presumably the first and only viral protein synthesized from the incoming viral genome because it is required for viral RNA synthesis. (Other viral proteins are translated from subgenomic mRNAs.) Once viral RNA synthesis begins, more gene 1 protein products are translated from the newly synthesized genomic RNA. The primary gene product (from ORF 1a and 1b), which is predicted to be nearly 700 to 800 kd, is cotranslationally or posttranslationally processed into multiple proteins by its own proteases. ORF 1a contains at least two protease domains: a papain-like cysteine protease (PLP) and a chymotrypsin-picornavirus 3C–like protease (3CLp) (90,144). In some viruses (e.g., MHV, HCoV-229E, and TGEV), there are two copies of the PLP domain, PLP1 and PLP2. PLP and 3CLp cleave the polyprotein into multiple proteins through a complex series of processing intermediates, some of which have not been unequivocally identified. In MHV, PLP1 is responsible for cleaving the aminoterminal proteins p28 and p65 from the polyprotein (11,12,24,60,62) (Fig. 6). The remaining portion of the polyprotein (including both ORF 1a and ORF 1b) is most likely processed by 3CLp (157,162,299,300). 3CLp itself is cleaved from the polyprotein by its own autoprotease activity into a protein of 27 kd, which has both trans- and cis-acting proteolytic activities (158,165,166,299). The 3CLp-mediated cleavage sites were predicted by computer analysis to be mostly at Q/S or Q/A sites (90,144); many of these have been confirmed by experimental analysis. A 100-kd protein from ORF 1b is thought to contain the polymerase domain (92,157), although the polymerase activity has not been directly demonstrated. A genetic complementation group thought to be responsible for mRNA transcription has been mapped to the coding region for this protein (223). A 67-kd protein has been shown to include the helicase domain (61). Many of these proteins and possibly their processing intermediates are colocalized with the newly synthesized viral RNA and, thus, are presumably present in the RNA replication complex, which is associated with the membranous structures in the infected cells (61,237,265). PLP2 has recently been shown to cleave at the upstream border of MP1 domain (112).

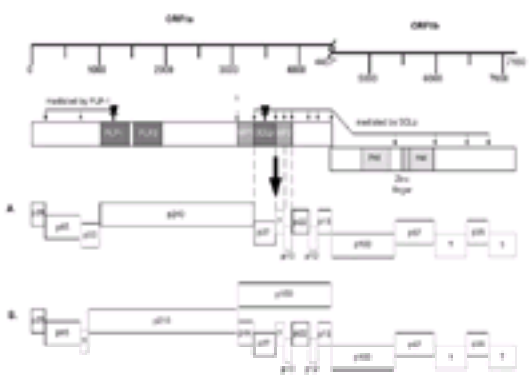

FIG. 6. Presumptive proteolytic products of the murine hepatitis virus (MHV) gene 1 (polymerase). Unlike the structural proteins of coronaviruses, which are each encoded by a separate mRNA, the proteins composing RNA-dependent RNA polymerases are formed by virus-encoded proteolytic processing of a precursor polyprotein. Open reading frames (ORFs) 1a and 1b are translated into a polyprotein by a ribosomal frame-shifting mechanism. The predicted and confirmed functional domains of ORF 1a and 1b are indicated. Two versions of the presumptive proteolytic processing pathways are shown. The *dashed lines* represent the unconfirmed products or cleavage sites. The full-length primary translation product and intermediates are not shown. The functions of most of these peptides are not yet known. PLP1,

PLP2, papain-like cysteine protease 1 and 2; 3CLp, poliovirus 3C-like protease; Pol, predicted polymerase; Hel, predicted helicase; MP, membrane-binding domain. (Courtesy of Susan C. Baker and Mark Denison.)

S Protein

The S protein is cotranslationally inserted into the rough endoplasmic reticulum (RER) and glycosylated with N-linked glycans. The protein is linked by multiple intramolecular disulfide bonds to form a complex structure and then oligomerized into homotrimers (58,199). Transportation of the S protein to the Golgi complex is accompanied by trimming of high mannose oligosaccharides and the addition of terminal sugars to form mature glycans. The S2 domain undergoes fatty acylation, probably on cysteine residues (225,255). Cleavage of S into S1 and S2 occurs after the conversion of glycans from simple to complex forms (272), either in the Golgi complex or extracellularly. Typically, the cleavage site is flanked by several basic amino acids (38,170); coronavirus S proteins that lack these residues, such as those of HCoV-229E or FIPV, are not cleaved. Most of the S protein accumulates in the Golgi of infected cells, where it participates in virus particle assembly; however, some S oligomers are transported to the plasma membrane, where it may mediate cell–cell fusion (91,272).

M Protein

The M protein is synthesized on membrane-bound polysomes and inserted into the ER membranes by an internal signal sequence (215). M protein is highly hydrophobic and spans the membrane three times (7,216). In IBV and TGEV, the aminoterminal domain of the M protein, which is located on the luminal side of the ER, is cotranslationally glycosylated with N-linked glycans (247); however, the corresponding domain in MHV is posttranslationally glycosylated by O-linked glycans in the Golgi apparatus (106,196,197). The mature M protein accumulates in the Golgi apparatus, but unlike S, it is not transported to the plasma membrane. The nature of the membrane-targeting sequence in the M proteins of different coronaviruses is variable (163,171).

HE Protein

The HE protein is cotranslationally glycosylated by N-linked glycans in the RER and forms disulfide-linked dimers of 165 to 170 kd (104,117,290). It is transported to the Golgi, where the N-linked glycans are converted to the complex form (290) and incorporated into the envelope of budding virus particles. HE protein that is not incorporated into budding virions is transported to the plasma membrane and expressed on the cell surface (117).

N Protein

The N protein is translated on free polysomes and rapidly phosphorylated on serine residues in the cytosol (247), but the extent of phosphorylation and its functional significance are not yet known. Some N protein may be associated with cellular membranes (4,247), where it participates in viral RNA synthesis and virus budding. Interestingly, some antigenic peptides of the N protein can be recognized on the surface of infected cells by T cells (25,251,277).

E Protein

The acylation of the MHV E protein is the only posttranslational modification known to occur in E protein (295). This protein is localized primarily in the perinuclear region in infected cells but is also expressed on the cell surface (87,295).

Assembly and Release of Virions

The first step in virus assembly is the binding of N protein to viral RNA to form helical nucleocapsids. Efficient packaging of genomic RNA into MHV virions requires a specific RNA signal that consists of a stretch of 61 nucleotides in the 3' end of gene 1b, about 20 kb from the 5' end of the genome (80,266,284). This sequence, found only in the genomic-length RNA, specifically binds the N protein (188). Thus, the interaction between the N protein and this packaging signal is likely the initial step of nucleocapsid formation. BCoV, TGEV, and IBV virions also package small amounts of all subgenomic mRNAs, which do not contain this packaging signal (103,235,236,298). These virion-associated mRNAs have been postulated to serve as templates for amplification of the subgenomic mRNAs for these viruses (237). Even DI RNAs without a typical packaging signal can be incorporated into virions, albeit inefficiently (40,182). The packaging of subgenomic mRNAs and these DI RNAs into virions may be mediated by the binding of N protein to the leader sequences of these RNAs (249).

Once the nucleocapsid is formed, it interacts with the M protein at the cellular membranes (254), most likely the ER or the Golgi complex. Studies have shown that the N protein by itself cannot be packaged into virions; it can be enveloped only together with the viral RNA (27,271), suggesting either that M protein interacts directly with the viral RNA or that the viral RNA–N protein interaction induces a conformational change in the N protein, enabling it to interact with the M protein. This interaction may lead to the formation of the spherical internal core shell surrounding the nucleocapsid (211) and, at the same time, enable the nucleocapsid to be packaged into budding virus particles, which are formed on the membranes of the ER and Golgi.

Although the interaction of the nucleocapsid with M protein likely triggers the packaging of the nucleocapsid into virions, the formation of virus particles cannot occur without an additional viral protein, the E protein. In fact, formation of virus-like particles, which do not have nucleocapsids, can occur in the presence of the M and E proteins alone (27,271). Studies showed that most mutations of the E protein resulted in altered virus morphology (76), and most alterations of the M protein abrogated virus-like particle formation (56). MHV virions can be released from tunicamycin-treated, virus-infected cells as spikeless, noninfectious particles that do not contain the S protein (106), indicating that S protein

is not essential for virus particle formation.

Virus budding is first detected at a specialized membrane structure called the *budding compartment,* located between the ER and the Golgi (66,121,263,264), where the M protein is anchored (121). Virus budding is most likely triggered by the interaction of E protein with the M protein located on the membrane. Because E protein in cells can be found at sites other than the ER or Golgi complex (86,292), the virus budding site is likely dictated by the M protein. It should be noted that coronavirus budding never occurs on the plasma membrane probably because the M protein is never found on the plasma membrane.

E protein is considered to be a minor component of the virion. The ratio of M to E protein in virions can be as high as 100:1 (271); thus, although the E protein is required for the initiation of virus assembly and budding, it may serve only as a scaffolding protein that is not an essential part of the mature virion. The expression of E protein induces curvature of the M-containing intracellular membrane (271); thus, E protein may be involved in the pinching off of the budding virions into the budding compartment.

The S and HE proteins are incorporated into virions through their interactions with M protein. The formation of S–M and HE–M complexes occurs in the pre-Golgi complex (195,200). These two complexes then form an S–M–HE ternary complex before the glycoproteins undergo trimming of their sugar chains (197). Thus, the processing of virion-associated glycoproteins most likely occurs as virions pass through the Golgi. After budding, virus particles may undergo further morphologic changes within the Golgi, resulting in the appearance of mature virus particles with a compact, electron-dense internal core, as they reach the secretory vesicles (213,218). Virions accumulate in large, smooth-walled vesicles, which eventually fuse with the plasma membrane to release virus into extracellular space (91). Virus release is restricted to certain areas of cells; for example, MHV-A59 virions are released from the basolateral surface of certain polarized murine cells (214). The mechanism of release site restriction is unknown.

Effects on Host Cells

Coronavirus-induced cytopathic effects vary with the virus strain and the host cell. Infection with certain coronaviruses, such as MHV, BCoV, IBV or FIPV, induces cell fusion in culture and in infected tissues. Even those coronaviruses that cause little or no cell fusion induce rounding and lysis of cells (84,89). The mechanisms of coronavirus-induced cytopathic effects are poorly understood. Some MHV strains are known to inhibit translation of cellular proteins (98,239) and cause selective inhibition of transcription of some cellular genes (132). Infected cells may undergo fragmentation and rearrangement of the Golgi apparatus late in infection (143). TGEV and some MHV strains may also induce apoptosis in some cell types, which may be mediated by the E protein (3,22,71). A combination of these virus-induced effects may contribute to the cytopathic effects observed in host cells late in infection.

Persistent coronavirus infection occurs readily in cell culture. Generally, after the initial cytocidal infection, carrier cultures arise, in which only a fraction of the cells produce infectious virus at any time, and virus production continues for months (89,105,140). Cells in persistently infected cultures are resistant to superinfection with wild-type virus, and various replication-defective mutants are frequently selected from these cultures (84,89,102,105,252). These mutant viruses may modulate virus dissemination in culture. Virus persistence in culture may also be due to the selection of coronavirus-resistant cells, whereby only a small number of cells remain susceptible to coronavirus infections, thus limiting the extent of viral dissemination (103,174,220). Both viral and cellular evolutions likely contribute to the maintenance of persistent infections. In fact, the virus and host cells often coevolve during persistent infection, resulting in the selection of both resistant cells and virus mutants with an expanded host range (46,224). HCoV-229E has been demonstrated to establish persistent infection in human oligodendrocyte and glial cell lines (6).

Although most coronavirus infections in animals are acute and self-limited, persistent coronavirus infection *in vivo* can occur in immunocompromised hosts, such as nude or newborn mice (20,21,209,261,278). Some temperature-sensitive or monoclonal antibody neutralization-escape mutants of MHV are particularly prone to cause persistent infection in animals (32,78,122). Persistency also has been noted in natural infections of feline enteric coronavirus (FECoV) in cats (96). In such cases, FECoV may undergo serial evolution, forming a distinct virus quasi-species in each cat. These chronic FECoV carriers would be resistant to superinfection (96).

CORONAVIRUS GENETICS

Virus Mutants

Like most RNA viruses, coronaviruses are thought to mutate at a high frequency because of the high error frequencies of RNA polymerases (246). However, in one case in which the entire MHV genome was sequenced after repeated passages of the virus in culture, surprisingly few mutations were detected (146). Nevertheless, multiple types of mutants have been isolated.

Temperature-sensitive (ts) MHV mutants have been classified into at least seven complementation groups (145), five of which are RNA negative, that is, they cannot synthesize RNA at the nonpermissive temperature (145,223). All of the RNA-negative mutations have been mapped to locations within gene 1 (15), suggesting that at least five separate functions of gene 1 products are required for viral RNA synthesis. Several complementation groups of RNA-positive mutants replicate viral RNA at the nonpermissive temperature but show altered cytopathic effects or fail to produce infectious virions (15,145). The RNA-positive mutants have defects in the genes encoding the S or N structural proteins (123,188,205). Some ts mutants differ in virulence from wild-type virus in animal infections. For example, although the wild-type JHM strain of MHV causes acute encephalitis in mice, some of its ts mutants cause a subacute demyelinating disease (93,125).

Deletion mutants also occur frequently. Many natural MHV strains have deletions of up to 200 amino acids in a hypervariable region of the S protein and show altered biologic properties *in vivo* (14,85,203). The most striking example

of the biologic importance of deletion mutations is the emergence of PRCoV from TGEV. TGEV causes epizootic enteric infections in pigs. In the early 1980s, PRCoV emerged in Europe as a new virus that caused widespread epizootic respiratory infections in pigs (141). Nucleotide sequence comparison of the two viruses showed that PRCoV was a derivative of TGEV with a large deletion within the S protein (31,202,281). Similar PRCoV strains have emerged independently in the United States as deletion mutants in the S gene of TGEV (9,141). FIPV most likely arose from deletion mutations of FECoV in a similar manner (273).

RNA Recombination

A unique feature of coronavirus genetics is a high frequency of RNA recombination, particularly in MHV (136). Although nonsegmented genomes of RNA viruses generally exhibit very low or undetectable recombination frequencies, the recombination frequencies for the entire coronavirus genome have been calculated to be as high as 25% (15). RNA recombinants were first isolated during co-infection with different ts mutants of MHV at the nonpermissive temperature (137). Additional recombinants were isolated using selectable genetic markers such as neutralization-escape mutants and strains that differ in cell fusion activity (113,115,116,181). To date, RNA recombination has been demonstrated for MHV, TGEV, and IBV, both in tissue culture and in experimental and natural animal infections (13,114,126,276).

The high frequency of RNA recombination in coronaviruses is probably the result of the unique mechanism of coronavirus RNA synthesis, which involves discontinuous transcription and polymerase jumping (136). It is possible that the viral polymerase associated with the incomplete nascent RNAs dissociates from its template at a random point and switches to a homologous site on a different RNA template to complete RNA synthesis by a copy-choice mechanism (14,136).

RNA recombination is an important mechanism in the natural evolution of coronaviruses. For example, new strains of IBV in poultry flocks are the result of natural recombination between different field strains (34,110,131,276). RNA recombination may also play a role in the evolution of different coronavirus species. For example, a reversal in the order of the M gene and gene 5 on the IBV and MHV genomes (see Fig. 3) may have occurred because of homologous recombination at consensus intergenic regions between the two genes in a progenitor of one of the viruses. Recombination may also explain the acquisition of the HE gene from an mRNA of influenza C virus by a progenitor of the group II coronaviruses (168). Some biotypes of FECoV appear to have arisen by recombination between FECoV and canine coronavirus (97).

RNA recombination has been developed into a potent genetic tool to introduce desired RNA sequences into coronavirus genomes. Cells are transfected with a DI RNA containing RNA sequences with desired mutations and then infected with a ts mutant that has a defect in the N gene. Recombination can take place between the DI RNA and the viral RNA at any homologous site; some of the resulting wild-type viruses may incorporate the part of a DI RNA sequence that contains the introduced RNA sequences and can be selected by using the appropriate selection markers (123,130,147,188,205). This approach, termed *targeted RNA recombination* (123), is an important tool for genetic manipulation of coronaviruses because full-length infectious cDNA clones of coronavirus genomic RNA are not yet available for most coronaviruses.

Defective-Interfering RNA

When a coronavirus such as MHV is passaged at a high multiplicity of infection, new RNA species smaller than the genomic RNA emerge (185). These are DI RNAs, which can replicate only in the presence of a helper virus and may interfere with the replication of the helper virus. DI RNAs have been detected for MHV, IBV, and TGEV during viral replication in cell culture (185,189,207). Three different types of DI RNAs have been demonstrated (177). The first type, typified by the DIssE RNA (177) of MHV, replicates efficiently but is not packaged efficiently into virions. However, small amounts of this DI RNA can be nonspecifically incorporated into virions; thus, it can be maintained and amplified during serial virus passages in culture (182). The second type, typified by the DIssF RNA (177) of MHV, contains a packaging signal that enables it to be incorporated into virions efficiently (186,266). The third type, typified by the DIssA RNA (177) of MHV, is not a true DI RNA because it has retained the ability to replicate. It contains small deletions at multiple sites, is nearly the size of the viral genomic RNA, encodes a functional polymerase, and can replicate even in the absence of a helper virus (118,182). All of the DI RNAs contain both the 5' and 3' ends of the viral genome, which include the cis-acting signals for RNA replication. Most of them also contain an ORF encoding a protein that is fused from different viral proteins (183). The presence of an ORF, which may or may not encode functional viral proteins, may enhance the fitness of the DI RNA during evolution (55,119,153), although the ORF or its protein product is not necessary for RNA replication (153,208).

During serial passages of viruses in cell culture, the original DI RNAs frequently disappear, and new ones of different sizes are generated (177). The continuous evolution of DI RNAs is often due to recombination between the original DI RNA and the RNA of helper virus (82). DI RNAs with a longer ORF have a selective advantage over those with a shorter ORF, contributing to the evolution of DI RNA (119,268). DI RNAs have not been detected during natural coronavirus infections; thus, their biologic significance in coronavirus infection is not clear.

CONCLUSIONS

Coronaviruses are unique among RNA viruses in many aspects of their viral structure and replication. They are characterized by exceptionally large RNA genomes, nested subgenomic mRNAs, discontinuous transcription mechanism, high-frequency RNA recombination, and the unusually large number of gene products associated with RNA synthesis. Coronavirus RNA incorporates two different gene expression strategies: polyprotein processing for gene 1 and one–gene–to–one–mRNA expression for the other genes, probably a reflection of their unusual evolutionary origin. Many questions regarding the coronavirus replication cycle remain unresolved, including the mechanism of mRNA transcription, the functions of gene 1 proteins and other nonstructural proteins, and the mechanisms of virus entry and assembly. Recent findings suggest that the structure of virions and the role of cellular factors in viral replication need to

be reevaluated.

Coronavirus research has been hampered by the lack of infectious cDNA or RNA transcripts, so that standard reverse genetics approaches are inapplicable. Construction of a functional full-length genomic cDNA has been difficult because of the large size of the coronavirus RNA genome. Only recently did the construction of an infectious coronavirus cDNA (for TGEV) succeed (2). Such infectious recombinant genomes will undoubtedly faciltate the coronavirus research. In addition, studies of the related but less complex toroviruses and arteriviruses should also further enhance our understanding of the exceptionally complex coronavirus replication cycle.

CHAPTER 36 Coronaviruses

Kathryn V. Holmes

HISTORY OF CORONAVIRUSES

Coronaviruses cause common respiratory and enteric diseases of humans and domestic animals (209,246). The structure of the coronaviruses was first determined by negative-stained electron microscopy. Avian infectious bronchitis virus (IBV) was found to have an array of large spikes on the viral envelope that resembled a crown (14). Mouse hepatitis virus (MHV), human respiratory coronaviruses (HCoV), and coronaviruses of domestic animals were found to share the same structure and, later, the same genome organization and replication strategy (1,30,31,209). In virions of some coronaviruses, including HCoV-OC43 and bovine coronavirus (BCoV), an additional layer of shorter spikes composed of the hemagglutinin-esterase (HE) glycoprotein was also observed on the viral envelope (103,104,258). Thin sections of coronavirus-infected cells and tissues showed that virions formed by budding at intracellular membranes, in a site between the rough endoplasmic reticulum and the Golgi apparatus called the *budding compartment* (43,227). Numerous virions of HCoV-229E were observed adsorbed to the plasma membranes of infected cells, but coronaviruses do not bud from the plasma membrane (170). The structure of the coronavirus nucleocapsid was more difficult to visualize than that of paramyxoviruses. The long, monopartite positive-stranded RNA genome of coronaviruses is encapsidated by the viral nucleocapsid protein, N, to form a long, flexible, helical nucleocapsid (136).

Classification and Nomenclature

Coronaviruses, toroviruses, and arteriviruses are now classified as members of the order Nidovirales, a group of enveloped, positive-sense RNA viruses that all synthesize a 3' co-terminal set of subgenomic mRNAs in infected cells (30). The toroviruses and coronaviruses are genera within the *Coronaviridae* family that differ in genome length, structural proteins, and nucleocapsid structure. The arteriviruses are classified as a separate family within the Nidovirales order. Arteriviruses have icosahedral nucleocapsids and markedly smaller genomes than coronaviruses. Like many coronaviruses, toroviruses cause enteric disease in humans and animals (109,212). Toroviruses in negative-stained stool specimens have sometimes been confused with coronaviruses by electron microscopy. This chapter discusses the coronaviruses that infect humans and studies on related coronaviruses of animals that shed light on the replication, pathogenesis, epidemiology, and prevention and treatment of human coronaviruses.

There are three groups of coronaviruses, with little or no serologic cross-reactivity between antigens on virions of the three groups (see Chapter 35). There are two groups of mammalian coronaviruses, and avian coronaviruses IBV and turkey coronavirus (TCoV) form a third group (67,176). The prototype of the first group is HCoV-229E. Coronaviruses of pigs (transmissible gastroenteritis virus [TGEV] and porcine respiratory coronavirus [PRCoV]), cats (FCoV), and dogs (CCoV) are related viruses in this group (176). The second group of mammalian coronaviruses includes the prototype MHV, and coronaviruses of humans (HCoV-OC43), rats (RCoV), cattle (BCoV), pigs (HEV), and other species (176). Antigenic cross-reactivity of the nonstructural proteins of coronaviruses has not yet been studied.

A brief summary of coronavirus genome organization, RNA transcription, and replication is presented below. More detailed discussions of these topics are found in Chapter 35 and in several reviews (24,121,209,213).

Genome Organization

Coronavirus genomes are monopartite, single-stranded, positive-sense, polyadenylated, and capped RNAs ranging from 27 to 32 kb in length (121,213). The complete nucleotide sequences of many coronavirus genomes have been determined (18,52,76,127). The order of the genes encoding the viral RNA-dependent RNA polymerase and the four common structural proteins, the spike (S), envelope (E), membrane (M), and nucleocapsid (N) proteins is the same for all coronaviruses: Pol-S-E-M-N (213). Genomes of coronaviruses in the MHV group also have a gene encoding the hemagglutinin-esterase (HE) glycoprotein located between Pol and S (131,213,258). Coronavirus genomes also include a variety of additional open reading frames (ORFs) that encode two to four nonstructural proteins of unknown functions.

These genes are not highly conserved among different coronaviruses. They are inserted into the genome in various sites between the genes that encode the polymerase and structural proteins (213,257). In the genome, a common intergenic sequence (IS) of about 7 bases is found at the 5' end of each gene (121). This IS sequence is essential for the formation of subgenomic RNAs because mutations in the IS can prevent the expression of the subgenomic RNAs, and insertion of an IS into a replicon can cause transcription of a subgenomic mRNA (96,142,226).

Subgenomic RNAs

Coronavirus-infected cells contain multiple overlapping subgenomic, capped, and polyadenylated mRNAs with a common 3' end (121). Each subgenomic mRNA and the viral genomic RNA, which also serves as an mRNA, is translated to yield only the protein encoded by the 5' gene on the mRNA. After the cap at the 5' end of every mRNA is a leader sequence about 70 bases in length that is the same as the sequence at the 5' end of the genomic RNA.

Small quantities of subgenomic negative-stranded RNAs corresponding to each subgenomic mRNA are found in infected cells (23,199,200,202). These have a poly(U) sequence at the 5' end and a sequence complementary to the leader at the 3' end. Several alternative mechanisms have been proposed to explain the presence of the leader at the 5' end of each subgenomic mRNA and the generation of the subgenomic negative strands in infected cells (121,201). These models are described in Chapter 35.

In infected cells, there are considerable differences between the numbers of subgenomic RNA transcripts that encode each of the structural genes. Because it is near the 3' end of the genome and present in all subgenomic viral mRNAs, the *N* gene is found in infected cells in much larger amounts than the *S* gene, which is about 8 kb upstream of *N.* The *N* gene is more highly conserved among isolates of the same coronavirus than the *S* gene. Therefore, the *N* gene has been used for initial studies on reverse transcription–polymerase chain reaction (RT-PCR) detection of viral RNA in infected cells. A highly conserved region from the polymerase gene has also been used to develop a consensus RT-PCR assay that can detect 11 coronaviruses in all 3 groups (217).

Replicase

The replicase gene found at the 5' end of all coronavirus genomes is enormous, about 20-kb long, with two partially overlapping ORFs, ORF1a and ORF1b, joined by an elaborated pseudoknot that acts as a ribosomal slippery site (77,121). Expression of this mRNA is different from that of the coronavirus subgenomic mRNAs. Like the nonstructural proteins of picornaviruses and alpha-viruses, the coronavirus gene 1 is translated as a polyprotein that is cotranslationally cleaved by a chymotrypsin-like protease (3CLpro) and one or two papain-like cysteine proteases found in the nascent protein (75,78,79,225,259,260). The proteins generated by these cleavage events in coronavirus-infected cells are now being characterized (75,249). Domains of the polyprotein that have homology to RNA polymerase and helicase, and an ATPase activity associated with the 1b protein of HCoV-229E have been identified (84,121). Some of the ORF1 gene products are associated with membranes in the cytoplasm of infected cells, and RNA synthesis occurs at or near this site (15,47,239). Complementation between temperature-sensitive, RNA-negative mutants of MHV have revealed at least eight complementation groups associated with ORF1 (8,214). Analysis of the processing of the polymerase polyprotein and characterization of the functions of the cleavage fragments may lead to identification of new targets for drugs to treat coronavirus infections.

Genetic Heterogeneity

In general, RNA-dependent RNA polymerases have a much higher error frequency than DNA-dependent polymerases. Based on an estimation of one error per 10,000 bases, the coronavirus RNA polymerase may generate about three random mutations in each about 30-kb genome produced in an infected cell. This would generate a population of genetically different viruses or quasi-species even in virus preparations derived from a single plaque. In addition to this high frequency of mutation, coronaviruses use RNA recombination as another way to generate genetic diversity in virus populations (24). RNA recombination between genomes of different strains of a coronavirus has been shown to occur with a high frequency in MHV, and recombination also occurs in other coronaviruses (120,141,143). Recombinants between vaccine strains and virulent IBV strains have been isolated from flocks of chickens in the field (117,245). Recombination between canine and feline coronavirus genomes has apparently generated variant coronaviruses that can be horizontally transmitted in cats (83). Nucleotide sequence analysis indicates that recombinants have probably also occurred naturally between TGEV and CCoV, generating a virus that is virulent for dogs (251).

RNA recombination may also generate viruses with deletions in their genomes. Many coronaviruses have strains that differ from each other by large deletions in or near a site within the N-terminal domain of the spike glycoprotein, S. Strains of MHV that differ in virulence and tissue tropism have deletions of different sizes in a hypervariable region in the N-terminal domain of S, as well as point mutations in S (194). The position of the deletions is correlated with the presence of a predicted stable stem-loop structure in the corresponding region of the S gene (195). Virulent enterotropic strains of porcine TGEV spontaneously give rise to strains that have deletions of more than 200 amino acids in a hypervariable region in the amino-terminal domain of the S glycoprotein (6). These strains are called *porcine respiratory coronavirus* (PRCoV) because they fail to cause enteric disease, replicate only in the respiratory tract, and are much less virulent than TGEV. Very large deletions in the genomes of coronaviruses generate subgenomic defective interfering (DI) RNAs that can be replicated in cells co-infected with a virus with an intact genome (53,80,132,144,155,177,226). Some DI RNAs that can be encapsidated in nucleocapsids and released from cells in enveloped virions were used to identify an about 69-nucleotide packaging signal on the positive-stranded genomic RNA (17,42,155,254).

Genetic studies of coronaviruses have been done using targeted RNA recombination (145,146,197). Cells inoculated with an infectious virus are transfected with cDNA of a minireplicon RNA derived from the same virus that has been altered by site-directed mutation. Within the cell, RNA recombination generates viral genomes in which the mutated gene or genes are substituted for the wild type. Selectable markers such as host range, temperature sensitivity, or monoclonal antibody selection are used to select the desired recombinants for studies of virus replication and pathogenesis. Targeted RNA

recombination has been used to map determinants of coronavirus pathogenesis, such as host range, tissue tropism, and virulence (116,126,129,145,181,197).

The high frequency of RNA recombination in coronavirus-infected cells may also account for the observation that the genomes of different coronaviruses contain a variety of genes that encode nonstructural proteins, and perhaps for the presence of the *HE* gene of the group 2 coronaviruses (162,242). The coronavirus *HE* genes have about 30% amino acid sequence similarity to the *HE* gene of influenza C virus (131). Possibly in a cell that was simultaneously infected with influenza C and a coronavirus ancestral to the group 2 coronaviruses, a nonhomologous RNA recombination event occurred between the coronavirus genome and the mRNA that encodes the HE glycoprotein of influenza C. Expression of an HE glycoprotein that binds to a sialic acid moiety on cell membranes would potentially help the coronavirus to bind to cells, increasing viral infectivity (244). Genes that are inserted into a coronavirus genome downstream of ORF1 are only expressed if a short conserved IS is located immediately upstream of the ORF so that a subgenomic mRNA with this ORF at its 5' end will be made and translated (121). Several of the nonstructural genes of coronaviruses are not required for virus replication in tissue culture or in animals, and their functions are not yet known (160). Because they are in helical nucleocapsids, coronavirus genomes may not be constrained in length like the genomes of viruses with icosahedral capsids. Therefore, if convenient methods are devised to insert foreign genes into coronavirus replicons as expression vectors, quite large insertions might be feasible.

HUMAN CORONAVIRUSES

Virus Isolation

Although coronaviruses of birds and many animal species can readily be isolated from infected tissues and serially propagated in continuous cell lines, isolation of human coronaviruses from infected individuals has only rarely been achieved (22,98,99,135,148,189,235,258). Hamre and Procknow isolated HCoV-229E from a patient with an upper respiratory infection by serial blind passages in secondary cultures of human embryonic kidney cells (68,69). Several other human coronaviruses were similarly isolated from colds at the same time. Some human coronaviruses that could not be isolated in cell lines were isolated from patients with colds by inoculation of human fetal tracheal or intestinal organ cultures (1,22,235). Most of the human coronaviruses that were grown in this way were never successfully adapted to serial passage in continuous cell lines and are no longer available for study. HCoV-OC43 and the antigenically related human coronavirus OC38 were isolated in human fetal tracheal organ culture, and then serially passaged by intracerebral inoculation into suckling mouse brain (148). Several human coronaviruses were isolated from adults with colds by a combination of growth in human diploid fibroblasts and inoculation of human volunteers (124). Human enterotropic coronaviruses were isolated from infants or children with gastroenteritis or necrotizing enterocolitis by inoculation of human fetal intestine or human rectal or kidney cell lines, and several of these viruses are closely related to BCoV (36,158,189,235,258). Differences in clinical symptoms were observed in human volunteers inoculated with several HCoV-229E–related viruses (188). Because very few isolates of human coronaviruses are available for study, little is known at the molecular level about the extent of genetic variability of the coronaviruses that commonly circulate in the human population (73,115). Strains of most avian and mammalian coronaviruses show extensive variation in their spike genes that can sometimes be correlated with differences in virulence and tissue tropism (94,102,118,119,187,194). Sequence analysis of HCoV genes in clinical specimens and in additional virus isolates is needed to reveal the extent of genetic diversity among human coronaviruses. This information will show how much antigenic drift occurs in human coronavirus S proteins over time and whether specific mutations in human coronavirus S glycoproteins are correlated with differences in pathogenesis.

Detection of Human Coronaviruses

Human coronavirus replication in organ cultures was initially detected by visualization of virions by electron microscopy (1). The genomes of the prototype HCoV-229E and HCoV-OC43 strains have been sequenced, and monoclonal antibodies to viral structural proteins are available (37,76,211). Therefore, it is now feasible to detect human coronavirus replication in human cell cultures and in some clinical specimens using RT-PCR and immunoassays (64,165,184,185,211). HCoV-OC43–related virions that express an HE glycoprotein on the viral envelope can also be detected by hemagglutination and acetyl esterase assays, and growth of this virus in cell cultures can be detected by hemadsorption, binding of erythrocytes to infected cells (100,258). Assays to detect antibodies directed against coronaviruses use infected cells in culture, extracts of infected cells, recombinant coronavirus proteins, or, for HE-expressing viruses, hemagglutination inhibition assays (64,138,139). HCoV-OC43 forms plaques in the HRT-18 line of human rectal tumor cells and grows in human rhabdomyosarcoma cells, human macrophages, primary human fetal neural cells, and human neural cell lines (3,37,204). HCoV-229E forms plaques in several human respiratory epithelial cell lines, such as MRC-5, WI-38, and L132, and replicates in human rhabdomyosarcoma cells, human type II pneumocytes, primary human neural cells, and human neural cell lines (4,16,204,222,237). HCoV-229E also replicates and causes cell fusion in human macrophages and macrophage cell lines (174). HCoV-OC43 can be passaged in suckling mouse brain (148). HCoV-229E has been serially passaged by intranasal inoculation into human volunteers (10,13,20,26,188,233).

PATHOGENESIS AND PATHOLOGY OF HUMAN CORONAVIRUSES

Entry into the Body

Natural infection of humans with human respiratory coronaviruses occurs through exposure to respiratory secretions. Intranasal inoculation of human volunteers with these viruses results in common colds (10,13,20,26,188,233). Coronaviruses of animals and birds are transmitted by the respiratory or enteric routes, depending on the virus. Because coronaviruses are enveloped, they are less stable in the environment and in clinical specimens than most nonenveloped viruses, such as rhinoviruses. In general, coronavirus infectivity can best be maintained at neutral or mildly acidic pH (122,221).

Receptors

Human aminopeptidase N (hAPN), a 150-kd zinc-binding glycoprotein with endopeptidase activity, is the receptor for HCoV-229E (256). Human APN is expressed on the apical surfaces of respiratory and intestinal epithelium as well as on myelocytic cells, on kidney tubular epithelium, and at synaptic junctions (5,169,208). Expression of recombinant hAPN in nonhuman cells makes them susceptible to HCoV-229E infection (256). In human cell cultures, treatment with some monoclonal antibodies directed against hAPN blocks virus infection, as do some inhibitors of hAPN activity, such as phloridzine (256). However, some mutants of hAPN that lack protease activity can still serve as receptors for HCoV-229E (44). Porcine coronaviruses TGEV and PRCoV, which cause enteric and respiratory symptoms, respectively, both use porcine APN (pAPN) as receptors (45), and many feline coronaviruses (FCoV) use feline APN (fAPN) as receptors (45,46,230). There are two biotypes of FCoV that may differ in the use of fAPN as a receptor (89,159).

Interestingly, HCoV-229E cannot use pAPN as a receptor, and TGEV cannot use hAPN (108), although the human and pig APN genes are 80% identical in nucleotide sequence. Inoculation of cells expressing recombinant chimeras of human, feline, or porcine APNs showed that 8 amino acids in the N-terminal region of hAPN near amino acid 291 are required for HCoV-229E receptor activity, whereas a different region of pAPN, amino acids 717 through 813, is a determinant of TGEV receptor activity (12,44,106,107 and 108). Perhaps these regions lie close together on the receptor glycoprotein in its native configuration. Feline APN can serve as a receptor not only for FCoVs but also for HCoV-229E, TGEV, and CCoV, which cause disease in humans, pigs, and dogs, respectively (230). These observations suggest that the progenitor of the group 1 coronaviruses may have been a feline-like coronavirus that used fAPN as its receptor, and that the S glycoproteins of HCoV-229E and the porcine coronaviruses TGEV and PRCoV may have later become adapted to recognize APNs of their respective hosts. Because feline cells and murine cells expressing recombinant fAPN can be infected with the group 1 coronaviruses of humans, pigs, cats, and dogs, it is possible that cats co-infected with feline and nonfeline coronaviruses serve as “mixing vessels” in which recombination between the coronavirus genomes could occur (83,230).

HCoV-OC43 does not use hAPN as its receptor (256). This virus binds to cells by means of the HE glycoprotein or the viral S glycoprotein, which can recognize 9- *O*-acetylated sialic acid moieties on the cell surface (115,244). Treatment of susceptible cells with neuraminidase makes the cells more resistant to HCoV-OC43 and BCoV infection but does not abrogate infection (114,206). It is not yet clear whether interaction of the S glycoprotein of HCoV-OC43 with another as yet unidentified receptor is also necessary for virus infectivity. Interestingly, like the HE glycoprotein of group 2 coronaviruses, the S glycoprotein of TGEV, a group 1 coronavirus, also recognizes *N*-acetyl 9-*O*-acetylated sialic acid moieties as well as *N*-glycolylneuraminic acid on plasma membranes of porcine cells (205,207). Point mutations in two amino acids between amino acids 145 and 155 in the amino-terminal domain of S of TGEV block virus binding to 9-*O*-acetylated sialic acid and block hemagglutination, but do not prevent virus entry through the pAPN receptor glycoprotein (113). These mutations lie within the hypervariable region of S that is spontaneously deleted in PRCoV, and PRCoV does not bind to this sialic acid moiety. The nonhemagglutinating mutant TGEV viruses have markedly reduced enteropathogenicity. Possibly, binding of virions to sialylated residues somehow increases viral stability and facilitates virus infection in the gastroenteric tract (113). The HE glycoproteins of HCoV-OC43, BCoV, and some MHV strains have acetyl esterase activity that can release sialic acid residues from 9- *O*-acetylated sialic acid moieties (115,244). This receptor-destroying activity of coronavirus HE glycoprotein, like that of the neuraminidase glycoprotein of influenza A virus, may aid in releasing virions adsorbed to 9- *O*-acetylated neuraminic acid moieties on the plasma membranes of infected cells and facilitate spread of virus to uninfected cells.

Replication in Polarized Cells

In polarized epithelial cells *in vitro,* HCoV-229E adsorbs preferentially to the apical plasma membrane where the hAPN receptor glycoprotein is concentrated (Blau and Holmes, in preparation). Coronaviruses are apparently released from infected cells by an exocytosis-like process that follows budding of virions into the pre-Golgi budding compartment (228). Virus release can be at the apical or basolateral membranes, or both, depending both on the virus and the host cell type (192,193). Coronavirus-infected epithelial cells die after several days and are shed from the epithelium. Apical release might efficiently spread virus among cells in the respiratory or enteric tracts, whereas basolateral release might facilitate systemic spread of the virus (192). *In vitro,* HCoV-229E virus can be released both from apical and basolateral surfaces of polarized epithelial cells expressing hAPN (Blau and Holmes, in preparation).

Cell and Tissue Tropism

Most coronaviruses first replicate in epithelial cells of the respiratory or enteric tracts. Some, including PRCoV and HCoV-229E, are believed to replicate principally in respiratory epithelial cells such as type II pneumocytes, where they produce virus and cause local respiratory symptoms (237). Other coronaviruses, including TGEV, BCoV, HEV, CCoV, FCoV, and MHV, infect respiratory epithelial cells and epithelial cells in the enteric tract. These viruses cause diarrhea that is particularly severe, sometimes fatal, in young animals (11,179). Inapparent enteric infection of adult animals maintains the virus in the population (56,255). It is not clear how these enveloped viruses retain their infectivity in the presence of the bile and proteolytic enzymes in the enteric tract. Perhaps because coronavirus envelope glycoproteins are extensively glycosylated, the virions are highly resistant to degradation by proteases in host tissues (33). In fact, when BCoV in group 2 is grown in certain cell lines, treatment of virions with trypsin is required to activate cell fusion activity and virus infectivity *in vitro* (220). On virions, the protease cleaves the spike glycoprotein only at one specific site near the middle of the molecule. Cleavage of newly synthesized S glycoproteins may be done by furin or other trypsin-like proteases in infected cells or by extracellular enzymes after release of virions (57). Some mutants of group 2 viruses that lack this specific protease site in S are delayed in virus entry and cell fusion and form small plaques (85), but other mutants that are not cleaved in S can cause extensive cell fusion (215). In contrast, the coronaviruses in the HCoV-229E serogroup do not have a protease cleavage site in their spike glycoproteins, and protease treatment of virions is not required for activation of virus infectivity. The virulence and tissue tropism of TGEV are determined by the spike glycoprotein, as demonstrated by targeted RNA recombination (197). Although the general structure of S proteins in different coronaviruses is conserved, there is relatively low sequence homology between *S* genes of the three

coronavirus groups.

Like coronaviruses of many other species, human coronaviruses have occasionally been implicated in enteric disease, particularly in newborns (36,63). The evidence for human enterotropic coronaviruses depends on visualization by electron microscopy of coronavirus-like, virus-like particles (VLP) in stools of infants with diarrhea, serologic studies of outbreaks of infant diarrhea, and infrequent isolation of coronaviruses from stools of infants and children with diarrhea (28,62,135,175,189). However, the role of coronaviruses in human diarrhea is not yet firmly established. The electron microscopic evidence is not compelling because other enveloped viruses such as human toroviruses (50,93,109,110 and 111) and even fragments of intestinal brush-border membranes resemble coronaviruses in negative-stained fecal preparations. In studies of nursery outbreaks of enterocolitis, VLPs were also observed in stools from infants without diarrhea (61). Because the immunologic responses of neonates are not strong, serologic evidence of infection in these patients is difficult to obtain. Rises in antibody titers against HCoV-OC43– related coronaviruses detected in sera of adults in contact with the sick infants could be due to respiratory infection, rather than enteric infection. There is significant serologic cross-reactivity among coronaviruses in group 2, so that rises in antibody titer do not unequivocally implicate a particular virus within this serogroup as a cause of disease (87,134,152). Isolation of putative human enterotropic coronaviruses has only rarely been achieved. Some coronavirus-like VLPs observed by electron microscopy in stools of patients with diarrhea could be passaged only once in organ cultures of human fetal enterocytes *in vitro* or in human embryo kidney cells (36). A putative human enterotropic coronavirus was isolated from stools of an infant with diarrhea by growth in human fetal intestinal organ cultures. The virus was neutralized by sera from adults in contact with the infant (189). The virus was adapted to growth in the J774 line of murine macrophages and the C6/36 mosquito cell line (130). Nucleotide sequence information on this viral isolate is not yet available. Several coronaviruses in group 2 that were propagated from human diarrheal stool samples in human or murine cell lines were found to be more closely related to bovine coronavirus strains than to the prototype HCoV-OC43 strain by reaction with monoclonal antibodies and by nucleic acid sequence analysis (158,240,258). Either these patients were infected with bovine coronavirus or viruses very similar to BCoV can circulate among humans and cause enteritis.

In addition to local infection of the respiratory or enteric tracts, several coronaviruses spread to other epithelial cell types where they cause symptoms of disease. For example, rat coronavirus strains cause respiratory infection or sialodacryoadenitis due to infection of the salivary and lacrimal glands (178). RCoV can also interfere with reproduction by infecting the female urogenital tract (238). Human coronaviruses have been associated with middle ear infections (184).

Several coronaviruses cause systemic infection in their natural hosts. HEV of swine causes enteric infection and is neurotropic (2). Infection spreads to nerves that innervate the stomach of infected piglets, prevents emptying of the stomach, and results in vomiting and wasting disease. Feline coronaviruses cause enteric disease in cats, but in some infected animals, virus mutants arise that cause a fatal systemic disease called *feline infectious peritonitis,* in which virus is detected in the plasma and ascitic fluids and infects many tissues (81,82). Strains of IBV that are nephrotropic cause death of chickens from acute kidney disease (95). Some strains of MHV, such as MHV-RI and MHV-Y, are strictly enterotropic, whereas other strains are respiratory tropic, neurotropic, or hepatotropic (11). Some MHV strains can spread to the liver, spleen, thymus, and brain, where they cause hepatitis, prolonged immunomodulation, acute encephalitis, and subacute or chronic focal demyelinating encephalomyelitis (39,85,123). Infection of macrophages is important in the spread of virus *in vivo* (7). SJL/J mice, which have many mutations in the virus-binding domain of the CEACAM1 glycoprotein isoforms that serve as MHV receptors in susceptible mice, are highly resistant to MHV infection, and macrophages isolated from these animals are also resistant to infection (19,51,105,219).

Coronaviruses Associated with Systemic Human Diseases

Human coronaviruses have occasionally been associated with pneumonia, particularly in immunosuppressed patients, or with neurologic symptoms and myocarditis (55,191). Of particular interest because of the induction of a multiple-sclerosis (MS)-like disease in rodents by murine coronavirus, is the possible role of human coronaviruses in MS. Coronavirus-like particles were observed by electron microscopy in a perivascular lesion in the brain of a patient with MS (224), and coronaviruses related to HCoV-OC43 and very similar to MHV were isolated from brain of two MS patients by passage in mice or murine cell lines (60,248). RT-PCR studies have identified sequences from the nucleocapsid genes of HCoV-229E and HCoV-OC43 in human brain tissue and cerebrospinal fluid (40,48,218). HCoV-229E RNA was detected in about 44% (40 of 90) of human brains tested, with about equal frequency in brain from MS patients and patients who died from other neurologic diseases or normal control subjects (218). HCoV-OC43 sequences were detected in about 23% (21 of 90) of the brains tested, with 36% incidence in brain from MS patients and 14% in that of controls. Both HCoV-229E and HCoV-OC43 can cause persistent infection in primary cultures of human fetal brain cells *in vitro* (3,4). The importance of human coronaviruses as a cause of diseases outside the respiratory tract remains to be determined.

Immune Responses

Studies in human volunteers were done to analyze the pathogenesis and immune responses of colds caused by human coronaviruses (13,20,21 and 22,25,26 and 27,233,234,236). Virus was inoculated intranasally, and patients were studied for development of symptoms, shedding of virus in respiratory secretions and changes in titer of antiviral antibody in serum and respiratory secretions. Fifty percent of volunteers inoculated with HCoV-229E developed colds. The incubation period was 2 to 4 days, and the mean duration of disease was 7 days (20). In this study, colds due to coronaviruses were generally classified as mild, although they were associated with significantly more nasal discharge than rhinovirus colds in volunteers. Other clinical features of coronavirus colds included headache (85%), sore throat (54%), malaise (46%), cough (31%), chills (31%), and fever between 37.3° and 38°C (23%). Eighty percent of the inoculated volunteers, including some who had clinically inapparent infection, excreted virus in respiratory secretions by day 3, and virus shedding had ceased by day 6 (20).

More than 80% of the adult volunteers had neutralizing antibodies against HCoV-229E in their sera before virus inoculation due to previous infections. However, most of the seropositive volunteers could be reinfected by the same virus. After virus inoculation, significant rises (fourfold or greater) in the level of virus-neutralizing antibody titers were

observed in 60% of volunteers (21), and rising serum antibody titers during convalescence could also be observed using hemagglutination inhibition assays and enzyme-linked immunoassays (64,138,139).

Treatment of volunteers with intranasal interferon-a before and after human coronavirus inoculation reduced the incidence of colds and the severity of symptoms as well as the amount of virus shed. Children who have more than six upper respiratory infections per year were found to have lower interferon responses to infection with coronaviruses and other respiratory viruses than children who have one or no upper respiratory infections per year (183).

Further studies on responses of natural killer (NK), B, and T cells to human coronavirus infection and on cytokine and chemokine expression during coronavirus infection are needed to elucidate the role of the immune response in symptoms, clearing of viral infection, and resistance to reinfection.

Virus Shedding

Coronaviruses are shed from the infected respiratory or enteric tracts. Pigs infected with PRCoV readily transmit the virus to other animals, likely by means of aerosols (125). Enterotropic coronaviruses of animals, such as TGEV and bovine, canine, and feline coronaviruses, can be spread by feces from infected animals (81). Enterotropic BCoV spreads efficiently among cattle and is also transmitted to sheep, deer, and other ungulates, perhaps by exposure to contaminated pastures of BCoV-infected cattle (140,229,231). Humans inoculated with respiratory coronaviruses shed virus from the respiratory secretions on day 3, but virus shedding was undetectable by day 6 after inoculation (20).

Virulence

There is no convenient small animal model for the study of the pathogenesis of respiratory infections caused by human coronaviruses. In human volunteers inoculated intranasally with a human coronavirus, the severity of symptoms varied markedly among infected individuals (20). Clearly, host factors play an important role in human coronavirus disease. In general, coronaviruses of animals cause the most severe diseases in primary infections of neonatal animals (11,179). Adult animals may develop clinically inapparent infections when exposed to the virus, shedding virus that is capable of causing severe disease in neonates (255). Genetic factors of the host can affect susceptibility to coronavirus diseases. At least three murine genes have been identified in inbred strains of mice that make animals more resistant to MHV infection than highly susceptible strains (7,19,49,51). These genes affect the virus yield, the innate immune response, and the functions of virus receptors. Cheetahs are highly vulnerable to fatal disease caused by feline coronaviruses, possibly because cheetahs have little polymorphism in their histocompatibility genes (54).

Variations in virulence may also be attributed to coronavirus strain differences. Strains of coronaviruses that vary significantly in virulence have been isolated from infected animals, and differences in the virus genomes have been identified. Strain differences in susceptibility to coronavirus virulence have been attributed to susceptibility of the S protein to cleavage by protease; expression of HE glycoprotein on the viral envelope and in infected cells; point mutations or deletions in the gene encoding the S glycoprotein; ability to use alternative cellular receptors; tissue tropism of virus strains; and the ability of some strains to cause persistent infections *in vivo.* In human coronaviruses, the extent of virus strain differences and the role of such differences in the virulence of human coronavirus disease are not known. As described previously, although coronavirus infection of humans occurs frequently throughout life, few strains of human coronaviruses can be propagated *in vitro,* and only a few of these strains have been used for infection of human volunteers (21,188). The extent of sequence variability among the human coronaviruses in groups 1 and 2 that circulate in humans remains to be determined.

Persistence

Some coronaviruses can cause persistent infection *in vitro* and *in vivo,* but the molecular mechanisms of persistence of these RNA viruses are not fully understood. Persistent infection *in vitro* has been studied for several coronaviruses, including MHV in murine fibroblasts and neural cell lines, and HCoV-229E and HCoV-OC43 in human respiratory cell lines or human neural cells (3,4,9,32,58,65,90). Detailed studies on the mechanism of persistence of the human coronaviruses and on possible changes in virus during persistence have not yet been done. Persistent infection of MHV in mouse fibroblast cell lines generates carrier cultures in which 10% to 30% of cells express viral antigens, expression of the virus receptor CEACAM1a is markedly reduced, and small plaque viruses with mutations in the S glycoprotein replace the wild-type virus and continue to be produced for months or years (9,35,65,86,198,203). MHV viruses isolated from persistently infected cells *in vitro* have point mutations in the S glycoprotein, including some that eliminate the protease cleavage site between S1 and S2 in the S glycoprotein. These mutations are associated with reduced infectivity of the virus, entry of the virus at endosomes rather than at the plasma membrane, loss of cell-fusing activity, reduced virus yield, and altered virus tropism *in vivo* (58,168). Some MHV mutants from persistently infected murine cells exhibit extended host range (35,203). Mutations in other viral genes in addition to S may also be associated with virus persistence (34).

Persistent coronavirus infection *in vivo* may result from failure of the immune response to clear virus infection, insufficient neutralizing antibody in the respiratory or enteric fluids, virus mutation to escape the immune response, absence of cytotoxic T-lymphocyte (CTL) epitopes on viral proteins that could promote clearance of infected cells, sequestration of virus in an immunologically privileged site, or virus-induced immunomodulation, among other factors. TGEV was persistently shed for 18 months in the feces of a sow with inapparent enteric infection, and the virus could be transmitted to susceptible 3-day-old piglets that developed acute gastroenteritis (255). As is true for enteric infection with several other types of viruses, the presence of neutralizing antibodies in the serum of the sow did not necessarily correlate with the ability to prevent reinfection or to clear virus infection from the enteric tract. Feline coronavirus can be shed in the feces for up to 7 months (82). An epitope in the S protein that is recognized by CTLs in C57BL/6 mice is deleted in MHV mutants isolated from persistently infected animals (180). The neurotropic MHV-JHM strain can cause prolonged persistent infection in mouse brain and spinal cord. Virus from brain from persistently infected animals had point mutations and a variety of deletions in the hypervariable region of S (194). Persistence of MHV in mice depends on many

factors, including the strain, age, and immune status of the mouse, and the strain, inoculum dose, and route of inoculation of the virus (11,223). Acute transient inapparent infection of adult mice with MHV can alter the cytokine profile of the animals acutely and for months after clearance of infectious virus (39). The virus-induced alterations in cytokine expression may alter the responses of the animal to other infectious agents. Persistence of human coronavirus RNA in a substantial proportion of human brain tissue or spinal fluid was detected by RT-PCR, although it is not yet certain whether the entire genome is present in the brain (40,48,163,218). Infectious virus has not been isolated from these specimens. The route by which human coronaviruses reach the brain and the clinical significance, if any, of the persistence of coronavirus RNA in human brain have not been determined.

EPIDEMIOLOGY

Neutralizing antibodies to coronaviruses related to HCoV-229E or HCoV-OC43 are detectable in the sera of pediatric and adult populations (20,21,101,153,185). Studies with human volunteers show that despite the presence of anticoronavirus antibody in the serum, reinfection of the respiratory tract with clinical symptoms can occur (234). Individuals can be reinfected with the same strain of virus within 1 year after the first inoculation, although there is considerable variation in the degree of illness associated with the two inoculations (20,74). The frequent susceptibility of adults to reinfection with a closely related coronavirus suggests that a variety of antigenically distinct human coronaviruses circulates in the population (188).

Natural outbreaks of colds caused by coronaviruses occur predominantly during the winter months, although in children, two peaks in late autumn to early winter and early summer were detected (91). In general, outbreaks of HCoV-229E in a community occur at 2- to 4-year intervals, and outbreaks of HCoV-OC43 occur in alternate years when the incidence of HCoV-229E infection is low (157). Prospective studies of respiratory infections in families, schools, and military populations were done in the 1970s and early 1980s using coronavirus isolation in tissue culture or organ culture, as well as electron microscopy, enzyme-linked immunosorbent assay (ELISA), and detection of rises in complement-fixing or neutralizing antibodies in the serum in association with clinical symptoms (71,91,99,124,150,153,156). These studies indicated that the frequency of colds due to coronaviruses varied in different populations from 5% to 30% depending on the time of year, the population studied, and the methods used in the study. The recent development of RT-PCR assays for human coronavirus infections and the availability of monospecific and monoclonal antibodies to detect viral antigens in clinical samples will allow more accurate estimates of the incidence and epidemiology of colds in humans (40,73,167,184,185,211,253).

It is generally believed that there are no animal reservoirs for human coronaviruses and that the viruses spread only among humans. However, S glycoproteins of human and animal coronaviruses within each serogroup are antigenically related, and it is not yet certain whether some coronaviruses circulate among humans and one or more mammalian species (88,152,243,258). The extent of genetic variation among human coronaviruses from different outbreaks is unknown. There are biologic differences among human coronaviruses isolated from different outbreaks of disease (147,188). Nucleotide sequences of the genes encoding the S glycoproteins of only a few HCoV-299E–related viruses and HCoV-OC43 virus have been determined to date (73,76,115,161). The S protein of the prototype HCoV-229E strain isolated by Hamre in the United States in 1966 differed from the LP strain isolated in the United Kingdom in the 1970s by only one amino acid, whereas the sequence of the *S* gene from respiratory washings of an adult with upper respiratory disease from Ghana in the 1990s differed from the prototype HCoV-229E *S* gene by only 47 of 1012 amino acids (73). There is considerably more amino acid sequence variation in *S* genes of group 2 coronaviruses of humans and animals, particularly in the S1 region. The deduced amino acid sequence of the S protein of the HCoV-OC43–related hemagglutinating coronavirus isolated from a child with diarrhea was 99% identical to a BCoV *S* gene sequence (258). In addition, other characteristics of the genome of the human virus resembled BCoV more than HCoV-OC43, including the presence of several ORFs downstream of *S* that are found in the BCoV genome, but absent in the genome of the prototype HCoV-OC43 (258). The spike glycoproteins of TGEV, CCoV, and FCoV are more closely related to each other than to that of HCV-229E (252). Cats and dogs must at least occasionally have been co-infected with feline and canine coronaviruses to permit the recombination in the spike gene that generated the FCoV biotype II viruses (83). To understand how human coronaviruses spread, new epidemiologic studies are needed that employ sensitive and strain-specific monoclonal antibodies, RT-PCR analysis of viral genes, and improved methods for isolation of infectious viruses from clinical specimens.

CLINICAL FEATURES OF HUMAN CORONAVIRUS INFECTION

HCoVs in both the 229E- and OC43-related serogroups cause upper respiratory signs and symptoms in adults and children that vary in frequency and severity in different outbreaks. The symptoms of common colds in volunteers inoculated with human coronaviruses and human rhinoviruses are similar (20,22,188,234,236) (Table 1). Volunteer studies showed that in adults, the mean incubation period of colds caused by coronaviruses is 3.3 days, with a range of 2 to 4 days (20). Many of the volunteers inoculated intranasally with HCoV-229E got febrile colds. Other symptoms included rhinorrhea, headache, malaise, chills, sore throat, and cough (20). Symptoms lasted for a mean of 7 days, with a range of 3 to 18 days. Symptoms varied considerably among different patients inoculated with the same coronavirus, perhaps because of differences in previous exposure to related viruses (20,188). About half of volunteers inoculated intranasally with HCoV-229E developed symptoms of the common cold, and 30% of volunteers had asymptomatic virus infection with shedding of virus from the upper respiratory tract (20). Shedding of infectious virus from apparently healthy individuals and from people with cold symptoms is an important factor in the epidemiology of coronavirus infection.

	Coronaviruses		Rhinoviruses	
	229E	OC43	Type 2 (HGP or PK)	OC
No. of volunteers inoculated	26	75	213	251
No. of volunteers getting colds	13 (50%)	34 (45%)	78 (37%)	77 (31%)
Incubation period (days)				
Mean	3.3	3.2	2.1	2.1
Range	2-4	2-5	1-5	1-4
Duration (days)				
Mean	7	6	8	10
Range	3-10	2-17	2-19	2-26
Maximum no. of handkerchiefs used daily				
Mean	23	21	14	18
Range	8-103	0-120	2-38	2-60
Malaise (%)	46	47	39	37
Headache (%)	85	93	90	88
Chill (%)	31	16	25	15
Pyrexia (%)	23	21	14	18
Mucopurulent nasal discharge (%)	0	62	83	80
Sore throat (%)	54	79	87	73
Cough (%)	31	44	68	58
No. of volunteers with colds of indicated severity				
Mild	10 (77%)	24 (71%)	63 (80%)	36 (47%)
Moderate	2 (15%)	7 (20%)	12 (15%)	28 (36%)
Severe	1 (8%)	3 (9%)	4 (5%)	13 (17%)

TABLE 1. *Clinical features of colds produced by inoculating four viruses*

When inoculated with the same virus a second time, an individual may have either a similar syndrome or a milder or more severe one (188). Patients who had symptomatic coronavirus infection showed rises in neutralizing and complement fixation antibody titers in the serum after inoculation that waned after months (26,112). The severity of colds caused by coronaviruses differs in different outbreaks, but most people with coronavirus colds develop only mild to moderate symptoms (20). There are no pathognomonic features of coronavirus-induced upper respiratory infections, so it is impossible to establish the etiology of a virus cold based on clinical findings alone (22).

Lower respiratory tract infections with coronaviruses were observed in some pediatric populations, but not in other studies (149,153,154). Asthma may be triggered by infection with coronaviruses as well as other respiratory viruses (128). In military recruits, coronaviruses accounted for about 30% of pneumonia cases (250).

DIAGNOSIS

Most human coronavirus infections are not diagnosed because the upper respiratory disease is relatively mild and self-limited, and no drugs are available to provide more than symptomatic relief. Only a small number of prospective studies on the etiology of human viral upper respiratory infections included sensitive assays to detect coronavirus infection (124,147,157,165,184). Although early studies relied on detection of coronavirus infection of animals and humans by immunoelectron microscopy, isolation of infectious virus in cell culture or organ culture, and rises in antibody titers detected by complement fixing or neutralizing antibodies, more recent studies have used much more sensitive and specific nucleic acid hybridization, RT-PCR, nested RT-PCR, quantitative PCR, and *in situ* hybridization assays to identify the presence of several viral genes and mRNAs in clinical specimens (59,66,164,165,166 and 167,172,210,217). Sensitive assays have been developed to detect coronavirus RNA in the feces of infected animals (70,81,82,92,172,186,232). Coronavirus infection can also be detected by immunofluorescence of cells shed into respiratory secretions, and serologic responses to coronavirus infection can be detected in human sera using recombinant viral proteins (154,185). Both group-specific antibodies and strain-specific monoclonal antibodies are being used for immunofluorescence and ELISA studies to detect coronavirus antigens (137,173,190). Although these sensitive and specific diagnostic tests for human coronavirus infection are not yet commercially available, assays are used for diagnosis of animal coronavirus infection.

Upper respiratory tract infections of humans caused by coronaviruses are associated with a variety of clinical signs that differ from one outbreak to another and from one individual to another (29,156,157,188). Clinical symptoms depend in part on previous infection with the same strain of human coronavirus (188). Therefore, colds caused by coronaviruses cannot be distinguished by clinical criteria alone from colds caused by rhinoviruses and other respiratory viruses (124). Previous studies on the etiology of colds have determined that about 15% to 30% of colds are caused by coronaviruses in adult and children (91,133,137,153). Recently, prospective studies to identify viral causes of upper respiratory infections in a pediatric population using RT-PCR have found that HCoV-229E and HCoV-OC43 may cause about 15% of colds (184). In addition, HCoV-OC43 was detected by RT-PCR in middle ear fluids of children with middle ear infections associated with colds (182,184).

Viral infections of the upper respiratory tract can precipitate asthma attacks (216). Coronaviruses are among multiple viruses that can precipitate wheezing or asthma attacks in susceptible individuals (128,151). In a prospective study of children younger than 6 years of age who had colds and HCoV antigens in the upper respiratory tract demonstrated by ELISA, 30% had wheezy bronchitis (91). It is likely that virus-induced inflammation and cytokine production play important roles in virus-induced asthma. Further studies are needed to understand the pathogenesis of increased reactivity of airways during human coronavirus infection.

PREVENTION AND CONTROL

The three principal reasons for developing sensitive assays for rapid diagnosis of human coronavirus infection are to elucidate the epidemiology and pathogenesis of coronavirus infections in humans, explore the possible significance of virus strain variation in virulence, and use only appropriate drug therapy for coronavirus infections when drugs to treat or prevent colds become available. Several strategies for treating human rhinovirus infection are being investigated, including specific inhibitors of the essential viral proteases that process the virus polyprotein; new inhibitors of the cascade of cytokines and inflammation that cause many of the symptoms of colds; molecules that block rhinovirus-receptor interactions, such as soluble receptors for rhinoviruses or antibodies to a rhinovirus receptor; and molecules that intercalate into the pocket beneath the floor of the canyon in the rhinovirus capsid, preventing receptor binding or blocking essential receptor-induced conformational changes in the virus capsid (41,72). Most of the potential drugs against rhinovirus colds would be unlikely to be effective for coronavirus colds because of differences in the

structures, receptors, and replication strategies of rhinoviruses and coronaviruses.

At present, there is no drug therapy for human coronavirus infections other than over-the-counter drugs that provide symptomatic relief. Potential drugs against coronaviruses include inhibitors of viral RNA-dependent RNA polymerase; the virus-encoded proteases essential for processing of the virus-encoded RNA-dependent RNA polymerase; coronavirus budding or release from infected cells, which may involve hemagglutinin-esterase; virus binding to specific cell surface receptors, such as hAPN for HCoV-229E; and the receptor-induced conformational changes in the virus spike glycoprotein that are required for virus entry.

No vaccines are available to prevent human coronavirus infection, but vaccines against common veterinary coronaviruses, such as IBV and CCoV, are routinely used to prevent serious disease in young animals, and various strategies to improve immunizations for veterinary coronaviruses are being tested (171,196). PRCoV acts as a naturally attenuated vaccine against TGEV. Infection of the respiratory tract of pigs with PRCoV causes inapparent infection or mild disease and may help to protect the animals from serious enteric disease on subsequent exposure to virulent TGEV (125).

There are several potential problems associated with development and use of live attenuated coronavirus vaccines. First, natural infection with virulent coronavirus strains does not prevent repeated episodes of disease caused by the same strain of virus. Therefore, new ways to stimulate protective immunity must be devised to create vaccines that will be more effective than natural infection. Second, for human coronaviruses, the number of different viral epitopes that must be included in a single vaccine is not known because the extent of the genetic heterogeneity of virus strains in circulation is not known. Third, because of the high frequency of RNA recombination in cells that are co-infected with two coronaviruses, recombination between live attenuated vaccine virus and virulent wild-type virus can occur in infected individuals. Variant strains of IBV that arose by recombination of vaccine and wild-type strains have caused outbreaks of disease in chicken flocks (117,245). Finally, an important problem that has prevented development of a vaccine to prevent feline infectious peritonitis (FIP) is the recognition of immune potentiation of feline coronavirus disease (179). FIP occurs most commonly in seropositive animals that have previously been infected with an enterotropic feline coronavirus (38,179,247). Recent studies suggest that FIP results from mutation of enterotropic FCoV strains that lead to systemic spread and virus persistence in some cats (241). The mechanism of immune enhancement of FCoV disease is not yet understood.

PERSPECTIVES

Coronaviruses in two distinct serogroups cause repeated episodes of upper respiratory infection in humans. Although the disease is generally mild to moderate, self limited, and patients recover within a week, common colds are an important economic problem because of the high incidence of disease with consequent loss of productivity. In addition to causing colds, human coronaviruses have been implicated in middle ear infections, exacerbations of asthma, pneumonia, diarrhea in infants, and myocarditis. Very few isolates of coronavirus can be propagated in cell culture. The extent of genetic variation among human coronaviruses that may be associated with differences in virulence and protective antigens has not yet been determined. Although considerable progress has been made in developing diagnostic tests to detect human coronaviruses, and in understanding the epidemiology of human coronaviruses, significant efforts are needed to develop small animals that provide models for diseases caused by human coronaviruses in which to test future drugs that may block coronavirus infection. Vaccines to prevent human coronavirus diseases do not appear feasible at this time. Potential targets for development of new drugs to treat coronavirus infections are being identified by studies on viral genes, gene products and replication strategy. In order to use such novel drugs wisely, sensitive and rapid techniques are needed to distinguish coronavirus infections from infections caused by the many other viruses that cause colds such as rhinoviruses. RT-PCR and immunoassays specific for coronavirus RNA and proteins provide powerful and rapid new diagnostic tools for study of the pathogenesis and epidemiology of human coronaviruses. Identification of the viral cause of an upper respiratory infection prior to selecting the appropriate antiviral therapy is likely to be expensive. Therefore, therapy for the common cold may depend upon use of combinations of several drugs, each of which inhibits one type of common cold virus.

CHAPTER 37 Arteriviruses

Eric J. Snijder and Janneke J. M. Meulenberg

The family of *Arteriviridae,* which was established in 1996, comprises four enveloped, positive-stranded RNA viruses: equine arteritis virus (EAV), lactate dehydrogenase–elevating virus (LDV), porcine reproductive and respiratory syndrome virus (PRRSV), and simian hemorrhagic fever virus (SHFV). The unification of these previously unclassified viruses was the direct result of the sequence analysis of their genomes during the 1990s, which significantly advanced our understanding of the molecular properties and replication cycle of arteriviruses. In combination with a number of distinct biologic properties, including the unique properties of their structural proteins, their virion morphology, and the ability to establish persistent infections, this provided the basis for the classification of arteriviruses as an independent family. The same molecular studies also revealed an intriguing relationship with the family *Coronaviridae* (see Chapter 35) at the level of genome organization and expression. The replicase genes of the two virus groups are assumed to share common ancestry, despite striking differences in virion structure, genome size, and biology. The evolutionary link between arteriviruses and coronaviruses is most convincingly reflected in their common genome expression strategy, which includes the generation of a nested set of subgenomic (sg) mRNAs. It is the latter property that formed the basis for the name Nidovirales (*L. nidus,* meaning nest) that was given to the novel order comprising the arterivirus and coronavirus families in 1996.

HISTORY OF ARTERIVIRUSES AND ARTERIVIRUS DISEASE

Three of the four arteriviruses (EAV, LDV, and SHFV) were first isolated and characterized 30 to 40 years ago (30,84,101). The porcine arterivirus PRRSV emerged in the late 1980s to early 1990s (18,116), causing vast epidemics of a previously unknown reproductive and respiratory swine disease in both North America and Europe. Remarkably, the subsequent molecular characterization of PRRSV strains from both continents (1,66,74,76) revealed extremely large genetic differences, especially considering the short time period (about 4 years) between the appearance of the disease in North America and Europe. These observations strongly suggest that the two PRRSV genotypes evolved separately from non–disease-causing viruses and are only distantly related to a common ancestor.

The consequences of arterivirus infection can range from an asymptomatic persistent or acute infection to abortion or lethal hemorrhagic fever. Macrophages appear to be the primary target cell for all arteriviruses (82,83). The natural host range of arteriviruses is restricted to horses and donkeys (EAV), pigs (PRRSV), mice (LDV), and several genera of African and Asian monkeys (SHFV). Recently, chickens and Mallard ducks, which were exposed to PRRSV in drinking water, were reported to shed the virus in their feces, suggesting that they may be susceptible to PRRSV infection (120).

In nature, EAV and PRRSV are transmitted primarily by the respiratory route (64,103,115). The severity of disease can vary greatly and is influenced by the strain of the virus and the condition and age of the infected animal. EAV and PRRSV infections can be subclinical but can also lead to a variety of symptoms, including the necrosis of small muscular arteries from which the name of the family prototype EAV was derived. Both viruses can cause abortion in pregnant animals and may persist in the semen of infected males, which makes sexual transmission an important secondary route of infection (100,103).

The name of the mouse arterivirus LDV is derived from the increase in the level of lactate dehydrogenase (LDH) caused by the virus in the blood of infected mice (84). LDV has been used extensively as an *in vivo* research model (11,83). The virus infects a renewable subpopulation of macrophages and is able to escape immune surveillance. Usually, this persistent infection is largely asymptomatic, but in certain inbred mouse strains, neurovirulent LDV variants can cause a fatal age-dependent poliomyelitis (19).

SHFV was isolated from outbreaks of fatal hemorrhagic fever in macaque colonies (101). The virus appears to be

endemic among several species of African monkeys (*Erythrocebus patas, Ceropithecus aethiops, Papio anuibus,* and *Papio cyanocephalus*), in which it causes asymptomatic acute or persistent infections depending on the virus strain (44,59). The epizootics and disease in captive macaques, during which mortality approached 100%, are probably explained by inadvertent SHFV transmission by humans from African monkeys to macaques.

On the basis of morphologic criteria (size, an isometric core, and the presence of an envelope), arteriviruses were regarded as unclassified togaviruses or flaviviruses or as members of a “floating genus” for many years. An important milestone was the sequence analysis of the EAV genome in 1991 (22), which revealed the unexpected relationship with members of the coronavirus family. Since then, the availability of cloned arterivirus sequences has rapidly increased our understanding of the properties of the viral RNAs and proteins. The recently developed infectious cDNA clones of EAV (26,105) and PRRSV (65) will allow an even more sophisticated analysis of the replication cycle and biologic properties of arteriviruses.

VIRION STRUCTURE AND PROPERTIES

Arteriviruses are spherical, are 40 to 60 nm in diameter, and possess a relatively smooth surface that lacks large projections (Fig. 1; reviewed in 10,82, and 91). They consist of an isometric, possibly icosahedral, nucleocapsid of 25 to 35 nm, which is surrounded by an envelope carrying cuplike structures. The buoyant density of arteriviruses is 1.13 to 1.17 g/cm^3 in sucrose, and their sedimentation coefficient ranges from 214S to 230S. The virions are highly unstable in solutions containing low concentrations of nonionic detergents or at a pH other than 6 to 7.5. Furthermore, they lose their infectivity quickly when stored at temperatures of 4°C or higher.

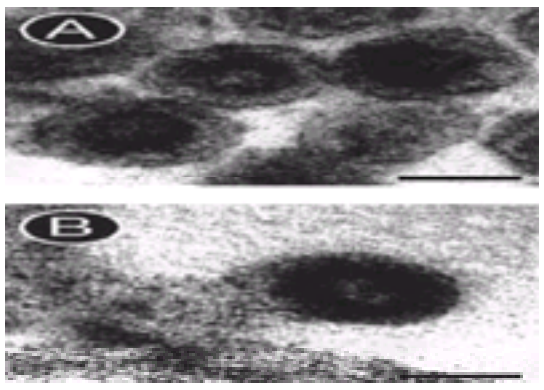

FIG. 1. Electron micrographs of arterivirus particles. **A:** Negative staining of extracellular porcine reproductive and respiratory syndrome virus (PRRSV) particles (*bar* is 27 nm). **B:** Equine arteritis virus (EAV) particle budding from smooth intracellular membranes (*bar* is 25 nm). (From ref. 91, with permission.)

The arterivirus nucleocapsid is composed of the 12.7- to 15.7-kb RNA genome and the nucleocapsid protein N (Fig. 2). The lipid bilayer that surrounds the nucleocapsid contains five or six envelope proteins, an unusually large number compared with other positive-stranded RNA viruses. Two of these proteins are major structural components: the nonglycosylated integral membrane protein M and the “major” glycoprotein (25,35,68). The nomenclature of arterivirus envelope glycoproteins has not yet been standardized. For example, the major glycoproteins have been designated G $_L$, VP-3P, GP$_5$, and p54 in the case of EAV, LDV, PRRSV, and SHFV, respectively (Table 1). For convenience and clarity, in this chapter we refer to the glycoproteins as GP $_x$, where x indicates the number of the open reading frame (ORF) in the genome from which the protein is expressed (Fig. 3; see Table 1 and later discussion).

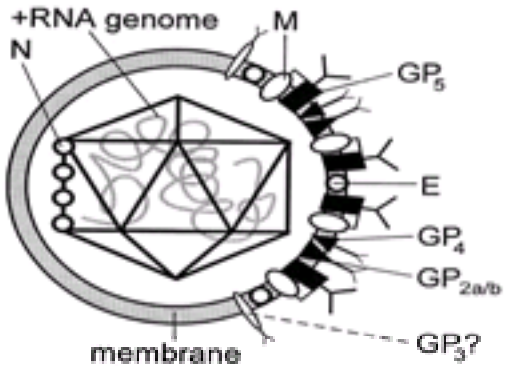

FIG. 2. Schematic representation of an arterivirus particle. The location of the structural proteins GP $_{2a/b}$ to GP$_5$, E, M, and N is shown (see also Table 1 and Fig. 3). Note that the glycoprotein nomenclature of simian hemorrhagic fever virus (SHFV) deviates from that of the others, that not all proteins depicted here have been identified in all four arterivirus particles, and that conflicting data on the presence of GP $_3$ in virions have been reported for porcine reproductive and respiratory syndrome virus (PRRSV).

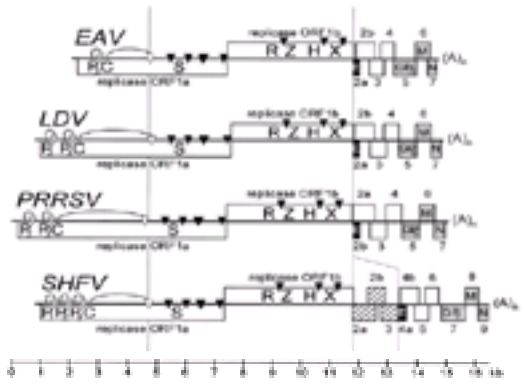

FIG. 3. Overview of arterivirus genome organizations. The family prototype equine arteritis virus (EAV) is shown at the *top.* The replicase open reading frames (ORFs) 1a and 1b are followed by the gene encoding the E protein (*black*), three genes (ORFs 2a and 2b to 4) encoding minor glycoproteins, and the genes for the major structural proteins GP_5 (GP_7 in simian hemorrhagic fever virus [SHFV]), M, and N (*gray*). The 3'-proximal region of the SHFV genome contains a large insertion (*hatched area*) containing three ORFs that may encode additional glycoproteins. In the replicase ORFs, the position of known (EAV) or predicted (lactate dehydrogenase–elevating virus [LDV], porcine reproductive and respiratory syndrome virus [PRRSV], and SHFV) polyprotein cleavage sites are depicted. *Black arrowheads* represent sites cleaved by the nsp4 serine protease (*S*). The papain-like protease domains (*P1* to *P3*) in the nsp1 region, the nsp2 cysteine protease (*C*), and their (predicted) cleavage sites are also shown. In the ORF 1b polyprotein the four most conserved domains of nidovirus replicases are depicted: the RNA-dependent RNA polymerase (*R*), putative zinc finger (*Z*), RNA helicase (*H*), and nidovirus-specific domain (*X*).

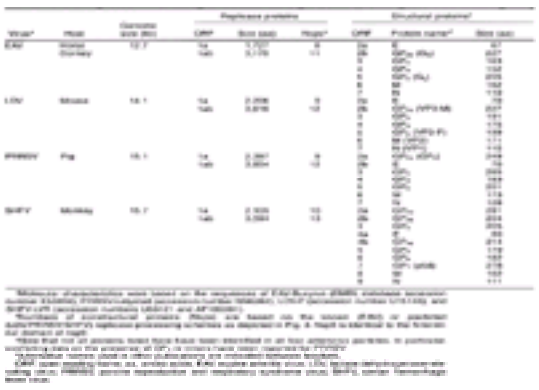

TABLE 1. *Molecular properties of arteriviruses*

The glycoproteins $GP_{2a/b}$ (PRRSV, EAV, and LDV) and GP_4 (EAV and PRRSV) were experimentally identified as minor virion components (29,35,67,92,111). A fourth glycoprotein, GP_3, was suggested to be a minor structural glycoprotein in a European PRRSV isolate (111) but a nonstructural protein in a Canadian isolate (63). A novel nonglycosylated structural protein was recently detected in EAV particles and was provisionally designated E (for envelope) protein (92).

GENOME STRUCTURE AND ORGANIZATION

The arterivirus genome is a positive-stranded, 3' polyadenylated RNA molecule. At the 5' end, the SHFV genome was reported to contain a type I cap structure (86); in addition, cap analog was found to be an essential component of *in vitro* transcription reactions to generate infectious PRRSV and EAV RNA from full-length cDNA templates (65); L.C. van Dinten and E.J. Snijder, unpublished data). Full-length genomic sequences (see Table 1) have been obtained for EAV (22), European and North American isolates of PRRSV (1,66,74,76), two LDV strains (40,81), and recently also for SHFV (85; T. R. Maines and colleagues submitted for publication).

The arterivirus replicase gene, which consists of the large ORFs 1a and 1b, roughly occupies the 5'-terminal three fourths of the polycistronic arterivirus genome (see Fig. 3). In contrast to the more conserved ORF 1b region, the size of ORF 1a is variable (encoding between 1,727 and 2,502 amino acids), a property that largely explains the genome size differences among arteriviruses (see Table 1). The significance of the small potential ORF found in the leader sequence upstream of the replicase gene in EAV, PRRSV, and SHFV is unclear (52,91). However, inactivation of the EAV leader ORF was recently shown not to affect virus replication in cell culture (73).

The region downstream of the replicase gene contains a set of 7 to 10 relatively small genes, most of which have both 5'- and 3'-terminal sequences that overlap with neighboring genes (see Fig. 3 and Table 1). These genes encode mostly (or exclusively) structural proteins, they are translated from sg mRNAs (see later), and their organization is generally well conserved in the arterivirus genome. An exception is a region downstream of the SHFV replicase gene, which contains three additional ORFs, comprising about 1.6 kb (90). Sequence comparisons suggested that these ORFs may have arisen from the duplication of ORFs 2 to 4 by an RNA recombination event (41).

THE ARTERIVIRUS REPLICATION CYCLE

Attachment and Entry

Upon transfection of genomic RNA, arteriviruses can replicate in several cell lines that are not susceptible to infection with virus particles (49,65). Furthermore, cell lines that are resistant to LDV can be infected by murine coronavirus and LDV pseudovirions (32). Certain cell lines have been reported to become LDV susceptible when they are first infected with murine leukemia virus (50), although these results have not been reproduced by others (82). These data suggest that cell tropism is determined by the presence of an as yet unidentified receptor on the cell surface. In the case of PRRSV, infection of MARC-145 cells could be prevented by prior incubation of virus or cells with heparin and also by treatment of the cells with heparinase (51). Therefore, it was proposed that a heparin-like molecule on the surface of MARC-145 cells may serve as an attachment molecule for PRRSV. More recently, a 210-kd membrane protein from porcine alveolar macrophages was identified as a putative receptor for PRRSV (31). Two monoclonal antibodies directed against this as yet uncharacterized protein were found to block attachment of the virus to these cells.

The entry pathway of PRRSV was investigated using drugs that affect the pH of intracellular membrane compartments (55). It was shown that a low pH in these compartments is required for virus entry, which most likely occurs through the standard endocytotic route. Entry was also blocked by cytochalasin D (75), a compound that inhibits receptor-mediated endocytosis. Electron microscopy revealed PRRSV particles contained in relatively small vesicles, which appeared to be clathrin coated (55). Similar observations were made during the initial stages of LDV infection in macrophages (54).

Genome Replication

The arterivirus replication cycle (Fig. 4)occurs entirely in the cytoplasm of the infected cell. A genome-length negative strand is generated that serves as the template for genome replication. In addition, nested sets of sg negative strands and sg mRNAs are generated, which are each other's complement. The transcripts in each set are both 5'- and 3'-coterminal with each other and with the corresponding genome-length RNA (Fig. 5 and see later discussion).

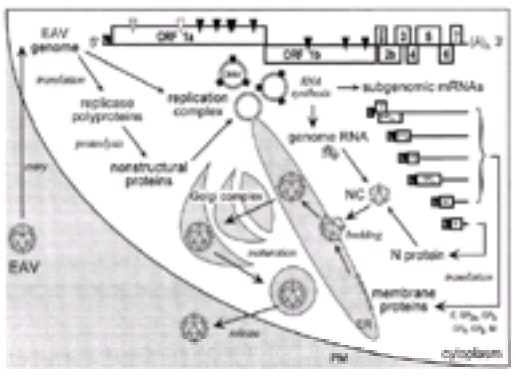

FIG. 4. Overview of the life cycle of the arterivirus prototype equine arteritis virus (EAV). The EAV genome organization, including replicase cleavage sites (*arrowheads;* see Fig. 3), is shown at the top of the figure. The nested set of subgenomic (sg) mRNAs with their common leader sequence (*L*) is depicted at the right. ER, endoplasmic reticulum; PM, plasma membrane; DMV, double membrane vesicle; NC, nucleocapsid.

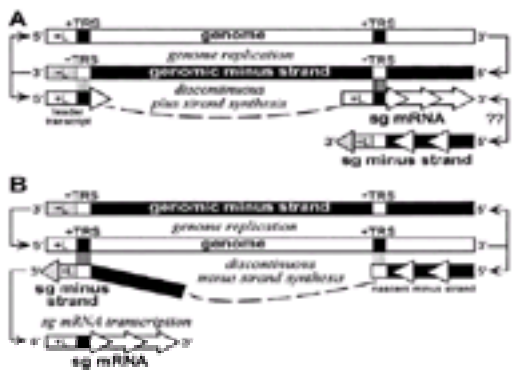

FIG. 5. Transcription models illustrating the discontinuous step during arterivirus mRNA synthesis, which involves TRS base pairing (109) and has been postulated to occur either during positive-stranded synthesis (model A) or during negative-stranded synthesis (model B). See also references 9,87,91, and 109 as well as Chapter 35 and references therein. Depicted are the genomic RNA and one of the subgenomic (sg) RNAs. Positive and negative strands are shown as *black bars* and *white bars,* respectively. The position of the positive transcription-regulating sequences (TRSes; *black boxes*), negative TRSes (*white boxes*), and leader (*+L*) and antileader (-L) sequences is indicated. **A:** Leader-primed transcription model. Discontinuous transcription was first proposed to occur at the level of positive-stranded RNA synthesis, through positive leader priming on complementary (negative) body TRS sequences in the full-length negative-stranded template. Transcription of sg negative strands from mRNA templates may occur, but in this model, such negative transcripts are assumed to be nonfunctional (“dead-end”) products. **B:** Discontinuous negative-stranded extension model. Negative-stranded synthesis is either continuous, yielding the full-length negative strand for genome replication, or discontinuous, yielding an sg negative strand that subsequently serves as the template for sg mRNA synthesis. The latter model is supported by data recently obtained from mutagenesis studies using an EAV full-length cDNA clone (109) and is also consistent with most of the observations made for coronaviruses using biochemical and genetic methods.

Little is known about the RNA signals involved in arterivirus genome replication. The coding regions of the genomes are flanked by 5'- and 3'-untranslated regions of 156 to 221 and 59 to 117 nucleotides, respectively. However, natural and synthetic defective interfering RNAs, which were recently generated for EAV, invariably required at least 300 nucleotides from both genome termini for efficient replication. This suggests that replication signals partially overlap with coding sequences (72). The interaction of these RNA signals with viral or host proteins is a largely unexplored field. However, four host proteins from MA-104 cells were reported to bind to *in vitro* generated transcripts representing the 3' end of the SHFV genomic negative strand (48). The same four proteins, which remain to be identified, apparently interact with transcripts representing the corresponding region of the LDV and EAV negative strands, suggesting the involvement of a common set of host factors in the initiation of arterivirus positive-stranded RNA synthesis.

Subgenomic mRNA Transcription

One of the hallmarks of the replication cycle of arteriviruses (and other Nidovirales) is the generation of a nested set of sg mRNAs (Fig. 5) from which the (mostly structural) genes in the 3' end of the genome are expressed. The sg mRNAs are 3' coterminal, but they also have a common 5' leader sequence (24), which is derived from the 5' end of the genome. After conventional cis-splicing was ruled out as the mechanism of EAV leader-to-body fusion (23), it was postulated that arterivirus sg mRNAs are synthesized by a discontinuous transcription mechanism similar to that previously proposed for coronaviruses. Clearly, this concept is supported by the presumed common ancestry of the arterivirus and coronavirus replicase genes (22,27,91). Furthermore, in both virus groups, short conserved transcription-regulating sequences (TRSes) are present at the 3' end of the leader sequence and at the 5' end of the transcription units for each of the sg mRNA bodies (reviewed in 91). The observation that arterivirus-infected cells contain a nested set of sg negative-stranded RNAs, complementary to the sg mRNAs, was another important parallel with coronaviruses (14,21).

A substantial number of models for nidovirus sg mRNA synthesis have been proposed, in particular for coronaviruses, and have been reviewed extensively (see Chapter 35; references 9,87,91; and references therein). Initially, the observation that the positive TRS at the 3' end of the leader could base pair with the negative TRS upstream of each transcription unit in the genomic negative strand led to the proposal of a leader-primed transcription model (see Fig. 5**A**) for coronaviruses. In this model, base pairing between the positive and negative TRSes is followed by extension of the leader to yield an sg mRNA. The detection of sg negative strands, however, indicated that the discontinuous step could also occur during the synthesis of negative-stranded rather than positive-stranded sg RNAs. This concept was subsequently supported by biochemical and genetic studies with coronaviruses and resulted in a model (see Fig. 5**B**) in which discontinuous extension of negative strands yields sg templates for sg mRNA synthesis (87).

Recently, direct proof of base pairing between the positive leader TRS and the negative body TRS was obtained from reverse genetics studies using an EAV infectious copy DNA (cDNA) clone (109). Site-specific mutations introduced in the positive leader TRS can be compensated by the introduction of the same mutation in the positive body TRS, thereby preserving the potential for base pairing between the positive leader TRS and the negative body TRS (Fig. 5). It was even possible to maintain partial transcription activity after substituting all five conserved nucleotides of the EAV TRS, which indicates that this sequence per se does not serve as a recognition signal for viral or cellular proteins involved in discontinuous transcription. Furthermore, the TRS sequences found in mRNAs generated by TRS mutants with partial transcription activity (109) provided additional support for the model of discontinuous negative-stranded synthesis (see Fig. 5**B**). The mechanism by which the transcription complex is translocated between body and leader TRSes, a step that may resemble copy choice RNA recombination (9,109), remains to be elucidated. Obviously, specific interactions between proteins (viral or cellular) and RNA sequences in both nascent strand and template are likely to be its driving force. Future studies may also reveal why several arterivirus mRNAs are generated from multiple or nonconsensus TRSes in the 3'-terminal region of the genome (reviewed in 91).

Translation and Posttranslational Processing

Translation of the arterivirus genome, the first step in virus replication (see Fig. 4), yields two large replicase polyproteins: the ORF 1a protein (1727 to 2502 amino acids) and the ORF 1ab protein (3175 to 3959 amino acids). ORF 1b translation requires a –1 ribosomal frame shift just before ORF 1a translation is terminated (22). The ORF 1a and 1b overlap region contains two signals that are assumed to promote this event: a so-called slippery sequence, which is the actual frame-shift site; and a downstream RNA pseudoknot structure. The functionality of the frame-shift signal has been demonstrated for EAV: using a reporter gene construct, a frame-shifting efficiency of 15% to 20% was observed (22).

The posttranslational fate of the arterivirus replicase polyproteins has only been studied extensively for EAV, and an apparently complete processing scheme has recently been obtained (94,106,108,112). The EAV ORF 1a and ORF 1ab polyproteins are cleaved 7 and 10 times, respectively, by three different ORF 1a–encoded proteases (see later). In combination with the ribosomal frame shift, this leads to the generation of 12 processing end products, or nonstructural proteins (nsp1 to nsp12) and a large number of processing intermediates. Of the processing end products, nsp1 to nsp8 are generated from the ORF 1a polyprotein, whereas nsp10 to nsp12 are entirely ORF 1b–encoded. The putative RNA polymerase subunit, nsp9, consists of a small, ORF 1a–encoded N-terminal domain, which is identical to nsp8, and a large, C-terminal part that is encoded by the 5'-proximal region of ORF 1b. In addition to the three proteases described for EAV, both LDV and PRRSV possess a fourth nonstructural proteolytic activity (20,40,66), which mediates the rapid release of an additional N-terminal cleavage product. The additional protease resides in the extreme N-terminus of the ORF 1a protein and may be a duplication of the papain-like cysteine protease (PCP) domain present in the C-terminal domain of EAV nsp1 (20). The recent sequence analysis of the SHFV replicase gene has revealed an even more complex situation: in this virus, an array of 3 PCP domains appears to be present in the 480-residue region upstream of the nsp1–nsp2 junction (see Fig. 3). This raises the total number of arterivirus nonstructural proteases to five (T. R. Maines and colleagues, submitted for publication).

With the exception of the smallest sg species, the arterivirus mRNAs are structurally polycistronic. However, they are generally assumed to be functionally monocistronic. A notable exception is mRNA2 of EAV (see Fig. 4), which was

recently proposed to be a functionally bicistronic mRNA from which both GP_{2b} and the newly discovered E protein are expressed (92). Likewise, mRNA2 of LDV and PRRSV and mRNA4 of SHFV are probably used to express the corresponding genes of these other arteriviruses. Another mRNA of SHFV, mRNA2, was proposed to be functionally bicistronic, but in this case, the expression of two ORFs (2a and 2b) from this mRNA remains to be demonstrated (41).

In contrast to most other major groups of animal positive-stranded RNA viruses, virus-encoded proteases are apparently not involved in the maturation of nidovirus structural proteins. In the case of arteriviruses, structural protein proteolysis appears to be limited to the (cotranslational) removal of N-terminal signal sequences from each of the glycoproteins.

Replicase Proteins and Replication Complex

The nidovirus replicase gene encodes two polyproteins of extraordinary size and complexity. Although a number of (putative) functions have been inferred from comparative sequence analysis, the detailed functional dissection of the complex array of nidovirus nonstructural proteins is yet to be started. In view of the two-fold size difference between the replicases of arteriviruses and coronaviruses, these future studies will undoubtedly reveal both novel similarities and differences between the two groups. At this stage, it appears that the functions encoded by replicase ORF 1a and ORF 1b fall into different categories. The role of ORF 1a–encoded functions in the regulation (by proteolytic processing) of the expression of replicase subunits has been firmly established. Furthermore, a number of hydrophobic ORF 1a–encoded subunits have been implicated in replication complex formation. The ORF 1b–encoded proteins, on the other hand, appear to be more directly involved in viral RNA synthesis.

For EAV, protease domains have been identified in nsp1, nsp2, and nsp4. These proteases and their corresponding cleavage sites are well conserved in other arteriviruses. EAV nsp1 and nsp2 both contain a cysteine autoprotease domain that mediates, probably exclusively in *cis,* their rapid release from the polyprotein (93,95). The presence of one (LDV or PRRSV) or possibly even two (SHFV) additional protease functions upstream (see Fig. 3) is a remarkable feature of the arterivirus replicase, suggesting considerable genetic flexibility and adaptation to host-specific circumstances.

The nsp4 serine protease (SP) is the arterivirus main protease and a member of a relatively rare group of proteolytic enzymes, the 3C-like serine proteases (96). The SP combines the catalytic triad of classic chymotrypsin-like proteases with the substrate specificity of the 3C-like cysteine proteases, a subgroup of chymotrypsin-like enzymes named after the picornavirus 3C proteases. Specific residues in the substrate-binding region of the SP are assumed to determine its specificity for cleavage sites containing a (Glu/Gln)-(Gly/Ser) dipeptide (96, 106,112). Eight SP cleavage sites have now been identified: five in the C-terminal half of the ORF 1a protein, a region in which alternative processing occurs (112); and three in the ORF 1b–encoded polypeptide (106).

With the exception of part of nsp1, all EAV replicase subunits localize to the perinuclear region of the infected cell (104,108), where they are associated with intracellular membranes, predominantly or exclusively those of the endoplasmic reticulum. This complex has also been shown to be the site of *de novo* viral RNA synthesis. Recent biochemical and electron microscopy studies have implicated hydrophobic ORF 1a–encoded subunits (in particular, nsp2, nsp3, and nsp5) in replication complex formation (36,104). Upon arterivirus infection, host cell membranes are modified into vesicular double membrane structures that carry the arterivirus replication complex (80,104). The formation of such closely paired membranes and double membrane vesicles (DMVs) is a typical feature of arterivirus-infected cells and had been described many years ago (8,97,117). Expression of EAV nsp2 to nsp7 in a heterologous expression system induced strikingly similar structures, indicating that DMV formation does not depend on other viral proteins or EAV-specific RNA synthesis (80).

Predictions relating to the functions of the arterivirus ORF 1b–encoded replicase subunits are largely derived from comparative sequence analysis. Putative RNA-dependent RNA polymerase and NTP-binding RNA/helicase motifs were identified in nsp9 and nsp10, respectively (22,40,43,66). Recently, both the NTPase and duplex-unwinding activities of EAV nsp10 were demonstrated using *in vitro* assays (89). These studies also revealed a close functional relationship to the helicase of coronaviruses (88,89). Furthermore, ORF 1b encodes two additional conserved domains that appear to be unique to nidoviruses: a conserved domain in nsp11 and a Cys/His-rich domain in the N-terminal region of nsp10, upstream of the helicase. The nsp10 Cys/His-rich domain was previously proposed to have metal-binding properties (43) and was recently implicated in a remarkable mRNA transcription defect. The serendipitous replacement of Ser-2429 by Pro, which is located at the C-terminal border of the nsp10 Cys/His-rich domain, rendered the EAV full-length cDNA clone noninfectious owing to an almost complete block of sg mRNA transcription (105,110). However, this mutant replicated its genomic RNA efficiently, showing that arterivirus replication and sg mRNA transcription are (at least in part) separate processes. Recently, a more extensive mutagenesis study of the EAV nsp10 Cys/His box has strengthened the notion that this domain is involved in both genome replication and sg RNA transcription and may have unique zinc-binding properties (107).

A second (putative) zinc finger protein with a specific role in sg RNA synthesis is EAV nsp1 (102). This most N-terminal replicase subunit was shown to be dispensable for genome replication, but absolutely required for sg RNA transcription.

Major Structural Proteins

Arteriviruses possess a set of six or seven structural proteins, a number that is unusually large compared with other positive-stranded RNA viruses. The three major structural proteins GP_5 (and its equivalent GP_7 in SHFV), M, and N are encoded in this order by the three most 3' ORFs of the arterivirus genome (see Fig. 3 and Table 1). The N proteins are small (12 to 15 kd) and highly basic, which may facilitate their interaction with the genomic RNA during assembly of the nucleocapsid. The regions of N that are important for this interaction have not yet been defined. The EAV N protein was shown to be phosphorylated and constitutes about 20% to 40% of the protein content of the virion (25).

The nonglycosylated M protein (16 to 20 kd) is the most conserved structural protein of arteriviruses. It resembles the

coronavirus M protein in that its N-terminal half presumably traverses the membrane three times (25,35,66). This results in a N_{exo}-C_{endo} configuration with a short stretch of only 10 to 18 residues exposed at the virion surface. One of the membrane-spanning fragments is thought to function as a signal sequence. Although little is known about the function of the arterivirus M protein, it probably plays an important role in virus assembly and budding, as has been shown for coronaviruses. The M protein accumulates in the endoplasmic reticulum, where it forms disulfide-linked heterodimers with the 24- to 54-kd major glycoprotein, GP_5 or GP_7 (28,34). A Cys residue in the short N-terminal ectodomain of the M protein is most likely involved in the formation of an intermolecular disulfide bridge with a Cys residue in the GP_5 ectodomain. The GP_5–M heterodimers, which are essential for infectivity, are transported to the Golgi complex (28) and are incorporated into virus particles at some point during this process.

Despite considerable differences in primary structure, the major glycoproteins of arteriviruses (GP_5 or GP_7) share common structural features. They contain an N-terminal signal sequence that is assumed to be cleaved from a short ectodomain. In the case of LDV and PRRSV, the latter is about 30 amino acids long and contains one to three N-linked glycans (35,66,74). The putative ectodomain of EAV GP5 is 95 residues long and usually possesses a single N-linked polylactosamine side chain (25). In some strains, however, an additional N-glycan chain is present (39). Also, in the case of LDV, GP_5 glycosylation occurs by the addition of variable numbers of lactosamine repeats (56). Nonneuropathogenic and neuropathogenic strains typically contain three and one polylactosaminoglycan chains, respectively (see later). The internal hydrophobic region of GP_5 is assumed to span the membrane three times and to be followed by a cytoplasmic domain of 50 to 72 amino acids. Although one might speculate that the arterivirus major envelope protein is involved in receptor recognition, no direct experimental evidence is available thus far.

Minor Structural Proteins

The minor envelope protein encoded by EAV and LDV ORF 2b, PRRSV ORF 2a, and SHFV ORF 4b (see Fig. 3) is a typical class I membrane protein. It contains an N-terminal signal sequence, a C-terminal transmembrane segment, and an ectodomain possessing complex-type N-glycans when the protein is incorporated into virions. It has been shown that intracellular EAV GP_{2b} exists as four monomeric species owing to the formation of intrachain disulfide bonds but that only disulfide-linked GP_{2b} homodimers are incorporated into virus particles (23,27). In contrast, the equivalent PRRSV GP_{2a} protein is present in virions as a monomer (67).

The PRRSV and EAV GP_4 proteins were also identified as minor glycoprotein constituents of the virus particle (92,111). They contain an N-terminal signal sequence and a potential C-terminal membrane anchor, which are typical for class I integral membrane proteins. Conflicting data on the presence of the GP_3 glycoprotein in PRRSV particles have been reported. Whereas GP_3 was detected in purified virions of a European PRRSV strain using specific monoclonal antibodies (111), the protein could not be immunoprecipitated from a purified virus preparation of a Canadian strain (63). However, small amounts of the latter protein were detected in a soluble form in the medium. Topologic studies on the corresponding LDV protein also suggested that it is secretory protein, but thus far, this protein has not been detected in cell lysates or the medium of infected cells (37).

The recently discovered E protein of EAV, which is encoded by a gene conserved in all arteriviruses, has further extended the collection of arterivirus structural proteins (92). The hydropathy profile of this small hydrophobic nonglycosylated protein suggests that it is an integral membrane protein with an uncleaved signal-anchor sequence in the central part of the molecule. Although the specific functions of the envelope proteins of arteriviruses remain to be elucidated, it has been shown by reverse genetics that the EAV E, GP_{2b}, GP_3, GP_4, GP_5, and M proteins are essential for the production of infectious progeny virus (73,92).

Assembly and Release

The EAV N protein was found to co-localize partially with the replication complex. Because it has been established that N is not required for genome replication or sg mRNA transcription (73,105), this observation suggests that genome encapsidation may occur (or begin) at the site of viral RNA synthesis. Arteriviruses acquire their envelope by budding of preformed nucleocapsids into the lumen of the smooth endoplasmic reticulum or the Golgi region (62,97,117). Most arterivirus envelope proteins are retained in intracellular membranes, but their specific roles in assembly have not yet been established. After budding, virions accumulate in intracellular vesicles, which are transported to the plasma membrane and release the progeny virus. The generation of aberrant nucleocapsid structures or unusual elongated virions was observed for various arteriviruses.

VIRUS PROPAGATION AND PATHOGENESIS

Growth Features

With the exception of EAV, arteriviruses have a very restricted host specificity. LDV grows in primary cultures of mouse macrophages but not in macrophage or other cell lines (83). In addition to primary macrophages from their respective hosts, SHFV and PRRSV replicate in cell lines of African green monkey kidney cells (MA-104 and derivatives thereof) (6,44,53). Most European PRRSV strains, however, have to be adapted to these monkey kidney cell lines before reasonable titers are obtained. EAV replicates efficiently in primary cultures of horse macrophages and kidney cells as well as in a variety of cell lines, such as baby hamster kidney, rabbit kidney, and African green monkey kidney cell lines (83,91).

One-step growth experiments have shown that the replication cycle of arteriviruses is short, with maximal progeny virus titers released by 10 to 15 hours after infection. The maximal titers obtained in cell culture are 10^6 to 10^7 tissue culture infectious dose ($TCID_{50}$) per milliliter for PRRSV but may exceed 10^8 plaque-forming unit (PFU) per milliliter for EAV and SHFV (91). The infection of macrophages and cell lines is highly cytocidal, resulting in rounding of the cells and

detachment from the culture plate surface. PRRSV, SHFV, and EAV are titrated by end-point dilution or plaque assays. However, LDV is titrated *in vivo* in mice because the percentage of susceptible cells in primary mouse macrophage cultures is too low to detect their destruction (83).

Epidemiology and Pathogenesis of Equine Arteritis Virus

Despite its worldwide distribution, EAV has rarely caused disease outbreaks. The first recognized and most severe epizootic occurred in 1953 in Bucyrus, Ohio (30). Subsequently, milder outbreaks have been reported from Austria, Canada, Italy, Poland, Switzerland, and the United States. The apparent discrepancy between the high incidence of the virus and the low number of recorded disease outbreaks is explained by the predominantly subclinical course of infection. Transmission of EAV occurs primarily through the respiratory and venereal routes (64,103). The latter route of infection involves transmission to brood mares by persistently infected “carrier” stallions, which shed the virus in their semen (103). So far, no natural hosts other than horses and donkeys have been reported for EAV. EAV initially replicates in lung macrophages. The virus then spreads to bronchial lymph nodes, from where it becomes disseminated throughout the body. By the third day of infection, a viremia has developed, and virus can be isolated from practically all tissues. In the few cases that EAV causes disease, clinical features are characteristic vascular lesions, necrosis of small muscular arteries, acute anorexia, and fever, usually accompanied by palpebral edema, conjunctivitis, nasal catarrh, and edema of the legs, genitals, and abdomen. Infection of pregnant mares frequently results in abortion (30).

Epidemiology and Pathogenesis of Porcine Reproductive and Respiratory Syndrome Virus

PRRS was detected first in 1987 in the United States and subsequently spread rapidly to Canada. In Europe, the first outbreaks were recognized in Germany in 1990 and were followed by outbreaks in the Netherlands, Belgium, Spain, the United Kingdom, France, and Denmark (114). Today, PRRSV infection is ubiquitous in all swine-producing areas of the world, including North and South America, Europe, and Asia. Severe abortion storms had a resurgence in 1996 to 1998 in the United States. During the past several years, however, the number of acute disease outbreaks has decreased, and mild subclinical infections are more common, especially in areas in which the virus is endemic. PRRSV is shed in saliva, respiratory tract secretions, oropharyngeal secretions, urine, and semen. Although it has been proposed that PRRSV is primarily transmitted through aerosols, airborne transmission was extremely difficult to achieve under experimental conditions (121). PRRSV can also cross the placenta and infect the fetus.

The clinical signs and pathogenesis of PRRSV infection are influenced by many factors, including host age, breed, sex, immune status, and virus strain. Typical signs include fever, anorexia, labored respiration, lymphadenopathy, gross and microscopic lesions in the lung, and reproductive failure characterized by delivery of weak or stillborn piglets or autolysed fetuses (114). The virus primarily infects alveolar lung macrophages and macrophages of other tissues. Twelve to 24 hours after exposure, young pigs, sows, and boars become viremic, a state that can last from 1 to 2 weeks in mature animals to 8 weeks in young pigs. The virus infection may persist in swine for prolonged time periods (up to 2 to 5 months). PRRSV was shown to replicate in testicular germ cells, such as spermatids and spermatocytes, a property that may explain the excretion of infectious virus in semen (99). PRRSV induces apoptosis *in vitro* in macrophages and in germ cells (98,99). The GP_5 protein is thought to play a role in the induction of this process (98), but the relevance for pathogenesis *in vivo* is unclear.

Epidemiology and Pathogenesis of Lactate Dehydrogenase–Elevating Virus

LDV was first discovered in laboratory mice (84). The virus was also isolated from wild mice in several countries, although the worldwide incidence is not known. Despite a lifelong viremia and virus secretion in urine, feces, and saliva, horizontal transmission of LDV between mice is inefficient, except in the case of fighting males (77). In contrast, transmission from mother to offspring through the placenta or breast milk is much more efficient as long as anti-LDV immune responses have not yet been elicited (83).

Infection of mice with LDV leads to a lifelong viremic but asymptomatic infection that is maintained by continuous rounds of cytocidal replication of LDV in a renewable subpopulation of macrophages (78). Twenty-four hours after infection, LDV titers of 10^{10} infectious dose (ID_{50}) per milliliter are present in the plasma, which then decrease to a level of 10^{4} to 10^{6} ID_{50}/mL. These titers remain present throughout the life of the mouse, together with elevated levels of LDH and other serum enzymes, owing to the destruction of macrophages that play a role in the clearance of this enzyme. LDV can be detected in the spleen, lymph nodes, thymus, and liver of persistently infected mice. Immune complexes of 150S to 300S are formed, most likely as a consequence of the polyclonal activation of B cells (12). Neurovirulent LDV variants can cause a fatal age-dependent poliomyelitis in certain inbred mouse strains that are of the Fv-1 $^{n/n}$ genotype and carry N-tropic, ecotropic MuLV proviruses (19). The replication of these ecotropic MuLVs in the glial cells of the spinal cord was proposed to render the anterior horn neurons susceptible to cytocidal LDV infection. Consequently, the development of age-dependent poliomyelitis might result from a combination of increased expression of the ecotropic MuLVs and a decreasing ability to mount a motor neuron–protective anti-LDV response.

Epidemiology and Pathogenesis of Simian Hemorrhagic Fever Virus

SHFV was first isolated in 1964 from diseased macaques in research centers in the Soviet Union and the United States (101). The virus was readily transmitted from the initially infected rhesus monkeys (*Macaca mulatta*) to other macaque species (*Macaca fascicularis* and *Macaca arctoides*), whereas members of other monkey genera did not show clinical symptoms. Subsequently, similar epizootics among macaques occurred in various primate centers in the United States and Europe. SHFV can spread rapidly within a colony, most likely by direct contact and aerosols. In contrast to the other arteriviruses, SHFV is not transmitted transplacentally from mother to offspring (45). Natural SHFV outbreaks among macaques have not been reported, but the incidence of persistent subclinical infections in wild patas monkeys appears to be high. It has been proposed that these persistently infected monkeys may be the source of virus causing the epizootics in macaque colonies (59).

Clinical signs in macaques consist of early fever and mild facial erythema and edema, followed by anorexia, dehydration, and various hemorrhagic manifestations. The macaques usually die within 2 weeks after infection, with mortality rates approaching 100%. Macrophages are the primary target cells for SHFV, and a causal relationship exists between the cytocidal infection of these cells by SHFV and the clinical symptoms of hemorrhagic fever (44).

IMMUNOLOGY AND VACCINES

Humoral Immune Response

Antigenic cross-reactivity between different arterivirus species has not been demonstrated. Although antibodies to arterivirus structural proteins can be detected within 1 week after infection, the four viruses can all establish persistent infections. The mechanisms by which arteriviruses can evade the host immune response remain to be elucidated.

Sera from EAV-infected horses recognize the N, M, GP_5, and GP_{2b} proteins (17,60). PRRSV-infected pigs contain antibodies directed against GP_{2a} to GP_5, M, and N, the antibodies directed to N being most abundant (58,68). Different epitopes of the PRRSV N protein were identified using monoclonal antibodies. Some of these were specific for European strains; others were specific for U.S. strains. An immunodominant antigenic domain was mapped to the central region of the N protein (70,85).

Neutralizing antibodies from arterivirus-infected animals are predominantly directed to the major glycoprotein GP_5 (12,16,42). Furthermore, various neutralizing MAbs directed against GP_5 of EAV, LDV, and PRRSV have been isolated. The neutralization site of EAV and LDV GP_5 was mapped to the ectodomain of the protein (2,16,56). Recent immunization studies using alphavirus-based expression vectors have shown that the coexpression of EAV GP_5 and M is required for the induction of neutralizing antibodies in mice (3). For PRRSV, a second neutralizing MAb-binding domain was identified in the ectodomain of the GP_4 protein (71). Because this region is highly heterogeneous among different strains of PRRSV, it is most likely subject to immunoselection. PRRSV-specific MAbs directed against GP_5 were more effective in virus neutralization than those directed against GP_4 (113). The immunogenicity of the SHFV structural proteins has not been studied in detail.

The production of neutralizing antibodies in EAV-infected horses coincides with virus clearance, suggesting that the humoral immune response plays an important role in recovery (38). In contrast, neutralizing antibodies against LDV and PRRSV are first detected 1 to 2 months after infection, are produced at low levels, and do not or hardly reduce viremia (12,58,118). It has been proposed that LDV- and PRRSV-specific antibodies actually enhance virus replication because it was observed that virus uptake in macrophages *in vitro* was increased in the presence of antibodies (13,118). Although anti-LDV antibodies do not prevent LDV replication in macrophages, several studies indicated that they specifically protect motor neurons from infection by neuropathogenic LDV strains and thereby prevent the onset of age-dependent poliomyelitis in mice (46,82). In contrast to nonneuropathogenic LDV strains, these neuropathogenic LDV strains are not able to establish persistent infections in mice. *In vitro* neutralization assays with plasma from infected mice and neutralizing MAbs showed that neuropathogenic LDV strains were more efficiently neutralized than nonneuropathogenic strains (15). This was not due to sequence differences in the GP_5 neutralization domain because synthetic peptides representing these sequences were bound with equal efficiency by neutralizing antibodies in enzyme-linked immunosorbent assays (56). In the case of nonneuropathogenic strains, however, the GP_5 ectodomain was found to contain three polylactosaminoglycan chains, as opposed to the presence of a single polylactosaminogly can in the ectodomain of neuropathogenic strains. Hence, it was postulated that the nonneuropathogenic strains can establish persistent infections because neutralizing antibodies bind less efficiently to the highly glycosylated ectodomain of their GP_5 surface protein (15,56).

The humoral immune response against SHFV varies with the species of monkey and the virus isolate that is tested (44,45). The rapid death of macaques after SHFV infection precludes an effective host immune response. Virulent SHFV strains, which cause acute disease in patas monkeys, induced neutralizing antibodies 7 days after infection. The production of neutralizing antibodies correlated with the complete clearance of the virus from the circulation by 21 days after infection. On the other hand, SHFV strains that cause a persistent infection in these monkeys induce very low titers of nonneutralizing antibodies.

Cell-Mediated Immune Response

Cellular immune responses to arterivirus infection have not yet been characterized in detail. Cytotoxic and helper T-cell responses were detected in LDV-infected mice but did not reduce LDV replication (33). T-cell proliferation responses in pigs infected with PRRSV were detected at low levels between 4 and 12 weeks after infection (4). These responses were mainly directed to the M, GP_{2a}, and GP_5 proteins (5). Additional studies are required to determine whether there is a correlation between T-cell responses *in vitro* and protection *in vivo.*

Vaccines

For the economically important arteriviruses EAV and PRRSV, live attenuated (Arvac, Ford Dodge Laboratories, Fort Dodge, IA; RespPRRS, Boehringer Ingelheim Animal Health, St. Joseph, MO; Prime Pac PRRS, Schering Plough, Kenilworth, NJ) and killed vaccines (Artervac, Ford Dodge Laboratories, Sligo, Ireland; Suipravac-PRRS, Laboratorios Hipra, Gerona, Spain) are commercially available. The live vaccines induce long-lasting protection but do not completely prevent reinfection with wild-type virus and virus transmission. Recently, adverse effects of vaccination of Danish pig herds with a modified live PRRS vaccine have been described (7), which were probably caused by reversion of the vaccine virus to virulence. Acute PRRS-like symptoms, including an increased number of abortions and stillborn piglets, were experienced in vaccinated herds. Furthermore, vaccine virus was transmitted from vaccinated to nonvaccinated

boars in several cases, resulting in viremia and shedding of vaccine virus into semen (61). In this respect, the killed vaccines are safer but are less efficacious in the induction of protection. Promising results have been obtained in DNA vaccination experiments with plasmids expressing the GP_5 protein of PRRSV (81). Neutralizing antibodies and lymphocyte proliferation responses were detected in DNA-vaccinated pigs, and the spread and clinical signs of challenge virus were reduced. These results suggest that GP_5 of PRRSV might be a good candidate for a DNA-based subunit vaccine.

EVOLUTION

The comparison of nidovirus genome organizations and the phylogenetic analysis of conserved replicase domains indicate that nidoviruses represent a distinct evolutionary lineage among positive-stranded RNA viruses (10,22,27,40,91). In arteriviruses and coronaviruses, related replicase genes and replication strategies have been combined with seemingly unrelated sets of structural genes. The different sets of structural genes that have been acquired by various nidovirus genera suggest the extensive involvement of RNA recombination in their evolution. The RNA recombination frequency during coronavirus replication is remarkably high (see Chapter 35), a characteristic that is probably determined by replicase properties and that may also be reflected in the mechanism of sg mRNA synthesis (109). It has been hypothesized that the acquisition of a novel N protein gene, giving rise to a virus core with different structural properties, may have created the possibility for an ancestor of the coronavirus branch to increase its genome size and diverge from the arterivirus branch (40).

The occurrence of (frequent) RNA recombination during arterivirus evolution has been postulated and is supported by recent experimental studies. Upon co-infection of mice with two phenotypically distinguishable LDV strains, a high recombination frequency in the 3'-terminal part of the genome was observed (57). Furthermore, two closely related North American PRRSV strains were reported to recombine during *in vitro* mixed infections in MA-104 cells (119). RNA recombination was also implicated in two apparent rearrangements of arterivirus genomes (see Fig. 3): the presumed duplication or triplication of the arterivirus nsp1 protease domain (20; T. R. Maines and colleagues, submitted for publication), and the insertion of three genes in the SHFV genome (41). As a result of the last mentioned event, SHFV contains three additional ORFs that are absent in the other arteriviruses (see Fig. 3). Because the proteins encoded by SHFV ORFs 4, 5, and 6 display similarity with the proteins encoded by ORFs 2a, 2b, and 3, it was proposed that these genes may have been either duplicated by an SHFV RNA recombination event or derived from a more distantly related arterivirus by heterologous RNA recombination (41).

The variation in arterivirus genome length is mainly due to major sequence differences in the N-terminal part of replicase ORF 1a. A phylogenetic analysis of the RNA-dependent RNA polymerase motifs of EAV, LDV, and PRRSV suggested that the EAV-branch diverged from a common ancestor before the LDV and PRRSV lineage (40). The relatively large evolutionary distance between EAV on one hand and LDV and PRRSV on the other is further illustrated by the amino acid sequence differences between structural proteins (69). Similar sequence comparisons indicate that SHFV occupies an intermediate position but is more closely related to LDV and PRRSV than it is to EAV (10,90). The close relationship between LDV and PRRSV structural proteins (32% to 53% amino acid sequence identity) has led to the hypothesis that the latter virus may have originated from interspecies transfer of LDV from mice to pigs or vice versa, an event that must have been followed by a substantial period of independent evolution of the virus in its new host (82).

Comparison of the amino acid sequences of the M and N proteins of two LDV strains revealed that these are more conserved than the polypeptides encoded by ORFs 1 to 5 (95% to 99% versus 75% to 87% identity, respectively) (82). Among EAV field isolates, the M and N protein sequences are also more conserved than those of other structural proteins. Similar conclusions were drawn from a recent analysis of the structural genes of sequential virus isolates from persistently infected carrier stallions (47). In the latter study, an overall sequence variation of about 1% per year was observed for the structural protein-coding region of the genome. However, the proteins encoded by ORFs 3 and 5 were found to evolve much more rapidly, suggesting that these polypeptides are subject to strong selective pressure in the host (47).

Striking sequence diversity was detected between North American and European isolates of PRRSV: the structural proteins of virus isolates from the two continents shared only 54% to 79% sequence identity (77). The GP_5 protein is the most variable structural protein, with only 51% to 55% sequence identity between North American and European isolates, whereas the M protein is the most conserved structural protein, with 78% to 81% of the residues being identical (69). Sequence comparisons between the replicases of the European Lelystad virus isolate and two U.S. isolates also revealed major differences (1,76). Replicase subunit nsp2 was found to be the most variable nonstructural protein: the sequence of the U.S. strains was 102 amino acids longer than that of Lelystad virus and shared only 32% of identical amino acids. On the basis of these large genetic differences, the PRRSV isolates from North America and Europe were concluded to represent two distinct genotypes, which must have evolved independently in swine populations before PRRS emerged on both continents.

PERSPECTIVES

The molecular characterization of four arterivirus genomes has revealed that these viruses generate about 20 protein species (excluding replicase-processing intermediates) and 14 to 18 RNA molecules (positive and negative strands). Most of these molecules have been defined in basic terms only, and understanding the molecular details of their role in the viral life cycle is one of the important challenges for the next decades of arterivirus research. For example, the characterization of the six or seven structural proteins and their role in the assembly of the arterivirus particle promises to be a complex issue. Likewise, the regulatory role of replicase proteolysis in the viral life cycle and the assembly and function of the arterivirus replication–transcription complex are largely unexplored fields. Both assembly and RNA synthesis depend on host cell membranes and probably also on the host proteins they contain. Thus, intracellular virus–host (protein–protein and protein–lipid) interactions are likely to be uncovered. The identification of the arterivirus receptor and possibly other host factors involved in entry and uncoating might explain the highly specific tropism of this group of viruses. At the RNA level, primary sequences and RNA structures involved in replication, discontinuous

transcription, and encapsidation are being defined. The recently developed systems for arterivirus reverse genetics are expected to be of great value for these molecular studies as well as for research into molecular pathogenesis, viral persistence, immunity against arterivirus infections, and the development of improved arterivirus vaccines.

An intriguing final question is whether arteriviruses will emerge or be identified in other host species. On the basis of the plasticity of arterivirus genomes and the fact that (at least) a number of arteriviruses can be transmitted by aerosols, these viruses can be assumed to have ample opportunity to cross species barriers. In fact, it is quite possible that they may already have done so. Looking at the inapparent and persistent infections caused by the known members of this virus group, it may be difficult to detect arterivirus-induced disease in other species. Also in this respect, the availability of complete genomic sequences for these viruses, which display no antigenic relationship, is essential and may form the basis for the development of rapid assays for detecting known and novel arteriviruses.

CHAPTER 38 *Rhabdoviridae:* The Viruses and Their Replication

John K. Rose and Michael A. Whitt

The *Rhabdoviridae* are enveloped RNA viruses that are the simplest of all the nonsegmented negative-stranded RNA viruses classified in the large order of Mononegavirales. The genetic organization of rhabdoviruses is similar to that of the larger *Paramyxoviridae* and *Filoviridae* of the same order, and many aspects of rhabdovirus transcription and replication are similar as well. Because the genomes are in the negative (noncoding) sense, all of these viruses must carry an RNA-dependent RNA polymerase in the virion. The first such polymerase was identified in a rhabdovirus (8). Soon after infection when the viral genome is released into the cell, the RNA-dependent polymerase transcribes the genome to make subgenomic viral mRNAs that are translated to make viral proteins. Viral genome replication requires ongoing viral protein synthesis and results in synthesis of full-length copies of the antigenome followed by synthesis of full-length genomes that are subsequently packaged to form progeny virions.

CLASSIFICATION

Viruses of the family *Rhabdoviridae* are widely distributed in nature, where they infect vertebrates and invertebrates as well as many species of plants. The rhabdoviruses that cause rabies and economically important diseases of fish appear to have life cycles confined to vertebrate species. All other rhabdoviruses are thought to be transmitted to vertebrates and plants by infected arthropods, which may be the original hosts from which all rhabdoviruses evolved. Shope and Tesh (191) have provided an excellent review of the ecology and classification of rhabdoviruses that infect vertebrates. Characteristically, all rhabdoviruses have a wide host range, although many have adapted to grow in specific hosts and at their particular ambient temperatures.

In addition to numerous plant rhabdoviruses (85), more than 70 rhabdoviruses of vertebrates have been identified and classified. The viruses of the family *Rhabdoviridae* known to infect mammals, including humans, have been classified into two genera: the *Vesiculovirus* genus, whose name is derived from vesicular stomatitis virus (VSV); and the *Lyssavirus* genus, otherwise known as the rabies and rabies-like viruses. The well characterized viruses of these two genera are listed in Table 1, which was adapted from the review by Shope and Tesh (191), with modification based on Bilsel and colleagues (17). Unlike vertebrate rhabdoviruses that replicate in the cytoplasm, the related *Bornaviridae* replicate in the nucleus (as do plant rhabdoviruses) and are now classified as a separate virus family.

Virus	Source of virus in nature
Vesiculovirus (VSV) genus	
VSV—New Jersey	Mammals, mosquitoes, midges, blackflies, houseflies
VSV—Indiana	Mammals, mosquitoes, sandflies
VSV—Indiana 2 (Cocal)	Mammals, mosquitoes, mites
VSV—Indiana 3 (Alagoas)	Mammals, sandflies
Jurona	Mosquitoes
Carajas	Sandflies
Maraba	Sandflies
Piry	Mammals
Calchaqui	Mosquitoes
Yug Bogdanovac	Sandflies
Isfahan	Sandflies, ticks
Chandipura	Mammals, sandflies
Hirame	Mosquitoes, sandflies
Porton-5	Mosquitoes
Lyssavirus genus	
Rabies	Dogs, cats, wild carnivores, bats, cattle, humans
Lagos bat	Bats
Mokola	Shrews, humans, dogs, cats
Duvenhave	Humans, bats
Duvenhage	Humans, bats
Obodhiang	*Aaneyxus* mosquitoes
Kotonkan	*Culicinides* mosquitoes

Adapted from refs. 17 and 191, with permission.

TABLE 1. *Members of two major rhabdovirus genera*

Among the animal rhabdoviruses, many of those belonging to the genus *Vesiculovirus* infect biting insects. At least some of these insects can transmit the viruses to animals, and insect transmission may explain the seasonal nature of the disease. The list of insect vectors that may transmit vesiculoviruses to animals includes blackflies, sandflies, and mosquitoes. Evidence for insect-to-animal transmission has been reviewed in detail recently (112). The VSVs found commonly in the Western Hemisphere are divided into two distinct serotypes, called *New Jersey* and *Indiana,* and these share about 50% amino acid sequence identity in their glycoproteins (60,174). Detailed subclassification of the viruses within these serotypes has been described based on extensive nucleotide sequence analysis (17,18,143). In addition, these studies noted a remarkable genetic stability of the viruses over many years of natural infection in particular geographic locations, despite the well-known high rate of mutation of VSV and other RNA viruses passaged in tissue culture (197).

The New Jersey and Indiana serotypes of VSV infect insects and mammals (see Table 1) and cause the economically important disease called *vesicular stomatitis* in cattle, horses, and swine. The disease, which has been thoroughly and recently reviewed (112), is characterized by vesicular lesions of the tongue, gums, teats, and hooves, and its symptoms resemble those of foot-and-mouth disease. Infected animals recover from VSV infections within about 2 weeks. Vesicular stomatitis is enzootic in Mexico, Central America, and northern South America, and small-scale outbreaks occur relatively frequently in the southwestern United States. Other serotypes of VSV, such as Chandipura and Isfahan, are found outside the Western Hemisphere in India and Iran and have also been associated with vesicular disease in domestic animals (226). The Chandipura glycoprotein sequence shares about 40% amino acid sequence identity with either the Indiana or the New Jersey glycoproteins (129). In contrast, the glycoprotein of the distantly related rabies virus shares only about 20% amino acid sequence identity with the VSV G protein (173).

VSV infection has been observed in people exposed to infected animals or inadvertently exposed in the laboratory (49,88). Infection in humans can result in influenza-like symptoms lasting a few days or in vesicular lesions of the mouth, but infection may often be asymptomatic. A very high percentage of humans living in rural areas where VSV infection of animals is common (eg, rural Panama) have high titers of antibody to VSV (207), but VSV infection is not normally associated with human disease in these areas. The pathogenesis of the rabies viruses is quite distinct from that of the vesiculoviruses and is described thoroughly in Chapter 39.

VIRION STRUCTURE

Rhabdovirus virions are composed of an external membrane derived from the cell in which the virus grew and an internal ribonucleoprotein core (Fig. 1). The single viral glycoprotein spans the membrane once and forms an array of about 400 trimeric spikes that extend from the viral membrane. The glycoprotein spikes are clearly visible in the electron micrograph of bullet-shaped VSV particles, shown in Figure 2. About 1,800 molecules of the viral matrix (M) protein are inside the viral envelope between the membrane and the nucleocapsid core. This core contains the single negative strand of genomic RNA, which ranges from about 11 to 12 kb in length in different rhabdoviruses. The bullet-shaped particles, 180 nm long and 75 nm wide, are typical of all rhabdoviruses, except certain plant rhabdoviruses that are bacilliform in shape and almost twice the length (85).

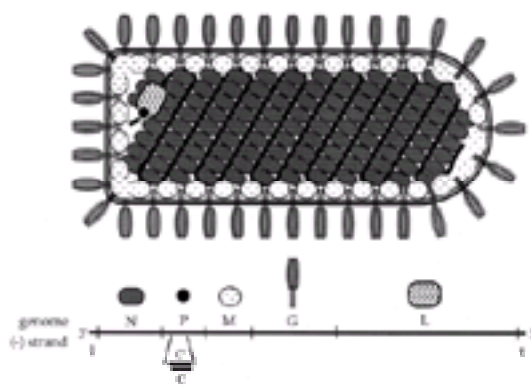

FIG. 1. Schematic representation of vesicular stomatitis virus (VSV) showing the two major structural components: the nucleocapsid (RNP) core, which contains single-stranded RNA tightly encased in the major N protein and the minor polymerase proteins L and P; and the membrane bilayer containing the transmembrane glycoprotein (*G*) and the peripheral matrix (*M*) protein, which adheres to the inner membrane surface and binds to the RNP core. Shown below is the gene order of the VSV genome with symbols representing the expressed proteins. The region of the P gene encoding the C proteins is indicated. (Modified from a drawing by Dr. Randall Owens.)

FIG. 2. Electron micrograph of vesicular stomatitis virus (VSV), negatively stained with phosphotungstic acid. Disrupted virions show the helical nucleocapsid core. The surface of intact virions shows protruding glycoprotein spikes.

The genomic RNA is in a tight complex with about 1,200 molecules of nucleocapsid protein that are arranged like beads on a string along the RNA, with each N protein molecule covering about nine nucleotides. This ribonucleoprotein complex is coiled into a tightly packed helix of about 35 turns within the virion. This helix is clearly visible in the two disrupted particles seen in Figure 2, and extended nucleocapsids from disrupted particles are visible as well. The viral RNA-dependent RNA polymerase, composed of the L and P proteins, is associated with the nucleocapsid core, and L and P proteins are present in about 50 and 500 molecules per virion, respectively. The gene order for VSV is diagrammed in Figure 1, with symbols for the structural proteins encoded by each of the genes. As discussed in detail later, separate mRNAs corresponding to each gene are transcribed sequentially beginning at the 3' end of the genomic RNA. Even during transcription and replication of full-length genomes, the genome and antigenome RNAs remain in a tight complex with the N protein.

Table 2 lists the molecular weights of VSV (Indiana serotype) proteins, predicted from the gene sequences, the number of molecules of each found per virion, and the physical characteristics of virus particles. The protein composition of the particles is constant except for the glycoprotein (G), which can vary considerably. VSV particles produced early in infection can have at least three-fold less G protein per virion than those produced late in infection (116). In addition, VSV incorporates cellular and other viral membrane proteins into its envelope quite promiscuously. For example, when foreign membrane proteins are expressed at high levels from VSV recombinants, the foreign proteins can represent as much as 25% of the total protein in the VSV envelope (182). These studies emphasize the imprecise nature of VSV membrane assembly.

Proteins	Calculated molecular weight[b]	Molecules per virion
N	47,355	1,258
P (NS)	29,878	466
M	26,064	1,826
G	63,416	1,205
L	240,707	50

[a]Length, 180 nm; width, 75 nm; S_{20w}, 660 Svedbergs; density, 1.16 g/mL (in sucrose); RNA length, 11,161 nucleotides.

TABLE 2. *Composition and physical characteristics of vesicular stomatitis virus*[a]

GENOME STRUCTURE AND ENCODED PROTEINS

Rhabdovirus genomes contain a minimum of five genes in the order 3' N-P-M-G-L 5', as shown for the VSV Indiana genome in Figure 3. In VSV, two small proteins termed C and C' are encoded in a second reading frame within P, but these appear specific to vesiculoviruses and are not found in lyssaviruses. There are also significant variations in the genome structure of other rhabdoviruses. For example, fish rhabdoviruses generally have an extra small gene between G and L (100), plant rhabdoviruses can have an extra gene between P and M (72), and sigma virus of *Drosophila* has three genes between N and G as well as a 33-nucleotide overlap of the G gene with the preceding gene (206). The functions of these extra gene products are not known.

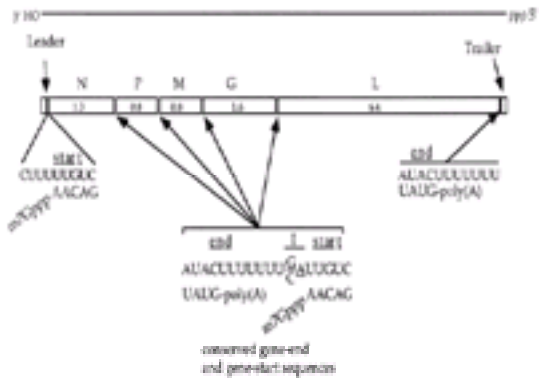

FIG. 3. Diagram of the vesicular stomatitis virus (VSV) genome showing the sequences at the gene junctions, including the polyadenylation signals, intergenic dinucleotides, and transcription initiation sites.

Rhabdovirus genomes have an extremely simple and compact arrangement with little wasted space. This is exemplified in the diagram of the VSV (Indiana serotype) genome (see Fig. 3). Each mRNA begins with the identical five nucleotide start sequence cap-AACAG, and terminates with the sequence UAUG-poly(A), and there are only two nucleotides between each of the genomic RNA regions encoding mRNAs (170). Only the very minimal conserved sequences, including the transcription termination and polyadenylation signals, intergenic dinucleotides, and transcription start signals, are required to signal mRNA termination, polyadenylation, and reinitiation of the subsequent transcript (183). The 5'- and 3'-noncoding regions on the mRNAs are typically short, although there are some virus-specific exceptions. The leader and trailer regions preceding and following the sequences complementary to the mRNAs are also short. Presumably, the genetic selection favoring rapid replication has prevented accumulation of extra sequences that would slow genome replication.

In light of this conservation of genome size in the rhabdoviruses, it is interesting to note that VSV can replicate its genome and assemble virus particles efficiently even when large additions are made to the genome. As discussed under Molecular Genetics of Rhabdoviruses, the reverse genetic system for VSV, first established by Lawson and associates (102), has allowed expression of foreign genes within the VSV genome when appropriate transcription start and stop sequences are included (183). Many VSV recombinants have been made that express extra genes. The addition of single genes of less than 2,000 nucleotides in length generally has little effect on VSV growth in tissue culture or on pathogenesis in mice (98,165,166,182,183), whereas the addition of two extra genes totaling 4,200 nucleotides, a 40% increase in genome size, decreased virus titers only about three-fold (68). Because the helical nature of the VSV nucleocapsid does not put major constraints on virus length, virus particles can grow longer without large effects on viral replication or packaging. The increase in particle length is as expected when particles are imaged by electron microscopy (182).

Nucleocapsid Protein (N)

The rhabdovirus nucleocapsid protein serves the critical function of tightly packaging the RNA genome into a RNase-resistant core that is the template for both transcription and replication. From the length of the VSV Indiana genome and the number of N protein molecules per virion (see Table 2), each N protein molecule would cover about 9 nucleotides of RNA. This N protein–RNA complex interacts with the P–L polymerase complex during transcription and replication, and with the M protein during nucleocapsid condensation, membrane binding, and budding. As discussed under Genome Replication, the VSV N protein recognizes specific packaging sequences in the 5' ends of both the genomic and antigenomic RNA, and the level of VSV N protein is thought to regulate the switch from transcription to replication.

Relatively little is known about the domain structure of the nucleocapsid protein, but deletion of the five C-terminal amino acids abolishes RNA-binding activity, and certain point mutations in this sequence can also prevent RNA binding (37). Other studies indicate that this domain of N protein is required for N–P protein interactions (204). The formation of N–P complexes is important for preventing N protein aggregation (40), which occurs when N protein is expressed at high levels in the absence of other viral proteins (76).

P Gene and Encoded Proteins (P and C)

The VSV P protein, or phosphoprotein, in combination with the L protein, forms the viral transcriptase–replicase complex (47). The P protein of VSV is an acidic protein of 265 amino acids (numbers from P of the Indiana serotype) (59) and is found in various phosphorylated forms in cells and virions. Sequence comparison studies have defined a domain structure for VSV P protein (18). It has an acidic N-terminal domain of 150 amino acids containing phosphorylation sites, followed by a highly variable region from residues 150 to 210 called the *hinge.* Domain II, also containing phosphorylation sites, spans from residues 210 to 244. Domain II is followed by a basic C-terminal domain III consisting of 21 amino acids. P protein is phosphorylated by casein kinase II on serine and threonine residues located in the N-terminal acidic domain (12), and, as discussed in the transcription section below, this phosphorylation is required to generate polymerase activity (11). The P protein forms trimers after phosphorylation, and only after trimerization is it able to bind the L protein and the N–RNA complex to form the active transcriptase (61). Binding of L protein also stabilizes the P trimer (61). The active polymerase complex is therefore an L–P3–N–RNA complex.

Recent studies have implicated phosphorylation of sites in domain II in regulation of P protein function during replication (81). It was suggested in that study and in an earlier study (33) that differential phosphorylation might regulate the switch from transcription to replication. As discussed under Genome Replication, differential phosphorylation may result in the formation of two distinct polymerase complexes: one that functions as a transcriptase and another that functions as a replicase (151). The P protein of Sendai virus and the P proteins of other *Paramyxoviridae* are also phosphorylated, and phosphorylation has been implicated in controlling P protein function. In a recent study, however, the major phosphorylation sites were eliminated from the Sendai P protein by mutagenesis of the gene. Replacement of the wild-type gene with the mutated gene in virus had no measurable effect on Sendai virus transcription or replication, and the mutant virus showed normal pathogenesis in animals (77). Although the paramyxovirus and rhabdovirus P proteins are highly divergent in sequence, these results suggest caution in interpretation of *in vitro* studies of rhabdovirus P protein mutants until the effects of the mutations are analyzed using reverse genetics of infectious virus.

In addition to encoding the P protein component of the viral polymerase, the VSV *P* gene encodes two small basic proteins of 55 and 65 amino acids from a second reading frame. This reading frame is presumably accessed by

ribosomal scanning and initiation at the second and third AUGs in the P mRNA (see Fig. 1). Expression of these proteins, called C and C', was first identified in cells infected with the New Jersey serotype of VSV (196), but similar proteins are also made by the VSV Indiana serotype (99).

Potential functions of the VSV C proteins were investigated by incorporating a mutated *P* gene eliminating C protein expression into infectious VSV. A stop codon was incorporated into the C and C' coding sequence in such a way that the P protein sequence was unchanged (99). Virus that no longer expressed C proteins showed growth kinetics identical to wild-type virus. The amounts of viral mRNAs and proteins synthesized and incorporated into virions were indistinguishable for mutant and wild-type viruses, and the kinetics of host protein synthesis shutoff were also identical for both (99). Although the C and C' proteins are dispensable for VSV growth in tissue culture, they are known to be conserved in all vesiculoviruses (196) and thus may play a role in viral pathogenesis or transmission by insect vectors. Studies on pathogenesis of C negative mutants in mice showed that they were no less pathogenic than the parental virus (A. Roberts and J. Rose, unpublished results). Pathogenesis in normal host animals, such as cattle, or replication in insects has not yet been examined.

Large Protein (L)

The first complete rhabdovirus *L* gene sequence was determined by Schubert for the VSV Indiana serotype (188), and since that time, numerous rhabdovirus *L* genes have been sequenced. All of these proteins consist of more than 2,100 amino acids in a single polypeptide chain. As discussed previously, the complex of L and P proteins constitutes the active RNA polymerase that copies the N–RNA template to produce mRNA, or complete antigenomes and genomes. The large size reflects the multifunctional nature of these proteins in transcription, replication, mRNA capping (2), methylation of 5' cap structures (74), polyadenylation (189), and replication of the viral RNA.

The domains of rhabdovirus L proteins involved in the multiple enzymatic activities have not been clearly mapped except for a potential methyltransferase domain (74). Rhabdoviruses and paramyxovirus L proteins all contain a highly conserved GDN motif (155), which is a variant of the GDD motif found in positive-stranded RNA virus polymerases. Mutations within this core motif in the VSV polymerase block transcription activity *in vitro,* and a mutant GDD retains partial activity (194). Mutations in the GDN sequence of rabies L protein abolish both transcription and replication activities in a mini-genome replication system (184).

The addition of poly(A) to rhabdovirus mRNAs is thought to result from repetitive copying by the polymerase of the U7 sequence found at the end of each gene (189). Mutations in L protein of VSV are known to cause aberrant polyadenylation of mRNAs and are consistent with a role for L in this process (79,80). In addition, a compound, *S*-adenosyl homocysteine, which blocks methylation of cap structures, also promotes synthesis of extremely long poly(A) on VSV mRNAs (175). This effect presumably reflects interference with normally coordinated functions of the polymerase.

There is also recent evidence that the VSV polymerase requires cellular translational elongation factors EF-1a, -1b, and -1g to be fully active (38). These proteins had not previously been identified as components of the VSV virion, perhaps because they are present only at very low levels. A precise stoichiometry of these factors relative to L protein needs to be determined in virions because the virion polymerase is active in generation of all viral mRNAs without addition of host factors (140).

Glycoprotein (G)

All rhabdoviruses encode a membrane glycoprotein consisting of about 500 amino acids in a single polypeptide chain. The VSV envelope contains about 1,200 molecules of this single transmembrane G protein that form 400 trimeric spikes (42,97) arranged in a coat on the virion membrane (see Fig. 1 and Fig. 2). The VSV G protein (Indiana) is synthesized as a precursor of 511 amino acids (174), from which an N-terminal signal sequence of 16 amino acids is cleaved after the protein is inserted into the endoplasmic reticulum (ER) (115). The VSV G protein is a typical type I membrane glycoprotein, with most of the amino acids exposed on the virion surface (Fig. 4). There are two sites of N-linked glycosylation, and both glycans are processed to the complex type (159). A hydrophobic domain of 20 amino acids spans the membrane, and a 29–amino acid cytoplasmic domain extends into the virion. A single molecule of palmitate is esterified to a cysteine residue in the cytoplasmic domain of some rhabdovirus G proteins (171,180), but the function of the palmitate is unclear because a mutant G protein lacking palmitate has normal membrane fusion activity, assembles normally into virions (224), and reconstitutes fully infectious virus (L. Buonocore and J. Rose, unpublished data).

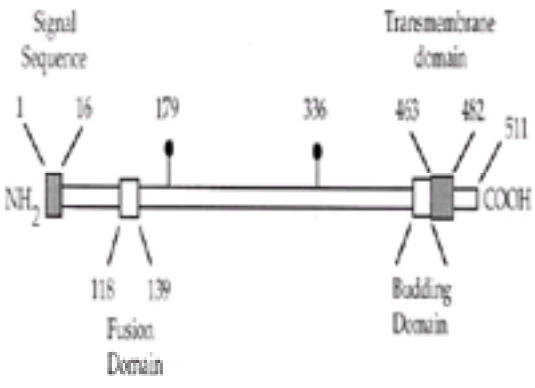

FIG. 4. Schematic of the vesicular stomatitis virus (VSV) glycoprotein illustrating the functional domains.

The VSV G protein has served as an important model for many studies on protein folding, assembly, and transport to the cell surface (43). Immediately after synthesis and before the correct disulfide bonds are formed, G protein associates with a molecular chaperone in the ER called *BiP* (GRP78), which assists in protein folding (125). Correctly folded monomers are released from BiP within about 3 minutes after synthesis, and these then assemble into trimers in about 7 minutes before leaving the ER. A second molecular chaperone, calnexin, recognizes monoglucosylated oligosaccharides on VSV G protein and is bound and released from VSV G with kinetics that are slightly delayed compared with those of BiP, suggesting sequential action of these two chaperones (69). Transport of G protein to the Golgi occurs within about 15 minutes, and protein appears on the cell surface after about 30 minutes (16).

Mutations in all three domains of the VSV G protein that affect transport from the ER have been analyzed in detail. Mutations in the extracellular domain typically prevent correct folding of G monomers and induce aggregation with BiP protein before trimerization (44). When VSV G protein monomers have severe folding defects, for example, because of an absence of glycosylation sites, they are found in large, disulfide-bonded aggregates that remain permanently bound to BiP protein in the ER (44,126,127,154). Mutations in the transmembrane domain can also affect transport by inducing aggregation and preventing transport, whereas mutations in the cytoplasmic domain that reduce the transport rate do not appear to affect the folding of the extracellular domain (44,172). These results indicate that the cytoplasmic tail of the glycoprotein contains a signal that accelerates protein exit from the ER, perhaps by signaling concentration of the protein at sites of vesicle budding from the ER. Detailed mapping of the cytoplasmic tail has implicated a diacidic signal Asp-X-Glu, where X represents any amino acid in accelerating export (144). Further studies have shown that this transport signal extends to a Y-X-X-aliphatic motif in the cytoplasmic tail (190). The VSV G cytoplasmic tail is required for sorting to the basolateral membrane of polarized MDCK cells (158), and the same signal (Y-X-X-aliphatic) that is involved in promoting G protein export from the ER is also involved in sorting to the basolateral membrane (210). Basolateral sorting of VSV G protein is presumably important for systemic spread of the virus, as occurs during natural infections of livestock.

VSV G protein trimers are not tightly associated, but instead are in a constant and rapid equilibrium with monomeric subunits in the ER (235) and at the cell surface (234), or when examined in solution after solubilization with detergent (124). Once assembled into virions, it is likely that a trimeric or higher-order G protein structure is stabilized by lateral interactions among trimers on the virion surface and by interactions with the internal virion components.

VSV G protein undergoes a conformational change at pH values below about 6.1, and this conformational change stabilizes the trimer (42). The low pH-induced conformational change presumably exposes a hydrophobic domain that can insert into a target membrane and mediate membrane fusion (52,163). A linear hydrophobic domain typical of fusion domains in other viral fusion proteins is not obvious in the VSV G protein sequence, although the N-terminus is somewhat hydrophobic. Initial studies with small hydrophobic peptides corresponding to the N-terminus of the mature VSV G protein showed that these could mediate hemolysis, and it was suggested that hemolysis might be equated with membrane fusion activity (178). However, a change in the peptide sequence that abolished hemolysis had no effect on fusion activity when introduced at the N-terminus of the VSV G protein (228). These results indicate that the hemolysis assay employing peptides is not always relevant to membrane fusion, but they do not rule out a direct role for the N-terminus in the membrane fusion process.

Studies with mutants of the VSV G protein have implicated the involvement of other domains in the fusion process. A site for N-linked glycosylation introduced at amino acid 117 completely abolished the membrane fusion activity of G protein without blocking folding, transport to the cell surface, or incorporation into virions (225). The proximity of this mutation to a sequence of 19 uncharged amino acids (amino acids 118 to 136) suggested that this domain might be involved in fusion. Analysis of linker insertion mutants that failed to induce cell fusion identified the same site as well as two other distant sites in G protein that affected membrane fusion (114). Additional studies pointed to the importance of amino acids 118 to 136 because mutations in this region either abolish fusion or affect the pH threshold for fusion (54,55,236). A hydrophobic photolabeling technique identified a peptide from residues 59 to 221 of VSV G protein interacting with the hydrophobic membrane core (45). Because this region encompasses residues 118 to 136, the result also provides support for the role of the 118 to 136 domain in membrane insertion during fusion. A region in a similar position in rabies virus G protein (residues 103 to 179) was identified using the same probe (45).

Matrix Protein (M)

The matrix (M) protein is the smallest and most abundant protein in the rhabdovirus virion. Despite its small size, M protein has many functions. VSV M protein plays critical roles in condensation of nucleocapsids during virus assembly, in disruption of the cytoskeleton, and in inhibition of host functions as described in the sections that follow. It also has an intrinsic ability to cause budding of vesicles from cells when expressed alone (89), a property that is probably important in natural budding and appears related to the presence of proline-rich motif that binds to WW domains of cellular proteins (71). A fraction of VSV M protein is associated with membranes in infected cells; most is cytoplasmic (30,31,131,231) whereas the rest of M protein is located in the nucleus of infected cells (123). Because of M protein association with the plasma membrane and with nucleocapsids, it has been proposed that M acts as a bridge between the viral envelope and the nucleocapsid (see Fig. 1). Recent studies of rabies virus support this location for its M protein (136), but other studies of VSV suggest that M protein may form a cigar-shaped internal structure, which has been proposed to form a scaffold around which the nucleocapsid is wound (9,10). It seems highly improbable that M protein could occupy different positions in rabies and VSV, but this issue awaits resolution with more definitive analytical techniques. A report that M protein can stabilize G protein trimers *in vitro* (119) and that membranes from cells expressing M protein bind nucleocapsids (30) also supports the idea that M bridges the gap between the nucleocapsid and the G protein. The VSV M protein is highly basic and does not contain hydrophobic domains that are sufficient to act as membrane spans. However, the amino terminus of VSV M may be membrane associated because it can be labeled with a hydrophobic photoaffinity probe (108).

The VSV M protein is phosphorylated on serine and threonine residues between amino acids 20 and 35, but the assembly functions of M protein are not disrupted when the major sites of phosphorylation are disrupted (92), and the

function of phosphorylation, if any, remains to be determined.

STAGES OF REPLICATION

The replication and assembly of members of the *Rhabdoviridae* family can be divided into distinct stages as depicted in Figure 5. Although many of these events occur simultaneously in an infected cell, it is convenient to consider the process of infection as a linear series of events that proceeds in the following order: adsorption, entry and uncoating, transcription, replication, assembly, and budding.

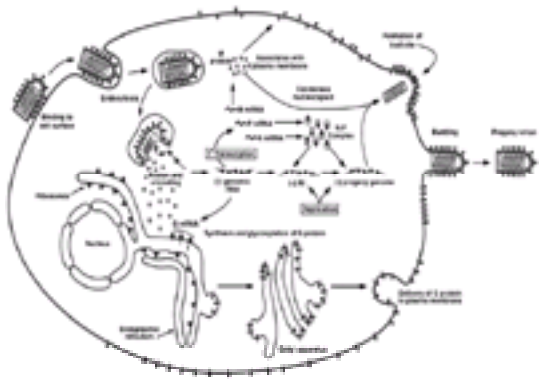

FIG. 5. Diagram of the life cycle of a rhabdovirus.

Adsorption

Rhabdoviral infection is initiated by attachment of virus to a receptor on the host cell surface. The receptors for the attachment of rhabdoviruses have been difficult to identify because of the generally broad host range and the binding properties of rhabdovirus particles. Virus adsorption is inefficient and difficult to quantitate for viruses in this family. For example, VSV binding is pH dependent, and maximal binding occurs between pH 6.5 and 6.0 (56,130); yet even at the optimal pH, binding fails to reach equilibrium (130). Furthermore, when virus is prebound at 4°C, only a limited amount of virus is internalized when cells are warmed to 37°C (130). However, virus infectivity can be increased more than 20-fold when virus is adsorbed at pH 6.3 versus when virus is bound at neutral pH (56). The pH dependence of binding correlates well with pH-induced conformational changes in the G protein (56), suggesting that the receptor-binding site in the envelope protein becomes exposed during the transition from the neutral to the acid conformation.

Kinetic analysis of VSV binding to Vero cells suggested that two separate sites (saturable and unsaturable) exist for attachment of VSV (179). To identify the saturable binding component, Vero cell membranes were disrupted with the dialyzable, nonionic detergent octyl- D-glucopyranoside. When analyzed in a competitive binding assay, the extract specifically inhibited the saturable, high-affinity binding of 35S-methionine–labeled VSV to Vero cells (177). The binding inhibitor was resistant to protease and neuraminidase but was inactivated by phospholipase C, suggesting it was a phospholipid. Of all phospholipids tested, only phosphatidylserine totally inhibited the high-affinity binding of VSV to Vero cells and also inhibited VSV plaque formation by 80% to 90% but did not block herpesvirus plaque formation (177). Based on these results, it is thought that phosphatidylserine may be one of the VSV receptors, at least on Vero cells. The identification of phospholipid binding domains in other rhabdovirus glycoproteins supports this idea and suggests that phosphatidylserine binding is a common feature of rhabdovirus envelope proteins (48).

The receptor for rabies virus has been controversial, and recent evidence indicates that several different receptors can be used. Sequence similarities between a region in the rabies glycoprotein and snake venom neurotoxins initially led to the hypothesis that the nicotinic acetylcholine receptor (AChR) is a receptor for rabies virus (109), and evidence supporting this has been obtained (62,70). Infection of cell lines that lack AChR, however, indicated that other molecules must also be used by rabies virus for entry (160). Recently, two additional receptors for rabies virus entry were identified. Using a random-primed cDNA expression library constructed from neuroblastoma cell (NG108) mRNA, the murine low-affinity nerve-growth factor receptor was identified as a functional receptor for street rabies virus (212). In a separate study, it was shown that the neural cell adhesion molecule can also serve as a receptor for the CVS (challenge virus standard) strain of rabies virus both in cultured cells and in mice (211).

Entry and Uncoating

After binding, the virions are endocytosed through a clathrin-dependent pathway typical of receptor-mediated endocytosis (130). Subsequent reductions in the pH of the endocytic compartment eventually trigger a membrane fusion reaction between the envelope of the endocytosed virion and the endosomal membrane. This fusion event is catalyzed by the G protein and results in the release of the ribonucleoprotein (RNP) core into the host cell cytoplasm (130). Either concomitant with membrane fusion or immediately after, M protein dissociates from the RNP core (164). The combined processes of membrane fusion and M protein dissociation constitute the uncoating event for rhabdoviruses. The trigger for M protein dissociation from RNPs is not known.

Transcription

The first synthetic event that occurs after uncoating of RNPs is transcription of viral-specific mRNAs by the L–P3 polymerase complex brought into the cell by the virion. Primary transcription occurs in the absence of protein synthesis, unlike genome replication, which requires newly synthesized N and P proteins and ongoing translation (41). The template for VSV transcription is the genome RNA complexed with the N protein in a ribonuclease-resistant form. As discussed

previously, both the L and P proteins are required for polymerase activity (47). The P protein does not possess any known enzymatic activity, but instead acts as an accessory factor that may modify the activity of L protein through the phosphorylation status of P. The importance of P protein phosphorylation for transcription has been studied most extensively for VSV. Phosphorylation of serine and threonine residues in the N-terminal domain I of P protein by casein kinase II converts P to a transcription-competent state using an *in vitro* transcription assay (12). Although the absolute requirement for P protein phosphorylation in transcription has been questioned (195), studies using a transcriptionally active VSV mini-genome expressed from plasmid DNA support the conclusion that phosphorylation is required for transcription *in vivo* (151). The additional negative charge of the phosphates presumably induces conformational changes and results in the formation of P protein trimers that bind to L protein to constitute the active polymerase (61). There is also a recent report that the L protein of VSV requires cellular translational elongation factors EF-1a, -1b, and -1g to be fully active in an *in vitro* transcription assay (38), indicating that host factors may also contribute to the activity of the polymerase.

Transcription begins at the exact 3' end of the genome, where the polymerase first synthesizes a small 47-nucleotide RNA called the *leader.* Each of the five mRNAs encoding the viral proteins is then synthesized in the order it appears from the 3' end of the genome. The leader is neither capped nor polyadenylated, but it is encapsidated once sufficient quantities of the N protein, in the form of N–P complexes, are synthesized.

Sequential transcription of VSV genes was first shown indirectly through the effect of increasing doses of ultraviolet (UV) irradiation on synthesis of the individual transcripts detected in a coupled transcription-translation system (7) and also by direct analysis of the transcripts separated by electrophoresis (1). Sequential transcription was also demonstrated directly by nucleic acid hybridization of sequences synthesized *in vitro* or by detection of specific oligonucleotides from the 5' ends of the mRNAs (83,84). The latter studies were inconsistent with independent initiation of mRNA synthesis on each gene because the synthesis of 5' mRNA sequences was dependent on transcription of the preceding mRNA. Studies involving reconstitution of purified nucleocapsid template with solubilized transcriptase showed that only leader RNA sequences are made initially and that mRNA oligonucleotides appear only after full-length leader has been synthesized (46). Thus, the VSV polymerase is not free to initiate transcription independently on each gene, and sequential transcription appears as a result of an obligatory entrance of all polymerases at the leader gene.

In vitro transcription studies also demonstrated that the VSV polymerase pauses for 1 to 2 minutes at each gene junction and then reinitiates synthesis on the downstream gene with only 70% to 80% frequency (83). The pause time may represent, at least in part, time required to copy repetitively the U7 sequence to generate the poly(A) on each mRNA.

Transcriptional attenuation is a common feature of nonsegmented negative-stranded RNA viruses, and this phenomenon results in a gradient of mRNA synthesis such that the N message is the most abundant in infected cells and the L message is the least abundant (83,214). Therefore, VSV transcription is both sequential and polar. The polarity of transcription is an inherent property of the polymerase, and attenuation results from events that occur when the polymerase interacts with cis-acting signals at each gene junction. Extra foreign genes inserted into VSV are subject to and exert the same 20% to 30% attenuation effect (98,167,183), and when VSV's own genes are rearranged, there is still a 20% to 30% attenuation at each gene junction regardless of gene order (6,217).

The mechanism leading to the generation of individual transcripts during a rhabdoviral infection is not completely understood, but there is strong evidence supporting a start and stop model for rhabdoviral transcription. In this model, the polymerase initiates transcription at the 3' end of the genome and then terminates transcription at the leader– *N* gene junction. The polymerase then reinitiates at the conserved start site 3' UUGUC . . . . 5' of the *N* gene, and sequential transcription ensues. There is evidence from a VSV mutant called *polR* that the polymerase can initiate internally at the *N* gene start site (32), but this seems to be a unique property of the *polR* mutant that results from a mutation in the N protein, and once the leader–*N* gene junction is traversed, subsequent transcription occurs by the start and stop mechanism.

The use of transcriptionally active VSV mini-genomes (described later under Molecular Genetics of Rhabdoviruses) has allowed the dissection of cis-acting signals that are important for transcript initiation, capping and methylation, and polyadenylation and termination. Using a dicistronic mini-genome system, it was found that the first three nucleotides of the conserved 3' UUGUC . . . . 5' start sequence (complementary to the cap-AACAG at the beginning of each mRNA) were the most important for VSV gene expression. The U at position 1 and G at position 3 were absolutely required for transcript accumulation in infected cells, whereas the second position could be a pyrimidine, although U was preferred (201). Remarkably, mutations at the second position and substituting a C for a U at the first position did not prevent initiation per se, but instead affected modifications at the 5' end of the mRNA as well as polymerase processivity (203). Because the polymerase is responsible for addition of the 5'-7mGpppG cap, the conserved sequences at the beginning of each gene appear to contain separate but overlapping signals for capping and for transcript initiation. Thus, transcript initiation and 5' end modification (presumably capping) are linked, yet separable, events.

The mechanism by which VSV transcripts are capped has not yet been defined, but because the entire VSV life cycle is carried out in the cytoplasm of the cell, it is thought that the host nuclear enzymes are not involved. Analysis of the cap structure found on VSV transcripts revealed that both the a and b phosphates of the 5'–5' triphosphate linkage of the guanosine cap are contributed by a guanosine diphosphate (GDP) donor (2). Therefore, the addition of the 5'–5' guanosine cap cannot be mediated by a covalent nucleotidyl transfer reaction with guanosine monophosphate (GMP) as occurs during typical eukaryotic capping. Available evidence indicates that the polymerase complex mediates the capping reaction because mRNAs generated during *in vitro* transcription reactions with detergent solubilized purified virions are efficiently capped (2). Although the L protein does share some sequence homology to nucleotide binding proteins, it shows no homology to covalent nucleotidyl transferases (192), and there have been no mutations identified in L protein that affect capping. However, viruses that are deficient in methyltransferase activity have been isolated, and the defect has been mapped to L protein (74). Recently, it was suggested that the GTP- and GDP-binding properties of the a subunit of EF-1 associated with L protein may play a role in the VSV capping reaction (38). It is possible that other host proteins may associate with L to mediate transcript capping, but as mentioned previously (L protein section), these must

be found on only a fraction of the polymerase complexes found in virions.

After transcript elongation, the polymerase encounters the conserved stop-polyadenylation signal consisting of 3'-AUAC(U7)-5'. Two events can occur once the polymerase reaches this sequence. For most transcripts, the polymerase pauses and reiteratively copies, or “stutters,” over the seven uridinylate residues to produce a poly(A) tail about 150 nucleotides in length before terminating. Occasionally, the stop-polyadenylation signal is ignored, and transcription continues past the intergenic region and through the next gene, generating a read-through transcript that becomes polyadenylated at the downstream stop-polyadenylation site (75). Studies to define the stop-polyadenylation signal revealed that reducing the length of the U7 tract, even by one nucleotide, or changing the C of the preceding 3'-AUAC(U7)-5' to any other nucleotide prevents termination and causes exclusive read-through transcription at the mutated gene junction (13).

After polyadenylation, the polymerase scans through the intergenic dinucleotide in a nontranscriptive mode until the next transcription start sequence is encountered (14,201,202). The attenuation of expression observed for downstream genes presumably results from some of the polymerases dissociating from the template after polyadenylation or during the transition from polyadenylation and termination to reinitiation at adjacent downstream gene.

Genome Replication

During transcription, the VSV polymerase responds to signals that result in the synthesis of the leader RNA and individual mRNAs. In contrast, during replication, the polymerase must ignore these signals and synthesize genome-length positive-stranded RNA. This RNA is then replicated to form the genomic negative-stranded RNA. Unlike transcription, VSV replication requires ongoing translation, particularly of viral N and P proteins. This was found initially because inhibition of protein synthesis by cyclohexamide would prevent RNA replication but not transcription (41). The original concept that the N protein alone is sufficient for replication of VSV RNPs has been superseded by evidence that ongoing synthesis of both N and P proteins, complexed in a 1:1 molar ratio, is far more efficient for supporting viral replication *in vitro* (152). The basis for this requirement was initially explained by a widely accepted model for negative-stranded virus replication, which also accounted for the switch from transcription to replication. In this model, encapsidation of leader RNA by newly synthesized N protein (22) causes an antitermination event that signals the polymerase to begin processive RNA synthesis such that the signals for mRNA initiation and termination are ignored (3,21). Therefore, once sufficient quantities of N protein (or more appropriately, N–P complexes) have accumulated, there is a switch from primarily discontinuous mRNA transcription to the synthesis of genome-length, positive-sense replicative intermediates (RI). The RI, like the genome, must also be fully encapsidated to serve as a template for the synthesis of progeny negative-sense genomes. This model is attractive because immediately after virus entry, transcription would be favored over replication. At later times, when the concentration of N protein increases, replication would be favored.

More recently, a modification of this model has been developed that suggests that transcriptase and replicase are two different complexes, each with a unique composition. The two-polymerase model arose from studies using P protein mutants that were defective in transcription but that could support efficient replication of VSV defective interfering (DI) RNAs (39,151). The P protein mutants either had substitutions in the conserved C-terminal basic residues and could bind N protein but did not interact efficiently with L protein (39), or were defective in domain I phosphorylation (151). Because phosphorylation is required for P protein oligomerization, transcriptional activation, and interaction with L protein, the transcriptase would be composed of an L–P3 complex, whereas the replicase would consist of an L–(N–P) complex in which P protein is not phosphorylated. Regulation of P protein phosphorylation and ongoing viral protein synthesis would therefore affect the formation of the two different complexes at different times after infection.

Encapsidation of the genome and antigenome by N protein is intimately tied to and essential for virus replication. Encapsidation occurs as the genomic RNA is synthesized rather than after synthesis is complete, which fits well with the antitermination model described previously for the switch from transcription to replication. It was recognized early that the RNA encapsidation signal must reside in the 5'-terminal sequences of the genome (the trailer region) and the antigenome (the leader) because the leader RNA, the RI, and progeny genomes are the only virus-specific products that are encapsidated (3,21,110). Sequence comparisons between different serotypes of VSV revealed that 14 of the 18 terminal nucleotides of the genome are highly conserved. From this observation, it was postulated that five adenine residues repeated at every third position from the 5' end of either the genomic or antigenomic RNA are important for the selective encapsidation of these RNAs (21,23). *In vitro* encapsidation reactions using synthetic RNAs containing the 19 terminal nucleotides of VSV and either purified N protein or N protein synthesized *in vitro* (36,141) supports this hypothesis. More recent studies using subgenomic replicons have confirmed that the 5'-terminal residues of the genome are critical for efficient encapsidation (151); however, it appears that sequences beyond the first 19 nucleotides, yet within the 5' terminal trailer region, are also important and greatly affect the efficiency of the process (221).

For rabies virus, leader encapsidation may also be regulated by the phosphorylation status of N protein. Unlike the VSV N protein, which is not phosphorylated, rabies N is phosphorylated on serine residues, and the unphosphorylated form of N protein binds more tightly to leader RNA *in vitro* (230).

One of the challenges in understanding rhabdovirus replication is that two distinct events must occur sequentially: first, production of a complete positive RNA strand complementary to the entire parental template, followed by production of complete negative-stranded (progeny) RNAs. There is also a significant asymmetry in the amount of positive-sense RI to negative-sense genome that is made in infected cells. For both rabies and VSV, the genome is about 20- to 50-fold more abundant than the RI. The basis for this asymmetry appears to result solely from the activity of the promoter sequences found at the 3' end of the genome or RI.

It had long been assumed that sequences at the extreme 3' end of the genomic and antigenomic RNA were important for polymerase binding and that the complementary sequences found at the 5' ends were required for encapsidation by N protein. Recently, specific sequences have been identified that play a role in regulating the balance between transcription of mRNAs, which are not encapsidated by N protein, and replication of the genome and antigenome, which

are encapsidated. Using deletion analysis and cDNA-derived model subgenomic RNAs based on a naturally occurring defective-interfering virus of VSV, Pattnaik and colleagues have shown that the signals necessary for both replication and encapsidation are present within the 5'-terminal 36 nucleotides and the 3'-terminal 51 nucleotides (149). This result confirms the long-standing hypothesis that the promoter for polymerase binding is contained within the terminal sequences of the genome. A subsequent study further delineated the minimal replication signal as being the 3'-terminal 24 nucleotides of the trailer complement; however, the sequence of the next 20 nucleotides, specifically those found at the 3' end of the positive-sense RI, serves as a specific enhancer of replication (113). Therefore, sequences at the 3' end of the antigenome of wild-type VSV provide the basis for differential (enhanced) replication of the genome over the antigenome in infected cells. Similarly, distinct elements in leader region have been identified that are important for transcription but that are not required for replication (221).

In an elegant demonstration of the power of reverse genetics, Finke and Conzelmann constructed an ambisense rabies virus genome that contained identical, transcriptionally active (genomic) promoters at the genomic and antigenomic termini and that transcribed a foreign gene from the antigenomic RNA. Analysis of replication products revealed that the ratio of genome to antigenome was 1:1 in infected cells, indicating that promoter strength was primarily responsible for maintaining the balance of genome to RI. This study also showed that packaging of rabies genomic or antigenomic RNPs into virions is random and depends only on the ratio of the RNPs in infected cells. For wild-type rabies virus, genomic and RI RNPs were present in cells at a ratio of 49:1 and were incorporated into virions at the same ratio. In contrast, the ambisense mutant genomic and antigenomic RNAs were packaged equally into virions.

Although the ratio of genome to antigenome is primarily affected by sequence-specific elements in the antigenomic promoter, there is evidence that other factors may also contribute to the replication efficiency of rhabdovirus genomes. For example, it has been suggested that the extent of terminal complementarity can also affect whether the template (in this case, a defective interfering RNA) predominantly directs transcription or replication (218). Thus, replication may also be regulated by interactions between the ends of the genome. These authors suggested that there is communication between the ends of rhabdoviral genomes through base pairing and that this somehow affects replication efficiency (218).

Assembly and Budding

The process of rhabdovirus assembly can be divided into three distinct phases: (a) encapsidation of newly replicated genomic RNA by N protein, (b) simultaneous condensation of the ribonucleocapsid core by M protein and association with the plasma membrane, and (c) particle envelopment and release. The first step, encapsidation, occurs in the cytoplasm and results when nascent genomic RNA associates with newly synthesized N, P, and L proteins to form RNP complexes. These are often referred to as *nucleocapsids* or *RNP cores.* Because RNA encapsidation is required for RNA replication and transcription, this step was described in the preceding section.

After encapsidation, the RNP complex associates with the plasma membrane and condenses into a tightly coiled structure called a *skeleton* before release from the cell. Numerous studies have demonstrated that the matrix protein is responsible for both of these events (10,64,93,121,122,136). Thus, M protein plays a critical role in virus assembly and budding. Most of our understanding of RNP condensation is derived from *in vitro* studies in which RNP cores are isolated from detergent solubilized virions in high salt buffers, which results in the release of M protein in a process somewhat analogous to virus uncoating after membrane fusion. RNPs isolated under these conditions appear as loosely coiled, extended filaments and are transcriptionally active. The process can be reversed by the addition of purified M protein to the extended RNP cores in low ionic strength buffers, which results in RNP condensation and the formation of skeleton-like structures similar to those seen within virions (142). The addition of M protein to RNPs also inhibits VSV transcription *in vitro* (29); therefore, the reversible nature of RNP condensation by M protein is thought to be critical for virus infectivity (121).

Condensation of RNP cores provides an explanation for the inhibitory activity of M protein, but it also poses a dilemma. How can viral transcription levels remain high when the cytoplasm of infected cells contain high concentrations of RNP cores and M protein? One explanation is that RNP condensation does not occur until the RNP cores associate with the inner leaflet of the plasma membrane just before budding (131,147); therefore, RNP condensation is a highly regulated process. The demonstration that 10% to 20% of M protein associates with the inner leaflet of the plasma membrane (30) and that the membrane-associated fraction can bind nucleocapsids partially stripped of M protein (31) provided an explanation for the regulated assembly of RNPs at the cell surface. However, recent evidence suggests that an additional priming event is needed because neither cytoplasmic nor membrane-associated M protein can bind to RNPs that are completely free of residual M protein (51). The priming event may involve the formation of specific M protein complexes (63) or may require modification of the RNP core by host factors (51). The topology of M protein with respect to the RNP core during RNP condensation has been a topic of debate and was discussed previously.

After RNP condensation, rhabdovirus particles are released from infected cells by budding from the cell surface. During budding, the condensed core becomes enclosed within a membrane envelope that, for VSV, has about 1,200 molecules of virally encoded G protein and smaller amounts of normal cellular membrane proteins. Early models of rhabdovirus assembly postulated that the incorporation of G protein into virions results from specific interactions between the cytoplasmic tail of G protein and components of the condensed RNP core (139,193). Evidence supporting this model came from studies showing that G proteins with truncated cytoplasmic tails were not efficiently incorporated into virions (223) and that the addition of the G tail was necessary for the incorporation of heterologous viral glycoproteins into virus particles (133,148). G protein, however, is not needed for VSV or rabies budding, although it greatly enhances budding efficiency (96,134,185,205). Cells infected with recombinant viruses recovered from plasmids in which the G gene was deleted produced noninfectious particles with the characteristic bullet-shaped morphology of rhabdoviruses. Therefore, interactions between G protein and the condensed RNP core are not required to initiate the budding process, although they enhance its efficiency 10- to 30-fold.

Studies to define a role of the G protein cytoplasmic tail in virus assembly have revealed that rabies virus and VSV have distinct requirements. Except in one case in which the cytoplasmic tail of a heterologous protein contained a sequence

that greatly reduced incorporation of the glycoprotein into VSV particles (87,148), appending the cytoplasmic tail of VSV G protein to heterologous proteins does not increase virus budding or glycoprotein incorporation (90,168,182). Similarly, the recovery of infectious VSV containing G proteins with truncated cytoplasmic tails or chimeric G proteins with foreign cytoplasmic sequences indicated that a short cytoplasmic domain is important for efficient virus budding but that the specific amino acid sequence in that domain was not important (181). In contrast, the assembly of foreign glycoproteins into rabies virus appears highly dependent on the rabies G cytoplasmic tail (132,133), although infectious rabies virus can be recovered when the entire cytoplasmic domain is deleted (134). The basis for this difference between rabies virus and VSV is not known, but it may reflect a fundamental difference in the way that the M–RNP core interacts or organizes the G protein spikes in the viral envelope.

In comparison with the role of G protein in virus budding, mutation or deletion of the M gene has a much more drastic effect on virus assembly. Temperature-sensitive M protein mutants of VSV produce very low levels of spherical or pleomorphic-shaped particles at the restrictive temperature (122). Similarly, a recombinant rabies virus lacking the M gene produces about 10^5 fewer particles than the wild-type virus, and these particles have a filamentous morphology (136). Complementation with the wild-type M protein expressed from plasmids increases virus budding (136) and converts both the VSV and rabies M mutants to the typical bullet-shaped morphology of rhabdoviruses (122,136). The observation that transient expression of M protein, in the absence of other viral proteins, causes membrane evagination and the release of small membrane-enclosed vesicles (89) supports the idea that M protein has an intrinsic budding activity. Such an activity is reminiscent of the ability of retrovirus Gag proteins, when expressed alone, to produce virus-like particles, and it has been proposed that rhabdovirus M proteins and retrovirus MA proteins may be structurally and functionally similar (107). The recent demonstration that a highly conserved motif (PPxY) in the N-terminus of rhabdovirus M proteins can functionally substitute for the late-domain (L domain) of an avian retrovirus gag protein provides support for this hypothesis (35). Point mutations in the PPxY motif of VSV M protein do not affect membrane localization but significantly reduce both M-dependent vesicle budding (71) as well as the amount of virus released from infected cells (86). Retrovirus L domains function in the last step of virus budding, namely membrane fission and virus release (227). Therefore, the PPxY motif in rhabdovirus M proteins may also be involved in virus release but not RNP condensation or the initiation of virus budding. Thus, high-level virus production results from the concerted action of both the M and G proteins, and only when M protein is absent do rhabdoviruses fail to assemble.

Although far from complete, the available data support a model of assembly in which nucleocapsids bind to regions of the plasma membrane enriched in both M and G proteins. Once nucleocapsids bind to these regions, RNP condensation occurs, and formation of the bud site is initiated. In VSV, specific interactions between the cytoplasmic tail of G protein and the condensed RNP core appear not to be required, although a short cytoplasmic tail of G may insert into a pocket on the condensed core and promote a specific arrangement of G trimers in the viral membrane (181).

VSV buds preferentially from the basolateral surface of polarized epithelial cells (25), a property that is likely important in systemic spread of the virus in infected animals. The sorting of VSV G protein to the basolateral domain of polarized cells independent of other VSV proteins (65,199) and the presence of a dominant basolateral sorting signal in VSV G (210) could explain the preferential polarized release of VSV from the basolateral surface. There is also evidence for independent polarized sorting of M protein to the basolateral membrane (15), but signals in M protein involved in the sorting have not yet been identified.

Because specific sequences in the transmembrane and cytoplasmic domains of VSV G are not required for efficient budding, it seemed likely that G protein sequences important for driving efficient budding would reside in the ectodomain. The recent identification of a “budding domain” in the membrane-proximal region of the G ectodomain provides support for this hypothesis (168). The mechanism by which this domain acts to enhance budding is not understood. It could act to promote association of large arrays of G protein, which would induce membrane curvature at the bud site, or it could have more indirect effects on modifying the local lipid environment to promote interactions with areas of the membrane containing M–RNP complexes. The final step in virus budding requires a membrane fission event that results in release of the virus from the host cell. Little is known about how this occurs, but it has been suggested that the PPxY motif in M protein facilitates virus release through the recruitment of host factors that contain WW domains (35,71).

The use of reverse genetic systems has greatly advanced our understanding of protein domains involved in rhabdovirus assembly, but there are still many questions that remain unanswered. For example, little is known about the contribution that host factors play in virus assembly and release. A complete understanding of the roles of individual viral proteins and of potential host factors involved in virus budding will likely require detailed structural information on the individual components as well as sophisticated biochemical assays to measure directly protein–protein and protein–lipid interactions.

Production of Defective Interfering Particles

As with many other viruses, passage of rhabdoviruses in tissue culture leads to accumulation of defective interfering viruses called DI particles. These particles have a normal VSV protein composition but have truncated RNA genomes lacking some or all of the viral structural protein genes and therefore they can only propagate in cells co-infected with parental virus. The DI particles out-replicate parental virus and rapidly accumulate to higher levels than parental virus during passage at high multiplicity. Elimination of DI particles from virus cultures can be accomplished by low-multiplicity infection and repetitive isolation of virus from single plaques. DI particles can also be separated from the parental virus based on velocity of sedimentation on sucrose gradients. Perrault (153) has provided an excellent review of the DI particle structure and formation.

Typical types of VSV DI particles are illustrated in Figure 6. The most common type of DI particle contains RNAs with complementary terminal sequences that rapidly self-anneal to form short stems or longer snap-back structures after the template-associated N protein is removed. These DIs lack the 3' leader sequence (Le) used to initiate transcription of the viral genes and replication of the antigenomic RNA. These DIs have a strong replicative advantage over standard genomes. Because of the self-complementary nature of the DI genome ends, replication of either strand initiates on the

complement of the 5' trailer sequence (Tr'). This is the same sequence that serves as the promoter for synthesis of VSV genomic RNA and is a stronger promoter than the 3' leader sequence (Le), which initiates synthesis of antigenomic RNA. This difference in relative promoter strengths discussed in the preceding section on genome replication would explain the excess synthesis of genomic RNA relative to antigenomic RNA in infected cells. DI RNAs that retain both ends of standard genome at their termini are less common and do not compete as well against the standard genome, probably because they, like the standard genome, are involved in transcription as well as replication and do not have as strong a promoter for their positive-stranded RNA replication.

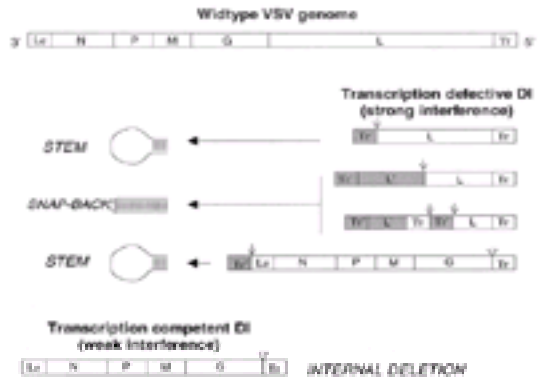

FIG. 6. Schematic representation of different classes of rhabdovirus DI particles. (Courtesy of Dr. J. Perrault, San Diego State University.)

Generation of DI RNA molecules from a standard virus is believed to occur after a viral polymerase with its attached nascent RNA chain dissociates from its template and resumes synthesis at a new site either on its own nascent chain or on a different template molecule (153). Generation of the first two types of DIs illustrated in Figure 6 could occur by a single switch (*arrow* indicates switch site) of the polymerase to copy its own nascent chain. Other, more complex types of DIs can result from multiple polymerase switches, including switches to downstream sites on a template to generate internal deletions (*triangles* in Fig. 6). Multiple switch events are possible, and DIs with more extensive genome rearrangements have been reported (146,176).

MOLECULAR GENETICS OF RHABDOVIRUSES

The ability to perform precise molecular genetic analysis of rhabdoviruses required the development of systems for recovering infectious viruses from DNA copies. Recovery of rhabdoviruses and other nonsegmented negative-stranded RNA viruses (NNS viruses) from DNA presented a unique problem because neither their genomic nor their antigenomic RNAs serve as mRNAs, and neither can be used directly to recover infectious virus. This contrasts with the positive-stranded RNA viruses in which the genomic RNA transcribed from DNA can be used to initiate infection. The minimal infectious unit for the NNS RNA viruses is the genomic RNA complexed with nucleocapsid and RNA polymerase proteins in a RNP complex. Because the NNS RNA viruses have genomes that are quite large (11 to 18 kb), it has not been possible to assemble their RNAs into infectious RNPs *in vitro,* an approach that did work earlier to introduce individual RNA segments into influenza virus (118).

Recovery of Infectious Rabies and Vesicular Stomatitis Virus from Plasmid DNA

Before the recovery of complete, infectious negative-stranded RNA viruses from DNA, several laboratories developed systems that allowed replication of small, defective negative-stranded RNA genomes or RNA mini-genomes that were derived from DNA copies. The RNA mini-genome constructs contained one or more genes flanked by short 3' and 5' sequences derived from the natural virus genome and containing the signals required for replication (reviewed in reference 167). The first such system for VSV employed a defective interfering particle RNA that was expressed from plasmid DNA (150). The VSV proteins required for replication of this RNA (N, P, and L) and for assembly of infectious particles (M and G) were provided by a vaccinia virus-based expression system (57). A related system was developed for a rabies virus mini-genome (34). The rabies construct contained short 3' and 5' rabies genomic sequences flanking an expressed bacterial gene (*CAT*). A similar mini-genome system was also developed for VSV and contained VSV *G* or *G* plus *M* genes flanked by VSV terminal genomic sequences (200). The replicating mini-genome and DI RNA systems were important for the eventual development of systems for recovery of complete infectious rhabdoviruses from DNA. As described later, however, they did not work to generate infectious virus starting with expression of the the negative-stranded genomic RNA.

The basic system for recovery of all nonsegmented negative-stranded RNA viruses was established first in the rhabdoviruses. In 1994, Schnell and colleagues (186) reported successful recovery of rabies virus from cDNAs. This was accomplished by transfecting cells with plasmids encoding the viral transcription complex components under T7 promoter control (N, L, and P) into cells that had first been infected with recombinant vaccinia expressing T7 polymerase (57). In addition, a plasmid encoding the full-length viral antigenome under T7 promoter control was transfected into the cells (Fig. 7). Supernatants from these cells contained infectious rabies viruses. Use of an antigenome instead of the genome is important because it avoids the problem of hybridization of genomic RNA to the mRNAs transcribed from the plasmids encoding N, P, and L proteins. When one starts with the positive-stranded antigenome, this RNA can form an RNP without any interference from the mRNAs. Once in RNP form, the positive strand can then be replicated to form full-length negative-stranded RNPs that are wrapped into RNPs as nascent RNA chains and thus are immune to interference from mRNAs.

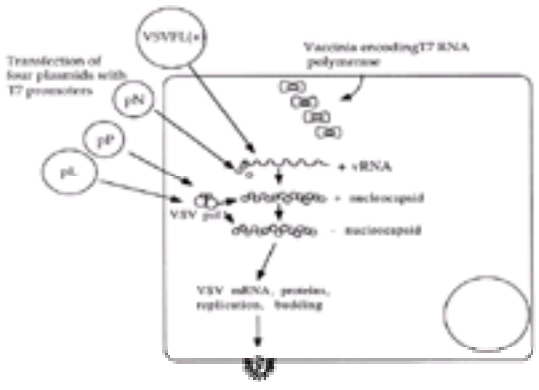

FIG. 7. Diagram of the system for recovery of rhabdoviruses from plasmid DNA.

Within a few months of the rabies report, infectious VSV was recovered from a plasmid DNA copy using a protocol very similar to that reported for rabies (102), and this was subsequently repeated (220). An infectious recombinant in which the Indiana serotype glycoprotein gene was replaced with the New Jersey serotype glycoprotein gene was also recovered, demonstrating the potential of the system for generating chimeric viruses (102). Subsequent application of the same or similar methodologies has led to recovery of numerous other NNS viruses from DNA copies (reviewed in 167).

Rhabdoviruses as Gene Expression, Vaccine, and Targeting Vectors

As described previously, the reverse genetic systems for rhabdoviruses have been crucial to dissecting numerous aspects of virus replication and assembly. Additional foreign genes can be introduced into recombinant rhabdoviruses, and foreign gene expression is generally stable (135,183). In VSV vectors, the expressed proteins can represent as much as 5% of the total cell protein 7 hours after infection (167,183).

The potential of recombinant VSVs as vaccine vectors was shown in a study in which a VSV recombinant expressing an influenza hemagglutinin gene was used in mice. A single intranasal inoculation with as little as 10 plaque-forming units induces a potent and protective immune response to influenza (166). VSV vectors have also been attenuated through mutations in the cytoplasmic tail of VSV G protein such that there is little or no pathogenesis even in 6-week-old mice (165), yet strong and protective immune responses are still generated. Ongoing studies of VSV vectors in rhesus macaques indicate a lack of pathogenesis and induction of strong cellular and humoral immune responses to encoded HIV envelope protein (J. Rose and colleagues, unpublished observations). These studies indicate that VSV may have potential as a vaccine vector in humans.

Other studies have illustrated the potential of recombinant VSVs as targeting vectors. A recombinant virus lacking its glycoprotein gene but encoding instead the human immunodeficiency virus (HIV) receptor and coreceptor was shown to incorporate both foreign glycoproteins into its coat. Furthermore, this virus could specifically target, infect, and kill HIV-infected cells *in vitro* (185). Related studies performed with rabies virus pseudotypes also suggested the potential of rabies as a targeting vector (133).

The potential of rhabdovirus recombinants as surrogate viruses for viruses that are dangerous or impossible to grow was illustrated by a recent study in which the VSV glycoprotein gene was replaced with an HIV envelope gene. In addition, a gene encoding green fluorescent protein was included (24). This virus infects cells using the HIV receptor and coreceptor and can be used as a fast and convenient assay for HIV neutralization. In another strategy, investigators have used a virus lacking G protein but encoding green fluorescent protein (GFP) to generate pseudotyped virus containing the envelope glycoprotein of Ebola virus. The pseudotypes allowed the identification of cell surface determinants important for Ebola virus infection (205) and resulted in the identification of a putative fusion domain in the Ebola glycoprotein (82) without the need to work under BSL-4 containment conditions. The promiscuous nature of VSV assembly that allows for extensive incorporation of foreign proteins into the envelope suggests that numerous similar applications are possible.

Given the extensive progress with reverse genetics of rhabdoviruses made recently, we can expect to see many new applications of this exciting technology in the years to come.

MOLECULAR BASIS OF PATHOGENESIS

General Aspects

Despite the similarities in structure between the lyssaviruses and vesiculoviruses, the former generally cause a relatively slow and progressive disease, and the latter cause acute disease that is eliminated rapidly by host immune responses. The pathogenesis of rabies virus is addressed in a subsequent chapter, and the veterinary aspects of vesiculovirus pathogenesis have been thoroughly and recently reviewed (112).

The basis for VSV pathogenesis appears intimately tied to the replication potential of the virus. For example, a mutation truncating the VSV G cytoplasmic domain from 29 amino acids to 9 amino acids reduces the virus yield only two-fold in tissue culture (181) but nearly eliminates pathogenesis in a mouse model (165). Complete elimination of the cytoplasmic domain reduces the virus yields about 10-fold (181) and completely eliminates pathogenesis in the mouse model while still allowing replication sufficient to induce strong immune responses (165). Similar results have been obtained using rearranged VSV genomes in which reduction in virus yield in culture correlates with reduced pathogenesis in animals (217). Rapid production of new virions is probably crucial to virus spread before immune responses result in virus clearance. In an infected animal, in which virus replication is likely an exponential process initially, even two-fold differences in final virus yield per cell in tissue culture are rapidly amplified to much greater differences in virus load in an

animal.

Almost all vertebrate cells tested and many invertebrate cells are susceptible to VSV infection. The replication of VSV can vary widely in different cell types, and infectious virus yields also vary, but little is known of the molecular basis for this variation. For example, VSV yields in baby hamster kidney cells (BHK-21) are about 100,000 particles per cell, of which about 10% can be infectious. Optimal VSV titers obtained in BHK cells range from 10^9 to 10^{10} per milliliter of medium. In contrast, VSV yields in HeLa cells are typically less than 5% of those obtained in BHK cells. The human lymphoblastoid cell line Raji is infected by VSV, but the viral RNA synthesis is low, and the VSV particles produced have an abnormal protein composition with only low levels of matrix protein (145,219). Rabbit corneal cells are infected by VSV but produce less than one infectious particle per cell. Co-infection with vaccinia virus reverses the block to VSV replication through an unknown mechanism (208). In *Drosophila* melanogaster cells, VSV establishes a persistent, noncytopathic infection, and virus titers are low (229). This may be due in part to a deficiency of VSV G protein in the viral particles that are produced (229).

At high multiplicities of infection in BHK cells, VSV cytopathic effects (cell rounding) can be evident 1 to 2 hours after infection. At lower multiplicity, the cytopathic effects may not be evident for 4 to 5 hours in BHK cells. In other cell types in which VSV replication is less robust, cytopathic effects often require longer to become evident.

The cell rounding effects of VSV appear to be due largely to expression of the VSV M protein. M protein expression alone in cells causes rounding and detachment by rapidly depolymerizing actin as well as tubulin and vimentin. This causes the breakdown of stress fibers, microtubules, and intermediate filaments (20,120,137,231). The VSV glycoprotein is also toxic to cells when expressed in large quantities, although stable cell lines can be made constitutively expressing low levels of G protein (53,158). The mechanism of toxicity of VSV G protein is not known, but it may involve a low level of membrane fusion activity even at neutral pH.

Inhibition of Cellular Protein Synthesis

VSV infection results in substantial inhibition of cellular protein synthesis within 3 to 4 hours after infection when the VSV proteins are the major proteins synthesized by the infected cells. When total poly(A)-positive mRNAs are purified from infected cells and translated *in vitro* in reticulocyte lysates, the mRNAs encode predominantly the VSV proteins, suggesting a major change in the ratio of viral mRNAs to host mRNAs in the infected cells (95). Lodish and Porter (117) carried out a study that suggested a competition mechanism for the inhibition of cellular mRNA translation. They found that the total amount of translatable mRNA in cells increased about three-fold after infection owing to substantial viral mRNA synthesis, and they suggested that inhibition of cellular protein synthesis could be explained at least in part by competition for ribosomes by the large excess of viral mRNAs. Based on analysis of polysome size, the efficiency of initiation of translation on cellular and viral mRNAs was found to be about the same in infected cells, but cellular ribosomes were distributed among more mRNAs after infection (117). A subsequent study (187) challenged this purely passive shutoff mechanism because severe limitation of VSV transcription did not substantially reduce the inhibition of host mRNA translation. However, a specific mechanism that discriminates between cellular mRNAs and viral mRNAs has not been identified. The fact that host mRNAs expressed from VSV recombinants are translated with efficiencies similar to viral mRNAs (98,182,183) suggests a lack of discrimination based on mRNA sequence alone, unless the selective specificity is present solely within the minimal 5'- or 3'-terminal nucleotides required on each mRNA as part of the VSV transcription initiation or termination signals.

Inhibition of Cellular Transcription, mRNA Transport, and DNA Synthesis

VSV infection results in inhibition of host cell mRNA synthesis and expression, and even a low level of the VSV matrix protein is sufficient for this inhibition (19). The mechanism of inhibition appears to result at least in part from inactivation of the transcription factor TFIID (233). In addition to having direct effects on host transcription, the VSV matrix protein blocks transport of mRNAs from the nucleus (73). This study showed that M protein interferes with transport that is dependent on the nuclear guanosine triphosphatase Ran-TC4 and its associated factors.

Other studies suggested a role for the VSV leader RNA in inhibition of RNA synthesis. VSV transcription is known to be required for inhibition of cellular RNA synthesis (216). Because the VSV leader RNA is transcribed first from the VSV genome, its transcription is most resistant to inactivation by UV light. Virions exposed to high doses of UV are still able to synthesize leader RNA and inhibit cellular mRNA synthesis (66), suggesting a role of the leader in this inhibition. *In vitro* transcription experiments using oligodeoxynucleotides having sequences homologous to leader RNA also supported a role for the leader in inhibition of transcription (67). However, other experiments showing a requirement for protein synthesis in inhibition of host RNA synthesis are not consistent with leader RNA alone being responsible for the inhibition of host RNA synthesis (156). The interpretation of the UV inactivation experiments was questioned by Whitaker-Dowling and Youngner (222), who showed that the doses of UV used to implicate leader RNA were sufficient to cause direct damage (cleavage) of VSV virion proteins.

The same types of UV inactivation experiments that implicated leader in inhibition of RNA synthesis also implicated leader in inhibition of cellular DNA synthesis. The mechanism of the inhibition is not known, but studies performed in an *in vitro* system for adenovirus replication showed that oligodeoxynucleotides corresponding in sequence to the VSV leader RNA could inhibit adenovirus DNA replication (162). The VSV leader is know to be rapidly transported into the cell nucleus after infection (101), a property consistent with a role in inhibition of both DNA replication and DNA-dependent transcription.

IMMUNE RESPONSES

There has been relatively little research on immunity to VSV in natural host animals, such as cattle, in which the virus infects epithelial cells and causes vesicular lesions. The virus is cleared effectively by the immune system, but the types of immune responses required for clearance have not been studied in the natural hosts. Interestingly, the immunity to

VSV after natural infection in cattle is not long-lived, and the same strain of VSV appears to be able to infect cattle in subsequent years, despite the presence of extremely high serum neutralizing antibody titers to the infecting strain (213). The mechanism of reinfection does not involve genetic drift in the virus glycoprotein as the sequence is unchanged in the reinfecting virus. There is also evidence that some VSV genomic RNA but not mRNA sequences can persist in experimentally infected cows after infectious virus has been cleared, but the mechanism of this persistence is not known (111).

Most studies of immunity to VSV have been performed in more tractable mouse systems, and the pathogenesis in laboratory mice is quite different from that in the natural host animals. When inoculated intranasally in some mouse strains, such as Balb/c or C57BL/6, VSV can infect the brain and cause a lethal encephalitis (78,161). VSV has also been found to replicate in the lungs of Balb/c mice after intranasal inoculation (165,166). Other routes of infection in mice, such as the intraperitioneal route, can induce immunity to VSV without significant pathogenesis, even when high titers of virus are inoculated. High and protective levels of antibodies to VSV persist in mice and diminish only two- to four-fold even 2 years after infection (165).

Role of Interferons

In VSV infection, as in infection with many other pathogens, interferons (IFNs) provide a critical front line of defense. Although VSV isolates differ in their ability to induce IFN (128), VSV replication is extremely sensitive to IFN action. The IFN response in mice slows the spread of VSV infection until an antibody response can completely control the infection. The importance of the IFN response was shown in IFN-a- and IFN-b-receptor–deficient mice (198). Infection of these mice results in rapid, disseminated VSV replication in multiple organs, and the mice die within a few days. Other studies with mice deficient in the JAK-STAT IFN signaling pathway have also revealed extreme sensitivity to VSV infection (138).

Roles of Antibody and Cytotoxic T Cells

The relative importance of antibody and cytotoxic T cells in immunity to viral infection varies depending on the virus and host in question. Antibody is a crucial component of immunity to VSV in mice. All neutralizing antibodies to VSV recognize the single exposed transmembrane glycoprotein G (94). Studies in IFN-receptor–deficient mice showed that passively transferred antibody to VSV G protected these mice efficiently against systemic infection (198). In contrast, passively transferred VSV-specific T cells were unable to protect these mice. The relative unimportance of T cells in immunity to VSV has also been shown in experiments involving mice lacking CD8+ T cells. These mice are as resistant to VSV as control mice with normal levels of CD8+ cells T cells (58). However, T-cell responses, although insufficient on their own, can protect from VSV-induced disease in an immunocompetent mouse. This was shown in experiments in which a T-cell response to purified VSV nucleocapsid protein protected mice from a normally lethal VSV infection (4).

Neutralization

Infection of mice by VSV induces a rapid production of neutralizing immunoglobulin M (IgM) antibody, which occurs independently of T-cell help, followed by appearance of neutralizing IgG antibodies that are dependent on T-cell help for their production (106). The ability of VSV to induce IgM independent of T-cell help appears to be related to the presence of G protein in a dense array on the viral surface (5).

The molecular requirements for antibody-mediated neutralization of VSV *in vitro* and protection against lethal disease *in vivo* have been studied in detail using a monovalent single-chain antibody and antibody fragments generated from VSV-neutralizing antibodies (91,103,104). These experiments demonstrate that neutralization of VSV and protection against disease do not require Fc-mediated mechanisms and that antibody cross-linking is not crucial for protection. Although the mechanism by which antibodies neutralize VSV has not been studied, it probably requires antibody physically shielding most VSV G spikes on the virion and thereby blocking attachment and fusion. This is likely because in rabies virus neutralization, the number of antibody molecules required for complete neutralization of a virion is at least half the number of viral glycoprotein spikes (50). Multiple epitopes binding neutralizing monoclonal antibodies have been described for the G proteins from the Indiana and New Jersey serotypes of VSV (26,105,215)

T-Cell Epitopes

Early studies in mice revealed that epitopes in both the VSV N and G proteins are recognized by cytotoxic T cells (157,232). The VSV Indiana nucleocapsid protein contains an immunodominant H-2 Kb epitope binding class I major histocompatibility complex in C57BL/6 (B6) mice. This peptide, N52-59 (RGYVYQGL), was among the first viral cytotoxic T-lymphocyte epitopes to be identified and sequenced (191). Subsequent studies have shown class II major histocompatibility complex restricted epitopes recognized by cytolytic T cells in Balb/c mice (27). The helper T-cell epitopes in the G protein have been analyzed with a complete panel of overlapping synthetic peptides. Three different helper T-cell epitopes in C57BL/6 mice and two in BALB/c mice were defined in VSV G (Indiana) (28).

CHAPTER 39 Rhabdoviruses

Carlos A. de Mattos, Cecilia C. de Mattos, and Charles E. Rupprecht

The family *Rhabdoviridae* consists of more than 175 different viruses isolated from both plants and animals. These enveloped viruses share a common elongated rodlike shape, encompassing single-stranded, negative-sense RNA as a primary unifying feature of the group. This distinctive morphology, of uncertain functional significance, separates rhabdoviruses from other taxa in the order *Mononegavirales*, the *Filoviridae* and the *Paramyxoviridae.* Rhabdoviruses can replicate in plants, in invertebrates, or in vertebrates. The *Rhabdoviridae* contain many members that are significant medical, veterinary, and botanic pathogens. This chapter concentrates on biologic features of the animal rhabdoviruses; it does not discuss either of the plant genera, *Cytorhabdovirus* or *Nucleorhabdovirus.* Currently, animal rhabdoviruses include three genera: *Lyssavirus*, *Ephemerovirus*, and *Vesiculovirus.* Many other rhabdoviruses have not received adequate study and are assigned to the family solely on the basis of morphology.

LYSSAVIRUS

History

Rabies is an archaic entity, one of the oldest recognized infectious diseases. Despite the historical preeminence of smallpox, influenza, and, more recently, AIDS, the continuing biomedical preoccupation with rabies is understandable because its “alarming manifestations in man and dog alike . . . and its almost inevitable progression to a fatal outcome have ensured unparalleled notoriety” (488). These concerns extend beyond the material to the spiritual plane, as revealed by the following prayer: “San Roque, San Roque, que este perro no me toque!” This supplication for protection to the patron saint against pestilence, taught to children in both the Old and the New World for invocation whenever they encountered a dog on the street, literally translates to “St. Roque, St. Roque, do not allow this dog to touch me!”—classically linking dogs, bites, and resulting misfortune. There is an even earlier passage that mentions the dangers of dog bites, in the pre-Mosaic Eshnunna Code of Mesopotamia, circa the 23rd century B.C.: “If a dog is mad and the authorities have brought the fact to the knowledge of its owner; if he does not keep it in, and it bites a man and causes his death, then the owner shall pay two-thirds of a mina [40 shekels] of silver. If it bites a slave and causes his death he shall pay 15 shekels of silver” (24).

Thus, ancient civilizations were quite familiar with rabies. In *The Iliad* (700 B.C.), Hector is compared to a rabid dog. Chinese scholars warned of the dangers of rabid dogs in 500 B.C., and Aristotle (4th century B.C.) correctly associated the disease with animals, but erroneously exempted humans from contracting it from a mad dog's bite. In Rome, Cordamus guessed that a poison (i.e., a “virus”) was present in saliva. Similarly, in the 1st century A.D., another Roman, Celsus, described clinical aspects of human infection: “The patient is tortured at the same time by thirst and by invincible repulsion toward water.” For prevention, he recommended immediate excision of the bitten tissue, cauterization of the wound by a hot iron, and, unfortunately, ducking the victim into a pool. The Hebrew Talmud, also dating from the 1st century, makes several references to the disease. Throughout the ages, ingestion of a wide variety of substances (e.g., the liver from a mad dog, crayfish eyes, a cock's brain or comb, or the cast slough of snakes pounded in wine with a male crab) and carrying sacred talismans were believed to be cures for rabies (24). Some have even suggested the basic

vampire and werewolf legends harken from human rabies cases (182).

A gradual transition from the medieval era of religious beliefs and superstitions to the Renaissance period of pragmatism and experimentation resulted in a remarkable treatise in 1546, entitled “The Incurable Wound” by Fracastoro. This Italian physician clearly stated that human beings are susceptible to rabies, and he vividly described a clinical case: “Its incubation [following a bite by a rabid animal] is so stealthy, slow and gradual that the infection is very rarely manifest before the 20th day, in most cases after the 30th, and in many cases not until four or six months have elapsed. There are cases recorded in which it became manifest a year after the bite. [Once the disease takes hold,] the patient can neither stand nor lie down; like a madman he flings himself hither and thither, tears his flesh with his hands, and feels intolerable thirst. This is the most distressing symptom, for he so shrinks from water and all liquids that he would rather die than drink or be brought near to water; it is then that they bite other persons, foam at the mouth, their eyes look twister, and finally they are exhausted and painfully breathe their last” (236). His portrayal of human rabies is accurate in that the incubation periods may extend from months to years after initial exposure (402), but a biting attack upon others by a rabid patient with resultant disease is an uncommon event (146).

Although rabies is known to have been widespread in the Old World for thousands of years, its occurrence in the New World is less understood because of a dearth of records prior to European arrival. Rabies in the Americas was reported by the Reverend Marmolejo in Mexico as early as 1709, but there is a suspicion that it was present before Columbus's arrival in the 15th century. For example, not long after the discovery of the Americas, the bishop Petrus Martyr-Anglerius wrote in his *De Rebus Oceanicis et de Orbi Novi Decades Octo*, “In several places bats not much smaller than turtle doves used to fly at them [the Spanish sailors and soldiers] in the early evening with brutal fury and with their venomous bites brought those injured to madness . . . [and] bats . . . come in from the marshes on the river and attack our men with deadly bite” (251). This may have been one of the first descriptions of rabies transmission by vampire bats. Elsewhere, in North America, some 200 years after initial Spanish invasion, canine rabies was described in 1753 from the Virginia colony, and later in foxes.

The bite of a rabid animal was considered a likely source of rabies infection by many, but it was only in 1804 that Zinke used dog saliva for transmission. Later in 1879, Galtier is credited with experimental rabies transmission to rabbits, and from rabbit to rabbit (253). Clinical descriptions formed the basis for diagnosis until the advent of light microscopy. A clear description of viral and neuronal interactions was made by Negri in 1903, with the detection of cytoplasmic inclusions (Negri bodies) in neurons of rabid animals (256). Reports of intraneuronal bodies specific for rabies stimulated debate concerning both their diagnostic utility and their nature. Although the diagnostic value of Negri bodies was established by 1913, their viral composition had to wait until the later development of electron microscopy.

Pasteur's research on rabies is perhaps the most well known historical achievement in the field. First, through adaptation of “street” (wild-type) virus to laboratory animals, he was able to change its properties. Today, one could apply the term *mutant* to his “fixed” virus strains. Second, Pasteur and his team developed concepts and experimental approaches to the first protective vaccination against rabies (253). Desiccated spinal cords from rabies-infected rabbits became the first rabies vaccine, and they were supposedly safe, although now it is known that the fixed viruses from which the vaccines were derived were not apathogenic but could actually cause the disease. July 6, 1885, is a milestone in the history of rabies. On that day, 9-year-old Joseph Meister was bitten at multiple sites by a rabid dog and received the first postexposure prophylaxis with Pasteur's vaccine. Remarkably, Joseph survived (253).

Pasteur's vaccine, with all its modifications, became the accepted rabies prophylactic throughout the world in the early 20th century. However, problems remained, because improperly inactivated virus caused rabies, and animal brain tissue induced allergic reactions leading to neuroparalytic accidents. Moreover, perhaps most importantly, the vaccine was not very effective in cases of severe bites, such as those inflicted on the face and neck by rabid wolves.

Postexposure prophylaxis against rabies through simultaneous administration of antirabies serum and vaccine was introduced in 1889 by Babes (15). This approach found few adherents and was forgotten until 1940, when interest in the use of serum containing rabies antibodies was revived. In a trial organized by the World Health Organization in 1954, the combined use of serum and vaccine was found to be more protective than vaccine alone (192), an observation later corroborated by Chinese findings (143). Today, the combination of serum and vaccine is the recommended standard for prophylaxis in human rabies exposure.

In the 1960s, a rabies virus grown in human diploid cells was used for production of a safe and efficacious vaccine (252,253), eliminating many of the problems connected with vaccines produced in brain tissue. This vaccine is being used widely throughout the world, although for economic reasons several developing countries still use nervous tissue vaccines. New generations of rabies vaccines will have both maximal efficacy and safety while still being affordable in regions with enzootic dog rabies.

Infectious Agent

Taxonomy

Classically, only one major serogroup was established within the *Lyssavirus* genus, although various serotypes were defined (367). Placement within the genus was determined by serologic cross-reactivity of viral antigens (e.g., complement fixation, immunofluorescence tests), primarily based on antigenic sites on the nucleoprotein (the N protein). Historically, placement of a species as a rabies or rabies-related virus was determined by recognition of antigenic sites of the glycoprotein (the G protein) via virus neutralization tests. More recently, sequence data became available for a number of lyssaviruses (48,245,280,403,433,505), and a trend toward genetic classification should continue. Virus species currently or putatively assigned to the *Lyssavirus* genus, all isolated from mammals, include rabies virus (RABV); Australian bat virus (ABV); Duvenhage virus (DUV); European bat virus, type 1 (EBV-1); EBV-2; Lagos bat virus (LBV); and Mokola virus (MOK) (Table 1). Two other viruses, Obodhiang and Kotonkan, found only in Africa and originally isolated from mosquitoes and midges, respectively (390), and Rochambeau virus (237), isolated from a pool of

mosquitoes, *Coquillettidia albicosta*, in French Guiana during 1973, have been suggested for consideration in the genus based on serologic data, but this awaits ultimate taxonomic assignment.

Lyssavirus	Host(s)	Geographic location
Rabies virus	Domestic and wild canids, mustelids, viverrids, and insectivorous and hematophagous bats	Worldwide, except for the Australian and Antarctic continents and some islands
Lagos bat virus	Fruit bats (Megachiroptera)	Africa
Mokola virus	Probably insectivore or rodent species	Africa
Duvenhage virus	Probably insectivorous bats	Africa
European bat lyssavirus 1	Insectivorous bats	Europe
European bat lyssavirus 2	Insectivorous bats	Europe
Australian bat lyssavirus	Fruit bats (Megachiroptera) and insectivorous bats	Australia

TABLE 1. *Members of the genus Lyssavirus of the Rhabdoviridae family*

Morphology and Physical Properties

Rhabdoviruses are enveloped, rod-shaped particles (Fig. 1), approximately 100 to 430 nm long and 45 to 100 nm in diameter, when mature (186). Animal rhabdoviruses are usually less than 180 nm, but those isolated from plants may be longer. Typically, mature virions appear either as bullet-shaped particles with one rounded and one flattened end, or as bacilliform particles that appear hemispherical at both ends (501). Defective-interfering (DI) particles have the same basic configuration but are shorter (20% to 50% the length of standard infectious viruses). DI particles resemble standard viruses in their protein and lipid composition, but they are not infectious, and 50% to 80% of the genome may be deleted (460). The linear RNA is encapsidated along its length (507). Typically, five polypeptides are encoded. The nucleocapsid or ribonucleoprotein (RNP) core exhibits helical symmetry with a diameter of approximately 30 to 70 nm, and it is surrounded by a lipid envelope. The virion outer surface is covered with projections (peplomers) approximately 5 to 10 nm long and 3 nm in diameter, except for the quasi-planar end (501). Peplomers are composed of trimers of the viral G protein (127,174).

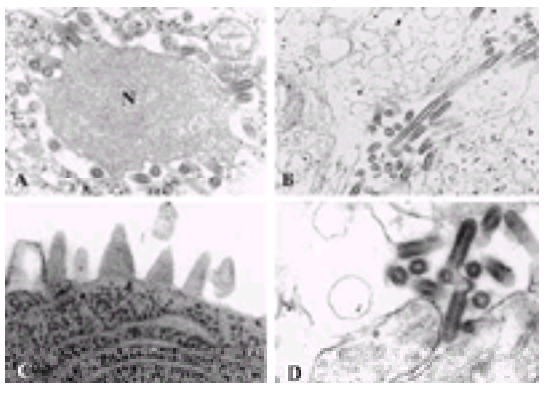

FIG. 1. Electron Micrographs of selected animal rhabdoviruses. **A:** *Lyssavirus*, Lagos bat virus. A typical Negri body (*N*) in the brain, with budding virions (×42,000). **B:** *Vesiculovirus*, vesicular stomatitis virus. Occasional anomalous elongated form of the virus (×35,000). **C:** *Ephemerovirus*, bovine ephemeral fever virus. Isolated from a cow in Australia, 1969. Late infection of VERO cell (×110,000). **D:** Unassigned, sawgrass virus. Isolated from a tick in Florida (×137,500). (Photographs courtesy of Sylvia Whitfield, CDC, NCID, DVRD, VRZB.)

The molecular weight is 300 to 1,000 × 10^6, and the buoyant density is 1.19 to 1.20 g/cm^3 in cesium chloride (CsCl), and 1.17 to 1.19 g/cm^3 in sucrose. Virus infectivity is stable in the pH range of 5 to 10, but it is rapidly inactivated at 58°C, by ultraviolet or x-ray irradiation, or by exposure to lipid solvents and oxidizing agents. Viral RNA accounts for 1% to 4% of the particle weight and has an estimated molecular mass of 4.2 to 4.6 × 10^6 daltons (11 to 15 kb in size). Virion RNA has a sedimentation coefficient of 42 to 45 Svedberg units and a buoyant density of 1.66 g/cm^3 (406). The RNA has a 5' terminal triphosphate and is not polyadenylated. The terminal sequences are complementary. Defective RNAs are significantly shorter than full-length RNA (by less than half), and replicate only in the presence of usually homologous helper rhabdoviruses (217).

Biologic Properties

Host Range and Infection of Experimental Animals

Rabies is an acute encephalitis caused by a lyssavirus. It is enzootic in all major regions of the world except Antarctica. The prototypic species of the *Lyssavirus* genus is RABV, which can infect warm-blooded animals under experimental conditions, but only mammals are significant natural hosts. Reservoirs include dogs, foxes, jackals, coyotes, raccoons, skunks, mongooses and their allies, and bats. Several countries, such as the United Kingdom and Japan, have become rabies free, once infected terrestrial animals were eliminated, but bats can reach even distant islands (370,477). Dogs are the most frequent vector for transmission to humans. The lyssaviruses DUV, LBV, and MOK are restricted to Africa (242). Although bats and small mammals such as shrews have been suggested as potential reservoirs (243), relatively

little is known about these African agents compared to RABV. In Europe, phylogenetic analysis of EBV genes after bootstrap resampling using maximum parsimony and neighbor-joining methods indicated low intrinsic heterogeneity, and it suggested at least two genetically distinguishable lineages, possibly related to spatiotemporal introduction from a different geographic location such as North Africa (12). Bats, such as *Eptesicus serotinus* and *Myotis dasycneme* and *M. daubentonii*, appear to be principal reservoirs for EBV1 and EBV2, respectively. Australia was believed to be free of the disease until 1996 (186), when indigenous lyssaviruses were discovered. These viruses appear to utilize either frugivorous *Megachiroptera* or insectivorous *Microchiroptera* as primary reservoirs, and they have caused at least two human deaths.

With the exception of RABV, the importance of the lyssaviruses as disease entities remains a matter of speculation (479). All mammals are probably susceptible to some degree, but experimental results suggest a hierarchy of species susceptibility (498). Very susceptible species include foxes, coyotes, jackals, and wolves (391,492). Cats (known as vectors but not as reservoirs), and some wildlife species, such as raccoons, are moderately susceptible to infection. The opossum (*Didelphis virginiana*) appears especially resistant (25). However, most experimental animal studies were performed before antigenic or genetic differences between viruses were appreciated as to their role in pathogenesis (193,327).

Since Pasteur's experimental inoculation of dogs and rabbits (335), many other species have been experimentally infected with RABV (452), including birds. No lyssaviruses have been isolated from cold-blooded vertebrates. Laboratory rodents, such as mice, have been extensively used for rabies diagnosis, vaccine potency testing, and pathogenic studies, although these taxa are epidemiologically insignificant as lyssavirus vectors or reservoirs (84,259), compared to the Carnivora and Chiroptera.

Propagation and Assay in Cell Culture

Early 20th century attempts to propagate RABV focused on central nervous system (CNS) tissue culture. In 1958, serial passage of fixed (laboratory strains) as well as street (primary field isolates) viruses was accomplished using primary hamster tissue cultures (246). Primary kidney cell cultures from hamsters, dogs, pigs, and other species are used for both primary isolation and laboratory propagation of fixed and street RABV (89,480). Continuous cell lines, particularly BHK-21, are commonly used for isolation and propagation of RABV because of their susceptibility to infection and high virus yields (376). The human diploid cell lines WI-38, MRC-5, and Vero can be used for commercial human rabies vaccine production (405,481,484), as well as avian and primate cell cultures (68). Although BHK-21 cells have been extensively used for propagation of fixed viruses, street RABV isolates may not be consistently recovered using these cells. Primary cell cultures or mouse neuroblastoma cell lines are frequently used for isolation of street RABV, although a wide variety of other cell types can be used for propagation (104). Two methods of virus titration for assessment of infective foci are the fluorescent antibody test (114,482) and the plaque assay (379). In general, lyssaviruses do not cause a specific cytopathic effect in cell culture. The plaque assay is useful for fixed strains of RABV that are well adapted to BHK-21 cells, but it provides inconsistent results with street viruses.

Chemical and Antigenic Properties of Viral Proteins

Rhabdoviruses generally encode five proteins, designated G (glycoprotein), N (nucleoprotein), P or NS (phosphoprotein), M (matrix protein), and L (RNA-dependent RNA transcriptase).

Glycoprotein

The G protein (102) is the primary surface antigen capable of inducing and reacting with virus-neutralizing antibodies (VNAs), and it is associated with receptor activities. Almost all major human and veterinary vaccines are based on the functional aspects of the G protein of RABV. The G protein gene has been cloned and sequenced from a number of lyssaviruses (9,95,436,505,509). Sequences contain a single open reading frame encoding a 522- to 524-amino-acid protein in lyssaviruses, with approximately 90% homology at the amino acid level. Mature G protein has 505 amino acids, resulting from cleavage of the N-terminal 19-amino-acid hydrophobic signal peptide, and it has three structural domains: the C-terminal cytoplasmic domain of 44 amino acid residues, the hydrophobic 22-amino-acid transmembrane domain, and the external antigenic domain extending from the transmembrane to the N-terminus (501). Within the antigenic domain are three to four putative glycosylation sites for addition of asparagine (N)-linked oligosaccharides, but not all sites are actually used (119,384,501,503). Fatty acid (palmitate) has also been found covalently linked to the cytoplasmic domain (175). A soluble form of G protein (Gs) is secreted from virus-infected cells; it lacks 58 amino acids from the C-terminus (129), which may result from proteolytic cleavage of newly synthesized protein. The Gs protein is antigenically identical to full-length protein but does not confer protection against lethal challenge (129). This difference may be related to the ability of G protein to aggregate or to form a multimeric structure more immunogenic than Gs monomers (501). With intracellular transport, G protein produced in the rough endoplasmic reticulum may exist in an inactive conformational state during transit through the Golgi apparatus, perhaps to avoid nonspecific membrane fusion (176).

Antigenic determinants of G protein to either B or T cells have been identified by using cyanogen bromide (CNBr)-cleaved peptide fragments or escape mutants resistant to neutralization. The CNBr fragments can be mapped and tested for antigenicity and immunogenicity (127). When administered to laboratory rodents, CNBr fragments induced antibody that bound to virus and G protein, but with low neutralizing activity, suggesting that antigenic structure of neutralizing epitopes was conformational. Based on groupings of escape mutant viruses of RABV from neutralization by one or more anti-G protein monoclonal antibodies (MAbs), three major antigenic sites (I, II, and III) were operationally delineated from both Evelyn-Rokitnicki-Abelseth (ERA) and challenge virus standard (CVS)-11 strains, and two additional sites (IV and V) were described on the G protein of the ERA strain (159,262,264). A minor antigenic site separable from site III by three amino acids was also delineated (34). Operationally defined antigenic sites correlated with the physical topography of the G protein by nucleotide sequence analysis of mutant variants representing different antigenic sites (502,504). Most of the antigenic structure of site III comprised a continuous distribution of epitopes closely arranged in

the primary structure. In contrast, antigenic site II consisted of discontinuous epitopes, and site I was revealed as an independent site containing a single epitope, not shared with epitopes of other defined sites. In general, most MAbs do not recognize G protein under conditions of reduction and alkylation, further suggesting that conformation derived from higher-order structure (secondary and tertiary) of the G protein is needed (127,502), but a few MAbs can bind to denatured G protein, indicating that these epitopes are probably continuous (57). Escape mutants to MAbs can possess a single amino acid change, with a histidine at position 264 (instead of arginine in the parent virus), and a methionine residue at position 44 replaced by isoleucine (122), and immunization with a synthetic peptide comprising amino acid residues 253 to 275 conjugated to keyhole limpet hemocyanin can result in VNA production and protection upon challenge with a lethal dose of virus.

Both CNBr cleavage fragments of G protein, and synthetic peptides corresponding to G protein amino acids, have been used to identify likely T-cell determinants. The CNBr peptides stimulated *in vitro* proliferation of T cells obtained from spleens of immune animals (293). Stimulation was observed using a 27-residue peptide corresponding to amino acids 18 to 44, and a 13-residue peptide corresponding to amino acids 32 to 44, believed to be T-helper-cell epitopes. The G protein has also been reported to be a cytotoxic-T-lymphocyte (CTL) stimulator (293). Analysis of secondary CTL responses *in vitro* of lymphocytes obtained from A/J mice by tryptic peptides and a CNBr fragment allowed identification of a single nominal determinant located between amino acids 130 and 178 of the G protein (292).

Compared to other lyssaviruses, MOK appears to be the most disparate member. The G protein of MOK is at least two amino acids shorter than RABV G protein (434), and it carries two potential glycosylation sites at positions 221 and 338. The MOK G protein shares only 54% homology with RABV G protein at the amino acid level. The most divergent amino acid changes occurred in the antigenic sites mapped to rabies virus G protein, partially explaining the absence of cross-protection (125).

Nucleoprotein

The N protein is the major component of the viral RNP. Amino acid sequences of RABV N protein have been deduced from the primary nucleotide sequence of several strains, including production virus (PV), CVS, ERA, and street Alabama Dufferin (SAD) (95,139,435,504). The amino acid sequence is 450 residues long, with a high degree (98% to 99.6%) of homology between different N proteins, correlating with antigenic similarity analyzed with MAbs (116,504), with the partial exception of the Flury high egg passage (HEP) strain. Sequencing of the N protein genes of LBV, DUV, and EBV showed an overall amino acid similarity of N-protein sequences with RABV of 77% (48). The phosphorylation site on RABV N protein is the serine residue at position 389 (124). Association of N protein in the RNP complex can diminish the opportunity for degradation by ribonucleases, may partially restrict RNA configuration, and could have regulatory functions during transcription (501).

Antigenic sites of RABV were suggested using competitive enzyme-linked immunosorbent assay (ELISA) (263). Most MAbs recognized conformational determinants, but some delineated sequential determinants from denatured N protein. Further mapping of B-cell epitopes was achieved by generating peptides, and by synthesizing peptides corresponding to amino acid sequences of immunoactive fragments, resulting in the identification of two linear epitopes on the N protein: an overlapping epitope located between residues 374 and 383, and another between amino acids 313 and 337 (124). Some linear epitopes may be expressed on the immature form of the N protein, whereas others may be created or exposed only after N-protein maturation (185).

The N protein is a major target antigen for T-helper cells, which cross-react among lyssaviruses (63,64,139). A human T-cell epitope on the N protein was been identified by using cloned T-cell hybridomas and synthetic peptides (65). Thus, viral RNP can prime T cells, elicit N-protein-specific antibodies, and serve to enhance immune responses (219). The N protein is a superantigen in Balb/c mice but not in other mouse strains (261).

Nominal Phosphoprotein Protein

The NS protein constitutes a part of the viral RNP and contains 297 to 303 amino acids (95,268). In contrast to divergence in the vesiculoviruses, sequence comparisons of RABV NS proteins show a high degree of homology, from 92% to 98% (268). The NS protein is phosphorylated (406), but sites of phosphorylation have not been precisely determined. Only threonine and serine residues are phosphorylated, and 16 of 40 serine plus threonine residues may provide phosphorylation sites within the N-terminal half of the NS protein (501). A unique cellular protein kinase has been discovered that phosphorylates NS protein, suggesting an important role in protein structure or function (191).

A B-cell antigenic determinant has been mapped between residues 75 and 90 of the NS protein (124). The NS protein expressed in vaccinia virus stimulates strong CTLs and weak T-helper cells in H-2 ^{k} mice (270), and the CTL epitope has been mapped to residues 191 to 206.

Matrix Protein

The M protein is believed to link the viral envelope with the RNP, and it contains 202 amino acids (95,351,436). Comparison of the amino acid sequences among different RABV strains showed 91% to 94% homology (214). The M protein also contains covalently linked palmitic acid (175). One primary function of M protein appears to involve the interaction with the cytoplasmic domain of the G protein and the RNP during virus assembly and budding (501). Its antigenic structure has not been widely studied.

RNA-Dependent RNA Transcriptase Protein

The L protein is the largest lyssavirus protein, containing 2,127 to 2,142 amino acids (95,437). Its functions include RNA synthesis, capping, methylation, and polyadenylation of viral RNAs (31,460,501), but because it is present in minute amounts, it is one of the least well studied lyssavirus antigens. Sequence homology among rhabdoviruses and other

members of the *Mononegavirales* (342,432) suggests evolution from a common ancestor. These regions may be functional domains responsible for the multiple catalytic activities of the L protein. A 400- to 450-nucleotide area, located between the beginning of the L gene and the end of the G gene, is bounded by transcription termination and polyadenylation-like signals, but it is a noncoding region, without apparent pseudogene functions (349,432).

Clinical Features

Rabies cases are almost always attributable to the bite of a rabid animal. For example, animal bites were the cause of 99.8% of 3,920 human rabies cases examined at various Pasteur Institutes between 1927 and 1946 (300). Nonbite exposures, which rarely cause rabies, include inhalation of aerosols (220,223,495), licks (273), transdermal scratches, or other unusual events that lead to contamination of an open wound or mucous membrane (154), such as corneal transplantation from an infected donor (228). Virus does not enter through intact skin. Recent bat RABV–associated human deaths in the United States may not have a reported exposure source (70,330), but these cases are most likely caused by bat bites in which either the risk was not appreciated or the bites were not immediately recognized by the patient. Disease development after exposure may depend in part on the location and severity of a bite, the species of animal responsible for the exposure, and the virus variant (15,23,328,391,453). Highest mortality tends to occur in persons bitten on the head and face (40% to 80%), with intermediate mortality in those bitten on hands or arms (15% to 40%), and least in those bitten on the trunk or legs (5% to 10%), or through clothing (<5%), when no specific vaccination was initiated (15,383,393,453).

The incubation period (the length of time between exposure to virus and development of clinical signs) is usually 1 to 2 months (154,466), but because it can vary from less than a week (210,337,340) to several years (3,16,402,485,491), rabies is one of the most variable of infectious diseases. The length of the incubation period may depend on the bite site and relative proximity to the CNS (3,230,393,419), severity of the bite, type and quantity of virus introduced, host age, and immune status (3,8,132,138,204,209,300,329,391).

Development of clinical rabies can be divided into three general phases: a prodromal period, the acute neurologic phase, and coma preceding death (154,210). During the prodromal period, lasting 2 to 10 days, symptoms are usually mild and almost entirely nonspecific and include general malaise, chills, fever, headache, photophobia, anorexia, nausea, vomiting, diarrhea, sore throat, cough, and musculoskeletal pain. One specific early symptom is abnormal sensation around the bite site, such as itching, burning, numbness, or paresthesia (132).

During the acute neurologic phase, patients exhibit signs of nervous system dysfunction such as anxiety, agitation, dysphagia, hypersalivation, paralysis, and episodes of delirium. Occasionally, priapism or increased libido may be observed (133). Cases in which hyperactivity is predominant are classified as “furious” rabies. When paralysis dominates, it is classified as paralytic or “dumb” rabies (86,248,454). From 17% to 80% of patients exhibit a pathognomonic sign of rabies, hydrophobia, believed to be caused by an exaggerated respiratory tract protective reflex (3,8,470,491). Hydrophobic episodes, initially triggered by attempts to drink and a variety of tactile, auditory, visual, and olfactory stimuli (210,491), may last from 1 to 5 minutes. Paralytic rabies can occur in about 20% of patients and may appear more frequently in persons exposed to certain variants, such as vampire bat rabies virus strains (221). In marked contrast to furious rabies, the sensorium is largely spared (212,221). Patients initially develop paresthesia and weakness, and finally flaccid paralysis, usually in the bitten extremity (86). Paralysis progresses to paraplegia and quadriplegia.

In furious rabies, the neurologic period ends after 2 to 7 days with coma or sudden death from respiratory or cardiac arrest (41). In paralytic rabies, the course is usually less rapidly progressive, with some patients living up to 30 days without intensive care (290). The final stage of the disease is coma, which lasts 3 to 7 days and results in death (41). In patients receiving respiratory assistance, survival may be prolonged for weeks (41,330), with death caused by other complications (36,137,204). At least four human cases have been documented in which recovery occurred. Three had exposure to animal bite (4,205,343), and one case occurred after suspected inhalation of rabies virus in the laboratory (66). None were spontaneous recoveries but rather were nonfatal vaccination failures, because the patients had either pre- or postexposure prophylaxis.

Clinical disease in animals is not unlike that of humans, except for the absence of hydrophobia. Signs are quite variable but may include altered phonation, pica, cranial nerve deficits, altered activity patterns, and loss of fear of humans (18).

Pathology and Pathogenesis

After inoculation of infectious saliva by bite, virus may either persist and replicate at the inoculation site for hours to weeks (74,77) or follow a relatively rapid centripetal course directly to the CNS (17), with replication and dissemination prior to the development of a significant immune response (75). Virus may replicate in muscle tissue (74,148,319) before progressing to the peripheral nervous tissue via neuromuscular connections. Mortality may be markedly reduced when infected limbs are cauterized or amputated (22) arguing for an initial productive infection in muscle cells. Several studies collectively suggest that RABV can infect muscle cells and replicate before invasion of the peripheral and central nervous systems (78), while others demonstrate that virus can enter the nervous system without prior local replication (17,385). Thus, during the incubation period, virus may reside in the periphery, it may remain sequestered within neurons, or perhaps it can persist in macrophages (350).

Neurotropism is a main feature associated with natural infection, with viral replication restricted almost exclusively to neurons. Virus may be taken up by unmyelinated sensory nerve endings of neuromuscular and neurotendinal spindles and motor end plates (203,282,472). Based on ultrastructural and immunofluorescence studies demonstrating viral clusters at neuromuscular junctions, and on the activity of substances such as a-bungarotoxin or D-tubocurarine, which specifically compete with the nicotinic acetylcholine receptor (AChR) and can reduce viral infectivity of chick myotubules *in vitro*, it has been suggested that RABV recognizes cholinergic binding sites (59,281,282). A similarity between amino acid residues 174 to 202 of the G protein and snake venom neurotoxins that bind at the site of the AChR have provided further evidence for virus attachment sites. However, other investigations have reached different conclusions based on

the relative susceptibility of cells in culture that express high-density AChR versus cells lacking AChR (352,441). Growth factors, neural cell adhesion molecules, and various phospholipids and glycolipids are also probably operative in determining viral neurotropism (352,431,442).

After peripheral nerve entry, virus moves centripetally within axons to the CNS at an estimated rate of 3 mm/hr (319,440). Evidence of transport by axonal flow in peripheral nerves comes from experiments in which transport of RABV was inhibited with colchicine and vinblastine (206,440). The form of the virus during axoplasmic transport, either as intact virus or as an RNP complex, remains unclear (90,183). Synaptic transfer of virus may ensue in the form of bare nucleocapsids (184).

Virus spread may be facilitated by movement across cell-to-cell junctions, supported by observations of budding on axonal membranes and viral inclusions at nodes of Ranvier (203). Viral distribution via cerebrospinal fluid (CSF) may also contribute to virus spread within the CNS (375).

Once virus reaches the brain, it spreads centrifugally to a variety of organs. The spread into the salivary gland, which represents the final phase of the infection, is important for transmission from animal to animal and from animal to human. Virus is found in salivary glands in the majority of rabid foxes, raccoons, skunks, and dogs (27,76,492,497). Much of the virus is produced in mucogenic acinar cells and is delivered into the saliva by normal secretory flow (318).

Other sites in which virus can be found include sensory nerve end-organs in oral and nasal cavities, taste buds, adrenal glands, pancreas, kidney, heart muscle, brown fat, hair follicles, retina, and cornea (321). Replication with large amounts of matrix and anomalous products may occur more frequently in tissues that contain low amounts of virus, such as the adrenal medulla, compared to tissues that produce large amounts of virus, such as the salivary glands (30).

Molecular mechanisms involved in virus pathogenesis remain largely unresolved. Several studies indicate that the G protein plays an essential role. Certain RABV variants belonging to a group that defined antigenic site III were found to be nonpathogenic (99,100,129). Use of antigenic variants representing operationally defined antigenic sites on the G protein showed that pathogenicity correlated with the presence of a determinant located within antigenic site III (99,100,130). The change in pathogenicity corresponded to a single amino acid substitution at position 333 of the G protein, which is arginine in the parent CVS and ERA viruses, and glutamine or isoleucine in the corresponding variant viruses (130). Study of MAb-resistant mutants isolated from a 5-fluorouracil-mutagenized stock confirmed that arginine-333 was replaced in nonpathogenic mutants (380).

Biologic relevance of arginine at position 333 in the rabies G protein was shown by *in vivo* and *in vitro* studies in which the pathogenic parent and nonpathogenic variant viruses were compared for their ability to infect neuroblastoma cells, to spread from cell to cell *in vitro*, and to spread through the brain (128). Entry halftime of pathogenic parental viruses was seven to eight times shorter than that of nonpathogenic variant viruses. Furthermore, apathogenic variant viruses were unable to spread from cell to cell in neuroblastoma cell cultures and displayed a lower rate of spread throughout the CNS (128). Other investigators showed that pathogenic viruses can apparently use different receptors or routes of entry from those used by their nonpathogenic derivatives (101,257), as well as differentially affect the expression of major histocompatibility complex (MHC) class II mRNA in the CNS (224).

Fusion of virus-infected cells may also be an important pathogenetic mechanism (313). irulent-type virus G protein but not the avirulent variant G protein induced fusion of neuroblastoma cells at neutral pH, suggesting that the syncytium-forming ability of the virulent type G protein is responsible for the more efficient spread of virulent virus in the brain.

Gross lesions in the CNS do not usually occur. Microscopically, inflammatory lesions are commonly noted in the spinal cord and brain stem (132,234,317,338,387). Demyelination and axonal degeneration of cranial nerves have been reported (309). Intensity of inflammatory lesions may depend in part on the host species, the virus strain, and the course of the disease (338). Relative immune suppression can result in less inflammation and abundant virus replication (1). Severe inflammation may be associated with virus isolates from bats, with Flury low egg passage (LEP), and with MOK and LBV (90). Prolonged virus infection can also produce intense encephalitic lesions (320). Characteristic changes in the CNS include formation of inclusion bodies within the cytoplasm of neurons (324). These Negri bodies are eosinophilic masses measuring 1 to 30 nm in diameter, and they consist predominantly of viral nucleocapsids. Negri bodies may not be readily evident, they can be confused with other inclusions, and their importance has been diminished with the advent of specific fluorescent antibody or immunohistochemical techniques.

The pathogenic pattern of street virus infections in the CNS can differ from that related to fixed virus infection. Often, street virus leaves neurons intact (225,317). Cytopathic differences between street and fixed virus infection include the appearance of large Negri bodies within neurons of street virus–infected mice (225). Many differential findings with experimental street virus infections in animals, such as the relative size or distribution of Negri bodies, are also observed in human rabies pathology.

Histopathologic changes in the CNS are often limited, not matching marked neurologic symptoms. Impairment of neurologic function rather than overt anatomic change may be responsible for clinical sign development. RABV infection has a selective effect on the electrophysiologic activity of neurons: It induces sleep alterations (187,188) and dramatic changes in the expression of immediate-early and late response genes (170). Expression of immediate-early genes such as egr-1, c-fos, and junB is strongly increased, whereas expression of late response genes, such as the gene that encodes the neurotransmitter enkephalin, is markedly decreased (170).

Programmed cell death, or apoptosis, may be an effective host response after viral infection of certain regenerating tissues, but it can clearly impact disease status when affecting neurons (226,427). The down-regulation of G protein expression by some viruses may contribute to viral pathogenesis by preventing apoptosis (312).

Immune Response

Antibodies induced by vaccination, particularly those with neutralizing activity, play a prominent role in immune defense against infection (218). Immunity may also be naturally acquired after multiple exposures to virus, on rare occasions (164). The G protein represents the only antigen that induces VNA and is able to confer immunity against a lethal challenge infection (102). The ability to induce VNA depends on the intact secondary and tertiary structure of the G protein (127,503). Protective activity induced by Gs is reduced compared with that of the virion-associated G protein (129). VNAs exert their protective effect by neutralization of extracellular virus, by complement-mediated lysis of virus-infected cells, and by antibody-dependent cytotoxicity (113). VNA can mediate viral clearance from the CNS without other immune effectors (123). The RNP is a major antigenic complex that induces a virus-specific antibody response, and antibodies directed against RNP can contribute to protection against infection (121,126,286). Animals treated with anti-N sera can be protected against a subsequent challenge with RABV, and anti-N sera can exhibit an antiviral activity *in vitro* (286). However, the mechanism by which anti-RNP antibodies inhibit viral replication remains unclear.

Infection with RABV results in the generation of virus-specific CD8+ and CD4+ T cells. The G protein is one of the antigens that induce CTL responses (293). Some mouse strains infected with virus also develop strong CTL responses to the NS protein (269). However, the role of CD8+ T cells in immune defense is unclear. Some investigators report clearance of rabies virus after transfer of RABV-specific T cells and protection against rabies by a CTL clone, whereas other investigators showed that CTLs are insufficient to protect against challenge, and *in vivo* depletion of CD8+ T cells had no effect on host resistance to street virus infection (238,269,339,344). In contrast, CTLs may actually be involved in the immunopathology and have been implicated in neuritic paralysis (418,476). By comparison, the induction of CD4+ T cells is an integral part of the protective immune response against rabies (120). Elimination of CD4+ cells abrogates the production of IgG neutralizing antibody in response to virus infection (339). The RNP contains major epitopes that induce CD4+ cell responses, and the majority of these T cells cross-react with other lyssaviruses (139). The RNP-specific T cells, which can augment the production of VNA through a mechanism known as intrastructural antigen recognition, are believed to be the major factor that mediates the protective immune response induced by internal viral antigens (124,168).

Diagnosis

Clinical diagnosis is not difficult if there is a documented, relevant history of exposure and subsequent compatible clinical signs or symptoms. However, because an exposure history may be lacking, rabies should be considered in any acute, unexplained neurologic disease of suspected viral origin that rapidly progresses to coma and death (21). Routine diagnosis is established by standard laboratory tests for specific virus isolates, antigens, nucleic acids, or VNA (198,400,469). Postmortem diagnosis should be performed on CNS specimens, especially the brainstem, hippocampus, and cerebellum (421). The fluorescent antibody test (400) and the avidin-biotin immunohistochemical technique (194) are sensitive and specific methods for detecting virus antigen (Fig. 2). Antibodies, particularly those that recognize continuous epitopes of the N protein, are useful because they provide consistently reliable results, even if the tissues have been fixed with formalin or embedded in paraffin (147,468). Examination of skin biopsies from the face (55) or hair-covered occipital portions of the neck for virus antigen (42,330) is a rapid method to diagnose human rabies before death. Rabies virus can be isolated from saliva by direct intracerebral inoculation into mice (254) or by infection of neuroblastoma cells (395). Fluorescent antibody examinations of corneal impressions may also occasionally lead to the diagnosis of human rabies (249). The reverse transcriptase–polymerase chain reaction assay (RT-PCR) has been used to amplify and sequence parts of the lyssavirus genome directly from brain, saliva, and other affected tissues (207,330,400). This not only allows detection of rabies virus–specific RNA but also permits insights into the identity of the virus variant by genetic sequencing. Detection of VNA in serum (330,398) late in the clinical course can be diagnostic for rabies, if the patient has not been previously vaccinated. Except for certain cases of postvaccinal encephalomyelitis, CSF antibodies are produced only in rabies-infected, not in vaccinated, individuals (471).

Treatment

No successful treatment of clinical rabies is available (134,210). The disease is fatal, with few exceptions, and no spontaneous recoveries are reported. Sedation and life support measures have been used to prolong life but not to prevent death. Thus, rabies treatment is a misnomer and usually refers to medical aid related to animal bite and disease prevention by postexposure prophylaxis (478). Future *in vivo* experimental approaches by a combination of virus

neutralization and inhibition of viral replication in the CNS should be encouraged, provided that an early diagnosis of rabies would be entertained (123,171,210).

Epidemiology

The domestic dog is the principal host and major vector of rabies throughout the world (145,465), particularly in the equatorial regions of Asia, Latin America, and Africa. International reporting of both human and animal rabies cases grossly underestimates the magnitude of the problem (307,455). Predominant wild reservoirs belong to the family Carnivora (21,244) and include foxes (40,103) in the Arctic (*Alopex lagopus*), Canada, central and western Europe (*Vulpes vulpes*), and scattered foci elsewhere throughout North America (e.g., *Urocyon cinereoargenteus*); the raccoon dog (*Nyctereutes procyonoides*) in eastern Europe, Scandinavia, and portions of Asia (83,258,332); coyotes, jackals (*Canis* species), and other wild canids in North America, Asia, and Africa (173); skunks (*Mephitis mephitis*, *Spilogale putorius*) in North America (79,80,190); procyonids, such as the raccoon (*Procyon lotor*), in the eastern United States (496); and viverrids (e.g., the yellow mongoose, *Cynictis penicillata*) in Africa and Asia. The Indian mongoose (*Herpestes auropunctatus*) was introduced into several Caribbean islands for snake and rat control during the 19th century and persists as a major agricultural and public health threat (142,285). Rabies detection in rodents is uniformly rare (84,259,315,493). Bat rabies predominates as a New World phenomenon, described primarily among the insectivorous species of the United States and Canada (some 40 species), and the three hematophagous vampire species (principally *Desmodus rotundus*) ranging from northern Mexico to Argentina (20,85). Renewed investigations suggest that other bat species may also be important throughout Latin America (116,117). Other lyssaviruses utilize bats in Africa, Europe, and Australia (12,26,183,381).

Lyssavirus epidemiology is influenced in part by host species distribution, abundance, demographics, behavioral ecology, dispersal, and interactions with humans (370). Because of its consequences when ignored, rabies is a reportable disease in many countries, although surveillance is inadequate, particularly in sylvatic hosts. Biased epidemiologic information usually derives from clinical reports or the examination of suitable brain material submitted to public health or veterinary diagnostic laboratories only after infectious contact with animals is suspected. Exposure is generally defined as transdermal contact, typically by a bite, or mucosal contamination with potentially infectious material, such as saliva or CNS tissue (499). The relative risk associated with other scenarios is difficult to define (71).

The spatiotemporal distribution and relative intensity of rabies infection in various mammalian species is often described based on the passive monitoring of suspicious contact cases. Active surveillance by structured examination of a field sample, irrespective of human–animal contact, is expensive, time consuming, and rarely performed. Unless justified, it may waste precious health sector resources and may lead to unnecessary exposure to the public or to improperly trained staff. Thus, compromise between active and passive monitoring remains the format for primary lyssavirus detection, disease prevention, programmed control, and, in some instances, attempted elimination assessment.

Recent surveillance efforts in the United States (255) illustrate the benefits of a systematic surveillance approach that serves to define rabies among single or multispecies assemblages. For example, during 1998, 7,961 rabies cases (a decrease of 7% since 1997) were tallied. In contrast to indigenous canine rabies of the 1940s, more than 90% of existing cases were from wildlife. Most (44%) resulted from the continued spread of raccoon rabies, which resulted from the progression of an outbreak initiated in the late 1970s when animals from an infected nidus in the southeastern United States were translocated to the Virginias (438). Cases increase as infection spreads within local populations. Other major wildlife contributors are bats (13%), skunks (29%), and foxes (6%). Cases of coyote rabies from an outbreak in southern Texas (91) continued a substantial decline. Domestic species included cats (4%), cattle (2%), and dogs (1%). Historically, Hawaii remained the only rabies-free state, never having reported a case of indigenously acquired rabies, partly because of its isolation (155,374).

The application of MAb technology (367) to the study of lyssaviruses has provided evidence for considerable antigenic variation, based on the N and G protein reactivities among both fixed and street RABV and between related viruses (215,247,302). Such MAbs have been particularly useful in determining the extent of natural antigenic variation among lyssaviruses isolated from wildlife within a restricted geographic area or from separate continents. In particular, distinctions between viruses isolated from bats and terrestrial carnivores became obvious (26,367,396,397,401,403). Notwithstanding genetic variation and the general tendency or relatively rapid evolution of RNA viruses toward the persistence of quasi-species (311), striking global patterns have emerged that are highly suggestive of a conservative strategy and stabilizing selection represented by any particular variant (46,323,397,401).

Extensive lyssavirus lineage analyses have been conducted to delineate genetic clusters or viral genotypes, to evaluate the phylogenetic diversity within each genotype, and to more precisely appreciate the divergence of wild isolates in each genotype. RT-PCR followed by sequencing or restriction endonuclease digestion using material extracted directly from infected brain tissues distinguishes at least seven genotypes (Fig. 3) (47,48 and 49). The African DUV and EBV lyssaviruses appear related, whereas the LBV and MOK viruses are phylogenetically distant from RABV. The ABV is most closely related to classical RABV. Intragenotypic viral clusters are also distinguishable, suggestive of historical, geographic, or host species relationships. Results are generally consistent with previous classifications using antigenic criteria (322,371,372,404).

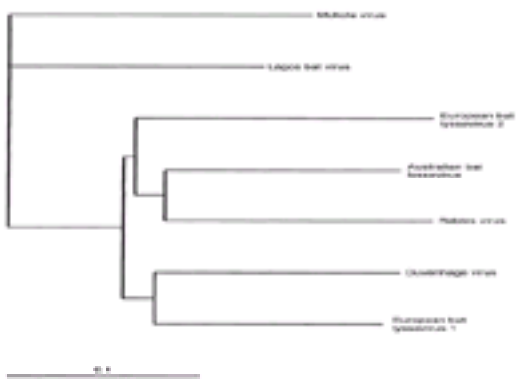

FIG. 3. Phylogenetic relationships among members of the *Lyssavirus* genus based on the nucleotide sequence homology of the nucleoprotein gene. GenBank accession numbers: AF006497, M31046, S59448, U22842, U22844, U22847, U22488.

Combined with historical, temporal, and spatial disease surveillance data, antigenic characterization with MAbs and nucleotide sequence analysis can assist in the assignment of isolates to different animal reservoirs (401,403,404). Recent North American surveillance data (399) suggest that two fox rabies foci in Canada, Alaska, and the northeast United States are related (369). Skunk rabies isolates appear to be distinct variants defining separate outbreaks in the north-central and south-central parts of North America, and California. Additionally, smaller independent foci involve foxes, dogs, and coyotes in Texas, as well as foxes in Arizona and portions of the southwest (91,255,397,401,403).

Antigenic or molecular characterization is useful for investigation of unusual or unexpected mortality, especially in domestic animals or humans with no obvious exposure history, because data obtained can be compared with variants from known animal reservoirs. For example, analysis of recent human rabies cases from the United States implicates viruses associated with insectivorous bats in the etiology of infection (330), and some bat isolates appear to possess unique pathogenic properties compared with isolates from the Carnivora (314).

In contrast to parts of Europe and North America where wildlife rabies predominates, in southeast Asia, Africa, and much of Latin America, dogs continue to be the principal causative vectors of rabies to humans. Realizing the critical importance of dogs as the primary reservoirs, the Pan American Health Organization began a program in 1983 to eliminate urban rabies from the principal cities of Latin America by the year 2000 (141). Results have been very encouraging (10). From the 1980s to the 1990s, the annual number of human rabies cases decreased from 350 to less than 114; rabies-specific mortality declined from 1.3 to less than 0.2 per million, and the proportion of 414 cities free of rabies increased from less than 75% to more than 80%. These results suggest that widespread vaccination of canine populations in Latin America and elsewhere (35,45,156,157) can reach the levels of herd immunity needed to prevent rabies epizootics, and that elimination of canine rabies, at least in urban areas, may be an achievable goal. Rabies transmitted by hematophagous bats, unique to the Americas, is an emerging public health problem (289,469), in addition to being a historically important disease of livestock with widespread economic implications (189).

Prevention of Rabies in Humans

Rabies is a significant global disease that results in death, with only a few exceptions (4). More than 4 million humans annually undergo antirabies prophylaxis, but an estimated 50,000 others die, primarily from the bite of an infected dog (307,455). Public health expenditures are thought to be substantial but have been poorly quantified (305). Regional epidemiologic surveillance and knowledge of viral pathogenesis can significantly reduce human morbidity from inappropriate prophylaxis and direct mortality ascribed to lyssaviruses by identifying reservoirs and unlikely exposures (386,493), developing treatment algorithms, and communication of risk to different occupational groups. Largely because of surveillance and veterinary efforts in developed countries with controlled canine rabies, actual human rabies deaths are now infrequent in these regions. Nevertheless, vigilance to minimize human mortality requires the annual treatment of tens of thousands of potential exposure cases, even in Europe and North America (197).

Postexposure prophylaxis in humans includes proper wound care and the administration of multiple doses of rabies vaccine, together with antirabies immune globulin (68,499). Although the inclusion of serum or antirabies immune globulin in the treatment protocol is not new (60), it is infrequent. Most cases of human rabies prophylaxis in Africa, Asia, and Latin America are with vaccine only (307), often with nervous system tissue vaccine (28,229,267,331,341). Human diploid cell rabies vaccines (HDCV) have been used in much of the developed world and form the standard for comparison with the Pasteurian neural vaccines from the 19th century (456,478), including its later phenolized derivatives (Fermi, Semple, and others). Modern inactivated cell culture vaccines (416) and antirabies immune globulin are major improvements over crude biologicals derived directly from animals, and they decrease the adverse events related to anaphylaxis or serum sickness (265,486). HDCV is one of only three vaccines now licensed in the United States (68) for either pre- or postexposure prophylaxis (Table 2 and Table 3). Other rabies vaccines are produced in avian embryo fibroblasts or in rhesus monkey renal cell culture, and aluminum phosphate may be used as an adjuvanted (67). Production of HDCV is relatively difficult, with limited viral yields, resulting in high production costs. Primary hamster kidney cell vaccines are used in China and parts of Asia (284). Biotechnologic advances, such as automated purification techniques, have resulted in vaccines that are more readily available, and thus at lower cost, such as a purified Vero cell rabies vaccine. Efficacy trials of these alternative vaccines using reduced doses, various immunization schedules, and alternative routes have been conducted worldwide in populations of highest risk (88). Serologic evaluation and long-term clinical observations of exposed individuals have demonstrated both high efficacy and safety of these new vaccines and schedules (87). At present, there is no evidence to suggest that prophylaxis failure is caused by antigenic variation of RABV (499). Rather, factors such as inadequate wound care, omission of potent serum, failure to infiltrate the wound with immune globulin, and delay or failure to follow recommended procedures have been implicated in human rabies cases

after vaccination (211,334,354,487). Future tactics for global rabies control will continue to focus on the need for potent, inexpensive pre- and postexposure biologicals (167,265,266) and schedules for humans, and on safe, effective vaccines for animals that are reservoirs for the disease (21,56,149,151,158,494,499).

Type of vaccination	Route	Regimen
Primary	Intramuscular	HDCV, PCEC, or PVRV, 1.0 mL, [deltoid area], one each on days 0,* 7, and 21 or 28
	Intradermal	HDCV, 0.1 mL, one each on days 0, 7, and 21 or 28
Booster	Intramuscular	HDCV, PCEC, or PVRV, 1.0 mL, [deltoid area], day 0, only
	Intradermal	HDCV, 0.1 mL, day 0, only

*Day 0 is the day the first dose of vaccine is administered.
HDCV, human diploid cell vaccine; PCEC, purified chick embryo cell vaccine; PVRV, rabies vaccine adsorbed.

TABLE 2. *Human rabies vaccine preexposure schedule—United States, 1999*

Vaccination status	Treatment	Regimen*
Naive	Wound cleansing	Treatment should begin with thorough cleansing of all wounds with soap and water. If available, an agent such as a povidone-iodine solution should be used to irrigate the wounds.
	RIG	Administer 20 IU/kg body weight. If anatomically feasible, the full dose should be infiltrated around the wound(s) and any remaining volume should be administered IM at an anatomic site distant from vaccine administration. The RIG should not be administered in the same syringe as vaccine, because RIG might partially suppress active production of antibody, and no more than the recommended dose should be given.
	Vaccine	HDCV, PVRV, or PCEC 1.0 mL, IM [deltoid area†], one each on days 0,* 3, 7, 14, and 28.
Previously vaccinated§	Wound cleansing	All postexposure treatment should begin with immediate thorough cleansing of all wounds with soap and water. If available, an agent such as a povidone-iodine solution should be used to irrigate the wounds.
	RIG	RIG should not be administered.
	Vaccine	HDCV, PVRV, or PCEC 1.0 mL, IM [deltoid area†], one each on days 0 and 3.

HDCV, human diploid cell vaccine; PCEC, purified chick embryo cell vaccine; RIG, rabies immune globulin; PVRV, rabies vaccine adsorbed; IM, intramuscular.
*These regimens are applicable for all age groups, including children.
†The deltoid area is the only acceptable site of vaccination for adults and older children. For younger children, the outer aspect of the thigh may be used. Vaccine should never be administered in the gluteal area.
§Day 0 is the day the first dose of vaccine is administered.
¶Any persons with a history of preexposure vaccination with HDCV, PVRV, or PCEC, prior postexposure prophylaxis with HDCV, PVRV, or PCEC, or previous vaccination with any other type of rabies vaccine and a documented history of antibody response to the prior vaccination.

TABLE 3. *Human rabies vaccine postexposure prophylaxis schedule—United States, 1999*

Rabies Control in Animals

Rabies is not considered a serious candidate for disease eradication at this time because of numerous and diverse wild reservoirs (72). However, the correlation between canine rabies and human fatalities has led to the successful application of herd health initiatives using vaccines of modified live agents and inactivated products (56), particularly in developed countries. Development of a suitable lyssavirus vaccine is not synonymous with either disease prevention or control, because a comprehensive domestic animal program also requires responsible pet ownership and the complexities inherent in the social, cultural, and religious aspects of the human–animal bond. Such a program entails stray animal management; leash law amendments; humane population curtailment (e.g., early spay/neuter programs); animal importation, translocation, and quarantine regulations; schedules for early preexposure vaccination of companion animals (in light of potential maternal immune inhibition); and rational postexposure management (68,69). Unlike postexposure prophylaxis of humans, euthanasia is usually recommended for the naive animal exposed to rabies, but this may eventually change with the development of safe and effective biologicals and protocols.

Current veterinary vaccines are more potent than the initial attenuated and inactivated vaccines used in the early part of the 20th century (13,345). However, because no vaccine is 100% effective, given poor cross-reactivity with some genotypes (457), and because correct identification of the properly immunized animal may be confusing, the vaccinated dog or cat is not exempt from confinement and close observation, particularly if human exposure occurs, whether provoked or not. This strict period of quarantine applies only to dogs, cats, and in some countries domestic ferrets (69). Human prophylaxis may be delayed during this time in nonenzootic canine rabies areas (394). In addition, pet vaccination status does not necessarily alter the need for euthanasia of an offending animal, regardless of vaccine potency or efficacy, if rabies is suspected.

In the case of free-ranging, nondomestic mammals, population reduction of major rabies reservoirs has been practiced for centuries. Except on rare occasions, it has not been generally regarded as a humane, long-term, cost-effective, or ecologically sound tool to control lyssavirus infection (115,195). A notable exception relates to hematophagous bats in Latin America. One of the first specific control methods was the use of anticoagulants applied topically to bite wounds on cattle, followed by systemic treatment of exposed cattle at risk, and finally topical treatment with anticoagulants of vampire bats themselves, exploiting their behavior of mutual grooming at the roost (161). Properly applied, these control efforts can spare the needless destruction of many beneficial nontarget bat species from nonspecific environmental alteration (316), perhaps some day to be augmented with novel vaccination strategies (382).

For more than four decades, efforts have been made to protect free-ranging wildlife against virulent street virus challenge by oral consumption of a potent vaccine contained within an attractive bait (494). In the past several years, millions of rabies-virus-vaccine-laden baits have been distributed over huge areas in western Europe (14,19,158,464), eastern Canada, and the United States for wildlife rabies control, with effective strategies designed in both rural and urban areas (271,359,360). Concerns about residual virulence and ineffectiveness (for other reservoir species) of the first generation of modified live oral viruses has led to the development of other attenuated and recombinant rabies vaccines

(19,39,158,260,274,336,365,368,483). After initial laboratory results with red foxes, efficacy, safety, and field studies with a number of oral vaccine candidates have been extended to other relevant carnivore species, including Arctic and gray foxes, coyotes, raccoon dogs, raccoons, skunks, and, domestic dogs (52,150,163,332,368,464).

A vaccinia–rabies glycoprotein (V-RG) vaccine was the first recombinant rabies vaccine to be constructed, field tested, and considered for regulation in Europe and North America for wildlife rabies control. This vaccine has been extensively reviewed to ensure safety (tested in over 40 species of mammals and birds) and efficacy (proven against severe rabies challenge in target species). Thermostability of the vaccine has been demonstrated under laboratory and field conditions. Following the success of the V-RG vaccine against fox rabies in Belgium (52) and France, preliminary field trials suggest its potential utility for rabies control in raccoons, foxes, and coyotes in the United States (144,196,356,361). Other orthopoxviruses (150,288) have been considered as vectors of lyssavirus antigens, but these have not been field tested to date.

The rabies G protein gene also has been inserted into the human adenovirus genome (346). Preliminary experiments have been encouraging, with adequate G protein expression in cell culture and efficacy demonstrated in several immunization trials in captivity (73,291,508). Newer constructs (e.g., rabies glycoprotein inserts utilizing the adenovirus E1 region, incapable of replication in host tissue) are also under consideration in a variety of species. In addition, an oral baculovirus-vectored vaccine induces protective immunity in raccoons (169). The potential for manipulation of the RABV genome has been simplified by the generation of infectious virus entirely from cloned cDNA (377). If future recombinant, replication-incompetent, inactivated, or DNA-based (140,227,272,287,310,333,366,506) vaccines prove both efficacious and economical (304,306), they may render a majority of previous biosafety concerns obsolete (308), paving the way for more widespread free-ranging wildlife and dog rabies control, particularly in developing countries (298).

VESICULOVIRUS

History

Vesicular stomatitis virus (VSV) is the best-studied member of the genus *Vesiculovirus* of the family *Rhabdoviridae.* It produces an acute disease in cattle, horses, and pigs characterized by fever, and vesicles in the mucosa of the oral cavity and in the skin of the coronary band and teat. Clinically, it is very similar to foot-and-mouth disease (FMD). VSV can also cause a disease with flu-like symptoms in humans.

Although VS was first reported in the United States in 1916 during an event that reached epidemic proportions in cattle and horses (420), a clinically similar disease was previously described in army horses in 1862, during the U. S. Civil War (299). In 1915, during World War I, French veterinarians described a disease clinically similar to VS in horses imported to Europe from the United Sates and Canada. At that time, the etiology of this disease could not be determined with certainty, but it could be transmitted from horse to horse by rubbing the saliva of a sick animal on the tongue of a healthy one, establishing the infectious nature of the disease (200).

In 1925, cattle transported from Kansas City, Missouri, to Richmond, Indiana, developed vesicular lesions in the mouth and initiated an outbreak of VS in the area. The disease was experimentally transmitted to horses and the infectious agent was maintained by serial passages in animals. This strain became the VS Indiana (VS I) strain (98). In 1926 an outbreak of VS in cattle occurred in New Jersey. The causative agent was found to be a filterable agent that could infect cattle, horses, and guinea pigs. This virus, serologically different from the VS I strain, is currently known as the VS New Jersey (VS NJ) strain (97,98). The VS I and VS NJ viruses represent the two serotypes most commonly isolated in the Americas. In the United States, the last reported outbreak of the VS I serotype occurred in 1965 (474). The VS NJ serotype was responsible for outbreaks in the United States in 1944, 1949, 1957, 1959, 1963, 1982–1983, 1985, and 1995 (51). In 1997 isolated cases were diagnosed in several horses in New Mexico, but this did not initiate an outbreak (11).

Between 1946 and 1954, during an important outbreak of FMD in Mexico (180), the joint Mexico-American commission for the control of this disease developed techniques for the differential diagnosis of FMD and VS based on the isolation of the agent and complement fixation methods (200). The VS I and VS NJ serotypes were isolated in Mexico in 1947 and 1948, respectively. The availability of a more efficient diagnostic methodology demonstrated that VS was prevalent throughout the year in the tropical areas of Mexico (200).

In South America, the disease was reported in 1939 in La Plata, Argentina (200). Later, VSV was isolated in Barinas, Venezuela, in 1941 and in Colombia in 1943 (200). Currently, VS is endemic in many Latin American countries and is responsible for important economic losses in the livestock industry. Disease caused by the VS NJ and VS I serotypes was reported in 11 countries of Latin America in 1996 (500).

Although the presence of VS was previously suggested in Africa in 1884 to 1887 and in Asia in 1944 (200), presently the disease is considered enzootic only in the Americas (500).

Other members of the VS serogroup are endemic in Asia and the Americas. Pyri virus was isolated from an opossum (*Philander opossum*) in Brazil in 1960 (428). Cocal virus was isolated from mites of the genus *Gigantolaelaps* from 11 rice rats (*Oryzomys laticeps velutinus*) trapped during September, 1961, on Bush Bush Island in the Nariva swamp in Eastern Trinidad Island (232,233). The VSV Alagoas serotype was isolated from domestic animals in the state of Alagoas, Brazil, during a VS outbreak (422). Chandipura virus was obtained from the sera of two patients with a febrile illness in Nagpur City, Maharashtra State, India, in 1965 during an epidemic of chinkungunya and dengue (37). This virus was also isolated from phlebotomine sand flies in West Africa in 1991 (165).

Isfahan virus was isolated from sand flies (*Phlebotomus papatasi*) collected in Dormian, Isfahan Province, Iran, during 1975 (426). Maraba virus was also isolated from sand flies (*Lutzomyia* sp.) collected in the state of Pará, Brazil. Although humans are infrequently infected based on serology, the actual public health significance of Maraba virus has not been

assessed (439).

Infectious Agent

Taxonomy

Based on the serologic cross-reactivity patterns and sequence analyses of the members of the *Vesiculovirus* genus, a unique serogroup, VS, has been established. The VS serogroup includes VSI (the type species of the genus), VS NJ, VS Alagoas, Chandipura, Cocal, Isfahan, Maraba, and Piry viruses (451). Other species tentatively assigned to this genus are BeAn 157575 virus, Boteke virus, Calchaqui virus, Carajas virus, eel virus American, Gray Lodge virus, Jurona virus, Klamath virus, Kwatta virus, La Joya virus, Malpais Spring virus, Mount Elgon bat virus, Perinet virus, Pike fry rhabdovirus (grass carp rhabdovirus), Porton virus, Radi virus, spring viremia of carp virus, Tupaia virus, ulcerative disease rhabdovirus, and Yug Bogdanovac virus. VSV will be the only member of the *Vesiculovirus* genus discussed extensively in this section.

Morphology and Physical Properties

The members of the *Vesiculovirus* genus share the general morphologic and physical properties described for the other members of the *Rhabdoviridae*, such as *Lyssavirus*. The viral genome is 11.2 kb in length. It presents a leader sequence of 50 nucleotides anteceding the N gene, an untranslated region of about 60 nucleotides located after the L gene, and intergenic regions formed by two nucleotides (451).

Biologic Properties: Host Range and Infection of Experimental Animals

The virus has been isolated from a variety of animals, including mammals and invertebrates. Naturally, the disease affects horses, cattle, and swine; sheep and goats are only rarely infected (180,200). In humans, VSV infections can induce symptoms that vary from influenza-like to encephalitic (348). Human infection is most common in rural areas where the disease is enzootic (153,200). In Panama, serologic evidence suggested a prevalence of 29% (388). Serologic surveys have shown that some species of wild ruminants, carnivores, marsupials, and rodents can be infected with the virus (428,474). Wild ungulates may play a role in the maintenance of enzootic cycles (160,475). Virus has been isolated from numerous insect species such as mosquitoes, midgets, and sand flies. In Panama and in Georgia, United States, VSV was obtained from phlebotomine sand flies (*Lutzomyia* spp.) (96,423). The virus has also been isolated from blackflies (*Simuliidae*) in Colombia (428), *Musca domestica* (166) and *Culicoides* spp. in Colorado (463), and mosquitoes (*Aedes* spp.) in New Mexico (417).

Other members of the VS serogroup have also been isolated from a wide variety of vertebrates and invertebrates. During the Rockefeller Foundation Virus Program (1951 to 1970), five human infections with Piry virus occurred in the New York and Belen laboratories (428). Serologic surveys revealed the presence of antibodies against Piry virus in specimens from *Proechimys* sp., *Caluromys* sp., *D. marsupialis*, and *Oryzomys goeldii* (428). Cocal virus was isolated from a *Heteromys* rat in Trinidad (429). Antibodies against Cocal virus were found in 68% of the *Oryzomys* rat species in Belen, Brazil, during an outbreak of the disease (429). The VS Alagoas virus was isolated from sand flies (*Lutzomyia* sp.) collected in Durania, Colombia, and affects humans, cattle, horses, and mules (422). Alagoas VNAs were found in sera collected from humans, opossums (*Didelphis marsupialis*), porcupines (*Coendou* sp.), and dogs in Arboledas and Durania, Colombia (422). After the first isolation of Chandipura virus, a retrospective serologic investigation in populations from different regions of India demonstrated that the prevalence ranged from 10% to 89%. VNAs were also found in camels, horses, cows, buffaloes, sheep, goats, rhesus and other monkeys (37), and hedgehogs (*Atelerix spiculus*) in Nigeria (241). This virus was isolated from *Phlebotomus* spp. in Aurangabad, Maharashtra State, India (118). Serologic studies on Isfahan virus found a high prevalence of VNAs in humans from several regions of Iran. The highest prevalence of VNAs was found in gerbils (*Rohmbomys opinus*), but no antibodies were found in domestic animals in Isfahan (426).

A wide variety of vertebrates and invertebrates have been experimentally infected with VSV by various routes of inoculation. The discovery that guinea pigs are highly susceptible to VSV provided one of the first and most important tools for virus detection (97). The intracerebral inoculation of suckling and adult mice, hamsters, rats, and chinchillas produces a fatal infection (200,474). Mice die of an acute encephalitis within 2 to 3 days after intracerebral inoculation, and the most important histopathologic lesions consist of occasional perivascular mononuclear cell infiltration and rare foci of necrosis (107). Horses, cattle, swine, and sheep are easily infected by inoculation with the virus into the epithelium of the dorsum of the tongue (180). Agouti (*Dasyprocta* sp.), anteater, aracari, armadillo, bats, birds, coati, and other animals have been experimentally inoculated by several routes to determine their role in VSV ecology (425). The experimental infection of cattle, sheep, goats, pigs, and ponies with Piry virus failed to produce lesions in the first four species and produced only limited ulcerations in ponies (489). In experimental infections of domestic animals with Isfahan and Chandipura viruses, only lesions at the intradermal lingual sites of inoculation were observed. Ponies, steers, and goats were affected by Chandipura virus, but only ponies showed lesions with Isfahan virus (490).

VSV has been experimentally inoculated in *A. aegypti*, with the infection successfully transmitted to mice (428,474). Sand flies (*Lutzomyia* spp.) (94) and blackflies (*Simulium* spp.) (105) are capable of transovarial transmission and infection of susceptible hosts. All members of the VS group are readily propagated by experimental inoculation of mosquitoes (429). Alagoas virus was replicated in *Lutzomyia longipalpis* by intrathoracic inoculation. Experimentally infected sand flies were able to transmit the virus transovarially to their progeny and to infect mice by bite (422).

VSV replicates efficiently in a broad spectrum of vertebrate and invertebrate cell lines. Most mammalian cells sustain virus replication, but they vary significantly in their susceptibility (459). Commonly, BHK-21 cells are used to obtain high virus titers (459) and Vero cells are used for virus isolation (474). Avian-derived cells such as primary chick embryo cultures support VSV replication, yielding high-titer preparations (89). VSV can also infect and replicate to high titers in cell culture systems derived from reptiles and fish, and replication can occur in several insect cell lines (89). The virus replicates in *Aedes albopictus* and *Ae. aegypti* cell lines without producing cytopathic effect (CPE), and it is easily

isolated in *Ae. albopictus* (C6/36) cell lines (89,459,474). A persistent infection with VSV can be established in *Drosophila melanogaster* cell cultures (458).

In vitro replication of VSV proceeds over a wide range of incubation temperatures, depending on the cell line. Highest titers have been obtained in mammalian and avian cells with incubation temperatures ranging from 31°C to 37°C (89,458,459). Temperatures of 11°C have been used with snake-derived cells (89). Several other factors can influence the virus yield in different cell systems, such as the presence of DI and interferon (89,459). Cell differentiation influences the cell susceptibility to VSV infection (458). Cultured human lymphocytes are resistant to VSV infection but support VSV replication after mitogen stimulation (44).

In mammalian and avian cell lines and in some clones of insect cells, VSV rapidly induces CPE (296). Fibroblasts and epithelial cells show characteristic pathologic changes during the early stages of VSV infection. In fibroblasts, the initial microscopic changes consist mainly of an increase of membrane pseudopods, while vacuolization is the principal change observed in epithelial cells. At the final stages of infection, cell rounding is present in both cell types (110). The observed CPE of VSV is the consequence of viral transcription (295) and not the inhibition of cellular RNA synthesis (162). In enucleated vertebrate cells, the virus propagates to nearly normal titers (162). Although VSV does not generally induce CPE, a clone of an *Ae. albopictus* cell line showed CPE at 28°C or 34°C. The ability of other clones from the same cell line to show CPE are temperature dependent (373). Plaque assay is the method of choice for the determination of virus titers. Any cell type in which VSV induces CPE can be used to titrate the virus, but BHK-21 cells are commonly used because the cell line is especially sensitive (89,458).

The VS NJ and VS I strains can be replicated by inoculation of embryonated chicken eggs using the chorioallantoic membrane route. Embryos inoculated at 7 days of incubation and maintained at 35° to 36°C die in less than 24 hours and yield the highest titers. However, embryos at 39° to 40°C may survive infection and present only proliferative lesions in the chorioallantoic membrane (392).

The other six members of this group can also be replicated in numerous mammalian cell lines such as Vero, BHK-21, HeLa, L, and MKTC (54,232,422,426,430,439). Piry and Chandipura viruses have been grown in chick embryo cell cultures (37,54), AP61 insect cells (165), and BSC-1 mammalian cells (37). Piry virus has been replicated in the allantoic cavity of 5-day-old embryonated chicken eggs (489).

Chemical and Antigenic Properties of Viral Proteins

Glycoprotein

The G protein is the serotype-specific antigen (62). There is only 50% homology at the amino acid level between the G proteins of the two major serotypes, I and NJ. The VS I G protein has 511 amino acids with an N-terminal signal peptide of 16 residues (363). The mature protein can be divided into three structural domains: the first 29 amino acids from the C-terminus comprise the cytoplasmic domain, the next 20 hydrophobic residues form the transmembrane domain, and the major segment of the G protein, extending from the transmembrane to the N-terminus, is the external antigenic domain. The VS I G protein is N-glycosylated at positions 178 and 335 (363) and also contains covalently linked fatty acid (palmitate and myristate) in the cytoplasmic domain of the molecule (82,362).

The VS NJ G protein contains 517 amino acids (172). Signal peptide sequence, glycosylation sites, and position and size of the transmembrane domain of VS NJ G protein are identical to those of VS I G protein. The VS NJ G protein is not acylated.

Using MAbs to either VS I or VS NJ G protein, several antigenic determinants have been operationally delineated. Four major antigenic epitopes that reacted with these neutralizing MAbs were found on each G protein (276,277 and 278). Those MAbs that recognized these epitopes did not cross-react between the G proteins of the two serotypes. A fifth neutralizing epitope shared by both G proteins was identified with a MAb derived from VS I that cross-reacted with VS NJ G protein. Many nonneutralizing epitopes also have been defined for the G protein of both serotypes (50,277). Most of the epitopes to MAbs recognize the G protein of VS NJ map to the center (residues 193 to 289) of the molecule, whereas the epitopes to MAbs reactive to the G protein of VS I map either to the cysteine-rich N-terminal domain (residues 80 to 183) or to the cysteine-poor C-terminal region (residues 286 to 428) (239). The VSV G protein also induces a CTL response. The CTLs generated by one serotype can lyse cells infected with the other serotypes (364). This heterotypic cell killing may be the result of cross-reacting epitopes of the VS I and VS NJ G proteins that are recognized by heterotypic nonneutralizing MAbs (277). A panel of overlapping synthetic peptides and CD4+ I-A-restricted T-cell hybridomas was used to analyze T-helper-cell epitopes of the VS I G protein (58). Of nine hybridomas, five were specific for amino acids 415 to 433, three recognized amino acids 52 to 71, and one reacted with amino acids 316 to 335. All three epitopes activated specific T-helper cells *in vivo* that were able to provide functional help in the production of anti-VSV-specific neutralizing immunoglobulin (Ig)G antibody. The comparison of the nucleotide and amino acid sequences of the G protein of the VS I and VS NJ serotypes with those of Cocal, Chandipura, and Piry virus identified several structural similarities between them (38). These proteins have N-linked glycosylation sites at identical positions. The cytoplasmic domains of the five proteins showed very little conservation, sharing conserved tryptophan/proline and cysteine residues at identical and multiple positions, indicating their importance in protein folding and function. The five proteins shared several regions of amino acid identity (38). Regions between positions 124 to 137 and 395 to 424 are involved in the membrane fusiogenic activity of the G protein. The functions of the region between positions 83 and 99 and other conserved regions of four to six amino acids are unknown (38).

Nucleoprotein

The VSV N protein has 422 amino acids and is the group-common antigen of the *Vesiculovirus* genus (33). The N proteins of the two major serotypes share 68.7% identity. The N protein of the VSV serotypes and that of Chandipura virus share 50% to 51% identity (297). Anti-N-protein MAbs have been generated and used extensively to study the

interaction of the N protein with viral RNA and other proteins during the process of virus transcription and replication (31). The VSV N protein may be the predominant cross-reactive antigen recognized by primary anti-VSV CTLs and also the major target antigen for secondary anti-VSV CTL responses (347). An octamer peptide (residues 52 to 59) of the VSV N protein has been defined that is recognized by VSV-specific CTLs in the context of the Kb histocompatibility antigen (449). The comparison of the deduced amino acid sequence of the N protein of Piry virus with VS NJ, VS I, and Chandipura showed an homology that varied from 51.1% to 55.5%. The hydropathic profiles of these four vesiculoviruses showed a high degree of similarity, and three potential functional domains were delineated.

Phosphoprotein

The VSV NS or P protein contains 274 amino acids for both VS I and NJ (179). The VSV P proteins among VSV strains are extremely divergent, and only 33% homology at the amino acid level was reported between the P proteins of the major serotypes, although the overall structure of the protein was retained (179). The P protein is phosphorylated at Ser-59 and Ser-61 in the NJ serotype, and at Ser-60, Thr-62, and Ser-64 in the I serotype. The P protein is sequentially phosphorylated first by cellular casein kinase, CKII, and second by a protein kinase associated with a cellular kinase that is tightly attached to the L protein and the N protein–viral RNA complex (81). Although constitutive phosphorylation of the P protein is not indispensable for VSV RNA synthesis, it could play a role in the multimerization of the P protein and possibly P–L complex formation (407). Three functional domains have been identified on the P protein in relation to its binding to the N protein–RNA template and the L protein. Domain I, an L-binding domain, is located at the N-terminal region of the P protein from amino acids 1 to 137. Domain II is located from residues 214 to 247 and may bind the L protein for transcription activation. Domain III is an RNA-binding domain located in the C-terminal region from residues 250 to 274. Domains I and II of the P protein from VS I are important for the association of the P protein with the viral L protein. The C-terminal region of the P protein is essential for its efficient association with the viral N protein (32).

Matrix Protein

The M protein of VSV contains 229 amino acids (363). The VSV M protein is known to be phosphorylated in VSV-infected cells, primarily on serine (93). The known functions of the protein are its participation in the virus budding process, mediating the binding of the viral nucleocapsid to the cell plasma membrane, and the inhibition of the host-directed transcription by unknown mechanisms (2). The M protein possibly contributes to the production of VSV CPE through its interaction with cellular tubulin (303). The antigenic structure of VSV M proteins has not been studied.

RNA-Dependent RNA Transcriptase

The VSV L protein, the largest protein, contains 2,109 amino acids and has a molecular weight of 241 kd (32). The L protein appears to be closely associated with the P protein in the virion. This association is essential for the L protein to achieve its complete functional capacity (32). Recent studies have shown that the L protein also needs to be associated to the cellular elongation factor-1abg for its activity (109). The L protein functions include RNA synthesis, capping, methylation, and polyadenylation of viral RNAs (32). The amino acid comparison of the L proteins of VS, RABV, Sendai, Newcastle, and measles viruses showed that there are at least four stretches of amino acids that are conserved among rhabdoviruses and paramyxoviruses (342). These regions may be the functional domains responsible for the multiple catalytic activities of the L protein.

Pathogenesis and Pathology

The mechanisms of VSV transmission are not completely understood. Ecologic factors and special conditions regarding the host and the etiologic agent have been implicated in the clinical presentation of the disease (199,200 and 201). Experimental transmission from animal to animal by direct contact has produced irregular results. The virus is unable to penetrate intact skin or mucosa, and for a successful transmission it needs to be introduced beneath the skin and mucous membranes via wounds and abrasions (200,235). The virus can also be transmitted by the bite of insect vectors such as mosquitoes (*Aedes* spp.) (428,474), sand flies (*Lutzomyia* spp.) (94), blackflies (*Simulium* spp.) (105), and other diptera (152).

In natural infection, the incubation period varies from 2 to 9 days, but usually the lesions develop between 2 and 5 days after exposure (208,235). The lesions of VS are indistinguishable from those of FMD. In cattle, initially the lesions are characterized by pink to white papules in the mouth that progress in 1 to 2 days to vesicles. The vesicles may coalesce and rupture, leaving a denuded area that heals in 1 or 2 weeks if there are no secondary infections (235). These lesions may also occur in the dental pad, lips, gums, muzzle, nose, teats, and feet. In the experimental inoculation of horses, it was observed that in the mouth, vesicles appeared 42 hours after inoculation, and 2 days after that, part of the dorsal epithelial covering the tongue sloughed off. In this experiment, vesicles also appeared in the feet. At necropsy, the spleen was enlarged, but no other lesions were observed in the internal organs (97). In the natural infection of horses, lesions can be found in lips, the corners of the mouth, muzzle, nostrils, ears, belly, prepuce, and udder (208). The lesions in pigs are similar to those described for cattle (201). The main microscopic changes consist of intercellular edema in the stratum spinosus that leads to cell dissociation and necrosis. Concomitantly, there is an inflammatory reaction of the mucosa and the lamina propria, with the presence of macrophages, neutrophils, and lymphocytes (235).

Although the development of secondary lesions in places other than the point of inoculation is suggestive of viremia, the virus could not be isolated from blood even at 6 hours after the experimental inoculation of pigs (92,353,408). The virus is present at its highest titer in the vesicular fluid, which represents a transient but very efficient source of virus for contact transmission (92). The virus can be isolated from specimens taken from saliva, tonsils, vesicular fluids of feet, and, in some cases, feces (92,353,408).

Persistent infection of livestock with VSV was postulated as a possible mechanism for viral maintenance in nature (202). Experimental studies were unable to demonstrate the presence of virus in tissues of inoculated pigs (202) and failed to corroborate this hypothesis. Viral RNA was detected in the tongue and draining lymph nodes in cattle 5 months after

experimental inoculation, but no viral RNA was detected in naturally infected cattle (283). No infectious virus could be isolated from these animals (283).

Immune Response

Antibodies, particularly those with virus-neutralizing activity, play a prominent role in the immune defense against infection. VSV has been extensively used as a model to study the immune response in mice (513). However, very little information is available about the immune response elicited in different natural hosts. All neutralizing antibodies are directed toward the G protein (240). In experimentally inoculated mice, VSV induces a very early neutralizing IgM response. This early response is T-helper-cell independent, and it is induced by the ability of VSV G protein to activate B cells directly (513). This ability is the result of the expression of the VSV G protein as repetitive epitopes that are in a rigid, densely packed “procrystalline” form in the virus envelope (513). A switch to an IgG neutralizing response occurs on day 6 to 8 after inoculation. Neutralizing titers of 10^{-4} and 10^{-5} are reached by days 9 to 12 and maintained for more than 6 months (279). The VNA response is sufficient to control the infection in affected animals (275). Adoptively transferred hyperimmune serum protected B-cell-depleted agammaglobulinemic mice from paralytic disease after VSV inoculation (181). Mice are susceptible to intravenous or intraperitoneal VSV inoculation until they are 3 weeks old.

Interferon seems to play an important role in the natural resistance of older mice to VSV infection (178). Eight- to 12-week-old mice devoid of interferon-mediated natural antiviral immunity were highly susceptible to VSV infection despite the ability to mount a normal humoral and cellular immune response against the virus (412). Also, an enhanced secondary antibody response was observed in mice and cattle when interferon gamma was included in the primary immunization (7).

Experimental infection of mice with VSV induces a strong CTL response that is not serotype specific (364). Although anti-G protein CTLs have been demonstrated, the N protein is the predominant cross-reactive serotype antigen recognized by anti-VSV CTLs (347). Humoral immunity develops after natural infection in horses, cattle, and swine, and antibodies can be demonstrated for more than 7 years after infection (201). Experimentally inoculated swine showed a VNA response that peaked at the third week after inoculation. VNAs were still detected at 18 weeks after inoculation at relatively high titers. When challenged for a second time, these animals did not develop lesions and showed a high secondary antibody response. The study of the antiviral T-cell response by stimulation of peripheral blood mononuclear cells with specific antigen indicated that T-cell immunity remained elevated for prolonged periods (353).

Epidemiology

The disease is present only in the Western Hemisphere, and it is enzootic in southern Mexico, Central America, and some regions of South America (473). In the United States, Ossabaw Island, off the coast of Georgia, is the only confirmed area where VS is enzootic (408). In the rest of the United States, the disease is sporadic. Historically, the disease appeared in approximately 10-year cycles, but in recent years it has occurred more frequently. Transmission of VSV during an outbreak remains unclear. Animal-to-animal contact plays a role in transmission between domestic species (51). Mechanical vector transmission has also been documented during epizootics. Virus isolations from nonbiting insects, such as *Musca domestica*, have been reported (166). Many potential biologic vectors of VSV have been suggested, but the phlebotomine sand fly, *Lutzomia shannoni*, is the only confirmed suspect in the United States (474).

In temperate zones, VSV outbreaks begin in late summer and end with the arrival of frost (180). In the United States, the outbreak during 1982–1983 was unusual because it continued throughout the winter months until the following spring (51). In tropical areas, the disease appears at the end of the rainy season and disappears with the advent of the dry season (474).

During outbreaks, morbidity rates in a herd usually range from 10% to 15% (473). Cattle generally recover in few days, but horses and pigs may develop lameness (200,473). A broad spectrum of wild mammals can also be affected (473). Typically, the disease affects only horses, cattle, and swine. Factors that influence the disease spread in dairy cattle have been studied. Coarse roughage, hard pelleted concentrates, poor general and milking hygiene, and insufficient teat sanitation play an important role (199). In the southeastern United States, feral swine had 10% to 100% antibody prevalence from 1979 to 1985 (410). Feral swine on Ossabaw Island showed 12% and 60% seroconversion between June and September in 1982 and 1983, respectively (411). In some enzootic areas of Central America, over 80% of the cattle have antibodies against VSV, but only 9% of the animals may present clinical signs in a particular year. In the same regions, wildlife also have a high seroprevalence to VSV (424). In tropical areas where the disease is enzootic, VSV seroprevalence in the human population may be as high as 48% (231). Serologic studies during outbreaks in Panama demonstrated a seroprevalence of 71% and 34% in personnel working with infected and noninfected cattle, respectively (53). A similar situation has been observed during VSV outbreaks in Colorado, where personnel (veterinarians, researchers, and regulatory staff) handling sick livestock showed an antibody prevalence of 13% whereas unexposed humans had a 6% seroprevalence (355).

The mechanism by which VSV is maintained in enzootic regions is not fully understood. Sand flies may transmit the virus from a putative reservoir (e.g., plants, wildlife, cattle) to livestock. Alternatively, VSV may be maintained in the sand fly population by transovarial transmission, and the insects infect susceptible animals during feeding (94). In some enzootic areas, feral swine have been suggested as a potential amplifying host (409). Molecular epidemiologic studies indicated that enzootic areas may be the origin of the virus responsible for outbreaks in epizootic zones (325). VSV may be introduced in a particular area by the movement of infected animals, wildlife, or insects, but the actual mechanism is unknown. Viruses circulating in enzootic areas present a high genetic diversity, with several lineages coexisting in the same region (326). Within enzootic areas, the viruses seem to adapt under selective pressures exerted by ecologic factors. Viruses from different ecologic areas within enzootic regions belong to different genotypes. Viral adaptation to different insect vectors or mammalian reservoirs might be determinant factors for this divergent evolution (357). Viruses

obtained from a particular outbreak showed a marked genetic homogeneity (325).

Clinical Signs

In cattle, after an incubation period of 3 to 9 days, the body temperature may reach 105° to 107°F. Temperature rise usually begins before vesicle development. Body temperature falls when the vesicles are fully formed, and the depression remains until rupture of the vesicles (98). Affected animals have increased salivation and a sharp reduction in milk production. Eating is difficult because of the sore mouth, with a consequent loss in condition. Lameness develops with foot lesions. If there are no complications, recovery occurs in 4 to 5 days (98). The disease follows an almost identical course in horses and swine (201).

Diagnosis

Because VS is clinically similar to FMD, differential diagnosis between the two diseases is of utmost importance, especially in countries free of the latter disease. Originally, inoculation of natural hosts with material from vesicular lesions was used for differential diagnosis. With the development of a complement fixation technique, a more rapid, sensitive, and accurate method was available for the differentiation of VSV and FMDV (200). Isolation of VSV from vesicular fluid or epithelium of the lesions in mice, embryonated eggs, or cell culture is not difficult (89). The virus can be identified by virus neutralization, complement fixation, or immunofluorescence (201). A rise in antibody titer in serum samples taken during the clinical and convalescent phases of the disease is evidence that the infection was caused by VSV. Virus neutralization and ELISA techniques are commonly used for this purpose (5). Recently, detection of VSV in clinical samples by RT-PCR has been described. This method is highly sensitive and specific, providing a rapid diagnosis and material for genetic characterization of the virus (216,358).

Treatment, Prevention, and Control

Supportive veterinary care of affected animals helps to prevent complications that may delay recovery. Vaccination against VSV has been practiced to only a limited extent. A modified live vaccine was used in parts of the United States, Central America, and Peru. VSV was attenuated in cell culture or chicken embryos. This vaccine, administered intramuscularly in cattle, induced protection from the disease for at least 1 year (201). During the 1985 epizootic in Colorado, an inactivated VSV NJ vaccine with virus propagated in cell culture was used in the field. Later, this vaccine was tested in an experimental trial and it induced antibodies that lasted for 175 days. Viral challenge of the experimental animals was not performed to assess the protection conferred by this vaccine (177). Recently, a recombinant vaccinia virus expressing the VSV I glycoprotein was developed and used to experimentally immunize cattle. Inoculated animals developed antibodies and resisted intradermal lingual challenge (294).

EPHEMEROVIRUS

History

The first reference to bovine ephemeral fever (BEF) can be found in the book *In the Heart of Africa* (378). Not until the mid-20th century was the disease reported in much of its natural range (415). Until 1966, when BEFV was grown in mice (450), research on the agent was restricted to transmission studies in cattle (89). The ability to cultivate BEFV in another system besides its natural host was a fundamental step in the study of the disease and its control (415).

Infectious Agent

Taxonomy

The members of the *Ephemerovirus* genus show a very low cross-neutralization reaction, but they are highly cross-reactive in complement fixation or indirect immunofluorescence tests. No serogroup has been defined within this genus. Phylogenetic studies suggested that the *Ephemerovirus* is more closely related to the *Vesiculovirus* genus than to the other members of the *Rhabdoviridae.* The viruses assigned to this genus include BEFV, Adelaide River virus, and Berrimah virus. Other viruses tentatively placed in this genus are Kimberley, Malakal, and Puchong virus (451). BEFV is the only member of the *Ephemerovirus* genus discussed extensively in this section.

Morphologic and Physical Properties

Although members of the *Ephemerovirus* genus share general morphologic characteristics with the *Rhabdoviridae*, they also present unique features. The viral genome of BEFV is 14.8 kb in length and contains 10 genes (3'-N-M1-M2-G-G_{NS}-a_1-a_2-b-g-L-5') separated by intergenic regions of 26 and 53 nucleotides (451). In contrast to BEFV, the viral genome of the Adelaide River virus is 14.6 kb in length and contains nine genes (3'-N-M1-M2-G-G_{NS}-a_1-a_2-b-L-5') separated by intergenic regions of one to four nucleotides (451).

Biologic Properties: Host Range and Infection of Experimental Animals

Only cattle and water buffalo are clinically affected by BEF (413), but on the basis of serologic evidence a wider range of wild ruminants can be infected (6,111). Suckling mice are susceptible to BEFV when inoculated by the intracerebral route (450), as are suckling hamsters and rats with mouse-adapted BEFV (222). In Kenya, virus isolation was reported from a pool of five *Culicoides* spp. (112), and in Australia BEFV was obtained from *C. brevitarsis*, *Anopheles brancoftii*, and a pool of several species of mosquitoes (415). BEFV can be isolated from infected blood by intravenous inoculation of chicken embryos (135). Cells of bovine origin are poorly susceptible to BEFV (136). The virus grows well in BHK-21 cells inoculated with infected mouse brain or bovine leucocytes. BEFV has also been adapted to hamster lung, Vero, and C6/36 cell lines. Primary inoculation of *Ae. albopictus* C6/36 cells with the leukocyte fraction of the blood with subsequent

passage through BHK-21 cells has been used for virus isolation, but this method is too slow for practical diagnosis (414).

Chemical and Antigenic Properties of Viral Proteins

Glycoprotein G

The glycoprotein G is the viral protein that induces protective neutralizing antibodies and is a structural component of the viral envelope (213). The BEFV G protein consists of 623 amino acids with a calculated molecular weight of 72.7 kd, and it has five potential glycosylation sites. The BEFV G protein has a 30.8% identity and a 53.4% similarity with the homologous protein of Adelaide River virus (467). Distinct neutralizing antigenic sites (G1, G2, $G3_a$, and $G3_b$) have been identified in BEFV G protein using MAbs in competitive assays and cross-neutralization tests (106). Selection of escape mutants allowed identification of several epitopes in the extracellular domain. Two B-cell epitopes were mapped in the G1 antigenic site, at positions 488 to 491 and 499 to 502. The mutation in site G2 mapped at amino acid 169 or 187. Antigenic site G3 appears to combine complex discontinuous epitopes, because mutations were located at positions 49, 57, 218, 229, and 265 (250). Alignment of BEFV G protein with the homologous protein of representatives among the *Vesiculovirus* and *Lyssavirus* showed similarities in the location of neutralizing epitopes. The conservation of cysteine residues suggests a similar folding pattern for these proteins (250).

Glycoprotein G_{NS}

The genome of BEFV and its close relative Adelaide River virus encodes a second glycoprotein, G_{NS}, that is located downstream of the G gene. G_{NS} is synthesized in approximately the same amount as G during cell infection (461), but it is not found in the mature virion. Intracellularly, G_{NS} is localized in the endoplasmic reticulum/Golgi complex, and it is associated with amorphous structures in the cell surface but not with viruses in the budding process. It is highly glycosylated, with a molecular weight of 90 kd. G_{NS} protein shares significant amino acid sequence homology with the G protein, but it does not induce protective neutralizing antibodies (213). The G_{NS} function is unknown. It was proposed that the gene coding for this protein originated by gene duplication by a copy-choice mechanism involving relocation of the polymerase in an upstream position during viral replication (467).

Nucleoprotein

The N protein of BEFV is 431 amino acids long with an estimated molecular weight of 49.519 kd (462). The N protein is phosphorylated (461). In amino acid positions 349, 362, and 371 there are serine residues that are potential phosphorylation sites and optimal substrates for CKII (462). Amino acid sequence comparison between N proteins of BEFV and members of the vesiculoviruses and the lyssaviruses showed regions of high homology (462). A more detailed analysis identified five potential domains with conservation of identical or structurally similar amino acids in the N protein of BEFV, VSV, and RABV (462). Serologic cross-reaction between BEFV and RABV N protein has been described (462). Polyclonal antibodies against BEFV, RABV, MOK, LBV, and DUV reacted with the N protein of BEFV and RABV viruses (462). Extensive cross-reactivity between rhabdoviruses has been reported (61). There has not been a detailed study of the other viral proteins. According to their molecular weight, relative abundance, and other characteristics, other viral proteins have been tentatively assigned putative functions, taking as a model the RABV proteins. The RNA polymerase activity L protein has been assigned to a 180-kd polypeptide that is core associated. The M protein function was tentatively assigned to a core-associated protein of 43 kd. The M2 function has been assigned to a phosphorylated core-associated protein of 29 kd (461). The functions of a1, a2, b, and g gene products are unknown (451).

Pathogenesis and Pathology

BEFV enters the body through the bite of an infected hematophagous arthropod (389) and is not transmitted by animal-to-animal contact (414). The site of primary replication is unknown (389). After an incubation period of 4 to 7 days, there is a viremia that lasts 3 to 4 days, with the virus in the neutrophil fraction (510). There is a marked neutrophilia with neutrophil infiltration of the serous membranes. Viral antigen can be detected in neutrophils and in the mesothelial cells (511). Neutrophils play an important role in the development of clinical symptoms and pathologic lesions of BEF. Neutrophil-depleted animals experimentally infected with BEFV did not develop clinical signs or detectable neutralizing antibodies, although they were viremic (510). While the clinical signs are being manifested, there is a marked increase of vasoactive amine activity that may be responsible for areas of increased permeability in the serous membranes. The increase in amine activity coincides with the peak of neutrophilia (445). Also, there is an elevation of plasma fibrinogen, regarded as a nonspecific response of the inflammatory process, and hypocalcemia (445). The hypocalcemia is responsible for some of the clinical signs such as anorexia, ruminal and intestinal stasis, and muscle fasciculation and paralysis. The basic lesion in BEF is a fibrinous polyserositis (511). This lesion involves synovial, pericardial, pleural, and peritoneal cavities. There is a characteristic accumulation of synovial fluid in the joints, as well as fluid accumulation in the abdominal, thoracic, and pericardial cavities. This fluid contains a large amount of neutrophils. Viral antigen can be demonstrated in these cells. This accumulation of fluid is the result of an arteritis of the small vessels (389).

Immune Response

Observation of sentinel cattle during a BEF outbreak showed that the animals had neutralizing antibodies by the third day after the clinical signs appeared. Sick animals were protected during later outbreaks (414). Transient protection against BEFV was observed in animals infected with arboviruses. Protection of these animals was thought to be the result of the production of interferon (414). Calves vaccinated with two doses of vaccine showed high and persistent neutralizing antibodies and resisted experimental challenge and natural infection (443).

Epidemiology

BEF is distributed throughout Africa, the Middle East, Southeast Asia, and northern Australia (415). It has never been

reported in the Americas. The disease occurs during summer and autumn and disappears with the arrival of the first frosts in subtropical areas. In the tropics, yearly occurrence is associated with the rainy season (415). Although transmission of the virus occurs via insect vectors, the difficulty of isolating the virus from insects hampers the recognition of the vector species involved in its transmission. BEFV was isolated from *Culicoides* spp. and from mosquitoes. In Australia, the geographic range of the disease is larger than that of the *Culicoides* species from which the virus was isolated (415). Two species of mosquitoes, *Culex annulirostris* and *Anopheles annulipes*, may be implicated in transmission in these areas (415). In general, morbidity is low, but in some outbreaks, all of the animals in a herd may be affected. In other instances, only 2% or 3% of the animals show clinical signs (415).

Natural disease occurs only in cattle and water buffalo. Although seroprevalences of 13% to 38% were reported in cattle in enzootic areas, a higher prevalence of 64% has been observed during outbreaks (108). The role of wild ruminants in the maintenance of BEFV in nature is not understood. Seroprevalences ranging between 28% and 54% were found in wild ruminants in Kenya, Zimbabwe, and Tanzania (6,111).

Clinical Signs

After an incubation period of 2 to 4 days, the first clinical sign is fever (40° to 42°C), accompanied by malaise and a severe drop in milk production. In 12 to 24 hours, fever remits, followed by a second febrile phase. During this second phase, the animals are depressed and anorexic and show muscle stiffness and lameness. Ruminal stasis, nasal and ocular discharges, and swelling of one or more joints are present. Subcutaneous emphysema may develop in some animals (413). The clinical signs persist for 1 or 2 days, and thereafter animals recover rapidly and totally. Clinical signs are much more severe in adults than in calves. Calves under 6 months of age show no clinical signs (43).

Diagnosis

Clinical diagnosis of BEF is based on its rapidity of spread and transient nature (43). For confirmation, virus isolation or the demonstration of an increase in antibody titer in paired serum samples is needed. Although impractical for routine diagnosis, cattle inoculation with blood from BEFV-affected animals is the most sensitive method for viral isolation. Isolation of BEFV in *Ae. albopictus* cells from the blood of infected animals, followed by direct immunofluorescence to detect the presence of viral antigens, has been used in experimental studies (446). Virus neutralization is commonly used to detect a rise in antibody titer between clinical and convalescent-phase serum (131). A complement fixation test was developed to detect antibodies using antigen prepared in BHK-21 cells, but it has not been widely applied (29). A blocking ELISA test compared favorably with the virus neutralization technique and did not detect cross-reactions with antibodies to Kimberly and Berrimah viruses (512).

Treatment, Control, and Prevention

Animals affected with BEFV should be rested and protected from inclement weather. The administration of phenylbutazone blocks the host inflammatory response, responsible for the clinical signs. The drug suppresses the synthesis of cyclooxygenase-dependent prostaglandins, hence modifying the inflammatory response *in vivo* (447). Parenteral administration of calcium solutions helps in recovery (444).

Vector control is very difficult, and vaccination is the only practical method for prevention of BEF. Several attenuated vaccines were produced by serial passage in mouse or cell culture (413). They provided protection against experimental challenge when mixed with adjuvants and given in several doses (413). Inactivated vaccines were developed in Japan and Australia (413), but they induced poor and unreliable immunity. More recently, vaccinia virus expressing the G protein elicited neutralizing antibodies in cattle, which were resistant to a subsequent viral challenge (213). Additionally, an experimental subunit vaccine consisting of purified G protein mixed with Quil adjuvant conferred protection against viral challenge when administered in two doses, 21 days apart (448).

PERSPECTIVES

Although there is a wealth of information about the chemical and biologic characteristics of some animal rhabdoviruses, other important aspects such as pathogenesis, mechanisms of virus maintenance, sylvatic transmission in endemic regions, and factors that contribute to the reemergence of disease in epizootic areas after long periods of epidemiologic silence, remain largely unknown. For example, no definitive reservoirs of either VSV or MOK have been identified with certainty. Moreover, rabies was believed absent from the entire continent of Australia until a novel bat lyssavirus was discovered, largely by accident, in 1996. From the standpoint of vaccine cross-reactivity, will the next discovery be as benign? Clearly, insights provided by innovative avenues of investigation may help to unravel remaining secrets of rhabdovirus transmission and perpetuation. As an example, co-feeding studies of infected and noninfected blackflies, *Simulium vittatum*, on nonviremic mice, recently demonstrated the possibility of infection of an insect vector on a nonviremic host (301), and findings such as these may contribute to an overall better understanding of the mechanisms for virus maintenance in nature, even in the absence of viremia in certain mammalian taxa. Given the dramatic global changes that have occurred during the last few decades, the perceived impact of environmental alterations on the relatively rapid evolution of the known *Lyssavirus*, *Vesiculovirus*, and *Ephemerovirus* groups, and the plethora of poorly studied and still unclassified rhabdoviruses, only the development of new interdisciplinary studies via international collaborations can evaluate the potential risk these agents may present as emerging public health and veterinary pathogens of tomorrow.

CHAPTER 40 *Filoviridae:* Marburg and Ebola Viruses

Anthony Sanchez, Ali S. Khan, Sherif R. Zaki, Gary J. Nabel, Thomas G. Ksiazek, and Clarence J. Peters

HISTORY

In 1967, multiple cases of severe hemorrhagic fever with nosocomial transmission among European laboratory workers led to the spectacular initial identification of Marburg virus and this new virus family (126,142). The virus came with African green monkeys imported from Uganda and the epidemic was controlled, with limited interhuman spread, when the monkeys and contaminated materials were disposed of. The next recognized filovirus activity was in 1976, when Ebola virus appeared simultaneously in the Democratic Republic of the Congo (DRC; then called Zaire) and Sudan (20,231,232). These epidemics were actually caused by two distinct forms of the virus, a fact not recognized until years later (26,47,144,197). In the ensuing years, only sporadic filovirus activity came to biomedical attention (6,76,93,112,162) and progress was made in the basic laboratory study of filoviruses.

In 1989, Ebola returned to center stage and borrowed a theme from the Marburg 1967 episode: It first came to the United States with imported macaques from the Philippines (105,166,169). This Reston species appears to be less pathogenic for humans, but outbreaks in macaques have shown it to cause a high degree of mortality in these monkeys. Furthermore, the quarantine rules put in place to prevent a recurrence of the 1967 Marburg epidemic limited the infection to the actual monkey quarantine facilities in this and subsequent importations (50). The actual origin of the Reston species of Ebola virus was never determined, although multiple importations occurred from the same monkey export facility (Table 1) (145).

†In one study, mortality in monkeys was estimated at 60% (89).
DRC, Democratic Republic of the Congo.

TABLE 1. *Outbreaks of Filovirus Disease*

Then from 1994 to 1996, Ebola virus apparently became active in broad areas in, or adjacent to, the central African rain forest. Small epidemics of the Zaire species occurred in Gabon (2,82) and a large outbreak caused severe disruption in Kikwit, DRC (33,119,194). A new species was noted to be active in Côte d'Ivoire (135). Subsequently, there has been no sign of the Zaire species of Ebola, but in September of 2000, serial human infections by the Sudan species appeared in northern Uganda. Active analysis of a string of new infections with Marburg viruses derived from different phylogenetic lineages in the eastern DRC in 1999 and 2000 is also underway (230).

With the exception of the recent Marburg outbreak, all the filovirus epidemics have followed a similar pattern. One

presumed index case leads to a chain of infection that is amplified by needle use or close human contact. The application of appropriate parenteral practices and barrier nursing as well as simple quarantine of sick patients has stopped all these outbreaks. All recognized filovirus outbreaks are summarized in Table 1. The high case fatality (25% to 80%) among infected humans, and the public imagination have amplified the apparent impact far beyond the actual disease significance. Nevertheless, we remain profoundly ignorant of the natural history of the viruses, there is no treatment, and relatively little is understood of the pathogenesis and immunology of the infections. They will continue to be a problem in Africa until proper hospital hygiene becomes practical and routine.

THE INFECTIOUS AGENTS

Classification

Filoviruses are taxonomically classified in the order *Mononegavirales* (160), which contains a large variety of enveloped viruses with nonsegmented, negative-stranded (NNS) RNA genomes. Initial morphologic observations of Marburg virus suggested that it might best be placed in the family *Rhabdoviridae*, but subsequent morphologic, genetic, physiochemical, and virologic studies of Marburg and Ebola viruses led to the creation of a separate family, the *Filoviridae* (120). The family is divided into two genera, currently designated as “Ebola-like viruses” and “Marburg-like viruses.” There are four species within the “Ebola-like viruses,” Zaire (type species), Sudan, Reston, and Côte d'Ivoire (Ivory Coast). A single species, Marburg virus, makes up the “Marburg-like viruses.” Division into two genera, *Ebolavirus* and *Marburgvirus*, is under consideration, with species names being assigned to the different Ebola virus lineages. There is no antigenic cross-reactivity between Marburg and Ebola viruses, but the Ebola viruses have common and unique epitopes.

Because of their aerosol infectivity, high mortality rate, and potential for person-to-person transmission, Marburg and Ebola viruses are classified as biosafety level 4 (BSL4) (WHO: risk group 4) pathogens, for which maximum containment facilities are required for all laboratory work (36,122). The biosafety level of the Reston subtype of Ebola may eventually be reconsidered because several documented human infections have not been associated with disease, but there is insufficient experience to recommend a change at this time.

Virion Morphology and Structure

Electron microscopy of Marburg and Ebola virions produced in tissue culture have shown them to be pleomorphic, appearing as either long filamentous (and sometimes branched) forms or in shorter U-shaped, 6-shaped, or circular configurations (Fig. 1, Fig. 2, and Fig. 3) (57, 78,157,173). The filamentous forms vary greatly in length (up to 14,000 nm), and an early study showed that the unit length associated with peak infectivity is 790 nm for Marburg virus and 970 nm for Ebola virus (120). A more recent comparison of filovirus isolates grown in various cell lines revealed the mean unit length of virions to be about 860 nm for Marburg virus and about 1,200 nm for Ebola viruses (78). Virions have a uniform diameter of 80 nm and are composed of a helical ribonucleoprotein (RNP) complex (nucleocapsid) with a closely apposed unit-membrane envelope (derived from host cell plasma membrane), whose surface is studded with 10-nm-long peplomers (Fig. 4). Nucleocapsids are 50 nm in diameter, with an axial space 20 nm in diameter and a helical periodicity of about 5 nm. Virion density is 1.14 g/mL as determined by centrifugation in a potassium tartrate gradient (121). Marburg and Ebola virions contain one molecule of noninfectious, linear, negative-sense, single-stranded RNA with a Mr of 4.2×10^6, constituting about 1 percent of the virion mass (177).

FIG. 1. Ebola virus. Unfixed diagnostic specimen, from the first Vero cell passage of the first human blood specimen examined in the 1976 epidemic. Filamentous virions unpenetrated (*top*, ×35,000) and penetrated (*bottom*, ×63,000) by negative-contrast medium (sodium phosphotungstate).

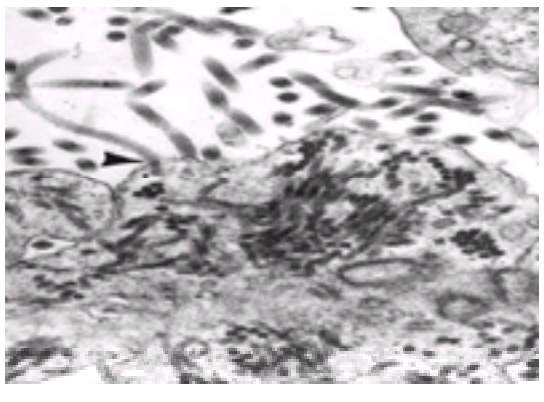

FIG. 2. Ebola virus. Vero cell culture, day 2; virions budding from plasma membrane (*arrow*) and preformed

nucleocapsids in cytoplasm (×28,000).

[b]Virion GP (peplomer) is in the form of a trimer of the GP_1–GP_2 heterodimer; MW is for the heterodimer.
[c]Expressed only by Ebola viruses (primary gene product of GP gene); MW is for the monomeric form.

TABLE 2. *Filovirus genes (3' to 58) and the functions and relative molecular weights of gene products*

Marburg and Ebola virus infectivity is quite stable at room temperature (20°C) and can resist desiccation (18), but it is largely inactivated in 30 min at 60°C. Infectivity is also greatly reduced or destroyed by high doses of ultraviolet light and gamma irradiation (40,56,146,223), lipid solvents, b-propiolactone, and commercial hypochlorite and phenolic disinfectants. [*Note:* Decontamination requires specific, controlled use of virus inactivating agents (34,36,122).]

GENETICS, VIRUS PROTEINS, AND REPLICATION

Genetics

As do all members of the order *Mononegavirales*, filoviruses contain a single-stranded, negative-sense RNA molecule as their genome. The primary structure of the genomic RNA has been determined for two Marburg virus isolates (from 1967 and 1980), as well as a 1976 isolate of the Zaire species of Ebola virus (27,28,60,61,124,191,192,218). The genomes of filoviruses are approximately 19,000 bases in length and contain seven sequentially arranged genes (see Fig. 4). These genomes are the largest of the order *Mononegavirales*, and their organization generally conforms to that seen for paramyxoviruses and rhabdoviruses. However, their complexity is more akin to viruses of the family *Paramyxoviridae.* The extragenic sequences at the extreme 3' (leader) and 5' (trailer) ends of the genomes of filoviruses are conserved, show a high degree of complementarity, and can form stem-loop structures (148,218). For all NNS RNA viruses, these sequences are important in the initiation of transcription and the replication of full-length genome RNA, and they serve as promoters for the virus polymerase; certain adjoining sequences may also be involved in promoter activity. Analyses of

defective interfering particles have shown the Ebola virus promoters to be contained within 156 and 177 nucleotide regions of the genomic and antigenomic RNA 3' termini, respectively (30). Genes are delineated by conserved transcriptional signals, beginning with a start site at the 3' genome end and terminating with a transcriptional stop (polyadenylation) site. Termination of transcription occurs at a series of five or six Us, where stuttering (repeated copying) by the polymerase results in the addition of long poly(A) tails to the transcripts. Polyadenylation/stop signals generally conform to the following consensus sequence: 3'-UAAUUC(U) $_{5–6}$. Transcriptional signals of filoviruses contain a common sequence, 3'-UAAUU, at the 5' end of start sites and at the 3' end of stop sites, a property that is so far unique to these viruses. In addition, there are other characteristics that distinguish filovirus genomes from those of other NNS RNA viruses. One unique characteristic is that filovirus genes tend to possess long noncoding regions at their 3' and/or 5' ends, which contribute to the increased length of the genome and may function in the stability of transcripts. Analysis of the 5' ends of filovirus transcripts shows a potential for the formation of conserved, stable, stem-loop structures, which might affect their stability and capacity to bind ribosomes (150,191).

Another unique feature of filoviruses is the positioning of certain neighboring genes. The genes of rhabdoviruses and paramyxoviruses are usually separated by short intergenic regions of one or more nucleotides, but some genes of filoviruses overlap one another (61,191,197,218). These overlaps are short, are limited to the conserved transcriptional signals, and are centered on the common 3' UAAUU pentanucleotide sequence described earlier. There is one overlap in the Marburg genome (VP30 to VP24 genes), but in the Zaire species of Ebola virus there are two overlaps (VP35 to VP40, and GP to VP30). The positioning of the Marburg virus overlap and a long intergenic region (that precedes the VP30 gene) appears to be shifted one gene with respect to the genome of the Zaire species of Ebola virus. Preliminary sequence analyses of other Ebola virus species (Sudan and Reston) have indicated that overlaps are also present in their genomes, indicating that this is a general feature of the family. Overlaps have been identified in the genomes of human and bovine respiratory syncytial virus (68 bases between M2/22K and L genes) (44) and two rhabdoviruses, Sigma virus (207) and Adelaide River virus (222), but these overlaps are not common features of their respective families. The rhabdovirus overlaps are shorter and are most like those of Ebola and Marburg viruses, but nonconserved sequences separate the transcriptional signals and do not overlap. The mechanism by which initiation of transcription of the 5' overlapping gene occurs is unknown, but for the short overlaps it is possible that the proximity of the polymerase allows recognition of the start site. The function of all these overlaps is at present unclear, but transcription attenuation of the downstream gene has been proposed for human respiratory syncytial virus (44). For Ebola virus (Zaire species), transcription of the VP40 and VP30 genes do not appear to be attenuated, and in the case of the VP40 gene, expression is very high.

The organization of the glycoprotein (GP) genes of Ebola viruses is quite unusual and provides an important distinction between Marburg virus and Ebola viruses. The Marburg virus GP gene encodes a single product, the GP, in a conventional open reading frame (ORF), whereas all Ebola viruses encode the GP in two ORFs (0 and -1 frames) that are expressed through transcriptional editing (197,216). The primary gene product of the Ebola GP gene is not the GP, however, but rather a smaller, nonstructural, secreted glycoprotein (SGP) that is released from infected cells in large quantities. The transcriptional editing event that leads to GP production occurs at a series of seven Us on the genomic RNA template and results in the insertion of an additional single A, which connects the GP open coding frames; approximately 20% to 25% of the transcripts are edited. The mechanism of insertion most likely evolved out of the polymerase's ability to polyadenylate by stuttering on a poly(U) template. However, insertion of a single nucleotide at the editing site appears to occur with a high degree of fidelity. Transcriptional editing is not unprecedented in the order *Mononegavirales*, as a similar type of editing has been demonstrated for the P gene of certain paramyxoviruses. However, the editing of Ebola virus GP gene transcripts is the only example of a virus glycoprotein that is expressed through this type of mechanism. Sequence analysis of the GP genes of Marburg virus isolates indicates that a nucleotide sequence that corresponds to the editing region of Ebola virus GP genes is absent (198), and efforts to detect a similar secreted form of the Marburg virus GP have been unsuccessful. The difference in filovirus GP gene organization provides important evidence pointing to a divergent evolution for Ebola and Marburg viruses.

Phylogenetic analyses of the family *Filoviridae* have been performed using the coding region of the glycoprotein gene (82,197,198,204,212). The evolutionary profile of the family (Fig. 5) indicates that (a) Ebola and Marburg viruses represent distinct lineages of filoviruses, (b) the four species of Ebola viruses also represent distinct lineages, and (c) there is an extraordinary level of genetic stasis within the lineages of Ebola virus. Nucleotide and amino acid differences between Marburg and Ebola viruses are both approximately 55%, whereas Ebola virus species show 37% to 41% differences in nucleotide and amino acid sequences (197). These same levels of sequence variation are also seen when other genes are compared. Within species of Ebola viruses, however, there is a remarkable degree of genetic stability (<2% change over up to 19 years), indicating that these viruses have most likely reached a high degree of fitness as they have adapted to their respective niches.

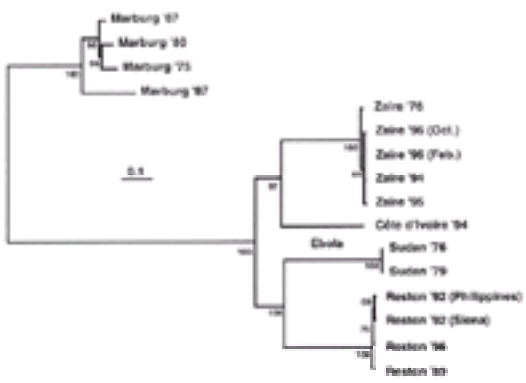

FIG. 5. Phylogeny of the family *Filoviridae.* This phylogenetic tree is derived from comparisons of nucleotide sequences for the GP gene coding regions. Analysis was performed using the Puzzle computer program (version 4.0) developed by Korbinian Strimmer and Arndt von Haeseler and the Treeview program of Roderic D. M. Page. The tree is a quartet puzzling tree derived from 10,000 quartet puzzling steps and is based on maximum likelihood values estimate using the

HKY model (88) and a uniform rate of heterogeneity. *Bar length* equals 0.1 nucleotide substitutions per site.

Marburg virus isolates have not shown the degree of variation seen among Ebola virus species, but two lineages of Marburg virus have been described (112,198). The 1987 isolate from Kenya appears to represent a separate lineage from the three previous isolates, but the difference (21% to 23% amino acid change) is not enough to constitute a separate species (198). Preliminary analysis of the 1999–2000 outbreak in Durba, DRC, suggests that both the recognized lineages are present (230). Phylogenetic analyses of deduced amino acid sequences of the entire L-gene coding region indicate that filovirus L proteins are more like those of paramyxoviruses than those of rhabdoviruses (A. Sanchez, unpublished data, 1995).

Virus Proteins

Filovirus proteins can be subdivided into two categories, those that form the RNP complex and those that are associated with the envelope (see Fig. 4 and Table 2). Those associated with the nucleocapsid are involved in the transcription and replication of the genome, whereas the envelope-associated proteins primarily have a role either in assembly of the virion or in receptor binding and virus entry.

Proteins Forming the RNP Complex

Nucleoprotein

The nucleoprotein (NP) is the primary structural protein associated with filovirus nucleocapsids (15,55,60, 121,123). The NPs of filoviruses are phosphorylated and range in size (Mr) from 96 to 104 kd, as determined from sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) analysis (12,14,55,139). Their predicted mass (deduced from nucleotide sequence analysis) is approximately 20 kd smaller than the size estimated from SDS-PAGE. The NPs of filoviruses can be divided into a hydrophobic N-terminal half, which contains all the cysteine residues, and a hydrophilic C-terminal half, which contains most of the proline residues and is extremely acidic (192,193). The acidic nature of the C-terminal half of the NP, together with its phosphorylation, may account for the anomalous SDS-PAGE migration noted through reduction of the binding of negatively charged SDS molecules. Comparisons of the predicted amino acid sequences of the NPs of Marburg virus and the Zaire species of Ebola virus revealed a significant degree of homology in their N-terminal 400 residues, but not in the remaining C-terminal residues (193). This lack of homology has been noted in the approximately 100 C-terminal amino acids of paramyxovirus NPs (74), where this region of the NP is thought to interact with the matrix protein during virus assembly. It was determined that a span of about 130 residues in the central region of the NPs of filoviruses showed marked homology with paramyxoviruses and to a lesser extent rhabdoviruses (193). In another study, which compared the NPs of pneumonia virus of mice to those of other paramyxoviruses, rhaboviruses, and Ebola virus, it was suggested that the first 350 to 400 amino acids retained a similar structure that contains conserved regions that very likely have common functions (7). The N termini of the NPs of these viruses may function in the binding of genomic RNA, and the variable region may interact with other virus proteins, such as the matrix protein.

VP30

The VP30 protein is a minor nucleoprotein, and like the NP it is phosphorylated and tightly bound in the nucleocapsid (55,123). The N terminus is rich in basic amino acids (particularly arginine) and may be involved in binding to virus RNA or the acidic C terminus of NP.

Polymerase

As with other negative-strand RNA viruses, the RNA-dependent RNA polymerase, or L (large) protein, of filoviruses is the largest and least abundant virus protein in both the virion and infected cells. The predicted amino acid sequences of filovirus L proteins contain three regions in the N-terminal region and a putative ATP-binding motif in the C-terminal region that are conserved in the polymerases of paramyxoviruses and rhabdoviruses (148,218).

VP35

The position of the VP35 gene in the genome corresponds to that of the phosphoprotein genes of rhabdoviruses and paramyxoviruses, but there is no evidence that VP35 is phosphorylated. Nevertheless, it appears that this protein has an essential role as a cofactor in transcription and replication, similar to that of the P proteins of other NNS viruses (15,149,151)

Membrane-Associated Virion Proteins

GP

The GP is the sole structural protein making up the virion surface spikes that mediate virus entry into susceptible host cells through receptor binding. GP is the most studied of the filovirus proteins, not only for its importance in virus entry and pathogenesis but because it is a prime target for vaccine development. Research on filovirus GP has been facilitated through the use of recombinant DNA technology to permit biochemical and functional assays without the constraints of working with the infectious filovirus (38,101,200,206,217,228,229); research on other filovirus proteins has been similarly impacted.

Virion spikes are composed of homotrimers of the GP (65,199) anchored in the membrane in a type I orientation and are heavily glycosylated with both N-linked and O-linked glycans (13,62,83,197,199,215). The GPs of filoviruses exhibit a fairly high degree of homology in their N-terminal and C-terminal regions, whereas the middle third is highly variable (even between Ebola virus species). The central/variable region is hydrophilic, whereas the conserved regions appear to be more hydrophobic and contain the bulk of cysteine residues, most of which are conserved between Marburg virus and Ebola virus GPs. The variable region also contains most of the predicted N-linked carbohydrates and most if not all of the O-glycans. The addition of O-glycans confers an extended, mucin-like property to the variable region, and the decreased secondary structure may allow mutations to be more easily tolerated (198). Analysis of the GP carbohydrate composition has shown that Marburg virus isolates lack terminal sialic acid when grown in Vero E6 or MA-104 cells, unlike the GPs of Ebola viruses, which contain abundant a(2–6) and/or a(2–3) linked sialic acids (62). No neuraminidase activity has been found with any filovirus GP, and the differences seen in sialic acid addition may be caused by differences in targeting as they are directed though the trans Golgi apparatus.

The GPs of all filoviruses are posttranslationally cleaved by furin, a subtilisin/kexin-like convertase localized in the trans Golgi, and there are indications from studies of other viruses that cleavage can control pathogenicity (127). A precursor form (GP_0) is cleaved close to the end of the variable/mucin-like region, yielding GP_1 and GP_2 molecules (199,217,220). This endoproteolytic processing of the Ebola virus GP_0 was found to be dispensable, as virus entry proceeded despite mutation of the furin site (229), but cleavage is most likely required for efficient activity in the natural host. The location of the cleavage site is conserved in Ebola viruses, but the site itself shows some variability (199,217). The furin cleavage site for the Marburg virus GP is in the same region as the Ebola virus GP, but it is positioned more toward the N terminus (67 residues) (220). GP_1 and GP_2 are linked together by disulfide bonding to form a heterodimer (197,199,217), and mutational analysis has determined that a single cystine bridge links these molecules (200).

The virion peplomers are formed by trimers of the GP_1-GP_2 heterodimer and probably assemble in the endoplasmic reticulum. Crystallization and x-ray diffraction studies of portions of a recombinant fragment of GP_2 showed that trimerization occurs when heptad repeat sequences form coiled coils (141,224,225). These rod-shaped structures are similar in appearance to the HA_2 of influenza, the gp41/transmembrane (TM) glycoproteins of retroviruses, and SNAREs (37,141,225). Within GP_2 is a highly conserved sequence (26 residues long) overlapping a portion of the heptad repeats that was found to have a strong homology with oncogenic retrovirus TM glycoproteins (17,27,191,226). This protein sequence from retroviruses has been referred to as an immunosuppressive motif, based on its ability to inhibit T-cell proliferation and impair other immunologic responses *in vitro* (43,87,116), but this property has not been adequately evaluated for the related motifs present in filovirus GP_2 molecules.

Near the N terminus of GP_2 is a putative fusion peptide that is capable of inserting itself into membranes that contain phosphatidylinositol and resemble the lipid composition of hepatocyte plasma membranes (186). This fusion peptide is located in a position that is similar, with respect to the heptad repeats, to that of paramyxovirus, retrovirus, influenza virus, and coronavirus envelope glycoproteins (199). The fusion peptide is internally positioned and flanked by two conserved cysteines that are predicted to form a disulfide bond, and it is very similar to the TM of Rous sarcoma virus and avian leukosis virus (75,200). This peptide is believed to mediate the fusion of host and virus membranes as they are brought together by a conformational change in the peplomer during the entry process (101).

The GP_1 molecules in the peplomer are oriented with the hydrophilic and highly glycosylated C terminus projecting outward into the aqueous environment. This region presumably contains the major determinants for receptor recognition and binding (199,234), whereas the more hydrophobic N-terminal region of GP_1 connects this molecule to GP_2 by a single disulfide bond (200); the N-terminal region probably contributes to the formation of the stalk structure as well. Figure 6 shows a hypothetical model for the structure of the Ebola virus peplomer that is based on x-ray diffraction studies of crystallized GP_2 (141,225), results of site-directed mutagenesis of GP (200), and predictions based on similarities to retrovirus glycoproteins (75). The structure of the Marburg virus peplomer should be very similar. The predicted structure in Figure 6 lacks detailed information regarding GP_1, and x-ray diffraction data for this component will be difficult to obtain because of difficulties in crystallizing extensively glycosylated molecules.

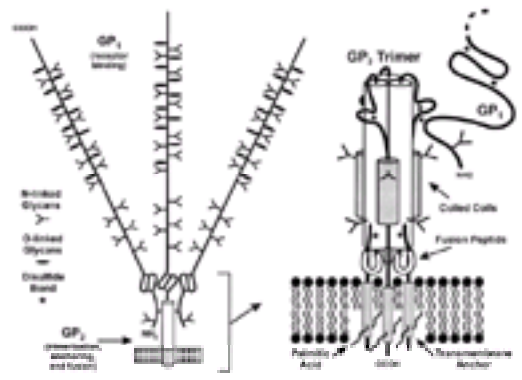

FIG. 6. Schematic representation of a proposed structure for the Ebola virus (Zaire species) surface peplomer (spike) predicted from genetic, biochemical, and x-ray diffraction studies (75,141,199,200,235). The *left* side of the figure shows the spike structure in which three molecules of GP_1 are covalently linked by a single disulfide bond to GP_2 molecules (Cys-53 is known and Cys-609 is predicted) arranged in a trimer and anchored in a lipid bilayer. The N-linked glycans shown attached to GP_1 are predicted from nucleotide sequence analysis (as are those of GP_2), but the number and position of all the O-linked glycans have been not been determined. The loops near the N-terminus of GP_1 formed by disulfide bonding are also predicted. At the *right* of the figure is shown a detailed depiction of the GP_2 trimer, which was generated from similarities to glycoproteins of retroviruses and from structural studies of crystallized, *Escherichia*

coli-expressed, partial sequences of GP_2.

VP40

The VP40 protein is believed to have a matrix protein function. This presumption is based on its being the most abundant protein in the virion, its somewhat hydrophobic profile, its release from purified virion nucleocapsids by nonionic detergents under low-salt conditions, and the position of its gene in the genome (55,61,121,191). By analogy with other matrix proteins, VP40 may facilitate virus budding by interacting with nucleocapsids and the plasma membrane (and at times with intracytoplasmic membranes, forming vacuoles) (185). Specific interactions of VP40 with membrane-associated GP and VP24 during the budding process may also occur. X-ray analysis of crystallized Ebola (Zaire) VP40 has been accomplished, and it should provide important insights into its function (51).

VP24

The VP24 is the third membrane-associated virus protein, and it has a decidedly hydrophobic profile. The role of this protein is unknown, but it may act as a minor matrix protein or function in the uncoating of the virion during infection.

Nonstructural Proteins

Secreted Glycoprotein and Delta Peptide

The SGP of Ebola viruses contains the same approximately 300 N-terminal amino acids as the GP, but the C terminus is unique (29 amino acids). Biochemical and antigenic analysis of SGP have shown that it is structurally distinct from GP (199,213). SGP forms homodimers that are linked in an antiparallel orientation by two disulfide bonds between the first and sixth cysteines on separate molecules. Dimer formation probably occurs in the endoplasmic reticulum. SGP is produced from a precursor molecule that, like GP_0, is cleaved by furin near the C terminus to release a short peptide (40 residues in length for the Zaire species) that contains O-linked glycans (no predicted N-glycans) and has been named delta peptide (214). Because delta peptide has only recently been described, no data on its biologic activity are currently available, but it is secreted from the cell and could have a role in pathogenesis. SDS-PAGE of the SGP shows that it migrates as a broad band containing at least three species, presumably caused by differences in processing of N-linked glycans. The function of SGP is unclear, but there is some evidence that it can bind to and inhibit the activation of human neutrophils (125,234). Because large amounts of SGP are present in the blood of acutely infected humans (195), it is plausible that SGP could contribute to the lack of inflammation seen in severe cases.

Virus Entry and Replication in Host Cells

The entry and replication of filoviruses follows the same paradigm established for rhabdoviruses and paramyxoviruses (5,128,221), and Figure 7 is a generalized depiction of the events. Infection of host cells is initiated by the recognition and attachment of surface peplomers (spikes) to receptor molecules found on the surfaces of host cells. This process of attachment may differ somewhat between Ebola and Marburg viruses, as retroviruses pseudotyped with GP have been shown to differ in their ability to infect host cells treated to alter receptor characteristics (38). An asialoglycoprotein receptor of hepatocytes has been shown to act as a receptor for Marburg virus (16), but it is likely that other receptors are also used by filoviruses. Following attachment, virions are presumed to enter the cell by a process of endocytosis, acidification of the endocytic vesicle, and fusion of virus and host membranes that releases the nucleocapsid into the cell cytoplasm, the site of replication (63,228). The negative-strand nature of these viruses makes transcription of the genome an obligatory event following release of the nucleocapsid into the cytoplasm. Polyadenylated, monocistronic mRNAs are synthesized from virus genes in a 3' to 5' direction (only encapsidated RNA can act as template). NP mRNA can be detected as early as 7 hours after infection, peaking at 18 hours (190). Translation of virus transcripts by the cellular machinery leads to a buildup of virus proteins (primarily NP), followed by a switch from transcription to replication. This switch results in the synthesis and encapsidation of full-length positive-sense RNA (antigenome), which serves as a template for the synthesis of full-length genomic RNA that is rapidly encapsidated. Depletion of irus capsid proteins causes a return to transcription, and eventually an equilibrium is established wherein transcription and replication are concurrent processes. Accumulated nucleocapsids in the cytoplasm can be detected as prominent inclusion bodies that can be easily visualized by light, immunofluorescent, and electron microscopy (129,157,235). When sufficient levels of negative-sense nucleocapsids and envelope-associated proteins are reached, a coalescing of these components occurs at the plasma membrane, or to a lesser extent at membranes forming intracellular vacuoles (59). Matrix protein is believed to facilitate the budding process by drawing the nucleocapsid tightly to the membrane, where it is enveloped and extruded from the cell as an infectious virion particle. Host cell protein synthesis is not shut down, but expression levels do diminish as the infection progresses.

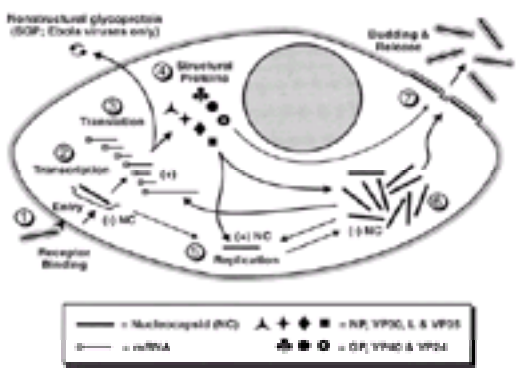

FIG. 7. Filovirus entry, replication, and release from a susceptible eukaryotic cell. The diagram shows stages of gene expression, genome replication, and virus assembly.

The growth of adapted strains of Marburg and Ebola viruses in cultured cells is striking. Intracytoplasmic vesiculation and mitochondrial swelling are followed by breakdown of organelles and terminal cytoplasmic rarification or condensation. Infection with the Reston or Côte d'Ivoire species of Ebola virus proceeds more slowly in tissue cultures, and cytopathic effects are usually less evident. Cytopathic changes can occur in concert with the accumulation of massive amounts of virus nucleocapsid material in intracytoplasmic inclusion bodies and large numbers of virions extracellularly.

Research directed at developing artificial replication systems for both Marburg and Ebola (Zaire) viruses, similar to those developed for paramyxoviruses and rhabdoviruses (180), will eventually enable the creation of infectious virus from DNA clones. T7 RNA polymerase-driven transcription of plasmids containing miniature versions of the Marburg and Ebola virus genomes (with a reporter gene) and encoding critical gene products (NP, L, VP35, and VP30) have been used to generate artificial nucleocapsids capable of being transcribed and replicated (149,151). The ultimate goal of such research will be the development of methodologies that enable specific engineering of filoviruses using recombinant DNA techniques. The ability to produce filoviruses with desired genetic modifications will provide an extremely powerful research tool to study replication, to dissect mechanisms of pathogenesis, and possibly to aid in vaccine development. However, concerns over the potential dangers and misuse of such systems have led to recommendations (and in some cases regulations) limiting the availability of the components, even to reputable institutions in which research is guided by the oversight of a biosafety committee.

CLINICAL FEATURES AND PATIENT MANAGEMENT

Filovirus infections in general are the most severe of the virus hemorrhagic fevers and much has been learned from close observations of acute human cases (29,71,76,100,142,169,171,174,196,231,232). The abrupt onset follows an incubation period of 4 to 10 days and is characterized by fever, chills, malaise, and myalgia. The subsequent signs and symptoms indicate multisystem involvement and include systemic (prostration), gastrointestinal (anorexia, nausea, vomiting, abdominal pain, diarrhea), respiratory (chest pain, shortness of breath, cough), vascular (conjunctival injection, postural hypotension, edema), and neurologic (headache, confusion, coma) manifestations. Bleeding is manifested as petechiae, ecchymoses, uncontrolled oozing from venipuncture sites, mucosal hemorrhages, and postmortem evidence of visceral hemorrhagic effusions. There is often a macropapular rash appearing around day 5; this is a valuable differential diagnostic feature and is usually followed by desquamation in survivors. Abdominal pain is sometimes associated with hyperamylasemia and true pancreatitis. In later stages, shock, convulsions, severe metabolic disturbances, and, in more than half the cases, diffuse coagulopathy supervene. Demise or improvement typically occurs around day 7 to 11, about the time the humoral antibody response is noted (Fig. 8) (132,142).

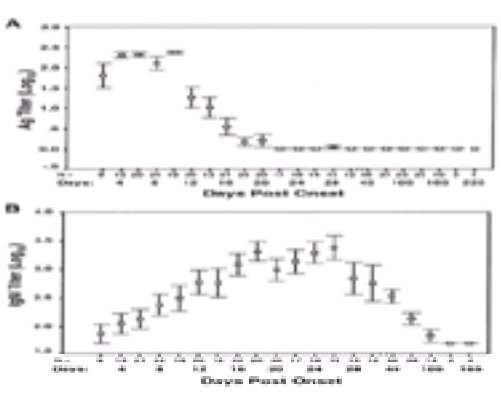

FIG. 8. Ebola Zaire antigen (**A**) and IgM (**B**) $\log_{10}$ titers from serum and blood of patients with laboratory-confirmed Ebola hemorrhagic fever. *Bars* represent 1 standard error of the mean for each time point. Time is shown in days after onset; time is divided into 2-day intervals up to day 30, and into 30-day intervals after 30 days. The numbers just under the horizontal axis are the number of cases in each time group.

The survivors have a prolonged convalescence with sequel including arthralgia, uveitis, psychosocial disturbances, and orchitis (142,184). Serologic studies have suggested that filoviruses of lower pathogenicity for humans (perhaps similar to the Reston species) may circulate in nature (11,111,114,133), and it was recently reported that asymptomatic infections of Ebola virus (Zaire species) occurred in the 1996 outbreak in Gabon (137). However, more extensive and controlled studies are required before such findings can be incorporated into the clinical understanding of human Ebola infections, especially those involving the Zaire species.

Clinical laboratory features of Ebola virus infection are less well documented than those for Marburg, but they appear to be similar. There is an early leucopenia and lymphopenia, subsequent neutrophilia, and marked thrombocytopenia, accompanied (in nonhuman primates) by abnormal platelet aggregation (67,69). Serum enzyme levels are elevated, typically with aspartate transaminase exceeding alanine transaminase, and with alkaline phosphatase and bilirubin levels normal or only moderately elevated. Later in the disease course, some patients may have biochemical and clinical jaundice.

The usual supportive measures for severely ill patients are indicated, including strategies more specific for those with

virus hemorrhagic fevers (167,172). There is no approved antiviral drug that is a useful treatment (ribavirin is ineffective) (97,167), nor are there other treatment modalities for filovirus patients. It is often surmised that improved supportive care will lead to an increase in survival, but there are no data on this subject. In fact, the very extensive virus involvement of the organs of these patients (235,236), the severe immunosuppressive lymphoid tissue lesions, and the lack of evidence of a humoral immune response in fatal cases taken together suggest that there may be a need for some method to limit virus replication before survival can be expected. Indeed, in 1996, a South African nurse infected from an Ebola patient received state-of-the-art care, yet ultimately died of the disease (179).

One approach to antiviral therapy has been the use of cellular S-adenosyl- L-homocysteine hydrolase inhibitors. These drugs are active *in vitro* and in mouse and nonhuman primate models (24,94). It is believed that these drugs act through the accumulation of S-adenosylhomocysteine and its selective inhibition of virus methylation reactions. Toxicity and pharmacokinetics are presently rate limiting in developing these drugs further.

Interferon (IFN)-a has shown relatively little *in vitro* (223) or *in vivo* (58,106) activity in experimental Ebola infections, even when given prophylactically. Patients have high levels of circulating IFN (211), and its use in postexposure prophylaxis would have the disadvantage of inducing fever and other side effects. A single report of treatment of a human infection with IFN and plasma is unconvincing although often cited as an example of the possible utility of these modalities (58).

Antibody therapy with simple convalescent plasma, which has been used successfully with Junin virus (172), seems to offer little in Ebola virus infections. Passive antibody therapy with polyclonal hyperimmune horse sera (19) is of only marginal utility in postexposure prophylaxis models in primates, requiring large volumes given within a very short time of inoculation (106,108,134). Several related approaches, however, may be useful. A human monoclonal antibody with neutralizing capacity was derived from bone marrow RNA libraries of convalescent Ebola patients by phage display, and it has shown protective capacity in the guinea pig model (143). In addition, murine monoclonal antibodies protective in the mouse model have been developed (227). These approaches offer hope for the development of postexposure treatments, but their usefulness will ultimately require validation using a primate model.

Less mainstream considerations include attempts to block the effects of the high levels of cytokines, a proposition that has proven to be difficult in septic shock and adult respiratory distress syndrome (211). During the 1995 Kikwit outbreak, seven of eight patients receiving whole blood transfusions from surviving patients lived (152). There were no controls and the transfusions were usually given to younger patients later in the epidemic and sufficiently late in their clinical course that some patients had already died—all factors that favor survival (188). Antibody is not a plausible candidate for an active ingredient in the transfused blood, but nevertheless the apparent success should prompt research into alternative approaches that might involve other soluble substances or cells in the transfused blood.

DIAGNOSIS

Clinical Diagnosis

Filovirus disease can be suspected in patients with a history of travel to an endemic area if they present with fever and constitutional symptoms. Rural travel, jungle or cave exposure, contact with sick persons, or contact with sick or dead primates all suggest need for additional concern. The laboratory should be used to exclude diseases such as malaria, leptospirosis, relapsing fever, shigellosis, rickettsial disease, and typhoid fever. Unless laboratory diagnosis is timely and accurate, empiric therapy for the other agents may be indicated. Malaria will be the most common potentially lethal confounder, but it must also be recognized that partially immune patients can be parasitemic without having malarial symptoms.

Laboratory Diagnosis

Ebola and Marburg Hemorrhagic Fever

The recent occurrence of Ebola (81,119,145) and Marburg hemorrhagic fever (230) outbreaks has offered an opportunity to utilize more recently developed diagnostic assays and technology on clinical materials collected from these patients. Patients in the acute stages of disease have high case fatality rates, and most of those who die do so without developing detectable antibodies. This emphasizes the diagnostic need for isolation of the virus or detection of its antigens or RNA.

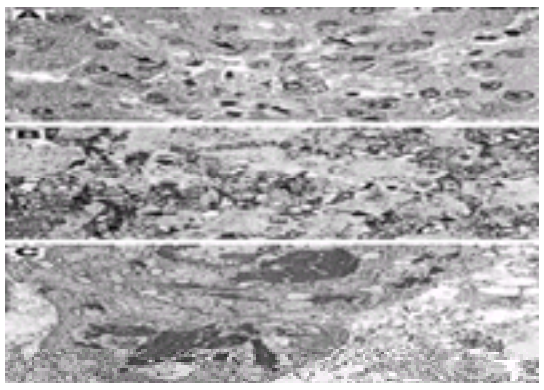
Before the diagnosis can be effectively accomplished, the specimens must be obtained and sent to a laboratory with the appropriate expertise and reagents. Because outbreaks have continued to include significant numbers of care givers who have direct contact with patients (6,72,119,179,231,232), those who collect samples need to take adequate barrier nursing precautions while obtaining the samples (34,122,164). Additionally, special care should be taken to avoid needle sticks and to dispose of the sharps in an appropriate manner so that others avoid needless exposure. Collection of specimens should be done with a mind toward sterility and prevention of cross-contamination of specimens; this has become particularly important in the day of ultrasensitive techniques such as reverse transcriptase–polymerase chain reaction (RT-PCR) amplification for diagnosis and characterization of the virus genome.

Although high-level containment is warranted because of the extreme hazard associated with handling the viruses, virus isolation remains relatively simple and sensitive: The virus grows well in a large variety of cell lines, although Vero or Vero E6 cells have been most used (161,165,209). The virus is relatively stable and some infectious virus may survive less than favorable handling and shipping; care should be taken to ensure the physical integrity for biosafety reasons and to maintain an adequate refrigerated or frozen state for biologic integrity of the sample to maximize diagnostic success. Clinical diagnostic criteria alone will not yield an etiologic diagnosis, particularly as the materials may be coming from relatively remote areas with relatively sparse clinical facilities.

An integrated approach to diagnosis is particularly useful when initial specimens from an outbreak or individual patients are being received. This includes attempts to isolate the virus, detect the virus antigens, and amplify the virus RNA by

RT-PCR with subsequent sequencing. Both antigen detection and the amplification of the virus RNA can be done on materials that have been rendered noninfectious. An efficient means of inactivating the virus for antigen detection (and serology) is the utilization of gamma irradiation from a cobalt-60 source (56). This allows the safe manipulation of the material outside of the containment laboratory, where work can be more expeditiously carried out. Likewise, the nucleic acid can be amplified by purification of the virus RNA from materials treated with guanidinium isothiocyanate, a chemical chaotrope that denatures the proteins of the virus and renders the sample noninfectious. Virus isolation, on the other hand, proceeds within the BSL4 laboratory where cytopathic effects from most of the virus strains can be recognized by microscopy and the virus identified by immunologic or electron microscopic means (see Fig. 1 and Fig. 2).

Detection of either Ebola or Marburg virus antigen by antigen-capture enzyme-linked immunosorbent assay (ELISA) has often been the most rapid means of diagnosing infections. The assay time is approximately 3 to 4 hours, and detection of antigen in the blood or serum of either nonhuman primates or patients in the acute course of the disease was very successful when compared to virus isolation or to RT-PCR for Ebola viruses (130,131,132 and 133,195). This assay was also useful in detection of virus antigen in frozen tissues (131). Filovirus antigens can also be detected by immunohistochemical (IHC) examination of formalin-fixed tissues by using specific polyclonal and monoclonal antibodies (Fig. 9). These methods have a unique role in cases in which archival tissues are the only specimens available for diagnostic testing. During the epidemic in Kikwit, Zaire, a novel and sensitive IHC test was developed at the Centers for Disease Control (CDC) in which skin biopsy specimens were used for the diagnosis of Ebola virus HF (82,138,236). Formalin-fixed biopsy specimens are not infectious, they may be taken in the most basic field conditions, and they may be sent without special precautions or refrigeration. This technique was useful for the diagnosis of fatal cases in subsequent Ebola outbreaks in Gabon (P. Rollin, personal communication, 1996) (236); lesser sensitivity was noted in the recent Marburg outbreak in the DRC (230).



P>**FIG. 9.** Pathologic features seen in the liver of an Ebola virus–infected human. **A:** Sinusoidal dilation and congestion and hepatocellular necrosis (H&E, ×250). Numerous filamentous intracellular Ebola viral inclusions (*arrows*) are seen in association with an area of coalescent hepatic necrosis. **B:** Ebola antigens are seen throughout tissue section in sinusoids, sinusoidal lining cells, and hepatocytes (*arrows*) (immunoalkaline phosphatase staining, naphthol fast red substrate with light hematoxylin counterstain, ×158). **C:** Electron micrograph of liver showing several large Ebola virus inclusions within infected hepatocytes (uranyl acetate and lead citrate stain, ×6,600). Abundant extracellular Ebola virus particles are also seen in hepatic sinusoids. Note variation in size and shape of viral particles associated with necrotic debris.

IgM-capture antibody ELISA proved useful in the diagnosis of recent infections in surviving patients (158). The IgG response of the patients was somewhat delayed and realistically could be expected only in the early convalescent sera of those patients who were destined to recover from their infections (132). The IgM antibodies detected by this test have been found to persist for only 2 to 3 months in macaques that were experimentally infected (133) and a similar relatively short period in surviving humans (132).

The use of RNA amplification by RT-PCR has added another rapid and sensitive tool for the diagnosis of Marburg or Ebola virus infections (189). The technique was first sparingly utilized during the 1989–1990 outbreak of the newly discovered Ebola Reston virus, but it has been used much more commonly in the recent human outbreaks in DRC in 1995 and in Gabon from 1994 to 1997, and in imported primates in Texas in 1996 and follow-up in the Philippines in 1996 (181,195). The RT-PCR should be combined with direct sequencing of the amplified product; this provides virus sequence information that enables phylogenetic comparison of the virus in a clinical specimen to other, previously recognized and characterized strains of the virus, and thus it can help determine the “molecular epidemiology” of an outbreak such as the multiple introductions in the series of Gabon outbreaks from 1994 to 1996 (82). Determination of sequence from amplified DNA product also mitigates one of the shortcomings of the technique: The high sensitivity of RT-PCR renders the technique prone to cross-contamination from other specimens or materials in the laboratory. If the sequence obtained from the clinical specimen matches that of control materials or previously recognized virus stains, skepticism is warranted. Precautions should be taken to perform RNA extractions in areas where chances of cross-contamination are minimized. We also recommend not reporting results on the basis of the initial PCR product but waiting until the sequence has been compared to that of other strains of the virus; the virologist should be satisfied that the product does not represent cross-contamination.

Retrospective Identification of Individuals Previously Infected with Ebola and Marburg Viruses by Testing for Virus Antibodies

Efforts to determine the prevalence of past filovirus infection with older generations of serologic tests, mostly the indirect fluorescent antibody test (IFAT) (113), have generally met with criticism because of the lack of specificity of the assay, as demonstrated when control groups with no exposure to filoviruses (32,169) were included. Individual filovirus antigens either tested with Western blot assay or expressed by molecular techniques have been developed for serologic tests to a limited degree, but using the assays for field testing with appropriate controls has been limited, leaving the applicability of these newer approaches largely unknown.

Experience with the IFAT during and following the 1989 Ebola Reston episode left us convinced of the lack of specificity of this assay for detecting past infections with filoviruses. This was evidenced by the finding of high prevalence among primate colonies containing only animals that had been bred in closed facilities for several generations without the occurrence of any disease recognizable as filovirus infection. Similarly, animal caretakers were found with moderate IFAT Ebola antibody prevalence, but there were also many individuals found to be positive among administrative personnel with little or no contact with the primates, and persons from the United States general population had an Ebola IFAT antibody prevalence of 2.7% (31). Even though the IgG ELISA test is more specific in nonhuman primates and North American human populations (133), background problems are encountered when testing populations from central African countries. There are many sera that nonspecifically bind to the noninfected antigen control, often to an extent that it is difficult to interpret the test. Adsorbing these sera with normal cell antigen does help but does not altogether obviate the difficulty.

Direct Visualization of Virus

Electron microscopy has been particularly useful in the diagnosis of filovirus infections (see Fig. 1 and Fig. 2). Negative-contrast electron microscopic examination of initial-passage cell culture supernates can be performed with safety after prefixation. Although the fine structure of virions is distorted, resolution of nucleocapsid structures within virions can establish the diagnosis (53,156,235). A similar approach may be tried on patient serum or plasma. For thin-section electron microscopic examination of patient tissues, any standard fixation (e.g., 1% glutaraldehyde in phosphate buffer), embedding (usually a rapid polymerization method), and staining system can be used. Most experience has been gained with examination of liver tissue, obtained at autopsy or via agonal biopsy. In several cases of Marburg and Ebola hemorrhagic fever, virions and uniquely structured inclusion bodies have been identified in liver tissue (153,173). Direct examination of body fluids has been valuable (80), but in inexperienced hands this can lead to a mistaken diagnosis if confirmatory methods are not available (118).

PATHOLOGY AND PATHOGENESIS

Infection in Experimental Animals

The pathology of Ebola virus infections has been extensively studied using tissues from outbreak cases and experimentally infected monkeys, guinea pigs, and mice. In general, the pathology of these models has a reasonable resemblance to that seen in humans (8,9,22,45,49,67,69,102,103,104,153,156,187,236,237). Of the animal models, the most realistic involves macaques, which undergo a course of infection after inhalation or injection that closely resembles the human disease (8,103). Other monkeys as well as guinea pigs serve as good experimental models, although a few passages in guinea pigs may be needed to adapt the viruses to that host (187). A mouse model has been developed for Ebola (Zaire species) (23), which is very advantageous given the abundance of reagents available for studying cell biology and immunology, and it also is useful for examining the genetic basis for the host responses to disease. However, the mouse model is probably the most distant from human infection, and data derived from these studies may not correlate with human disease and/or may be deficient in identifying certain processes.

In monkey models, the virulence of filoviruses is quite variable; a similar variability is seen in human infections (see later section, Epidemiology). Among Ebola viruses, the Zaire species is the most virulent and the Reston species is the least virulent (21,22,66,107). Infections with the Zaire species usually progress rapidly and are uniformly lethal 4 to 8 days after infection; as little as one infectious unit is required to cause disease. Naive animals can survive infections caused by the Sudan and Reston species, with times to death ranging from 7 to 14 days (21,22,66). Little is known regarding the virulence of the Côte d'Ivoire species in monkeys, but its slow growth in tissue culture tends to indicate a virulence similar to that of the Reston species. Monkeys can also survive infections with Marburg virus (112), and virulence appears comparable to that of the Sudan species of Ebola virus.

Pathology in Humans

The pathologic changes seen in patients dying with all filovirus infections are similar (52,53,153,154,235,236). Extensive necrosis is seen in parenchymal cells of many organs, including liver, spleen, kidney, and gonads; little infiltration is seen within infected tissues. The most characteristic histopathologic features are seen in the liver (see Fig. 9), where hepatocellular necrosis is widespread with intact, hyalinized, ghost-like cells often remaining in place amid large amounts of karyorrhectic debris. Often, extraordinary numbers of virions are present in this debris. Characteristic intracytoplasmic inclusion bodies (aggregates of viral nucleocapsid material) are present in intact hepatocytes. Light microscopic, electron microscopic, IHC, and *in situ* hybridization studies show concordance between tissue damage, the presence of viral antigens and nucleic acid, and sites of virus replication, suggesting that direct viral damage is one major element in the pathogenesis of the disease (see Fig. 9). Infection and damage to mononuclear phagocytes and endothelial cells are also characteristic of filovirus infections; Kupffer cells and capillary endothelium are major targets of infection. This is thought to play a critical role in the pathogenesis of filovirus infections through the secretion of physiologically active substances, including cytokines and other inflammatory mediators.

Significant injury to the microvasculature and increased endothelial permeability appear to be central to the pathogenesis of the shock and bleeding seen in filovirus infections. Spleen and lymph nodes show various degrees of lymphoid depletion with extensive vascular follicular necrosis and necrotic debris. These lymphoid lesions are also potentially very important in the outcome of infection, given the lack of an effective immune response in fatal cases (132) and the evidence for other forms of immunosuppression in surviving patients (117).

Pathogenesis of Disease

As noted earlier, cells of the mononuclear phagocytic system (macrophages and monocytes) have been implicated as sites of replication early in infection. Figure 10 is a schematic representation of the infection and spread of filovirus in

human and nonhuman primates. Filovirus infection of mononuclear phagocytes may also affect the signaling and processing of antigen, which could hamper the host's ability to mount a strong cell-mediated immune response. It has been proposed that sessile macrophages may act as vehicles for the transport of filovirus particles to specific organs (i.e., lung, liver, and spleen) (45,187,201,202), as they are highly susceptible to infection *in vitro* and they produce large amounts of infectious virions (59,98). Infected macrophages may also contribute to shock in fatal cases, as *in vitro* and animal studies have shown that cytokines, such as tumor necrosis factor (TNF)-a, are released (59,95,98); as noted later, elevated TNF-a levels are also seen in acute human cases of Ebola hemorrhagic fever (211). In a study of Marburg virus disease in guinea pigs (99), it was shown that treatment with anti-TNF-a serum on postinfection days 4 to 7 can prevent death (50% survival versus 100% mortality in controls), which is additional evidence for a possible role of cytokines in the disease process.

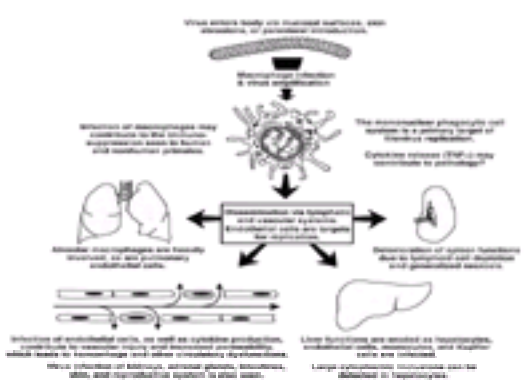


FIG. 10. Schematic illustration of the events and pathology associated with severe filovirus infections of human and nonhuman primates.

Elevated levels of cytokines [interleukin (IL)-2, IL-10, TNF-a, IFN-b, and IFN-g] have been detected in the serum of acutely infected patients who ultimately died of Ebola hemorrhagic fever during the 1995 Kikwit outbreak (211). High levels of cytokines may well contribute to the fatal outcome. Both Ebola and Marburg viruses grow well in human endothelial cells *in vitro* (86,87,203), which could account for the hemorrhaging and shock syndrome seen late in the disease. Infection of cultured human umbilical vein endothelial cells with Ebola Zaire have also shown that induction of immunomodulatory genes (MHC I family, IL-6, interferon regulatory factor-1, ICAM-1) and antivirus genes (2'-5'-oligoadenylate synthetase and PKR) by double-stranded RNA and interferons (IFN-a and IFN-g) is strongly inhibited by Ebola Zaire infection (85,86). Inhibition is selective, as induction of IL-6 and ICAM-1 by IL-1b is not inhibited (86). If these *in vitro* responses correspond to events *in vivo,* then infection of endothelial cells by Ebola virus would contribute to immunosuppression. These cells would be impaired in their ability to stimulate inflammation, cytotoxic T cell development, and humoral responses (via ICAM-1, MHC I, and IL-6, respectively), which could leave infected cells hidden from immune surveillance and clearance mechanisms.

In Ebola virus disease, it was initially speculated that SGP had a role as a decoy molecule that would help misdirect protective responses away from GP present on the surface of virions and infected cells. However, as their functional and structural properties came to light, it became evident that the roles of these two related glycoproteins differed dramatically. GP has been used to pseudotype murine retroviruses, and it directs these particles to cell types distinct from those recognized by SGP (234,235). Specifically, GP interacts preferentially with endothelial cells, though it may also bind to monocytes, hepatocytes, and other cell types. In contrast, SGP appears to bind to neutrophils through an interaction that involves the Fcg3 receptor, CD16 (125,234). Whether this interaction is direct or indirect remains uncertain, but it appears to affect neutrophil function, preventing the down-modulation of L-selectin in response to serum stimulation. SGP may also affect cell surface interactions of CD16 and other cell surface molecules that may affect cellular activation. Thus, it is likely that SGP inhibits the inflammatory response to infection, wheres GP promotes virus attachment and entry in endothelial cells, which are subsequently vulnerable to the virus's cytopathic effect.

It has been suspected that GP gene products have a major role in the pathogenesis of filovirus disease, partly because of the effects of the immunsuppressive motif found in GP_2, but also because of the potential to affect the functions of membrane-bound and/or soluble substances in the body (41,42,64,219). Recent studies have shown that the Ebola virus GP not only is capable of inhibiting T-cell proliferation in response to mitogen (41,42), but its expression in cultured human endothelial cells was observed to cause cytopathic effects (a decrease in aV integrin levels was noted), whereas expression of other virus proteins had little or no effect (234,235). This cytotoxic property was also demonstrated in explanted human and porcine blood vessels, resulting in endothelial cell loss and increased vascular injury (permeability). This toxicity was associated with the variable or mucin-like region, as deletion of this sequence abrogated the deleterious effect. It is expected that further characterization of the biologic activities of GP molecules will provide added support for their prominent role in pathogenesis.

Immunology and Protection

Filovirus infections of human and nonhuman primates are characterized by a lack of inflammation and the development of an undefined form of immunosuppression that inhibits the clearance of virus (171,196). In most fatal cases, antibodies against filovirus proteins are not detectable (see Fig. 8). In those cases that survive or where the disease is protracted, a slightly delayed humoral response is noted. In experimental animals, serum taken from convalescing patients or laboratory animals recovered from infection failed to protect consistently against disease, and antibody-mediated neutralization of virus replication in cell culture is inefficient and difficult to demonstrate (106,108,170,223). Because inflammation is lacking, cells of the mononuclear phagocytic system are infected, and humoral responses are inhibited, it appears that immune and inflammatory systems are both targets and potential responders to virus infection. However,

the role of specific lymphoid subsets and their possible mechanisms of immune protection are unclear.

Anecdotal reports that antibodies may protect against disease during outbreaks were contradicted by controlled studies in experimental primate models in which only minor delays in symptoms were seen following passive transfer of convalescent antibody, with no significant difference in overall survival (106,108). Recently, selected monoclonal antibodies derived from patients recovered from infection (143) were shown to neutralize Ebola virus infection in selected virus replication assays *in vitro*. Several classes of murine monoclonal antibodies directed against epitopes of the Ebola glycoprotein have since been identified, some of which provided protection against lethal challenge in a murine model of infection (227). These data suggested that antibodies may contribute to immune protection, but by themselves they are unlikely to be responsible for recovery or to confer solid protective immunity. The lack of a strong humoral response in fatal human and nonhuman primate infections, together with the inefficiency of antibody-mediated neutralization of virus, would suggest that a vigorous cell-mediated response is an important component in virus clearance (159). At the same time, it remains possible that selected, low-frequency antibodies can be found that may reverse the symptoms and outcome of infection and could prove therapeutically beneficial.

Attempts were made to develop killed vaccines to protect against filovirus disease using formalin-fixed or heat-inactivated virion preparations to immunize guinea pigs or nonhuman primates, and they were unsuccessful (1,39,96,99,140). Although humoral responses were generated in these animals, the preparations did not elicit strong protective immune responses. Encapsulation of killed, gamma-irradiated Ebola virions in liposomes containing lipid A has been shown to improve cytotoxic T-cell responses in mice (176), but protection against a lethal challenge was not examined. Traditional strategies of attenuating viruses for use as vaccines in humans would be unacceptable because of the potential for reversion back to a wild-type form. There is insufficient information on the pathogenicity of less virulent strains (such as the Reston subtype) passaged in human cells, and infection of monkeys appears to indicate that a strong cross-protective immunity does not develop (21,22,66), despite significant antigenic similarities among Ebola virus species.

Efforts to mimic natural infections through the use of recombinant DNA techniques to stimulate cytotoxic T-lymphocyte (CTL) responses via *de novo* synthesis of virus proteins (MHC class I restricted) have been very promising. Major progress in experimental vaccine development was reported first in the guinea pig, where it was possible to develop protective immunity against Ebola virus infection by genetic immunization (233). Immunization with plasmids encoding the virus NP, SGP, or GP elicited humoral and cellular immune responses against these gene products. In the case of NP, the response was primarily humoral in nature, whereas the exposure to SGP and GP revealed T-cell proliferative and cytotoxic responses. Although protection against lethal challenge was observed for each of these plasmids when animals were challenged within 1 month of the last immunization, long-lasting protection was observed only with GP or SGP. Protection correlated with antibody titer and antigen-specific T-cell responses to these gene products. These studies documented the feasibility of vaccination against Ebola virus infection and demonstrated that immunity can be developed to this pathogenic virus. Despite the correlation with antibody titer, it was not possible to provide protective immunity by passive transfer of immunoglobulin. Protection has also been observed in the murine model using plasmids expressing either NP or GP (210); immunity was long lived and CTL responses were induced.

An infectious replicon form of Venezuelan equine encephalitis (VEE) virus was also used in an attempt to induce protective immune responses against both Ebola and Marburg viruses. This system was used to immunize mice, guinea pigs, and monkeys (cynomolgus macaques) against the GP and NP of filoviruses (92,175), and it proved very effective in protecting animals against Marburg virus. For Ebola virus, protection has been induced in guinea pigs and mice, but monkeys have not been protected using the VEE replicon system. Immunization of guinea pigs with recombinant vaccinia viruses expressing Ebola virus GP has also shown some promise, but vaccinia viruses expressing NP, VP35, VP40, and SGP were ineffective in protecting against disease and death (84).

Vaccination with protein preparations also induces some protection against filovirus disease, as has been shown with a secreted form of the Marburg virus GP expressed in a baculovirus system (90,91). Partial protection against the homologous strain of Marburg virus was demonstrated, but this protection was much less effective against a genetically and antigenically disparate strain of Marburg virus (91).

The current trend in filovirus vaccine development is to use genetic immunization to prime the immune response and to boost with some other recombinant virus expression system. Genetic immunization is known to stimulate a strong cell-mediated immunity, which is critical to filovirus clearance and long-term protection, and boosting with a vectored system (VEE, vaccinia, adenovirus, or baculovirus system) stimulates a strong response that is not easily attained by continued DNA injections. It is anticipated that this approach will enable the stimulation of an immune response vigorous enough to protect nonhuman primates from lethal challenge.

Several recent reports provide insights into immunologic determinants of resistance and predictors of survival. Analysis of patients in outbreaks in northern Gabon in 1996 showed no difference in serum antigen levels between survivors and nonsurvivors during the first few days of illness, suggesting that host defense rather than early virus replication determines survival (4). A variety of immune responses were examined, including IFN-g levels in the serum, as well as T-cell responses measured using RT-PCR of mRNA. Patients who suffered from fatal infections showed a higher level of IFN-g protein initially, but mRNA levels for indicators of T-cell function such as CD3, CD8, perforin, or IFN-g fell. The decline in cytokine levels may reflect the loss of response of mononuclear cells such as seen late in sepsis (3), but the disappearance of T-cell receptor mRNA from blood suggests that actual cell death occurs. The presence of markers of apoptosis in the blood of patients who died, and decreases in the antiapoptotic molecule bcl-2 support the occurrence of widespread programmed cell death of T cells, as reported in lymphoid tissues of macaques infected with Ebola virus (77). Importantly, surviving patients developed more effective antibody responses to the virus nucleoprotein early and developed more sustained T-cell responses that persisted into the convalescent phase. These findings are consistent with other reports that markedly elevated levels of IFN-g, IFN-a, IL-2, IL-10, and TNF-a are associated with a poor prognosis during infection, as noted earlier (211).

There are also several similarities between human disease and relevant animal models of vaccine-induced protection. In

guinea pigs immunized with Ebola virus gene products, successful protection against lethal challenge was dependent on T cells. Both in humans and in guinea pig studies, the nucleoprotein elicited primarily a humoral response, whereas the GP antibody responses were relatively lower. The studies of natural infection in humans are thus consistent with those in rodent vaccination models. The development of antibody responses correlated with survival in the guinea pig and most likely reflected the successful T-cell responses required for antibody production, as has now been suggested in humans. It remains uncertain whether protection against early infection requires only T-cell immunity. More likely, innate immune or inflammatory responses are needed to more effectively contain virus replication. Although the humoral response is clearly not the major mechanism of recovery, it may have an ancillary role, as evidenced by the success of minor components of the polyclonal immune response to protect animals when they are rescued as monoclonal antibodies (227). Although the specific contributions of innate and acquired immunity in response to infection remain poorly understood, Ebola virus infection nonetheless serves as a model for the analysis of immunity to infectious causes of hemorrhagic fever and other virus infections. Further studies regarding its immunopathogenesis will help to define the pathophysiology of this disease and contribute to strategies for vaccine development.

EPIDEMIOLOGY

Marburg Virus

The first recognition of filoviruses and of filovirus disease occurred in 1967 when a physician in Marburg, Germany, noted a severe hemorrhagic illness among patients presenting to a local hospital. The primary patients had all handled monkey blood, tissues, or cell cultures traced to a shipment of African green (vervet) monkeys (*Cercopithecus aethiops*) exported from Uganda. Limited secondary spread was seen in contacts of the index cases in Marburg, Frankfort, and Belgrade, with the final toll being 26 primary and six secondary cases. The epidemic ceased with the euthanasia of the infected monkeys.

Between 1975 and 1987, three isolated index cases were identified among tourists or expatriates in sub-Saharan Africa, with no further transmission or only limited spread to a traveling companion or health care worker (76,112,198). In 1999, indigenous Marburg virus infection among native Africans in rural areas was first confirmed during a large and ongoing outbreak in Durba, northeastern region, DRC; those infected were mostly gold miners (230). Incidentally, this area has had multiple similar small outbreaks of a severe disease since 1994, with retrospective laboratory confirmation of Marburg infection in one survivor.

Ebola Virus, Zaire and Sudan Species

The first recognized outbreaks of Ebola hemorrhagic fever occurred simultaneously in northern DRC and southern Sudan in 1976, but they were caused by two distinct species (47,115,169,197). No index case was clearly identified in the Sudan outbreak, although initial cases originating in Nzara, Sudan, involved six workers at a cotton factory. The disease initially spread through nosocomial transmission, with the use of contaminated needles and lack of barrier nursing practices fueling the epidemic. The case fatality in the Sudan outbreak was 53%. The outbreak in DRC centered around a Belgian mission hospital in Yambuku, Equateur Region. During the 7-week period of the outbreak, 318 cases were identified with a case fatality of 88%. The single most significant factor in the spread of infection in the hospital was the reusing of syringes and needles, although secondary transmission to family members caused 45% of all recorded infections. The outbreak ended with closure of the hospital and quarantine of sick patients by local village practices.

The disease then vanished except for an isolated case in northwestern DRC in 1977 and a small outbreak in southern Sudan in 1979 associated with the same cotton factory in Nzara. Ebola hemorrhagic fever dramatically reemerged in DRC in 1995, when a total of 315 cases (81% case fatality rate) occurred over 7 months, centered in Kikwit but involving an additional 20 villages. The earliest documented patient was a charcoal worker, in whom the diagnosis was missed. For 3 months, the disease spread person to person in the community until it was amplified in the hospital setting and finally recognized.

Since then, three separate outbreaks caused by Ebola (Zaire species) were identified in Gabon over a 3-year period. In 1994, an outbreak of Ebola hemorrhagic fever occurred north of the provincial capital of Ogooue-Ivindo; it was retrospectively identified after originally being misdiagnosed as yellow fever. In January 1996, another outbreak, near the site of the 1994 outbreak, was linked to the butchering for consumption of a dead chimpanzee. In 1996–1997, there was a 7-month outbreak in Booue province, Gabon, involving 60 cases (case fatality, 75%) associated with eight generations of secondary cases and with secondary cases in the capital. A noteworthy case of secondary transmission involved the death of a nurse in Johannesburg who had been caring for a physician from Libreville, the capital of Gabon, with unsuspected Ebola hemorrhagic fever.

Most recently, the Sudan species has returned to biomedical attention in an epidemic beginning in Uganda in September 2000 and ending in January, 2001. More than 300 cases occurred with a case fatality of approximately 50%. The epidemic seems to have a single origin, with mechanisms of spread similar to that of prior outbreaks.

Ebola, Côte d'Ivoire Species

In 1994, a new Ebola species was isolated from an infected ethnologist in the Tai Forest reserve in Côte d'Ivoire. She had performed a necropsy on a chimpanzee from a troop that had lost several members to an illness later identified as Ebola (71,135). Later, a single seroconversion suggested a second surviving human case in nearby Liberia. This virus isolation extended the geographic distribution of known Ebola cases to include most of the African rain forest.

Ebola, Reston Species

In November 1989, an Ebola virus species with low or no pathogenicity for humans was recognized in a shipment of cynomolgus monkeys (*Macaca fascicularis*) housed at a quarantine facility in Reston, Virginia. These monkeys were

imported from the Philippines, and an unusually high mortality was observed in infected animals during quarantine. Simian hemorrhagic fever virus was also circulating in the facility (48), and efforts to culture this virus led to the detection of Ebola Reston (105). Four cases of acute filovirus infection were confirmed among the caretakers, none of whom experienced a clinical illness (166). Resumption of importation of monkeys has led to new outbreaks of monkey disease in the United States as late as 1996 (183) and Italy in 1992. Subsequent investigations have traced all the shipments except one to a single source in the Philippines. The mode of contamination of this exporter's holding compound has never been ascertained, although the virus either persisted or was reintroduced from wild-caught animals, resulting in continued movement of infected macaques. A few infected handlers were also identified by serologic methods without reports of severe illness or suspicious deaths among this cohort (31,32,35,89,145). Improved shipping, housing, and quarantine regulations have prevented human infections or hazard to the community in the United States (50).

Patterns of Filovirus Infections of Humans

The epidemiology of human infections in nature, besides the internationally recognized outbreaks, is unknown. However, the time elapsed between occurrence of the index cases and the recognition of the subsequent large outbreaks suggests that sporadic cases of unrecognized filovirus infections could readily pass unnoticed (109). The number of such identified clusters in this decade after a 20-year presumed hiatus may represent a combination of unidentified ecologic factors and increasing diagnostic interest in the wake of the Kikwit epidemic. Serologic surveys revealed antibody prevalence from 10.2% among gold panners in Gabon, to 9.3% among rural villagers in the DRC using ELISA-based assays. Ebola infection, potentially with nonpathogenic strains or strains of low pathogenicity, may be quite frequent in select rural African populations (81,111,133).

Whatever the source of the initial index case, person-to-person transmission is the means by which human filovirus outbreaks have been propagated. This generally involves intimate contact; secondary attack rates have not exceeded 10% to 15%, indicating that transmission is not efficient. However, this risk increases as a function of contact—for example, from 23% for family members sleeping in the same room as the patient, to 81% among persons providing active nursing care to a patient during the 1976 Sudan outbreak (6). The need for this intimacy is reflected in the relative paucity of infected children, who are less likely to be primary care givers for ill family members (54). Nosocomial transmission is a special problem and hospitals have often served as a source of disease amplification into the community and to health care workers. Health care providers pay a high price during the epidemics: A quarter of all cases during the 1995 Ebola Zaire outbreak were among health care workers. Extreme care should be taken with infected blood, secretions, excretions, tissues, and hospital materials and waste. Well-documented and surreptitious reuse of needles and syringes has also played a role in these outbreaks. And no person whose contact was exclusively parenteral during the 1976 Zaire outbreak survived. Sexual transmission has been reported with Marburg virus and appropriate precautions should be taken during 3 months of convalescence, based on isolation of filoviruses from semen, identification of virus RNA in genital secretions, and epidemiologic data (142,181,184).

Filoviruses are transmissible to nonhuman primates in the laboratory by aerosols (10,110), and virions have been identified in alveoli of infected monkeys (79,102,157,166). Furthermore, the outbreak of disease caused by the Reston species of Ebola virus among quarantined monkeys in 1989–1990 was strongly suspected to have been transmitted by droplets and perhaps small-particle aerosols (166). However, these animals were housed in a poorly ventilated building in which aerosols were likely to have been largely generated by handlers cleaning the facility. Aerosol transmission has not been unequivocally implicated in human outbreaks to date. Extremely efficient person-to-person transmission in the form of superspreaders, two individuals who may have been the source of infection for over 50 cases in the 1995 Ebola Zaire outbreak, has been recently reported (119). The mechanism of heightened transmission was not identified, although contact with the patient and/or cadaver was strongly implicated. In all episodes, isolation of patients and use of strict barrier nursing procedures, including protective clothing and respirators (special masks used for tuberculosis precautions provide a reasonably available source of protection), have been sufficient to rapidly interrupt transmission in the hospital. For community members, residual risks are present from cadavers, which should be handled accordingly (54).

Natural History of Filoviruses

The origin in nature and the natural history of Marburg and Ebola viruses remain a mystery despite a number of attempts to backtrack from human index cases in Africa or from monkey epidemics in Africa and the Philippines (25,46,136,155,182). Following the 1989–1990 Ebola Reston virus outbreak among monkeys imported from the Philippines to the United States, there was some speculation that nonhuman primates might be the primary reservoir. This would seem unlikely, given that filoviruses are highly pathogenic for nonhuman primates (66,70), and there has been no evidence for latent virus infection in these animals (68). It would seem that the viruses are zoonotic—transmitted to humans from ongoing life cycles in animals or arthropods (70,147). Lack of replication in arthropod cells or inoculated arthropods (208,223) argues against an arthropod intermediary for Ebola, but there are many possible arthropod hosts that have not been tested. The most extensive arthropod field surveys have failed to show any evidence for the presence of Ebola virus (178). Filoviruses share several biologic, ecologic, and virologic characteristics with Lassa virus, an arenavirus maintained by chronic infection of rodents in Africa: (a) the human infections caused by each are relatively insensitive to the antivirus effects of IFN, and in each cellular immunity is thought to play the dominant role in recovery, (b) each of the viruses has highly glycosylated peplomer proteins, possibly affecting immune surveillance and recognition, and (c) both viruses have a proclivity for infecting macrophages and induce immunosuppression after experimental infection in some hosts. The similarity of this overall profile suggests that filoviruses may establish persistent infection in a mammalian reservoir host(s).

Investigations of filovirus outbreaks in humans have provided circumstantial evidence that bats may be involved in the spread of filovirus disease. Two index Marburg virus cases were known to have visited the same bat-infested cave in Kenya, near the area in Uganda that produced the infected monkeys involved in the 1967 outbreak. Recently, many cases of Marburg virus disease in the northeast region of the DRC had some connection, directly or indirectly, with a bat-infested gold mine. Also, an index case in the first Ebola Sudan outbreak worked in a bat-infested factory building. Despite failure to detect virus in these environments, the possibility still exists that a transmission cycle among bats plays

some role in the natural history of filoviruses. This is supported by laboratory transmission studies, in which persistent infection of bats for up to 21 days following inoculation, with excretion in feces, has been documented (205). An extensive 3-month survey of native vertebrates following the 1995 outbreak in DRC, albeit months delayed from the purported index case, failed to identify Ebola-specific antibodies or a virus isolate in over 3,000 vertebrates sampled (136).

PREVENTION AND CONTROL

It is difficult to devise a strategy for primary prevention of human filovirus infections without knowing the reservoirs of the viruses in nature, without understanding what governs virus flow, and without knowing how human contact occurs. However, it is clear that the pattern of spread once the virus enters the primate population is by close contact. Thus, contact with sick or dead monkeys should be avoided. Humans with hemorrhagic illnesses should be taken to the hospital and nursed with barrier precautions. Methods to achieve barrier nursing, waste disposal, and other key elements inexpensively and practically in Africa have been devised, and a field-tested manual is available (138). One of the important elements is provision of sterile equipment for injections, a remarkable and tragic lack in Africa today.

CHAPTER 41 Paramyxoviridae: The Viruses and Their Replication

Robert A. Lamb and Daniel Kolakofsky

The *Paramyxoviridae* include some of the great and ubiquitous disease-causing viruses of humans and animals, including one of the most infectious viruses known (measles), some of the most prevalent viruses known (measles, respiratory syncytial, parainfluenza viruses, and mumps virus), a virus that has been targeted by the World Health Organization for eradication (measles), viruses that have a major economic impact on poultry and animal rearing (Newcastle disease and rinderpest), and some newly discovered viruses and diseases (pinniped morbilliviruses, Hendra virus, and Nipah virus). The *Paramyxoviridae* are enveloped, negative-stranded RNA viruses that have special relationships to two other families of negative-strand RNA viruses, namely the *Orthomyxoviridae* (for the biologic properties of the envelope glycoproteins) and the *Rhabdoviridae* (for the similarity of organization of the nonsegmented genome and its expression). The *Paramyxoviridae* are defined by having a protein (F) that causes viral–cell membrane fusion at neutral pH. The genomic RNA of all negative-strand RNA viruses has to serve two functions: first as a template for synthesis of mRNAs, and second as a template for synthesis of the antigenome (+) strand. Negative-strand RNA viruses encode and package their own RNA polymerase (RNAP), but mRNAs are synthesized only after the virus has been uncoated in the infected cell. Viral replication occurs after synthesis of the mRNAs and requires the continuous synthesis of viral proteins. The newly synthesized antigenome (+) strand serves as the template for further copies of the (–) strand genomic RNA.

CLASSIFICATION

The family *Paramyxoviridae* has been reclassified in 2000 by the International Committee on the Taxonomy of Viruses into two subfamilies, the *Paramyxovirinae* and the *Pneumovirinae. Paramyxovirinae* contains three genera, Respirovirus, Rubulavirus, and Morbillivirus. *Pneumovirinae* contains the genera Pneumovirus and Metapneumovirus. The new classification is based on morphologic criteria, the organization of the genome, the biologic activities of the proteins, and the sequence relationship of the encoded proteins, now that most of the genome sequences have been obtained. The recently isolated Hendra virus, from horses and humans in Australia, Nipah virus, from pigs and humans in Malaysia, and a tree shrew (*Tupaia*) Paramyxovirus are presently unclassified members of the *Paramyxovirinae.* Newcastle disease virus (NDV) and other avian paramyxoviruses have been included in the Rubulavirus genus, primarily because of their nonconserved intergenic junctions and lack of a C-protein open reading frame (ORF), hallmarks specific to the Rubulavirus genus (see later, and Fig. 6). However, the organization of the NDV P gene and its mRNA editing profile resemble those found for species of the genera Morbillivirus and Respirovirus, but not for other species in the genus Rubulavirus. Thus, further consideration of the appropriate taxonomy of NDV and avian paramyxoviruses is required.

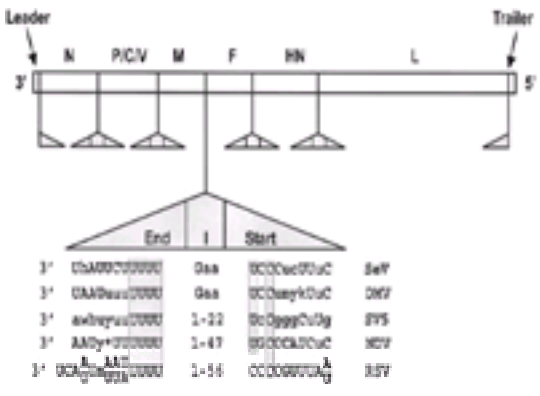

FIG. 6. Schematic diagram of a Paramyxovirus genome and the transcription end, intercistronic, and transcriptional start sequences. The positions of the extragenic 3'-terminal leader region and the 5'-terminal trailer region are shown. The conserved transcription regulatory sequences at the gene boundaries are indicated. These are sometimes known as E (end), I (intergenic), and S (start) sequences. The junctional sequences of representative viruses of each group, as (–) RNA, are shown. Nucleotides that are strictly conserved at each viral junctions are shown as *capital letters*; those that are mostly conserved (four of six junctions or better) are shown in *lower-case letters.* Other letters are used for less

conservation. *, includes nucleotide deletions.

The morphologic distinguishing feature among enveloped viruses for the subfamily *Paramyxovirinae* is the size and shape of the nucleocapsids (diameter of 18 nm, 1 μm in length, a pitch of 5.5 nm), which have a left-handed helical symmetry. The biologic criteria are (a) antigenic cross-reactivity between members of a genus and (b) the presence (Respirovirus and Rubulavirus) or absence (Morbillivirus) of neuraminidase activity. In addition, the different coding potentials of the P genes are considered and there is the presence of an extra gene (SH) in some rubulaviruses. The pneumoviruses can be distinguished from *Paramyxovirinae* morphologically, as they contain narrower nucleocapsids. In addition, the *Pneumovirinae* have major differences in the number of encoded proteins and an attachment protein that is very different from that of *Paramyxovirinae.* Examples of members of the three genera are shown in Table 1, and a phylogenetic majority-rule-consensus tree based on a combined cluster alignment of the nucleocapsid and phosphoprotein amino acid sequences is shown in Figure 1.

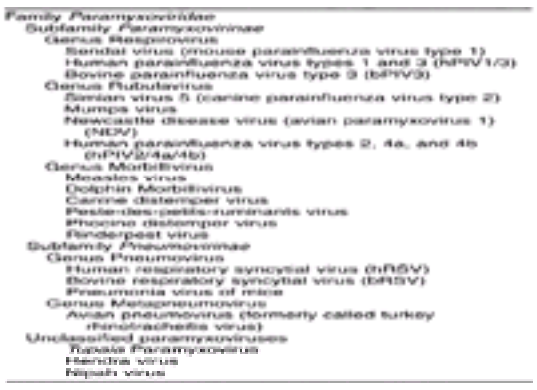

TABLE 1. *Examples of members of the family Paramyxoviridae*

FIG. 1. Evolutionary relationships of the *Paramyxoviridae*. Phylogenetic majority-rule consensus tree of the family *Paramyxoviridae* based on a combined cluster alignment of the nucleocapsid and phosphoprotein amino acid sequences of selected family members. Branch lengths represent relative phylogenetic distances according to maximum likelihood estimates based on the Dayhoff PAM matrix. Bootstrap support is 100% for all branching points, with the only exceptions being Hev (98%) and TPMV (77%). The following Paramyxovirus species are included in the cluster alignment (GenBank/EMBL/SwissProt accession numbers are given in parentheses): HeV (Hendra virus) (AF017149); TPMV (Tupaia Paramyxovirus) (AF079780); CDV (canine distemper virus) (P04865, P06940); PDV (phocine distemper virus) (P35944, P35939); DMV (dolphin Morbillivirus) (X75961, Z47758); MeV (measles virus) (Z66517); RPV (rinderpest virus) (Q03332, Q03335); NDV (Newcastle disease virus) (Z30084, Q06427); hPIV-4A (human parainfluenza virus 4A) (P17240, P22044); hPIV-4B (human parainfluenza virus 4B) (P17241, P21738); MuV (Mumps virus) (P21277, P19717); SV5 (simian parainfluenza virus 5) (AF052755); hPIV-2 (human parainfluenza virus 2) (P21737, P23056); SV41 (simian parainfluenza virus 41) (P27018, S60813); SeV (Sendai virus) (P04858, P04860); hPIV-1 (human parainfluenza virus 1) (P24304, P28054); hPIV-3 (human parainfluenza virus 3) (P06159, P06162); bPIV-3 (bovine parainfluenza virus 3) (P06161, P06163): oRSV (ovine respiratory syncytial virus) (Q83957, Q83956); bRSV (bovine respiratory syncytial virus) (P22677, P33454); hRSV (human respiratory syncytial virus) (P03418, P03421); PVM (pneumonia virus of mice) (P26589, U096449); TRTV (turkey rhinotracheitis virus) (U39295, U22110). Although not yet approved by the International Committee for the Taxonomy of Viruses, there is a wealth of data to suggest it is appropriate to remove NDV from the genus Rubulavirus and to designate it as belonging to a new avian genus of the *Paramyxoviridae*. (Adapted from ref. 276, with permission).

STRUCTURE AND REPLICATION STRATEGY OF THE*PARAMYXOVIRIDAE*

Paramyxoviruses contain nonsegmented, single-stranded RNA genomes of negative polarity, and they replicate entirely in the cytoplasm. Their genomes are 15 to 19 kB in length, and the genomes contain six to ten tandemly linked genes. A lipid envelope containing two surface glycoproteins (F and HN, or H or G), which mediate the entry and exit of the virus from its host cell, surrounds the virions. Inside the envelope lies a helical nucleocapsid core containing the RNA genome and the nucleocapsid (N), phospho- (P), and large (L) proteins, which initiate intracellular virus replication. Residing between the envelope and the core lies the viral matrix (M) protein that is important in virion architecture and that is released from the core during virus entry. In addition to the genes encoding structural proteins, paramyxoviruses contain “accessory” genes, which are found mostly as additional transcriptional units interspersed with the tandemly linked invariant genes. For the *Paramyxovirinae*, the accessory genes are found mostly as ORFs that overlap within the P gene transcriptional unit.

Intracellular replication of paramyxoviruses begins with the viral RNA-dependent RNAP (minimally, a homotetramer of P and a single L protein) transcribing the N-encapsidated genome RNA (N:RNA) into 5' capped and 3' polyadenylated mRNAs. The viral RNAP (vRNAP) begins all RNA synthesis at the 3' end of the genome, and it transcribes the genes into

mRNAs in a sequential (and polar) manner by terminating and reinitiating at each of the gene junctions. The junctions consist of a gene-end sequence, at which polyadenylation occurs by the reiterative copying of four to seven uridylates (followed by release of the mRNA), a short nontranscribed intergenic region, and a gene-start sequence that specifies capping as well as mRNA initiation. The RNAP occasionally fails to reinitiate the downstream mRNA at each junction, leading to the loss of transcription of further-downstream genes, and hence there is a gradient of mRNA synthesis that is inversely proportional to the distance of the gene from the 3' end of the genome. After primary transcription and translation, when sufficient amounts of unassembled N protein are present, viral RNA synthesis becomes coupled to the concomitant encapsidation of the nascent (+) RNA chain. Under these conditions, vRNAP ignores all the junctions (and editing sites), to produce an exact complementary antigenome chain, in a fully assembled nucleocapsid.

Virion Structure

The *Paramyxoviridae* contain a lipid bilayer envelope that is derived from the plasma membrane of the host cell in which the virus is grown (reviewed in ref. 43). *Paramyxoviridae* are generally spherical and 150 to 350 nm in diameter, but they can be pleiomorphic, and filamentous forms can be observed. Inserted into the envelope are glycoprotein spikes that extend about 8 to 12 nm from the surface of the membrane and that can be readily visualized by electron microscopy (EM). Inside the viral membrane is the nucleocapsid core (sometimes called the ribonucleoprotein core), which contains the 15,000- to 19,000-nucleotide, single-stranded RNA genome. Figure 2 is a highly stylized schematic diagram of the virions. F and HN are actually trimers and tetramers, respectively. No attempt has been made to represent the real abundance of F, HN, SH, or N subunits in the virion. The pleiomorphic nature of virion particles under EM is illustrated in Figure 3, and a comparison of the RNPs of influenza virus, rabies virus, and Sendai virus is shown in Figure 4.

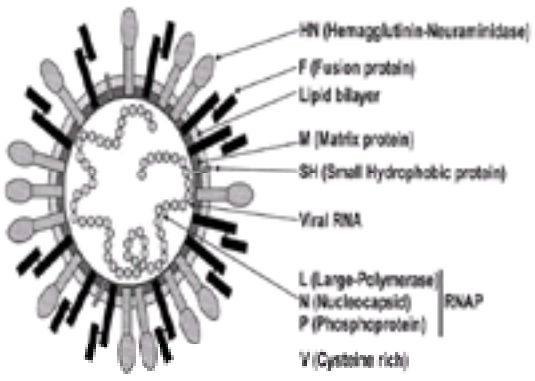

FIG. 2. Schematic diagram of a Paramyxovirus (not drawn to scale). The lipid bilayer is shown as the *gray concentric circle*, and underlying the lipid bilayer is the viral matrix protein shown as a *black concentric circle.* Inserted through the viral membrane are the hemagglutinin-neuraminidase (*HN*) attachment glycoprotein, and the (*F*) fusion glycoprotein. The relative abundance of HN and F is not illustrated by the diagram. The small integral membrane protein, SH, is found only in some rubulaviruses, such as SV5. The HN protein is thought to have a stalk region and a globular head, and the F protein consists of two sulfide-linked chains, F_1 and F_2. The HN protein is a tetramer and the F protein a trimer. Inside the virus is the negative-stranded virion RNA, which is encapsidated with the nucleocapsid protein (*N*). Associated with the nucleocapsid are the L and P proteins, and together this complex has RNA-dependent RNA transcriptase activity. For the rubulaviruses, the cysteine-rich protein V is found as an internal component of the virion, whereas for other members of the family, the V protein is found only in virus-infected cells. The nature of possible interactions between the cytoplasmic tails of the glycoprotein spikes and the matrix protein, and the interactions between the matrix protein and the nucleocapsid have not been fully elucidated and no attempt has been made to illustrate them.

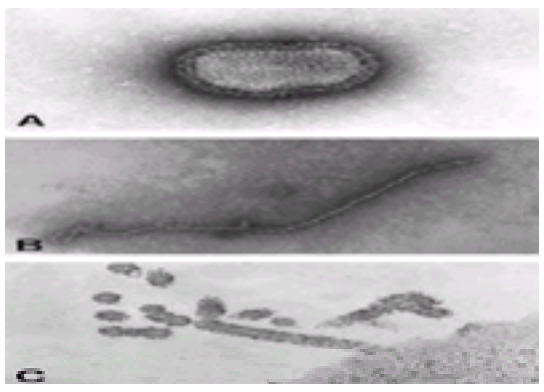

FIG. 3. Ultrastructure of SV5 virions revealed by negative staining. **A:** Negatively stained SV5 particle. The glycoprotein spikes on intact 150- to 300-nm virus particles can be observed (×226,280). **B:** Negatively stained SV5 nucleocapsid (×74,570). **C:** Budding SV5 virions particles from the surface of CV-1 cells. Colloidal gold staining of HN is shown (×24,700) (Micrographs courtesy of George Leser, Northwestern University).

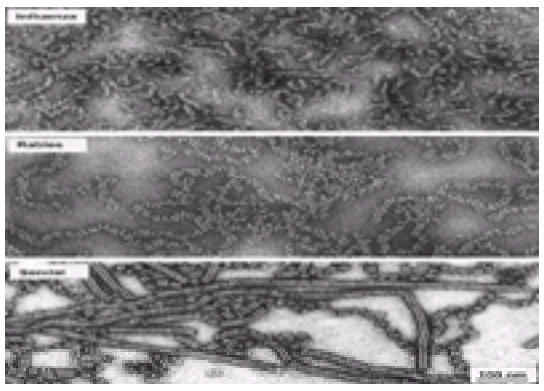

FIG. 4. Nucleocapsids of negative-strand RNA viruses. Electron micrographs of the nucleocapsids of three negative-strand RNA viruses, negatively stained with 1% sodium silicotungstate. *Top:* Ribonucleoprotein particles of influenza virus with a stoichiometry of 24 nucleotides per NP monomer. *Middle:* Nucleocapsids of rabies virus with a stoichiometry of nine nucleotides per N monomer. *Bottom:* Nucleocapsids of Sendai virus with a stoichiometry of six nucleotides per N monomer. All micrographs have the same magnification (bar = 100 nm). (Micrographs courtesy of Rob Ruigrok, European Molecular Biology Laboratory, Grenoble, France.)

The helical nucleocapsid, rather than the free genome RNA, is the template for all RNA synthesis. For Sendai virus, each nucleocapsid is composed of about 2,600 N, 300 P, and 50 L proteins (164). The N protein and genome RNA together form a core structure, to which the P and L proteins are attached. This nucleocapsid core is remarkably stable, as it withstands the high salt and gravity forces of cesium chloride density gradient centrifugation. By EM, the P and L proteins of nucleocapsids are not observed; they can be visualized only with the aid of antibodies (224). Holonucleocapsids (N:RNA plus P and L) have the capacity to transcribe mRNAs *in vitro*, presumably mimicking primary transcription in infected cells, and they are thought to be the minimal unit of infectivity.

When negatively stained preparations of Paramyxovirus nucleocapsids are viewed by EM, the most tightly coiled forms resemble the Tobamovirus tobacco mosaic virus (TMV)—that is, a relatively rigid coiled rod 18 nm in diameter, with a central hollow core of 4 nm and a helical pitch of about 5 nm (51, 52, 89). Unlike TMV, however, in which the nucleocapsid must disassemble so that its (+) RNA genome can function as a template, Paramyxovirus nucleocapsids function without disassembling; as far as we know, these nucleocapsids never disassemble naturally. This remarkable property is undoubtedly associated with the finding that, unlike TMV, these nucleocapsids are not rigid, although they become more rigid on trypsin treatment (194).

Sendai virus nucleocapsids exist in several distinct morphologic states at normal salt concentration (79, 113, 114). The most prevalent form in negatively stained preparations is the most tightly coiled one, with a helical pitch of 5.3 nm. Two other forms, one with a slightly larger pitch of 6.8 nm, and another with a much larger pitch of 37.5 nm, have also been noted. The fact that no structures of intermediate pitch have been found indicates that these are distinct states. It is thought that the template is copied without dissociation of N protein from the nucleocapsid, and the uncoiling of the nucleocapsid may be necessary for the polymerase to gain access to the RNA bases. It is possible that the viral polymerase traverses the nucleocapsid template by uncoiling the helix in front of it and recoiling it once the polymerase has passed a given position, much the same as cellular RNAP generates its template “bubble” in traversing dsDNA.

As expected, the diameter of the nucleocapsid decreases as the pitch increases and the nucleocapsid lengthens, and for Sendai virus the diameter is 3.5 nm less for the 6.8-nm form than for the 5.3-nm-pitch form. These latter values are very similar to those of Pneumovirus nucleocapsids, which also have a pitch of 7 nm. As discussed earlier, these differences in nucleocapsid morphology are used to distinguish the different *Paramyxoviridae*, but they probably relate mainly to the form that predominates in negatively stained preparations.

THE *PARAMYXOVIRIDAE* GENOMES AND THEIR ENCODED PROTEINS

Today we know the complete genome sequence for almost all members of the *Paramyxoviridae*, including Sendai virus, human parainfluenza virus 3 (hPIV-3), simian virus 5 (SV5), mumps virus, measles virus, canine distemper virus (CDV), and respiratory syncytial virus (RSV). (They are obtainable from the Web, at http://www.ncbi.nlm.nih.gov/.) The 15,000- to 19,000-nucleotide genomic RNA contains a 3' extracistronic region of about 50 nucleotides, known as the leader, and a 5' extracistronic region of 50 to 161 nucleotides, known as the trailer [or the (–) leader]. These control regions are essential for transcription and replication, and they flank the six genes (seven for certain rubulaviruses and eight to ten for pneumoviruses) (note that by the convention used for paramyxoviruses, the term *gene* refers to the genome sequence encoding a single mRNA, even if that mRNA contains more than one ORF and encodes more than one protein). The coding capacity of the genome of *Paramyxovirinae* is extended by the use of overlapping ORFs in the P gene. The gene order of a representative member of each subfamily is shown in Figure 5. At the beginning and end of each gene are conserved transcriptional control sequences that are copied into mRNA. Between the gene boundaries are intergenic regions (Fig. 6). These are precisely three nucleotides long for the respiroviruses and morbilliviruses but are quite variable in length for the rubulaviruses (1 to 47 nucleotides) and pneumoviruses (1 to 56 nucleotides) (see Fig. 6).

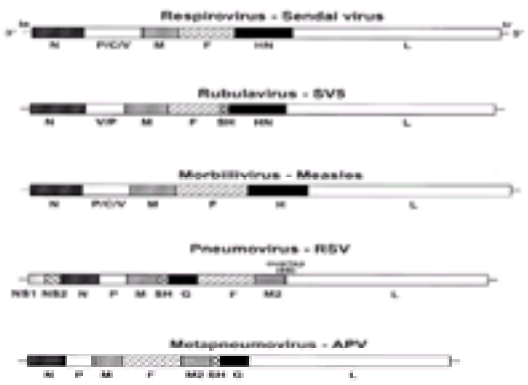

FIG. 5. Genetic map of a typical member of each genus of the *Paramyxoviridae*. The gene size is drawn to scale. Gene boundaries are shown by *vertical lines.* The hRSV L gene transcription overlaps that of the M2 gene by 68 nucleotides, and the bRSV overlap is 67 nucleotides, whereas PMV and APV do not have an overlap.

The Nucleocapsid Protein

The nucleocapsid (N) protein serves several functions in virus replication, including encapsidation of the genome RNA into an RNase-resistant nucleocapsid (the template for RNA synthesis), association with the P-L polymerase during transcription and replication, and, most likely, interaction with the M protein during virus assembly. The intracellular concentration of unassembled N is also thought to be a major factor controlling the relative rates of transcription and replication from the genome templates, by analogy to studies made on the Rhabdovirus vesicular stomatitis virus (VSV) (13,14).

The nucleotide sequence of the N gene of paramyxoviruses predicts that the N proteins range from 489 to 553 amino acids [molecular weight ratio (M_r) 53,167 to 57,896], and, unexpectedly for a protein that interacts with RNA, the protein has a net charge of –7 to –12, with the exception of mumps virus (+2). A comparison of these protein sequences, coupled with data obtained from protease digestions of nucleocapsids, suggests that N contains two domains. The N-terminal 80% of the protein of about 500 residues is relatively well conserved among related viruses, whereas the C-terminal 20% is poorly conserved, although this domain always contains a highly charged and mostly negative region (58,208). This hypervariable C-terminus appears to be a tail extending from the surface of a globular N-terminal body, because the C-terminal sequences of the SV5 and Sendai virus N protein in nucleocapsids are hypersensitive to trypsin digestion, leaving a 48-kd N-terminal core (53,114,194). However, the overall structure of the nucleocapsid seen by EM, and the resistance of the genomic RNA within this structure to nuclease attack are mostly unchanged by trypsin treatment (151). These data indicate that the determinants for the helical nature of the nucleocapsid, as well as the RNA binding domains, must lie within the highly conserved N-terminal body. Extensive deletional analysis indicates the N-terminal region of Sendai virus N protein is required for nucleocapsid assembly (18). For N proteins, an invariant sequence F-X4-Y-X4-S-Y-A-M-G (where X is any residue) is found near the middle of the protein in a region predicted to be hydrophobic, and it could be involved in N:N contacts during assembly (190), but the presence of several conserved aromatic residues also suggests that it may be involved in RNA binding. In any event, N does not appear to be a classic RNA binding protein, in that it does not contain any previously recognized RNA-binding motifs, nor does N interact with RNAs after transfer of the N protein to nitrocellulose membranes and probing with RNA (Northwestern blots). The C-terminal tail, on the other hand, contains most of the N-protein phosphorylation sites and antigenic sites (133,239).

The structure–function relationship of the Sendai virus N protein was examined using a cDNA-encoded genome of a defective-interfering (DI) particle, whose intracellular replication was directed by N, P, and L protein expressed from cotransfected cDNAs (58) (see later section, Molecularly Engineered Genetics). The entire C-terminal tail of N was found to be dispensable for assembling an encapsidated, complementary copy of the template, whereas deletions anywhere within the N-terminal body of the protein eliminated this activity. Thus, the C-terminal tail is not essential for assembling the nascent chain and helping the polymerase to ignore the junctions. However, templates that were themselves assembled with tailless N proteins were unable to act as templates for new rounds of genome replication. The highly charged domain of the C-terminal tail appears to be essential for this function, as deletions downstream of this domain have little or no effect. The precise template function of the N-protein C-terminal tail is unclear, but it may be required for the transition between helical states, as nucleocapsids with tailless N protein appear more rigid in electron micrographs (194). The tail, moreover, appears to mediate P-protein binding to nucleocapsids, as binding of antibodies specific to the C-terminal tail leads to the release of the normally tightly bound P proteins, both for Sendai virus and hPIV-1 (239). Whether P binds directly to this C-terminal tail domain is unclear, but if so, it could participate in the helical transitions thought necessary for template function.

The P Gene and Its Encoded Proteins

For the *Paramyxovirinae*, the P gene represents an extraordinary example of a virus compacting as much genetic information as possible into a small gene. The P gene gives rise to a plethora of polypeptides by means of using overlapping reading frames on a single mRNA transcript, by a remarkable process of transcription known as RNA editing, or pseudotemplated addition of nucleotides. The consequence of the addition of pseudotemplated nucleotides to an mRNA is that there is a shift of a translational reading frame into an alternative reading frame, and hence a new protein is translated (Table 2). In this chapter, it will be considered that the P genes of the *Paramyxovirinae* are composed of a series of modules that are combined in various ways via mRNA editing, or as additional modules expressed via unusual translational initiation (16,59,103,169). An illogical sequence of letters (C, C', D, I, P, V, W, X, Y1, Y2, and Z) has been used to name the various Paramyxovirus P gene products. However, based on some new biochemical data and some limited functional data for Sendai virus, a new nomenclature system is being introduced in this chapter, to describe the

different P modules encoded by the P gene.

		Ribosomal choice				mRNA editing		
Paramyxovirus	Host	P	V	C′	C	D	V	P
Sendai	Mouse	+	-	+	+	-	+	-
hPIV1	Human	+	-	+	+	-	-	-
bPIV3	Cattle	+	-	-	+	+	+	-
hPIV2	Human	+	-	-	+	+	(+)	-
Mumps	Human	-	+	-	-	-	-	+
SV5	Dog	-	+	-	-	-	-	+
hPIV2 and hPIV4	Human	-	+	-	-	-	-	+
NDV	Fowl	+	-	-	-	-	+	-
Measles	Human	+	-	-	+	-	+	-
Canine distemper	Dog	+	-	-	+	-	+	-
Rinderpest	Cattle	+	-	-	+	-	+	-
Phocine distemper	Seals	+	-	-	+	-	+	-

TABLE 2. *Examples of expressible P gene open reading frames*

All viruses of the *Paramyxovirinae* (with the notable exception of hPIV-1) contain an editing site, at which G residues are inserted into the P mRNA in a programmed manner during its synthesis (Fig. 7, the dotted vertical line) (35,215,274,281). The number of G residues inserted varies between the different viruses and appears to be matched to the organization of their alternate ORFs. The editing site separates each P gene into two segments, and it generates three different mRNAs in which the three possible reading frames downstream of the editing site are fused to a unique upstream ORF (see Fig. 7). These mRNAs are translated into three polypeptides with a common N-terminal segment and different C-terminal segments, called P, V, and W/D/I. In respiroviruses and morbilliviruses, additional P-gene complexity is provided by the presence of two (overlapping) ORFs (designated P-amino 1 and P-amino 2) upstream of the editing site, only one of which (P-amino 1) extends to the editing site. For Sendai virus and hPIV-1, the ORF that terminates before the editing site (P-amino 2, or C ORF) can also code for a nested set of up to four polypeptides, because of the use of four ribosomal initiation sites. For rubulaviruses, there is a single ORF upstream of the editing site (designated P-amino 2), which may be the counterpart of the respiroviruses and morbilliviruses C genes (see later). The mechanisms of expression of the protein products derived from the P gene are described later.

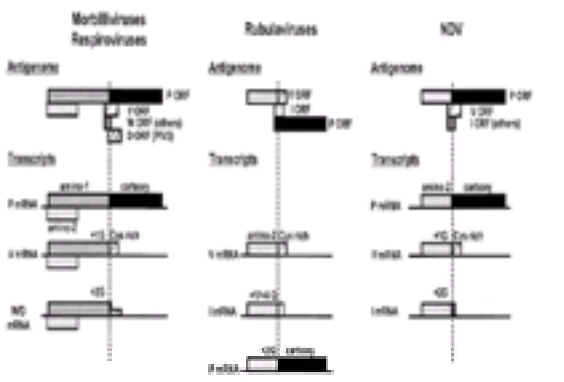

FIG. 7. Schematic diagram of the P gene of representative paramyxoviruses. For the respiroviruses and morbilliviruses, the mRNA for the P protein is transcribed faithfully (unedited) from the viral genome. Transcriptional RNA editing with the addition of one G nucleotide at the editing site produces an mRNA that encodes the V protein. Addition of two G nucleotides at the editing site produces an mRNA that encodes the W or D proteins (depending on the virus). The P mRNAs of the respiroviruses and morbilliviruses also contain the P-amino 2 (C protein) ORF at the 5' end of the mRNA independent of editing status (*light shading*). The unedited version of the Rubulavirus "P" mRNA encodes the V protein (*light shading*); the addition of two G nucleotides produces the P mRNA and the addition of one G produces the I mRNA. NDV follows the Respirovirus and Morbillivirus pattern, and its unedited mRNA is translated to yield the P protein, and RNA editing produces the V mRNA. The cysteine-rich domain of the V protein is indicated by *cross-hatching.* The RNA editing site, at which nontemplated nucleotides are added to the mRNAs is indicated by the *vertical dotted line.* As described in the text, the P gene is translated into a series of proteins that are thought to consist of a series of modules. P-amino 1 (*medium shading*) and P-amino 2 (*light shading*) are two modules upstream of the RNA editing site, and P-carboxy (*black shading*) is the P module downstream of the RNA editing site. Some sequence relatedness and limited functional studies have led to the speculation that P-amino 2 (C ORF) of Respirovirus is functionally related to the N-terminal module of the Rubulavirus P and V proteins. Thus, the P-amino 1 module is unique to the respiroviruses and morbilliviruses.

The Phosphoprotein

The P protein is the only P gene product that is essential for viral RNA synthesis (61), and it is involved in all its aspects. The Sendai virus P protein was first characterized as a homotrimer, but more recent biochemical evidence indicates the protein contains a coiled-coil domain that is tetrameric, and the entire protein is expected to be a tetramer (270). P protein is an essential component of the vRNAP and the nascent chain assembly complex (129), and additional P protein is also required during RNA synthesis (55). Although the L protein is thought to contain all vRNAP catalytic activities (222), L binds to the N:RNA template via the P proteins (129). This interaction between P and L requires a domain in P that maps to the C-terminal end of the coiled-coil oligomerization regions (Fig. 8) (62,238). This very C-terminal domain of P, which binds to the N:RNA, is predicted to form an a-helical bundle. These domains (all downstream of the editing

site) that fall in the region called P-carboxy are essential for viral RNA synthesis. For Sendai virus, the P-carboxy region is also sufficient for RNA synthesis, as this protein fragment by itself (residues 325 to 568) can substitute for intact P protein in all aspects of mRNA synthesis (55,63). Thus, the P-carboxy region represents the polymerase (pol) cofactor module. This region is relatively well conserved in predicted secondary structure for all viruses of the *Paramyxovirinae*, and all P proteins carry this essential module as the C-terminal segment of a fusion protein; this module is never naturally expressed by itself. For respiroviruses, morbilliviruses, and NDV, the P-carboxy pol-cofactor module is translated from the unedited mRNA (see Fig. 7); for the viruses in the genus Rubulavirus, the P-carboxy pol-cofactor module is translated from an mRNA with a 2G insertion (see Fig. 7). Although little is known about the RSV P protein, it too is predicted to contain a coiled-coil domain, and it interacts with itself in a yeast two-hybrid system (256). P protein oligomerization thus appears to be a general property of this virus family.

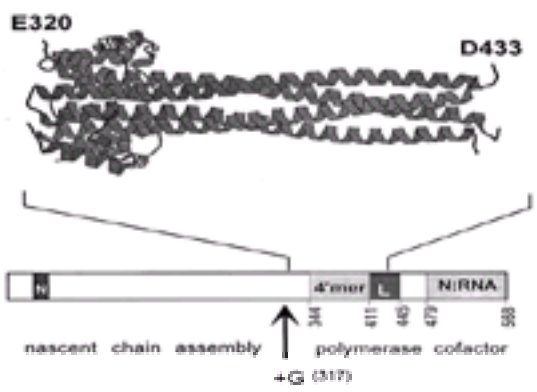

FIG. 8. Structure and function of the Sendai virus P protein. The P protein is shown below as a *horizontal bar.* Its known functional domains—namely, chaperoning unassembled N protein during the nascent chain assembly step of genome replication (N), self-assembly as a tetramer (4-mer), L protein binding site (L), and N:RNA binding site (N:RNA)—as determined by deletion analysis and discussed in the text, are indicated. Numbers refer to amino acid positions. The G insertion site (or editing site) in codon 317 used during mRNA synthesis, which separates the nascent chain assembly and polymerase cofactor domains of the P protein, is indicated. The core of the P protein homotetramer, a coiled coil of four parallel a-helices buttressed at their N-terminal ends by four short a-helical bundles (from E320 to D433), determined by x-ray crystallography (courtesy of Tabourieh and coworkers, EMBL, Grenoble, France, unpublished), is shown at the top of the figure.

For genome replication, in which RNA synthesis and assembly into nucleocapsids are coupled, at least for Sendai virus, one additional P-protein domain near the N-terminus (defined by deletion of residues 33 to 41) is also required (62). This domain apparently chaperones unassembled N protein during nascent chain assembly (assembly module), as the substrate for genome assembly is a P-N complex (129). The rest of the Sendai virus P protein is apparently dispensable for (unregulated) genome RNA synthesis and assembly, as a P protein in which residues 78 to 324 have been deleted is still quite active for mini-genome replication in transfected cells (62). The remaining P gene accessory proteins, like residues 78 to 324 of the Sendai virus P protein, are not required for the basic process of replicating viral genomes and expressing their mRNAs. Nevertheless, most of the accessory proteins play a role in regulating viral RNA synthesis, and/or in countering host cell defenses to viral infection. The properties and functions of the individual protein modules translated from the P gene are described next.

P Gene Modules (ORFs) Downstream of the Editing Site

Cysteine-Rich V ORF

The V ORF is found in the middle of the P gene of all three genera, and the V protein is expressed by all morbilliviruses and rubulaviruses, but only by some of the respiroviruses. In Sendai virus (281), bPIV-3 (219), the morbilliviruses (35), and NDV (258), the cysteine-rich V ORF is translated from an mRNA with a single G insertion, whereas in rubulaviruses the V protein is translated from the unedited mRNA (211,274). In either case, the resulting fusion protein is called V. The C-terminal portion of the V ORF is by far the best conserved of all the various P gene ORFs (Fig. 9), even though the V ORF is absent in hPIV-1 (184) and may not be expressed in hPIV-3 (76,93), both respiroviruses. There are seven perfectly conserved cysteine residues, and this domain binds two atoms of Zn^{2+} (176,212). The V domains of several (though not all) viruses specifically interact with the large subunit of the cellular damage-specific DNA-binding protein (UV-DDB) (175), but the consequences of this interaction and the function of V protein cysteine-rich domain remain to be elucidated. Like the P-carboxy pol-cofactor module, the cysteine-rich V ORF is found only as the C-terminal segment of a fusion protein; this module is never expressed by itself.

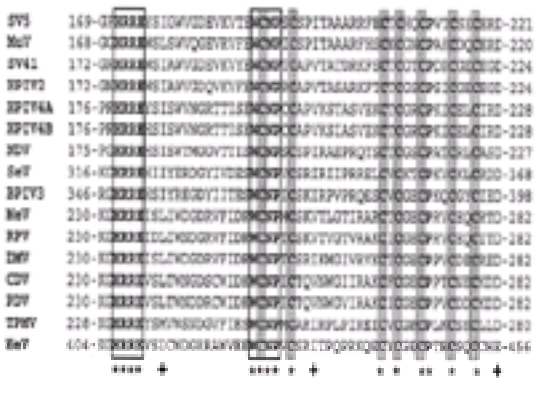

FIG. 9. Multiple amino acid sequence alignment of the conserved cysteine-rich C-terminal region of selected Paramyxovirus V proteins. *Numbers* indicate the amino acid position within the respective proteins. Conserved amino acid residues are shown in *boldface letters*, two areas of exceptionally high conservation are *boxed*, and the positions of the seven conserved cysteine residues are *shaded. Asterisks* and *plus symbols* below the alignment indicate identical and similar amino acid residues, respectively. The amino acid sequences of the Paramyxovirus species used in the alignment were from the P gene sequences indicated in Figure 1. (Adapted from ref. 276, with permission.)

The W/D/I ORF

The W/D ORF of respiroviruses and morbilliviruses is expressed from mRNAs with two inserted G residues (see Fig. 7). For most of these viruses, the insertion of two G residues into the mRNA is relatively rare and the ORF is closed by a stop codon shortly after the editing site. In these cases, it is referred to as the W ORF, and the ensuing P-amino-W fusion protein is called the W protein. The W ORF appears to serve mainly to truncate the P protein, producing essentially the N-terminal P-amino 1 assembly module of the P protein by itself. Despite the low abundance of +2G mRNAs in Sendai virus–infected cells (about 10% of the total P mRNA), the Sendai virus W protein can be easily detected (57). In two closely related respiroviruses (b-PIV-3 and hPIV-3) (92,243), the +2 ORF extends for 131 amino acids from the editing site (and is called D), and +2G mRNAs are not rare in h/bPIV-3-infected cells [it has been observed that mRNAs with one to six inserted G residues are almost equally abundant (93,219)]. The encoded P-amino 1-D fusion protein is called the D protein. The Rubulavirus protein in which the single upstream ORF (P-amino 2) is fused to the third possible (+1/+4) downstream ORF is also found in Rubulavirus-infected cells, and it is called I (119,211). However, because of constraints of the Rubulavirus mRNA editing mechanism, a single G is rarely inserted at this editing site, and the I protein is expressed from a +4G mRNA (211,274). Thus, the Rubulavirus P, V, and W/D/I proteins contain the N-terminal module of the P-ORF (P-amino 2), fused to, respectively, the P polymerase cofactor module (P-carboxy), the V ORF, and the W/D/I ORF (depending on the virus) in the remaining reading frame.

P Gene Modules (ORFs) Upstream of the Editing Site

Two types of P gene ORF are found upstream of the editing site, P-amino 1 and P-amino 2. The rationale for this nomenclature is based on the available data, and on speculation that P-amino 2 of Sendai virus (formerly called the nest set of proteins C', C, Y1, and Y2) have biochemical and sequence relationships to the N-terminal domain of the P protein of the rubulaviruses. Some limited data pertaining to the proteins of Sendai virus and SV5 involved in the interferon response to these viruses, also support the notion that the P-amino 2 domain of Sendai virus and the N-terminal P domain of SV5 are related in that they interact with different parts of the interferon-signalling pathway (see later). The P-amino 1 domain that is found only in respiroviruses and morbilliviruses is longer than P-amino 2 and is acidic in nature. P-amino 2, which is encoded by all P genes of the *Paramyxovirinae*, is shorter than P-amino 1 and is basic in nature.

P-Amino 1 Module

Unlike the downstream P-carboxy pol-cofactor module and the cysteine-rich V ORF module, whose conservation is evident across the entire virus subfamily, the ORF(s) upstream of the editing site are conserved only within each genus and can be very different between genera. For respiroviruses and morbilliviruses, the longer ORF (P-amino 1, with about 300 amino acids) that is fused to the downstream modules is relatively poorly conserved between genera, but they are all acidic in nature (pI of about 5.5). For Sendai virus, P-amino 1 contains a short region near the N-terminus (defined by deletion analysis) that is required to chaperone unassembled N protein as a P-N complex during the nascent chain assembly step of genome replication (62) (see Fig. 8). P-amino 1 also contains most of the serine and threonine phosphorylation sites of the P protein (23). The one or two major sites of each protein (and the respective kinases that catalyze the phosphorylation) are known for several viruses (66,136). For the respiroviruses, mutational analysis at these sites, within the context of an infectious cDNA and recovery of viable virus, has so far not been informative (134).

P-Amino 2, Including the C ORFs

As discussed earlier, two of the criteria used for considering the single Rubulavirus ORF (P-amino 2) with the C ORF of respiroviruses and morbilliviruses is that they are both about 170 amino acids and are basic (pI of about 10.5) and show a small degree of sequence relatedness. For respiroviruses and morbilliviruses, the C ORF overlaps the P-amino 1 module, and it is accessed by translational choice (Fig. 10). Morbilliviruses express one C protein (10) as do the newly isolated Hendra virus (301), Nipah virus (105a), and tree shrew Morbillivirus (276), whereas the respiroviruses, such as Sendai virus and hPIV-1, express four C-like proteins (C', C, Y1, and Y2) (60,99). The C protein ORFs of the respiroviruses and morbilliviruses are found at the same relative location on the P gene, and when their sequences are aligned there is clear conservation within each genus, but there is little conservation between these two genera. Although the NDV (avian Paramyxovirus) P gene does not contain a separate P-amino 2 ORF, the N-terminal domain of its P protein (before the editing site) is similar in size and overall charge to the P-amino 2 module and thus it may be a functional counterpart of the P-amino 2 (C) module. Similarly, for the rubulaviruses parts of the sequence of the V/P protein, shared N-terminal domain (P-amino 2) can be aligned with the Respirovirus P-amino 2 (C) protein sequence but not the Morbillivirus P-amino 2 (C) protein sequence (Fig. 11). Consistent with the different nature of the P protein N-terminal segments, the Respirovirus and Morbillivirus V proteins (P-amino 1 + V ORFs) are not found associated with viral nucleocapsids intracellularly or in virus particles (57,252), in contrast to the Rubulavirus V proteins (P-amino 2 + V ORFs), which are associated with intracellular nucleocapsids and found in virions (212,284). The various P-amino 2 ORFs may well serve different functions that are genus specific. Assuming that the various Paramyxovirus P proteins are functionally equivalent (N assembly module + pol-cofactor), the N assembly module would be contained within the P-amino 2 ORF of the Rubulavirus and NDV P protein.

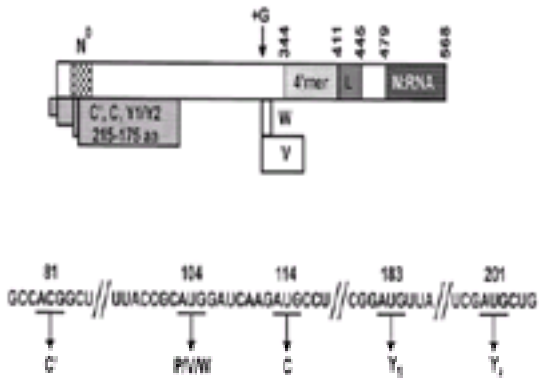

FIG. 10. Representation of the Sendai virus P mRNA to illustrate the use of multiple initiation codons. The nucleotide sequences surrounding the initiation codons for C', P, C, Y_1, and Y_2, all of which are derived from the C ORF, are indicated. The various functional domains of the P protein are also indicated. Note that the Y_1 and Y_2 initiation sites overlap the N assembly domain of P. The AUG codon at position 104 also starts the V and W proteins in the edited P gene mRNAs. All the initiation codons (the ACG for C8), except for the first one, are in a suboptimal context for initiation.

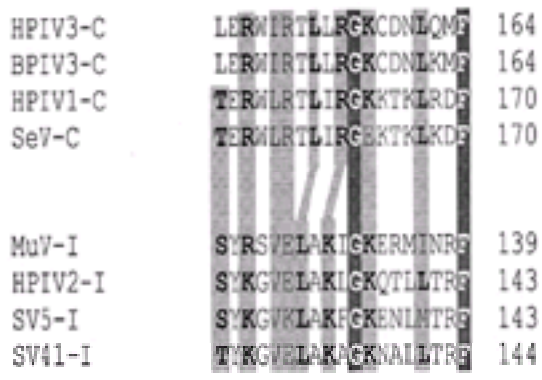

FIG. 11. A short stretch of sequence relatedness between the Respirovirus C proteins and P-amino 2 ORF of the Rubulavirus V/P/I proteins. Amino acid sequence relatedness of a region of the C proteins of hPIV-3, bPIV-3, hPIV-1, and Sendai virus (SeV) with the V/P/I proteins of mumps virus (MuV), hPIV-2, SV5, and SV41. The position of the phenylalanine whose mutation to serine in Sendai virus and hPIV-3 attenuates virulence, is shown on the *right.* Residues that are conserved by amino acid assignment and spacing within the segment are indicated by *black boxes*: residues that are semiconserved by assignment or spacing are indicated by *gray boxes.*

The Large Protein

The L protein is the least abundant of the structural proteins (about 50 copies per virion). The L gene is the most promoter-distal in the transcriptional map and thus the last to be transcribed. Its low abundance, its large size, and its localization to transcriptionally active viral cores suggested that it might be the viral polymerase. The L genes of most paramyxoviruses have now been sequenced and they are all of very similar length (about 2,200 amino acids), but there is little overall sequence homology outside the subfamily. There are, however, five short regions of high homology near the center of these proteins that are also conserved in the RNA-dependent RNAPs of other virus families (145,222). These regions are thought to represent structural features of a common, ancestral polymerase “fold” (222). Mutational analysis of the highly conserved residues of these homology regions indicates that these regions are essential for RNAP activity (257).

The P and L proteins form a complex, and both proteins are required for polymerase activity with N:RNA templates (61,105,129). The precise composition of the viral polymerase is unclear, but transcriptionally active nucleocapsids contain five to ten P proteins per L protein, and this complex can make mRNA *in vitro*, which is capped at its 5' end and also contains a poly(A) tail at the 3' end. Polyadenylation is thought to result from polymerase stuttering on a short stretch of U residues, but the capping step requires both guanylyl and methyl transferase activities. These latter activities are thought to be provided by the L protein, by analogy to VSV (see Chapter 38), and because similar reactions have not been described for cellular enzymes that operate in the cytoplasm. The Sendai virus L protein purified from virions was also found to phosphorylate the N and P proteins, and it has been suggested that L is the kinase (80) that has long been known to be associated with the viral core (160,235). However, the Sendai virus P and V proteins are phosphorylated when expressed in transfected cells in the absence of L (64), suggesting that phosphate addition to these proteins is the result of cellular kinases. In any event, the phosphorylation of these proteins appears to be a modification without an obvious function, as recombinant Sendai virus that lacks the major P protein phosphorylation site can be rescued and this virus grows normally both in tissue culture and in mice (134).

The Matrix Protein

The Paramyxovirus matrix (M) protein is the most abundant protein in the virion. The nucleotide sequence of the M gene and predicted amino acid sequence of many paramyxoviruses indicate that these proteins contain 341 to 375 residues (M_r about 38,500 to 42,500), are quite basic proteins (net charge at neutral pH of +14 to +17), and are somewhat hydrophobic, although there are no domains of sufficient length to span a lipid bilayer. In electron micrographs of virions, an electron-dense layer is observed underlying the viral lipid bilayer and this is thought to represent the location of this

protein. Fractionation studies of virions indicate that the M protein is peripherally associated with membranes and is not an intrinsic membrane protein. Reconstitution studies of purified M protein, and fractionation studies of infected cells indicate that the M protein can associate with membranes (84,162,200,245).

As a purified protein, the Sendai virus M protein can self-associate and form two-dimensional paracrystalline arrays (sheets and tubes) in low salt conditions (6,115,120), and there is a paracrystalline array of identical periodicity at the inner surface of the plasma membrane of infected cells when examined by EM after freeze-fracture (6). In addition, the M protein is also associated with nucleocapsids (261,299). The M protein probably contains amphipathic a-helices that insert themselves into the inner leaflet of the lipid bilayer, to coat this surface and organize its contacts with the helical nucleocapsid (15). Evidence that the M protein of Sendai virus interacts specifically with membranes expressing individually the F and HN glycoproteins has also been obtained, which implies that there is an interaction of the F and HN cytoplasmic tails with the M protein (246). Furthermore, genetically engineered recombinant measles virus and SV5 that lack glycoprotein cytoplasmic tails show a subcellular redistribution of the matrix protein (33,251). Thus, the M protein is considered to be the central organizer of viral morphogenesis, interacting with the cytoplasmic tails of the integral membrane proteins, the lipid bilayer, and the nucleocapsids. The self-association of M and its contact with the nucleocapsid may be the driving force in forming a budding virus particle (217). The relative abundance of basic residues in the M protein may reflect their importance in ionic interactions with the acidic N proteins.

Consistent with its central role in virus budding, M is often inactivated in persistent Paramyxovirus infections where budding fails to occur. For example, in subacute sclerosing panencephalitis (SSPE), a rare, progressive, and invariably fatal persistent measles virus infection of the brain, the M protein is either absent for a variety of reasons (reviewed in ref. 34) or, when present, is not associated with budding structures *in vivo* and is unable to bind to viral nucleocapsids *in vitro* (124,125). Although a genetically engineered recombinant measles virus that lacks an M protein has been obtained (32), it produces a four-log lower titer of released infectious particles than wild-type virus and remains mostly cell associated. Therefore it is reasonable to conclude that the M protein does play a very important function in virus assembly. Moreover, in model systems of persistent Sendai virus infection in culture in which the normally lytic infection is converted to a persistent one using DI particles, the change from a lytic to a persistent infection correlates mainly with M protein instability and an absence of budding structures (236).

The M protein of several paramyxoviruses is phosphorylated. For Sendai virus, a large proportion of the M protein is phosphorylated yet the M protein found in virions is not phosphorylated (163). However, a Sendai virus could be rescued from an infectious cDNA in which the single phosphorylation site in Sendai virus M protein had been eliminated (241). This M protein phosphorylation-minus mutant did not show an altered phenotype from wild-type virus in either cultured cells or mice. For the Rhabdovirus VSV, there is clear evidence that the VSV M protein that is associated with the RNP structure inhibits viral transcription (see Chapter 38). For *Paramyxovirinae*, there is no evidence that association of RNPs with M protein shuts down RNA synthesis in preparation for virus assembly, and this function may be carried out by another viral protein, such as the C protein.

Envelope Glycoproteins

All *Paramyxoviridae* possess two integral membrane proteins, and some rubulaviruses and all pneumoviruses encode a third integral membrane protein (Fig. 12 and Fig. 13). One glycoprotein (HN, H, or G) is involved in cell attachment and the other glycoprotein (F) in mediating pH-independent fusion of the viral envelope with the plasma membrane of the host cell. The assignment of specific biologic activities to individual glycoproteins was originally made on the basis of purification and reconstitution studies, mainly for the Sendai virus and SV5 proteins (248,250). For the respiroviruses and rubulaviruses, the attachment glycoprotein binds to cellular sialic acid–containing receptors, and these can be glycoproteins or glycolipids. The binding is probably of fairly low affinity but of sufficiently high avidity that these viruses agglutinate erythrocytes (hemagglutination). The attachment proteins of respiroviruses and rubulaviruses also have neuraminidase activity, and the proteins have been designated hemagglutinin-neuraminidase (HN). The Morbillivirus attachment protein (H) can cause agglutination of primate erythrocytes but lacks detectable neuraminidase or esterase activity. The restricted host range of measles virus for primate cells made it unlikely that sialic acid was the primary receptor for measles virus. It has been found that measles virus has a specific cellular receptor, the complement-binding protein known as either the membrane cofactor protein (MCP) or CD46 (74,201). The Pneumovirus RSV does not cause detectable hemagglutination, and the cellular receptor for RSV is not completely understood but it involves interactions with heparan sulfate, a glucosaminoglycan that is part of the extracellular matrix. Interestingly, the G protein of RSV can be deleted from the viral genome (146), and Sendai virus-like particles devoid of HN can infect cells via the asialoglycoprotein receptor (173). Both of these cases suggest the F protein may have a binding activity. After attachment of a *Paramyxoviridae* particle to the host-cell receptor, the viral envelope fuses with the host-cell plasma membrane, and the major viral protein involved in this process is the F glycoprotein.

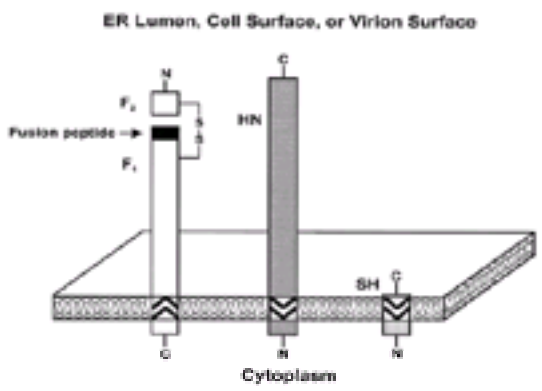

FIG. 12. Schematic diagram showing the orientation of Paramyxovirus integral membrane proteins. The F and HN protein orientations are shown. In *Paramyxovirnae*, only SV5 and mumps have an SH gene.

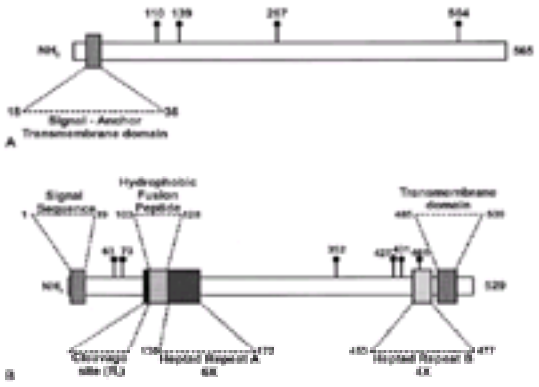

FIG. 13. Schematic diagram to show important domains and features of the Paramyxovirus glycoproteins. **A:** Hemagglutinin-neuraminidase attachment protein (based on the predicted sequence of the SV5 HN gene (121). The signal anchor transmembrane domain and the sites used for addition of N-linked carbohydrate (lollipops) (202) are indicated. **B:** Fusion protein (based on the predicted sequence of the SV5 F gene). The position of the signal sequence, the transmembrane domain, the cleavage site, the hydrophobic fusion peptide, and the heptad repeats A and B are indicated. The sites used for addition of N-linked carbohydrate (lollipops) (7) are indicated. R5 indicates the five arginine residues site for cleavage-activation. The heptad repeats A (six heptads) and B (four heptads) are shown.

Attachment Protein

The Respirovirus and Rubulavirus surface glycoprotein HN is a multifunctional protein as well as being the major antigenic determinant of the paramyxoviruses. HN is responsible for the adsorption of the virus to sialic acid–containing cell-surface molecules. In addition, HN mediates enzymatic cleavage of sialic acid (neuraminidase activity) from the surface of virions and the surface of infected cells. By analogy to the role of influenza virus neuraminidase (NA), it seems likely that the role of this neuraminidase activity is to prevent self-aggregation of viral particles during budding at the plasma membrane. These dual activities of HN can be modulated by halide ion concentration and pH (186). Whereas the halide ion concentration and pH of the extracellular environment is optimal for hemagglutination, Paramyxovirus neuraminidases have an acidic pH optimum (pH 4.8 to 5.5) suggesting that neuraminidase acts in the acidic *trans* Golgi network to remove sialic acid from the HN carbohydrate chains and from the F protein carbohydrate chains. In addition to the hemagglutinating and neuraminidase activities of HN, for most paramyxoviruses HN also has a fusion promoting activity—that is, coexpression of HN and F is required for cell–cell fusion to be observed (see later).

The nucleotide sequence of the HN gene is now known for every member of the *Paramyxovirinae*. The HN polypeptide chain ranges from 565 to 582 residues. For some strains of NDV, HN is synthesized as a biologically inactive precursor (HN_0), and 90 residues from the C-terminus are removed to activate the molecule (199,200). A schematic diagram of important features of the HN amino acid sequence is shown in Figure 13. The HN proteins are type II integral membrane proteins that span the membrane once. The HN protein contains a single hydrophobic domain, located close to the N-terminus, that acts as a combined signal and anchorage domain, targeting the nascent chain as it emerges from the ribosome to the membrane of the endoplasmic reticulum (ER) and ensuring the translocation of the polypeptide chain across the membrane, bringing about the stable anchoring of the protein in the lipid bilayer. This orientation of HN (see Fig. 12) is analogous to that of the influenza virus NA. Interestingly, all of the cellular enzymes that are resident in compartments of the exocytic pathway and that use carbohydrates as substrates are type II integral membrane proteins, suggesting evolution of all carbohydrate-modifying enzymes from a common progenitor.

The HN glycoproteins contain from four to six sites for the addition of N-linked carbohydrate chains. For the SV5 HN molecule, it has been shown that four sites are used (202). The Paramyxovirus HN glycoproteins have conserved cysteine, proline, and glycine residues between related paramyxoviruses, strongly suggesting a similarity of protein structure. HN forms an oligomer consisting of disulfide-linked homodimers that form a noncovalently linked tetramer. The oligomeric form of HN has been examined in detail by using bifunctional cross-linking reagents and sucrose density gradient analysis (179,193,203,237,275). Sendai virus HN molecules that were proteolytically removed from the surface of virions (at residue 131) retain enzymatic activity and with EM appeared as box-shaped molecules (10 × 10 nm) consisting of four subunits with fourfold symmetry (275). For the Paramyxovirus HN protein, the type II membrane orientation, the presence of a protease-accessible stalk that is not essential for enzymatic activity, and the existence of a tetrameric oligomeric form all parallel influenza virus NA. In addition, Paramyxovirus HN proteins contain a conserved sequence N-R-K-S-K-S that is similar to the known sialic acid binding site of influenza virus NA (280; reviewed in ref. 192). Computer modelling studies predicted that HN will have a b-sheet propeller motif similar to NA of influenza virus (50,166), and the recently obtained atomic structure of NDV HN bears out these predictions (54) (Fig. 14).

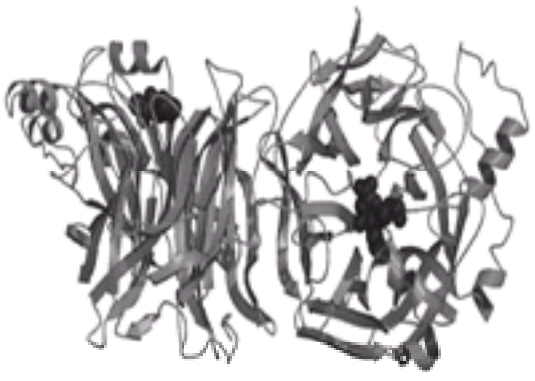

FIG. 14. The hemagglutinin-neuraminidase three-dimensional structure. Protease released, purified NDV HN was crystallized in the presence of the general sialidase/neuraminidase inhibitor 2-deoxy-2,3-dehydro-N-acetyl neuraminic acid (Neu5ac2n, or DANA). In the crystal, the molecule exists as a dimer whose parts are arranged such that the active sites are roughly at 90° to one another. The picture therefore shows a top and side view of each other monomer. The fold of each monomer is the characteristic b-propeller found in other neuraminidases, such as that of influenza virus. DANA is shown bound to the molecule. Structural studies have shown that the sialic acid binding (hemagglutinin) and sialic acid hydrolysis (neuraminidase) sites occupy the same location on the molecule. A structural difference was observed in HN crystallized alone or in complex with the receptor, suggesting a possible mechanism for transmission of a conformational change upon sialic acid binding that could trigger fusion through interactions of HN with the fusion protein. (Figure of the three-dimensional structure of the NDV HN provided by Susan Crennell, Toru Takimoto, Allen Portner, and Garry Taylor.)

For years, it was a matter of debate as to whether HN molecules contain combined or separate active sites for hemagglutinating and neuraminidase activities. Some evidence has been interpreted to indicate a single site that binds sialic acid tightly (hemagglutination) but hydrolyses the molecule slowly (neuraminidase) (249), whereas studies with temperature-sensitive mutants and monoclonal antibody inhibition of activities had been interpreted to suggest there are separate sites for the two activities (223,225). However, analysis of the atomic structure of the NDV HN protein suggests the presence of only a single sialic binding site (54).

The SV5 HN protein, upon being transported to the cell surface, is rapidly internalized by the clathrin-mediated endocytosis pathway (171). The signal for internalization is unusual as it is not located in the cytoplasmic tail but rather at the boundary of the transmembrane (TM) domain and the ectodomain (172). The reason for the internalization of SV5 HN, a process seemingly in conflict with virus assembly, is not known.

The Morbillivirus attachment protein (H) has extensive sequence relatedness and similarity with the HN glycoprotein of respiroviruses and rubulaviruses (reviewed in ref. 192). However, as discussed previously, the Morbillivirus H glycoprotein lacks detectable neuraminidase activity. Measles virus infection is restricted to cells derived from higher primates, and this observation eventually led to identification of the measles virus cellular receptor molecule as CD46, a complement cofactor (74,201), The measles virus receptor CD46 is a low-abundance cell surface protein, and in measles virus– infected cells the expression of CD46 is down-regulated. Therefore, CD46 is unlikely to cause virus aggregation during virus budding. Thus, measles virus, and morbilliviruses in general, may not need a neuraminidase activity in the manner in which other paramyxoviruses need a neuraminidase activity to act as a receptor-destroying enzyme to free the virus from the cell surface. The receptor for CDV and other morbilliviruses is not yet known.

The structure of the Pneumovirus attachment protein (G) is very different from the attachment protein of the *Paramyxovirinae*. The RSV G protein has neither hemagglutinating nor neuraminidase activity. The nucleotide sequence of the RSV G gene predicts that the protein is of about 289 to 299 amino acids (M_r 32,587), and it is a type II integral membrane protein with a single N-terminal hydrophobic signal/anchor domain (247,289). The G protein is found in virus-infected cells in both membrane-bound and proteolytically cleaved soluble forms. The distinguishing feature of the RSV G protein is the extent of its carbohydrate modification. On SDS polyacrylamide gel electrophoresis, the protein migrates with an apparent M_r of about 84,000 to 90,000, and the dramatic increase in molecular weight over that predicted for the polypeptide chain is because 8 to 12 kd is caused by the addition of N-linked carbohydrate (four potential addition sites) and 40 to 50 kd is caused by the addition of O-linked glycosylation (77 potential acceptor serine or threonine residues; 30% of total residues) (44,290, and references therein). Quite remarkably, it appears the RSV G protein is not essential for virus assembly or growth in tissue culture or animals, but it does confer a growth advantage. A virus that had been extensively passaged in cells was found to contain a spontaneous deletion of the G and SH genes (146), yet the virus replicated in Vero cells. In addition, the G gene has been deleted from recombinant virus recovered from an infectious cDNA clone (see Chapter 45). These finding suggest that RSV has an alternative mechanism for attachment to cells that does not involve G protein.

Fusion Protein

The Paramyxovirus fusion (F) proteins mediate viral penetration by fusion between the virion envelope and the host cell plasma membrane, and this fusion event occurs at neutral pH. The consequence of the fusion reaction is that the nucleocapsid is delivered to the cytoplasm. Later in infection, the F proteins expressed at the plasma membrane of infected cells can mediate fusion with neighboring cells to form syncytia (giant cell formation), a cytopathic effect that can lead to tissue necrosis *in vivo* and might also be a mechanism of virus spread.

Paramyxovirus fusion proteins are synthesized as an inactive precursor (F_0) that is cleaved by a host-cell protease. This releases the new N-terminus of F_1, thus forming the biologically active protein consisting of the disulfide-linked chains F_1 and F_2 (128,250). The Paramyxovirus F genes encode 540 to 580 residues (see Fig. 13). The F proteins are type I integral membrane proteins, which span the membrane once and contain at their N-terminus a cleavable signal sequence

that targets the nascent polypeptide chain synthesis to the membrane of the ER. At their C-termini, a hydrophobic stop-transfer domain (a TM domain) anchors the protein in the membrane, leaving a short cytoplasmic tail (about 20 to 40 residues). Comparison of the amino acid sequences of Paramyxovirus F proteins (reviewed in ref. 192) does not show overall major regions of sequence identity, but the similar placement of cysteine, glycine, and proline residues together with the overall hydrophobicity of the F proteins suggests a similar structure for all F proteins. The Respirovirus and Rubulavirus F_2 and F_1 subunits are glycosylated and there are a total of three to six potential sites for the addition of N-linked carbohydrate. For SV5 F protein, it is known that all four potential sites for addition of N-linked carbohydrate are used (7). The Morbillivirus F protein contains three sites in the F_2 subunit for N-linked carbohydrate addition, and all three sites are used, and there are no sites in F_1 for N-linked carbohydrate addition (2).

Protein sequencing studies of the F protein and nucleotide sequencing studies of the F genes have indicated that the N-terminal 25 residues of F_1 (fusion peptide) are extensively hydrophobic and this region of the F protein is highly conserved among F proteins of the *Paramyxovirinae* (up to 90% identity) (Fig. 15). The Paramyxovirus fusion peptides are thought to intercalate into target membranes, initiating the fusion process, and evidence for direct insertion into bilayers has been obtained using hydrophobic photoaffinity labeling probes (204). It has also been shown that the fusion peptides are sufficiently hydrophobic that they can act as a TM anchor domain to convert a formerly soluble protein to a membrane-bound form (210). The invariant nature of many of the residues of the fusion peptide between Paramyxovirus F proteins suggests a role more complex than preservation of hydrophobic residues required for a membrane-intercalating domain; neither signal sequences nor membrane anchorage domains show sequence conservation beyond their hydrophobic nature. It has been noted that if the fusion peptide is assumed to be an a-helix, then the invariant residues are located on one face of the helix (255). Interestingly, in a study on the conserved residues of the fusion peptide when the glycine residues at position 3, 7, or 12 were changed to alanine, and the altered F proteins expressed, a dramatic increase in syncytium formation was observed (130). Thus, the invariant amino acids in the fusion peptide may preserve a balance between high fusion activity and successful viral replication, as high fusion activity is deleterious to cell viability.

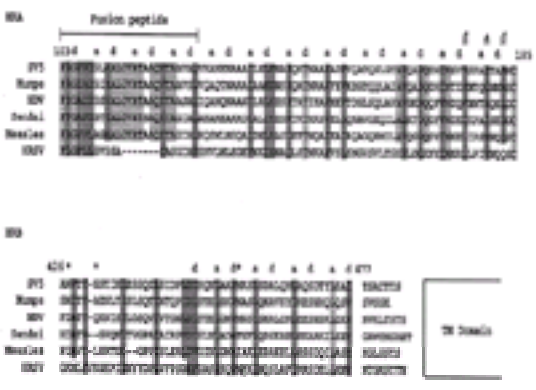

FIG. 15. Sequence alignment of the fusion peptide and the heptad repeats HRA and HRB of the SV5 F protein with that of other paramyxoviruses. Conserved residues among members of the *Paramyxovirinae* (i.e., not including hRSV) are *shaded light gray* and residues with similar properties (hydrophobic or charged) are *shaded dark gray.* Those residues that are also conserved in HRSV, which is evolutionarily distant from other paramyxoviruses, are indicated in the HRSV sequence with the appropriate shading. Letters immediately above the sequence indicate the predicted hydrophobic heptad repeat a and *d* residues. The predicted heptad is incorrect for residues 175 to 184, and the observed *a* and *d* residues in the atomic structure (see Fig. 16) are indicated above the predicted repeat and underlined. *Asterisks* indicate N-linked carbohydrate sites for the SV5 F protein. The SV5 sequence is numbered. NDV, Newcastle disease virus; HRSV, human respiratory syncytial virus. (Adapted from ref. 8, with permission.).

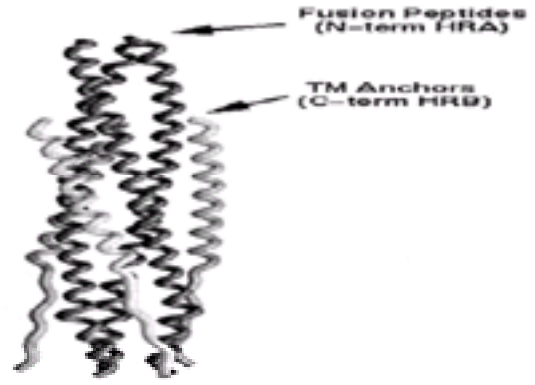

FIG. 16. The SV5 F1 core trimer structure. The complete SV5 F1 core trimer is shown. The central HRA (N-1) trimeric coiled coil is shown in *dark gray* and the buttressing antiparallel HRB (C-1) helices are shown in *light gray.* (Adapted from ref. 8, with permission.)

The fusion proteins of several widely disparate viruses share several important common features. The Paramyxovirus F protein, the human and simian immunodeficiency virus (HIV and SIV) gp160, Ebola virus GP, and influenza virus hemagglutinin (HA) protein all form homotrimers (26,39,85,237,296) that must be proteolytically cleaved to be biologically active (144,153,250). The resulting TM domain–containing subunits (Paramyxovirus F, F_1; HIV gp160, gp41; Ebola GP, GP2; influenza HA, HA_2), contain a hydrophobic fusion peptide at the new N-termini, which has been shown to insert into the target membrane during the fusion process (4,65,104,118). Additionally, two 4-3 heptad repeat regions are present in

each of these fusion proteins, one near the fusion peptide and one in close proximity to the TM domain (20,38). These regions are thought to be important in the fusion reaction, as mutations within these domains frequently lead to a fusion-deficient phenotype (29,42,240,254), and peptides corresponding to these regions have been demonstrated to block the fusion process (139,142,165,177,196,229,293,294,297,300).

The atomic structure of uncleaved and cleaved influenza virus HA are known (40,296). However, this is not the case for the intact glycoproteins HIV-1/SIV gp160, Ebola virus GP, or the Paramyxovirus F protein. However, biochemical, EM, nuclear magnetic resonance, and x-ray crystallographic analyses of most of HA_2 (22), portions of HIV-1/SIV gp41 (12,25,39,177,264,286,287), a portion of a retrovirus Env-TM domain (85), and most of Ebola virus GP2 (178,285) indicate that their heptad repeat regions show considerable similarity in that they all form trimeric coiled coils, with the N-terminal heptad repeat forming an interior, trimeric coiled coil surrounded by three antiparallel helices. This structure has been suggested to represent the final, most stable form of the protein, present either during or subsequent to membrane fusion, with peptide inhibitors most likely functioning by preventing formation of this core (12,177).

The Paramyxovirus F protein membrane proximal subunit (F_1) differs from that of HA_2, gp41, Env-TM, and GP2 because its ectodomain is much larger in size (383 residues versus 120 to 185 residues). F_1 contains two heptad repeat regions, one (HRA) adjacent to the fusion peptide and the other (HRB) adjacent to the TM domain (see Fig. 13). In contrast to the HA_2, gp41, Env-TM, and GP2 just described, where heptad repeats are separated only by small spacer regions, in paramyxoviruses about 250 residues separate the heptad repeat regions. Nonetheless, biochemical and EM analysis indicated that the Paramyxovirus heptad repeat peptides form a rod-shaped structure approximately 96 Å in length. Peptides (N-1) derived from HRA form a three-stranded a-helical coiled coil around which three peptides (C-1) derived from HRB are packed in an antiparallel manner. The N-terminus of N-1 and the C-terminus of C-1 are localized to the same end of the rod, placing the fusion peptides and TM domains close together (77,142). These biochemical data were confirmed by solving the crystal structure of the SV5 F_1 N-1/C-1 complex to 1.4 Å resolution (8). The 64 amino acids of N-1 fold into an 18-turn a-helix stretching the entire length of the coiled coil. The C-terminal 25 residues of C-1 form a seven-turn amphipathic a-helix, whereas amino acids 440 to 450 form an extended chain (Fig. 16 and Fig. 17).

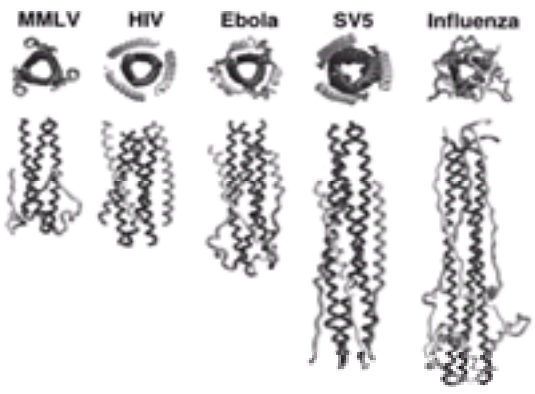

FIG. 17. Comparison of the SV5 F1 core trimer to other viral fusion protein structures. The proteins under comparison include the low-pH-induced influenza virus HA, $tBHA_2$, (22,41), HIV gp41 (39), murine Moloney leukemia virus Env-TM protein (85), and Ebola virus GP2 (285). The interior coiled coil is *dark gray* and the exterior polypeptide is *light gray.* Top and side views are shown for each molecule. (Adapted from ref. 8, with permission.)

Despite the similarity of core structure among these viral fusion proteins, there are important differences between the Paramyxovirus F proteins and other viral fusion proteins. Unlike influenza virus HA protein and HIV gp160, the Paramyxovirus F protein does not provide the primary binding role for the virus: Paramyxovirus primary binding to a target cell is mediated by the HN glycoprotein. However, as mentioned before, at least two *Paramyxoviridae* F proteins, those of Sendai and RSVs, appear to have attachment activity.

A large body of evidence suggests that viral fusion proteins undergo a conformational change to become fusion active (reviewed in ref. 117). For influenza virus HA, the cleaved HA (296) exists in a metastable conformation, trapped from achieving its lower-energy fusogenic conformation by a kinetic barrier. During virus uncoating in endosomes, the low pH environment of the endosomal lumen triggers a conformational change in HA, in which two separate a-helical regions in HA_2 (296) rearrange to form a single triple-stranded coiled coil (22,41). After this conformational change, the fusion peptide is relocated by about 100 Å to one end of the rod-shaped coiled coil (22): the basis of the “spring-loaded mechanism” of fusion (30). For HIV-1 gp120/gp41 and retrovirus Env-SU+Env-TM, binding to the viral receptor may induce the conformational change to release the fusion peptide (65,91,189). The trigger for the putative conformational changes of Paramyxovirus F proteins is unknown, although as described later for many paramyxoviruses there is a requirement for HN in mediating the fusion reaction (reviewed in ref. 161).

Although the Paramyxovirus F protein is the principal viral glycoprotein involved in virus–cell and cell–cell fusion, the emerging picture indicates the presence of a complex biologic machine. The SV5, measles virus, or RSV F cDNAs when expressed in mammalian cells cause syncytium formation (1,2,131,143,206,209,214), although it is important to note it is likely that many more cells express the F protein than are found in multinucleated cells (209). However, for many other paramyxoviruses including NDV, hPIV-2, hPIV-3, bPIV-3, mumps virus, and CDV (37,78,131,135,191,242,271,295,298) coexpression of F and HN (H for the morbilliviruses) is required for syncytium formation. Furthermore, there is a requirement that the homologous (i.e., of the same virus) HN, and not a heterologous HN, be coexpressed in the same cell (131,135,253). Thus, it has been suggested that a type-specific interaction occurs between the HN and F protein that is necessary for fusion to occur (135,161,253). A great deal of effort has been spent to map the regions of F and HN that interact. Mutations have been identified in the HN globular domain (68,188), stalk region (253,260,302), and TM anchor

(17,185) that decrease or abolish fusogenic activity with no effect on receptor recognition. Analysis of the fusion-promoting activity of chimeric HN molecules derived from different paramyxoviruses suggests that both the TM domain (with much of the stalk region) and parts of the globular head impart F specificity (70,265,278). Coimmunoprecipitation assays also indicate that F and HN can exist in a complex (259,298), and that for hPIV-3, F and HN undergo antibody-induced co-capping indicative of protein complex formation (298). Perhaps most intriguingly, a point mutation was found in the NDV HN globular head that abolishes both its receptor recognition and neuraminidase activity, and that also abolishes its ability to interact with F in coimmunoprecipitation assays (69). These latter data suggest that HN interacts with F only after binding its receptor.

A model that would rationalize the involvement of HN (or H) in fusion promotion is one in which the hypothesized conformational change in F to release the fusion peptide is highly regulated. For those *Paramyxovirinae* that require HN (or H) and F to be coexpressed to observe fusion, the first step would be the binding of HN (or H) to its receptor. On binding ligand, the HN (or H) protein would undergo its own conformational change, which in turn could trigger a conformational change in F to release the fusion peptide. In this way, F and HN operate as a coupled molecular scaffold to release and direct the fusion peptide to the target membrane (reviewed in ref. 161). Examination of mutants of SV5 F protein that require coexpression of HN to mediate fusion indicates that the HN function for F protein triggering can be supplanted by providing energy from raising the temperature, suggesting that the F–HN interaction provides energy to convert cleaved F from a metastable form to a fusogenic form (213).

Cleavage Activation

As discussed, the precursor F_0 molecule is biologically inactive and cleavage of F_0 to the disulfide linked subunits F_1 and F_2 activates the protein, rendering the molecule fusion-active and permitting viral infectivity. Thus, cleavage of F_0 is a candidate to be a key determinant for infectivity and pathogenicity, and for certain viruses this appears to be the case. Proteolytic activation of F_0 involves the sequential action of two enzymes, the host protease that cleaves at the carboxyl side of an arginine residue, and a host carboxypeptidase that removes the basic residues. The *Paramyxoviridae* can be divided into two groups: those that have F proteins with multiple basic residues at the cleavage site and those with F proteins that have a single basic residue at the cleavage site (Table 3). Cleavage of F proteins containing multiple basic residues at the cleavage site occurs intracellularly during transport of the protein through the *trans* Golgi network.

Data from Hosaka et al. (125).

TABLE 3. *Amino acid sequences upstream of the F protein cleavage site of some members of the* Paramyxoviridae

Furin is a cellular protease localized to the *trans* Golgi network, and its sequence specificity for cleavage is R-X-K/R-R. The available evidence suggests that furin, a subtilisin-like endoprotease, is the (or one of the) protease(s) that cleaves F proteins intracellularly (207; reviewed in ref. 153).

Paramyxoviruses that have F proteins with single basic residues in the cleavage site (e.g., Sendai virus) are not usually cleaved when grown in tissue culture and, thus, only a single cycle of growth is obtained. However, the F_0 precursor that is expressed at the cell surface and incorporated into released virions can be cleavage-activated by the addition of exogenous protease (250), leading to multiple rounds of replication. Purification of a protease from the allantoic fluid of embryonated chicken eggs has indicated that the endoprotease responsible for Sendai virus activation is homologous to the blood clotting factor Xa, a member of the prothrombin family (100,102). A protease with a similar substrate specificity is secreted from Clara cells of the bronchial epithelium in rats and mice, and this enzyme is probably responsible for activating paramyxoviruses in the respiratory tract. For NDV, the nature of the cleavage site correlates with virulence of the virus. Those strains with multiple basic residues in the F_0 cleavage site are virulent and readily disseminate through the host, whereas those strains with F_0 molecules having single basic residues are avirulent and tend to be restricted to the respiratory tract where the necessary secreted protease can be found (199).

Other Envelope Proteins

The rubulaviruses SV5 and mumps virus both contain a small gene located between F and HN, designated SH (122,123). The SV5 SH protein is a 44-residue, type II integral membrane protein that is expressed at the plasma membrane and is packaged in virions (see Fig. 12). The functional role of SH in the replicative cycle of SV5 is unknown, and in tissue culture cells it can be deleted from an infectious cDNA and recombinant SV5 recovered (111). For mumps virus, although an mRNA transcript derived from the SH gene has been detected (81,82), identification of the SH protein was accomplished only recently (262).

Members of the *Pneumovirinae* also encode an SH protein. The RSV SH protein contains 64 amino acids and is expressed at the plasma membrane of RSV-infected cells as a type II integral membrane protein, and it is packaged in

virions (49,205). In RSV-infected cells, four SH-related polypeptide species have been identified: The M_r 4,800 species is thought to result from the initiation of protein synthesis at an internal AUG codon; the M_r 7,500 species is unglycosylated SH; the M_r 13,000 to 15,000 species is SH containing one high mannose N-linked carbohydrate chain; and the M_r 21,000 to 30,000 species is generated by the addition of polylactosaminoglycan to the N-linked carbohydrate chain (3,205). The SH gene was found to be deleted spontaneously from a virus passaged extensively *in vitro* (146), and it has been deleted from recombinant RSV (21) with only minor alterations in virus growth properties in tissue culture cells, or in the respiratory tract of mice or chimpanzees. Thus, the role of the SH protein in the RSV life cycle is not understood.

Pneumovirus M2 Gene

The RSV M2 gene contains two partially overlapping ORFs, designated M2-1 and M2-2, which give rise to two proteins, M2-1 (194 amino acids) and M2-2 (90 amino acids), respectively (47). The mechanism for translating the M2-2 ORF is not clear, but it may involve a ribosomal stop-restart mechanism analogous to that used for synthesis of the influenza B virus BM2 protein (132) (see Chapter 46). The M2-1 protein is an essential transcriptional elongation factor (45,87), and in its absence the polymerase does not transcribe beyond the NS1 and NS2 genes (87). The M2-1 gene also increases RNAP processivity across the gene junctions, attenuating transcriptional termination (87,106,107). The M2-2 gene is not essential for RSV growth, as it can be deleted from a recombinant RSV (11,140). However, the DM2-2 virus grows slowly in tissue culture and there is an increase in transcription and decrease in RNA replication (11,140), suggesting that M2-2 protein is involved in regulating transcription and RNA replication.

Pneumovirus NS1 and NS2 Genes

The RSV NS1 (139 amino acids) and NS2 (124 amino acids) are considered to be nonstructural proteins, although the difficulty in purifying virions from contaminating infected-cell debris for this poorly growing virus makes this assignment provisional. Neither protein is thought to be essential for virus growth in cultured cells or in chimpanzees, as the genes can be deleted from a recombinant RSV, but growth *in vitro* and *in vivo* is reduced substantially (19,273,292). In a minireplicon system, when NS1 was expressed, it was inhibitory to both transcription and replication (5), and expression of NS2 at high levels had a small inhibitory effect on transcription and replication (272). Thus, the role of these accessory proteins in the RSV life cycle remains to be fully understood.

STAGES OF REPLICATION

As far as is known, all aspects of the replication of *Paramyxoviridae* take place in the cytoplasm. An overview of the life cycle of the virus is shown schematically in Figure 18, and a diagram indicating the differences between transcription and replication is shown in Figure 19. Unlike in influenza viruses, mRNA synthesis in *Paramyxoviridae* is insensitive to DNA-intercalating drugs such as actinomycin D (reviewed in ref. 43), and the *Paramyxoviridae* can replicate in enucleated cells (221). In cell culture, single-cycle growth curves are generally of 14 to 30 hours duration, but they can be as short as 10 hours for virulent strains of NDV. The effect of viral replication on host macromolecular synthesis is quite variable, ranging from almost complete shutoff late in infection for NDV, to no obvious effect with SV5.

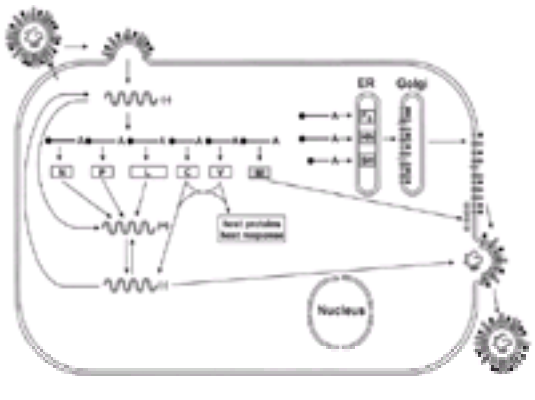

FIG. 18. Schematic representation of the life cycle of a Paramyxovirus. See text for details of the viral life cycle. The gradient of decreasing molar abundance of the mRNAs from N to L resulting from polar transcription is not illustrated [the 5' mRNA cap is indicated with a *filled circle* and 3' poly(A) tail by *(A)*]. Also not illustrated are the relative abundances of genomic nucleocapsid and antigenomic nucleocapsid (indicated with *wavy gray lines*, – and +, respectively). Secondary transcription by newly made genomic nucleocapsids also is not illustrated.

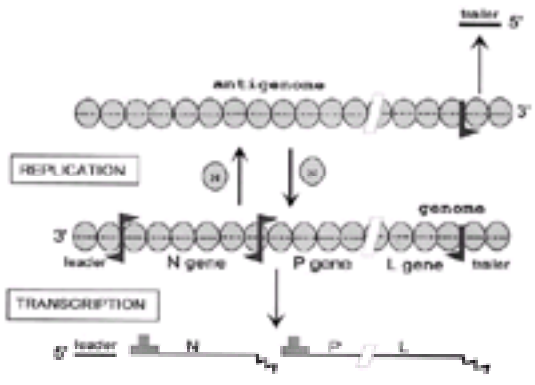

FIG. 19. Paramyxovirus RNA synthesis. Viral nucleocapsids, the templates for RNA synthesis, are shown as a linear array of N subunits (*ovals*), with *short vertical lines* and *arrowheads* indicating the gene junctions. The viral polymerase (P-L) transcribes the genome template, starting at its 3' end, to generate the (+) leader RNA and the successive capped

(*boxes*) and polyadenylated (*squiggly line*) mRNAs, by stopping and restarting at each junction. Once these primary transcripts have generated sufficient viral proteins, unassembled N (as a P-N complex) begins to assemble the nascent leader chain, and the coordinate assembly and synthesis of the RNA causes the polymerase to ignore the junctions, yielding the antigenome nucleocapsid. In this capacity, P acts as a chaperone to deliver N to the nascent RNA. The P-L polymerase can also initiate RNA synthesis at the 3' end of the antigenome in the absence of sufficient P-N, but only a (–) leader RNA (representing the 5' trailer of genome RNA) is made in this case. Note that genomic and antigenomic RNAs never appear as naked RNAs.

Virus Adsorption and Entry

For the respiroviruses and rubulaviruses, it has long been accepted that molecules containing sialic acid (sialoglycoconjugates) serve as cell surface receptors. This is based on the fact that sialidase of *Vibrio cholerae* acted as a “receptor-destroying enzyme” and protected the host cell from infection (reviewed in ref. 181). Sialic acid, the acyl derivative of neuraminic acid, is found both on glycoproteins and on lipids (sialoglycolipids or gangliosides). For Sendai virus, gangliosides function as both the attachment factor and the receptor for the virus (180,182,183). As described, the cellular receptor for the Morbillivirus measles virus is the cell surface protein CD46, and the cellular receptor for pneumoviruses, although not proven, seems to involve binding to glycosaminoglycans containing the disaccharide heparan sulfate and chondroitin sulfate B (88). Upon adsorption of the virus to the cellular receptor, the viral membrane fuses with the cellular plasma membrane at the neutral pH found at the cell surface, the consequence of which is the release into the cytoplasm of the helical nucleocapsids.

In the virus particle, the M protein shell is thought to make numerous contacts with the nucleocapsid. Upon fusion of the viral envelope with the cell plasma membrane and release of the nucleocapsid into the cytoplasm, a mechanism needs to exist to disrupt the M-N contacts. With influenza A virus, the factor that alters the equilibrium between self-assembly and disassembly is thought to be the difference in pH between the acidic uncoating compartment (endosomes) and the assembly site (plasma membrane). The driving force for Paramyxovirus uncoating is not known.

Viral RNA Synthesis

Viral Transcription (mRNA Synthesis)

All viral RNA synthesis begins at the very 3' end of the genome, and the cis-acting promoter sequences serve the dual function of initiating leader RNAs and antigenomes. The vRNAP for mRNA synthesis first has to transcribe the leader RNA before beginning mRNA synthesis at the N gene start signal (see Fig. 19). The recent discovery of two unexpected properties of the *Paramyxovirinae* has provided information on how vRNAP interacts with the genome 3' end to initiate RNA synthesis.

Requirement for Hexamer Genome Length for Efficient Genome Replication: The “Rule of Six”

Efficient replication of model mini-genomes in transfected cells requires that their total length be a multiple of six (Fig. 20) (27). For every Respirovirus or Rubulavirus examined to date using a mini-genome replication assay, RNA replication has been found to be much more efficient when the artificial genome was designed to be a multiple of six nucleotides. Out of 11 complete *Paramyxovirinae* genomic sequences determined to date, six were multiples of six, and it is likely that the deviation in the others will be found to reflect sequencing errors. Inefficient replication of non-hexamer-length genomes was not a result of the lack of encapsidation of the cDNA-expressed mini-genome but of the inability of vRNAP to initiate at the 3' end of these nucleocapsids. This hexamer rule is most likely related to the finding that each N subunit of the nucleocapsid is associated with precisely six nucleotides (79). The association of N monomers with nucleotide hexamers presumably begins with the first nucleotide at the 5' end of the nascent chain, and it continues by assembling six nucleotides at a time until the 3' end is reached, maintaining a precise hexamer arrangement (see Fig. 20). The efficiency of the 3'-end promoter then presumably depends on the position of the cis-acting sequences relative to the N subunits, and this is determined by the total number of nucleotides in the genome chain.

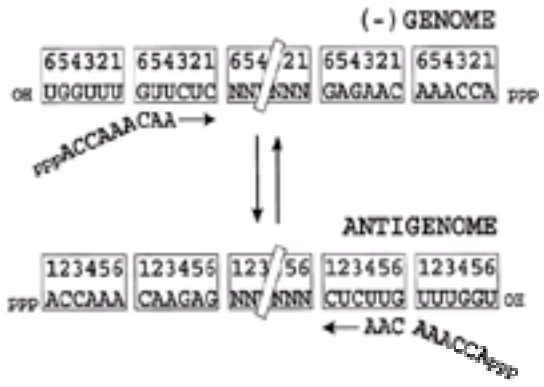

FIG. 20. Rule of six. A schematic representation of the rule of six for replicating the Sendai virus genome. Each *box* represents a single N-protein monomer associated with six nucleotides. ppp, 5' end; OH, 3' end.

Bipartite Nature of the Replication Promoter

The 3'-terminal 12 nucleotides of the genomes and antigenomes of each genus of the *Paramyxovirinae* are identical. This conservation at the termini highlights these two hexamers as a critical element of the replication promoter. The *Pneumovirinae* do not follow an integer rule (244); nevertheless, the extent of identity at the 3' termini of genomes and antigenomes is similar (187,228). For RSV, deletional and saturation mutagenesis has confirmed that the minimal genomic promoter is contained within the terminal 12 to 15 nucleotides of the 44-nucleotide-long leader region, although additional sequences downstream also enhanced RNA synthesis (see Chapter 45). For the *Paramyxovirinae*, it has not been possible to examine the limits of the replication promoters by deletion analysis (see later). Instead, sequence exchanges were made between the genomic and antigenomic promoters, which determines the relative replication efficiency of model mini-genomes (28). In this way, sequences that extended 30 nucleotides from the 3' end were found to affect Sendai virus replication efficiency.

Although sequences beyond the first 30 nucleotides of the Sendai virus genomic and antigenomic promoters could be exchanged freely (269), the deletion of any nucleotides downstream of the promoters, even if the hexamer rule was not violated, was highly deleterious (220,268). Similar results were found at the antigenomic promoter of SV5, where again sequence exchanges, but not deletions, downstream of the conserved 3'-end element were permitted (197). This suggested that a second promoter element lay downstream of the end element, and that the spacing between the two elements was critical for promoter function. This internal promoter element has been identified for both Sendai virus (268) and SV5 (197,198), and it consists of a single template C, or a 3'-GC dinucleotide, respectively, repeated three times with an internal spacing of precisely six nucleotides in the 13th, 14th, and 15th hexamer from the 3' end. The position of the two promoter elements is shown in Figure 21 in the context of the proposed structure of the Sendai virus nucleocapsid. As each turn of the nucleocapsid helix contains 13 N subunits, each associated with precisely six nucleotides (79), the terminal and internal promoter elements are aligned on the same face of the helix. Both promoter elements can then simultaneously interact with vRNAP to initiate RNA synthesis at the 3' end of the nucleocapsid. Morbilliviruses contain the same internal promoter element as respiroviruses, and all the members of the *Paramyxovirinae* probably contain bipartite replication promoters. In contrast, pneumoviruses do not appear to contain bipartite promoters, as RSV-based mini-genomes require only about 40 nucleotides from each genome end for efficient replication (see Chapter 45).

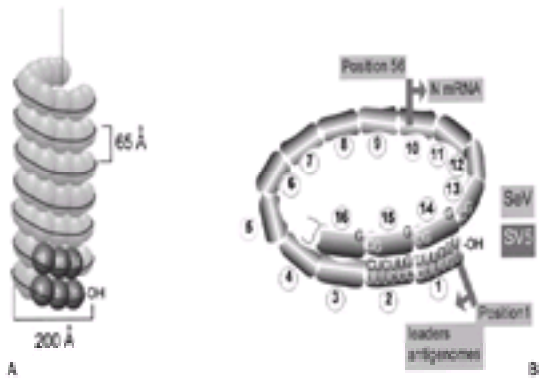

FIG. 21. Nucleocapsid structure, hexamer phasing of the nucleotide sequence, and the bipartite replication promoters of the *Paramyxovirinae*. **A:** A model of the Sendai virus nucleocapsid as an assembly of single N-protein subunits (*shaded spheres*), in the form of a left-handed helix with 13 subunits per turn, a pitch of 65 Å, and a hollow central core of 50 Å in diameter. The numbers refer to the position of each N subunit from the RNA 3' end. **B:** Expanded view of the first 16 N-protein subunits (drawn as *rounded rectangles*, numbered from the RNA 3' end) of the genome nucleocapsid. Positions refer to the nucleotide sequence relative to the RNA 3' (OH) end. The invariant elements of the bipartite genomic and antigenomic promoters of Sendai virus and SV5 are shown relative to the N subunits; each subunit contains precisely six nucleotides. The start sites for the leader RNA, antigenome RNA, and N mRNA are indicated with *arrows.* Note that both elements of the bipartite replication promoter are found on the same face of the helix, whereas N mRNA synthesis starts on the opposite face of the helix.

Primary Transcription

Early in virus infection, before the primary translation products have accumulated (or in the presence of drugs that inhibit protein synthesis at any tage of the infection), vRNAP is restricted to the production of leader RNAs and mRNAs. A leader RNA termination site has not been demonstrated by mutational analysis for any nonsegmented negative-strand RNA virus, and vRNAP that has initiated at the genome 3' end and reads through the leader–N junction may simply become nonprocessive and release its nascent chain heterogeneously within the N gene.

N mRNAs are invariably initiated opposite the second nucleotide of the 10th hexamer (see Fig. 21, genome map position 56) for the *Paramyxovirinae* (157). More than 90% of vRNAP that have initiated the Sendai virus N mRNA (and capped its 5' end) go on to finish the N mRNA (283). The processivity of this vRNAP during mRNA synthesis (transcription) is thus quite different from that which has initiated at the genome 3' end and reads through the leader–N junction in the process of RNA replication, which depends on concurrent assembly of the nascent chain for processivity. The vRNAP that has (re)initiated at position 56 in the process of transcription also responds to the cis-acting gene-end sequence at high frequency (see later), whereas during RNA replication these signals are ignored. mRNA 3' end formation and polyadenylation occurs by vRNAP reiteratively copying a short run of template uridylylates (four to seven long) within the gene-end sequence (see Fig. 6). This process leads to termination and release of the mRNA, and vRNAP is then free to move on to the next gene-start site and to reinitiate the next mRNA.

Initiation of a downstream mRNA depends on termination of the upstream mRNA consistent with a single vRNAP entry site at the genome 3' end. For respiroviruses and morbilliviruses, the next gene-start sequence is separated from the

gene-end sequence by precisely three conserved nucleotides (3'GAA; see Fig. 6). In contrast, for rubulaviruses, NDV, and pneumoviruses, the intergenic region is variable in length and sequence. Moreover, for RSV the L gene-start sequence is actually located upstream of the gene-end sequence of the upstream M2 gene (48). Thus, 90% of the transcripts that initiate the L mRNA terminate at the M2 gene-end sequence, generating aborted L mRNAs. The vRNAP is then free to scan the N:RNA in either direction for the L gene-start sequence, much as cellular RNAPs scan dsDNA in search of a promoter (86). The RNAP of *Rhabdoviridae* also scans the N:RNA for gene-start sequences after terminating an mRNA (see Chapter 38), and this scanning appears to be a general property of nonsegmented negative-strand RNA virus RNAPs following release of a completed mRNA.

The frequency with which vRNAP reinitiates the next mRNA at gene junctions is not perfect, and this leads to a gradient of mRNA abundance that decreases according to distance from the genome 3' end (36,127). This frequency can be regulated (at least in part) by the gene-start sequence, which is highly, but imperfectly, conserved. Reducing reinitiation at one junction leads to a coordinate reduction in the expression of all the downstream genes. Failure to terminate at a gene-end sequence, in contrast, leads to di- (or tri-) cistronic mRNAs in which only the upstream cistron is normally translated, because of the usual requirement that a eukaryotic ORF initiate near a 5' mRNA end. However, vRNAP that reads through a junction is spared falloff because of inefficient reinitiation. There are numerous examples of paramyxoviruses that specifically down-regulate the expression of particular enes, especially the F gene, by generating di-cistronic M-F mRNAs. In several cases, readthrough of this junction is associated with deviations from the consensus gene-end sequence; the most extreme example being the complete lack of an apparent gene-end signal in the M-F junction of SV41. For SV5, whose M gene-end sequence (3'-A**G**UUUCU$_4$) deviates from the consensus at a single position and contains the shortest U run (3'-A **A**NUUCU$_{4–7}$), lengthening the U run was without effect. However, converting the **G** five positions upstream of the U run to **A** restored vRNAP response to this gene-end sequence and prevented readthrough of this junction. However, analysis of genetically engineered recombinant Sendai virus and SV5, in which the gene termination, intercistronic region, and gene-start [EIS (see Fig. 6)] were switched for other EIS sequences, suggests that the simple model of transcriptional attenuation from the genome 3' end is not the only factor determining mRNA accumulation, particularly from the L mRNA (110,147).

RSV gene-end sequences are more diverse than their gene-start sequences (see Fig. 6). They operate at variable efficiency (see Chapter 45). This may be relevant to RSV infections, as the M2-1 protein not only increases vRNAP processivity between junctions during transcription, it also promotes readthrough of the junctions. M2-1 may play a role in fine-tuning the relative abundance of mono- and dicistronic mRNAs.

P Gene mRNA Editing

Most Paramyxovirus P genes contain a functional editing site at the start of the internal, overlapping V ORF (see Fig. 7). Transcription yields, in addition to faithful (unedited) mRNA, edited versions that contain variable numbers of inserted G residues. The number of G insertions that occur for each virus group mirrors their requirements to switch between the in-frame and *trans*-frame downstream ORFs (see Fig. 7). For the morbilliviruses, respiroviruses, and NDV, which require a single nucleotide insertion to shift to the V ORF from the genome-encoded P ORF, a single G is added as the predominant editing event (see Fig. 7). For the rubulaviruses, which require the insertion of two nucleotides to access the P-carboxy pol-cofactor domain of the P ORF from the genome-encoded V ORF, insertion of two Gs constitutes a high proportion of editing events. For bPIV-3 and hPIV-3, where both the V and D ORFs overlap the middle of the genome-encoded P ORF, one to six G residues are added at roughly equal frequency so that mRNAs encoding all three overlapping ORFs are transcribed.

As the paramyxoviruses replicate in the cytoplasm, they must provide enzymes for all aspects of their mRNA synthesis. Paramyxovirus vRNAPs polyadenylate their mRNAs by stuttering on a short run of template U residues (four to seven nucleotides long) at the end of each gene. By analogy to the polyadenylation mechanism, it was suggested that the G insertions at the specific site in the P gene (Fig. 22) would occur similarly by pseudotemplated transcription (35,138,274,281), and there is now strong experimental evidence that the insertions occur cotranscriptionally, by a stuttering mechanism (108,109,282). This mechanism of pseudotemplated transcription, outlined in Figure 23, would apply as well to mRNA polyadenylation if the mRNA–template hybrid is reduced to four base pairs (108).

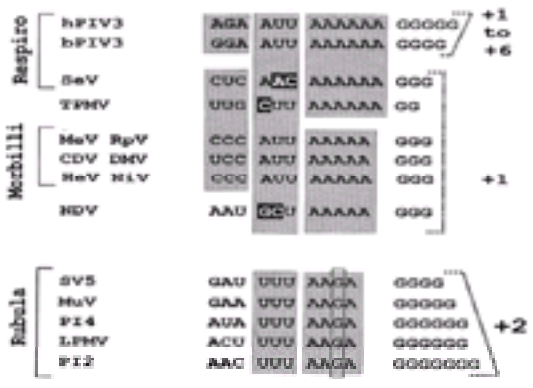

FIG. 22. Sequence relationships at the Paramyxovirus P gene editing sites. The sequences are written as (+) RNA, 5' to 3', and are grouped into the three current genera of the *Paramyxovirinae* except for NDV. Spaces have been introduced to emphasize the different elements of the sequence, and *shaded boxes* indicate sequence conservation. The short G run, which is expanded during mRNA editing, is shown on the right, together with the pattern of G insertions that occurs for each group. Note that the A run preceding the G run may be the only part of this cis-acting sequence that is strictly conserved according to genus. Also note that the second A residue upstream of the Rubulavirus G run is replaced by a G (highlighted with *rectangle*), which is thought to account for why most rubulaviruses insert a minimum of two G residues when stuttering begins (282).

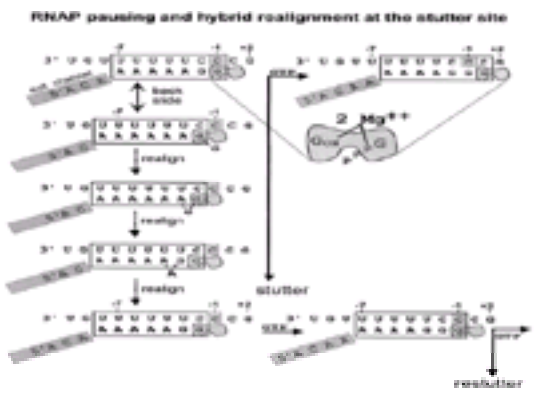

FIG. 23. A competitive kinetic model for Sendai virus RNAP stuttering elongation. The template and mRNA chains of the transcription elongation complex (TEC) at the editing site are shown schematically. The putative seven base-pair hybrid between the polypyrimidine tract of the (–) genome (top strand) and the polypurine run of the nascent mRNA chain (bottom strand) when the TEC is at the editing site is *boxed.* The NTP binding site (position +1) is empty. The nascent mRNA upstream (*left*) of the hybrid is proposed to enter an exit channel (*boxed in gray*) before reaching the surface of the RNAP, and this limits the length of the hybrid as TEC proceeds. The exit channel is thought to contain 10 nucleotides. The bipartite active site, in which the nascent mRNA 3' end (position –1) and the NTP a-phosphate are coordinated via two Mg^{++} ions is highlighted in *gray.* The TEC at the *top left* is at the editing site (middle template C, *boxed in gray*) and has just incorporated a strictly templated G (position –1). The TEC at the unique editing site presumably pauses because of backsliding of RNAP by one position along both the template and the mRNA chains, undoing the last base pair (bp) of the hybrid (and removing the mRNA 3' end from the active site) and reforming one bp upstream. RNAP at pause sites is envisaged as oscillating between the inactive backtracked alignment (*second line*) and the active alignment (*top line*). If a strictly templated GMP is the next nucleotide incorporated, RNAP moves past the unique stutter site and resumes normal elongation (*top right*). Alternatively, realignment of the hybrid also repositions the mRNA 3' end in the active site. Hybrid realignment when RNAP is in the backtracked state is initiated when the unpaired 3'G re-pairs with C-2 (*third line*), causing the penultimate G to bulge out. Realignment is completed on translocation of the single nucleotide bulge to the upstream side of the hybrid (*fourth line*), reforming a seven-bp hybrid that is nearly as stable as its predecessor (*fifth line*). The mRNA 3' G is now correctly repositioned in the active site, and nucleotide addition at this point leads to a single pseudotemplated G insertion, or stutter (lower-case g, *bottom right*). Having stuttered once, the transcription complex is back to where it started and has the same choices (second branchpoint, *bottom right*). Escape from stuttering occurs when TEC moves to a template position where hybrid realignment (stuttering) is no longer favored. Numbers above the genome sequence always indicate positions relative to the mRNA 3' end at the start of the stutter (*top left*, position –1).

Genome Replication

The (–) genome replicates via a full-length complementary copy called the antigenome, which, like the genome, is found only in assembled form. Compared to *Rhabdoviridae*, there are considerable amounts of antigenomes in Paramyxovirus-infected cells (10% to 40% of genome-sized RNAs for Sendai virus). Antigenomes can also represent 5% to 20% of the genome-sized RNAs in virus particles, as discrimination against antigenome nucleocapsids is poor during virus assembly (155,156,231). However, they contain no ORFs of any note and no mRNAs are known to be transcribed from them. The sole function of antigenomes is thought to be as an intermediate in genome replication, although the short trailer RNAs expressed from the antigenome 3' ends (see Fig. 19) may also play a role in preventing the host cell from undergoing programmed cell death (98).

A schematic diagram of the essential differences between transcription and replication is shown in Figure 19. After translation of the primary transcripts and accumulation of the viral proteins, antigenome synthesis begins. Here, ostensibly the same vRNAP (until then engaged solely in mRNA synthesis) copies the same template, but it now ignores all the junctional signals (and editing sites) and synthesizes an exact, complementary copy. Transcription and replication were first distinguished by finding that, when infected cells are treated with drugs that inhibit protein synthesis, mRNA synthesis continued normally but genome synthesis was lost very quickly (232). As genome synthesis and encapsidation appear to occur concomitantly, this requirement for ongoing protein synthesis has been associated with the continued supply of unassembled N necessary for genome encapsidation. The manner in which the coupling of genome assembly and synthesis leads to vRNAP ignoring the gene junctions and editing signals remains unclear (reviewed in ref. 158).

This coupling of genome assembly and synthesis also leads to a self-regulatory system for controlling the relative levels of transcription and replication. For VSV, the site for the initiation of antigenome encapsidation has been mapped to the first 14 nucleotides of the leader sequence, and for paramyxoviruses a similar situation appears to apply. In measles virus–infected cells, a rare polyadenylated transcript representing the leader and N gene sequences fused together is found, but only as a nucleocapsid, whereas the N mRNA is found only in a nonassembled form (31). As the leader sequences contain the encapsidation site, the leader must be separated from the body of the first mRNA (by termination and reinitiation at the first junction) to prevent the first mRNA from ending up in an assembled and untranslatable form. The proposed self-regulatory mechanism would then be quite straightforward; when unassembled N is limiting, vRNAP is preferentially engaged in mRNA synthesis, raising the intracellular levels of all the viral proteins, including unassembled N. When unassembled N levels are sufficient, some vRNAP would be switched to replication, thereby lowering the levels of unassembled N, as each initiation of encapsidation would commit about 2,600 N monomers to finish the assembled genome chain (154). The rare measles virus leader-N mRNA (31), described previously, was presumably made by vRNAP that began the synthesis of an antigenome nucleocapsid but nevertheless polyadenylated and terminated the chain at the second junction. The assembly and synthesis steps can then sometimes become uncoupled, possibly because assembly of the nascent chain does not keep pace with vRNAP movement as it approaches a junction. Whether

the level of unassembled N is the only mechanism that controls the relative levels of Sendai virus transcription versus RNA replication remains unclear. For RSV, however, there is increasing evidence that other viral gene products (e.g., the M2-2 protein) may also play a role (see preceding and Chapter 45).

Genome synthesis from antigenome templates is thought to take place in a fashion similar to that of antigenome synthesis, in that the promoter at the 3' end of the antigenome is also always “on,” and short trailer [also called (–) leader] RNAs are made from this region independently of ongoing protein synthesis (see Fig. 19). However, in contrast to synthesis from genome templates, there are no reinitiation sites on the antigenome template, so termination of the trailer RNAs in the absence of sufficient unassembled N protein serves only to recycle vRNAP. Under conditions of sufficient intracellular concentrations of unassembled N (and perhaps other viral proteins), encapsidation of the nascent trailer chain would quickly begin and this would prevent termination and lead to the synthesis on an encapsidated minus-strand genome.

Virion Assembly and Release

Like all other events in the life cycle of replication of paramyxoviruses, the intracellular site of nucleocapsid assembly is the cytoplasm. The nucleocapsids are thought to be assembled in two steps: first, association of free N subunits with the genome or template RNA to form the helical RNP structure, and second, the association of the P-L protein complex (152). By analogy to the mechanism of assembly of TMV nucleocapsid, which uses a defined nucleation site for the association of the first coat protein subunit with the RNA, and the observation that the Paramyxovirus mRNAs are not encapsidated (in contrast to antigenomes), it has been assumed that the (+) leader (5' end of the antigenome) and (–) trailer (5' end of the genome) regions contain specific sequences for initiating encapsidation (14).

The assembly of the second part of the virus, the envelope, is at the cell surface. In polarized epithelial cells, the *Paramyxovirinae* bud only from the apical surface. The viral integral membrane proteins are synthesized in the ER and undergo a step-wise conformational maturation before transport through the secretory pathway. The mechanisms of viral glycoprotein folding, oligomeric assembly, and sorting have been extensively characterized. Folding and conformational maturation of glycoproteins are not spontaneous events that occur in the cell. Rather, they are assisted by numerous folding enzymes and molecular chaperones. Viral integral membrane proteins, particularly HA and NA of influenza A virus, the G protein of VSV, and the HN protein of SV5 and Sendai virus, have been used extensively as paradigms of cellular glycoproteins, and much of the current understanding of the process occurring in the exocytotic pathway has been learned from studying these proteins (reviewed in refs. 73,116). Only correctly folded and assembled proteins are generally transported out of the ER. In the Golgi apparatus, the carbohydrate chains may be modified from the high-mannose to the complex form, and for those F proteins with multiple basic cleavage sites, cleavage occurs in the trans Golgi network. Finally, the glycoproteins are transported to the plasma membrane.

The mechanism by which the virus particle is assembled at the plasma membrane is unknown. As discussed, the viral M proteins are thought to play a major role in bringing the assembled ribonucleoprotein core to the appropriate patch on the plasma membrane to form a budding virion (Fig. 24). The protein–protein interactions involved in assembling a virion presumably must be specific, as cellular membrane proteins are largely excluded from the virions. It is presumed that the glycoprotein cytoplasmic tails make important contacts with the M protein, which, in turn, associates with the nucleocapsid. Genetically engineered recombinant measles virus and SV5 that lack glycoprotein cytoplasmic tails are defective in assembly and there is a relocalization of the subcellular distribution of the matrix protein (33,251). For Sendai virus HN protein, the cytoplasmic tail sequence SYWST has been shown to be important for incorporation into virions (263). Those *Paramyxovirinae* that have neuraminidase activity contain glycoproteins that lack sialic modification of their carbohydrate chains, and it is thought that the HN neuraminidase activity serves the same purpose as NA in influenza virus, to prevent self-binding and to prevent reattachment to the infected cell.

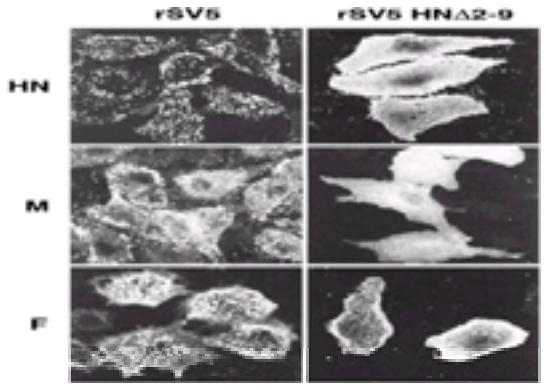

FIG. 24. Altered localization of viral proteins in cells infected with recombinant SV5 expressing an HN protein with a truncated cytoplasmic tail. In wild-type recombinant SV5 (rSV5)-infected cells, HN was found in highly localized patches on the cell surface, and it is likely that these patches are the sites of budding virus. In contrast, in cells infected with rSV5 HND2–9, a recombinant SV5 lacking residues two to nine of the HN cytoplasmic tail, a striking redistribution of the HN staining pattern was observed, with HN being distributed all across the cell surface. Concomitant with the altered HN staining pattern in cells infected with rSV5 HND2–9, a redistribution of the M protein straining pattern was observed. The similarity of HN and M staining patterns suggests that targeting of M protein into presumptive budding sites at the cell surface depends on the presence of an HN cytoplasmic tail. (Adapted from ref. 251, with permission.)

MOLECULARLY ENGINEERED GENETICS (REVERSE GENETICS)

The study of viruses and their interactions with host cells and organisms has benefited greatly from the ability to engineer

specific mutations into viral genomes, a technique known as reverse genetics (288). For RNA viruses, genome manipulation of the positive-sense RNA bacteriophage Qb was the first to be performed (90,266). The negative-stranded RNA viruses, in contrast to positive-sense RNA viruses, require that the virion RNA be assembled into an active transcriptase–replicase complex for the genome to initiate virus replication. Nonetheless, techniques to manipulate the genomes of nonsegmented negative-strand RNA viruses have now been developed (reviewed in ref. 230). The development of the system originally proved quite frustrating. A number of laboratories studying a number of different rhabdoviruses and paramyxoviruses, worked over a period of several years to establish the methods of reconstructing functional nucleocapsids from transfected cells. The concept of replicating mini-genomes using support plasmids providing N, P, and L proteins in *trans* was key to the development of the technology. This culminated in the successful recovery of infectious rabies virus in 1994, followed several months later by VSV, and several months later by Sendai, hRSV, and measles virus.

Rabies virus was rescued when plasmids encoding L, P, and N protein, as well as a plasmid containing the viral antigenome, all under control of the bacteriophage T7 RNA polymerase promoter, were transfected into cells infected with a recombinant vaccinia virus expressing the bacteriophage T7 RNA polymerase protein (vac-T7). For example, the following viruses have been rescued: VSV (170,291), measles virus (227), hRSV (45,141), Sendai virus (97,150,174), rinderpest virus (9), hPIV-3 (75,126), SV5 (112), NDV (218,233), and bRSV (19). A schematic diagram showing the general scheme for rescue is illustrated for SV5 in Figure 25. Some refinements to the original technique have been made, such as the use of stably transfected cell lines expressing the bacteriophage T7 RNA polymerase (in lieu of vac-T7 infection), or one or more of the viral proteins required for genome replication (19,227).

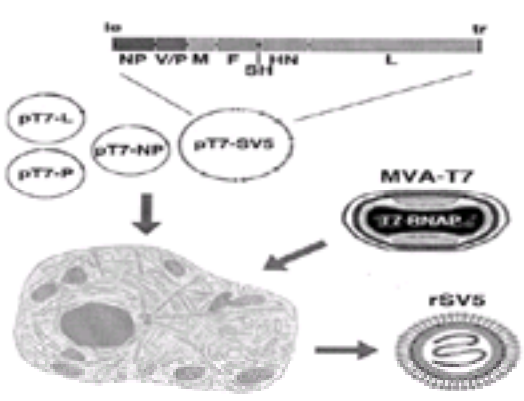

FIG. 25. Schematic diagram for generating infectious SV5 from cloned cDNA. Nonsegmented negative-strand virus rescue involves the transfection of plasmids encoding the viral P, N, and L proteins (and sometimes other viral proteins, depending on the virus), as well as the viral antigenome, all under control of the T7 promoter. The bacteriophage T7 RNA polymerase is provided either by infection with a vaccinia virus expressing T7 polymerase (in this case, modified vaccinia virus Ankara, MVA-T7) or by transfecting into cell lines that stably express the protein. pT7-SV5 contains a complete copy of the SV5 genome (15,246 nucleotides) and is flanked at one end by a bacteriophage T7 RNA polymerase (T7 RNAP) promoter and at the other end by a hepatitis delta virus ribozyme and T7 transcriptional terminator. The plasmids pT7-L, pT7-P, and pT7-N each contain the cDNA for the SV5 L, P, and N proteins, respectively, under the control of T7 RNAP promoters, such that mRNA transcripts encoding L, P, and N can be transcribed using T7 RNAP. A549 cells (a human cell line that is permissive for SV5 and can be efficiently transfected) were infected with MVA-T7 and transfected with pT7-SV5 and the three support plasmids pT7-L, pT7-P, and pT7-N. (Adapted from ref. 112, with permission.)

VIRAL ACCESSORY GENES AND THEIR INTERACTIONS WITH THE HOST

In all studies on reconstituting intracellular virus replication in transfected cells from model mini-genomes, only the P (as defined above), L, and N proteins were found to be strictly required to initiate genome expression and amplification. However, for RSV, coexpression of the M2-1 protein increases vRNAP processivity during transcription (46,87,107). For all the other accessory proteins, their initial coexpression was either without effect or it inhibited mini-genome replication. For the Sendai virus C protein, inhibition of replication was so severe that C coexpression from the P-protein support plasmid had to be suppressed to recover infectious virus (24). Despite these neutral or negative effects on genome replication and expression in transfected cells, reverse genetics has shown that the accessory genes also exert positive effects during natural infections of cells in culture, or in animals as a result of interaction with the host, such as countering the interferon system (see later).

Respirovirus and Morbillivirus V, W, and D Proteins

Infectious measles virus or Sendai virus engineered to have inactive editing sites (i.e., by introduction of mutations at the editing site, so that these viruses cannot express their V and W proteins) are viable, and they grow in cell culture slightly more rapidly than wild-type virus (67,148,252), consistent with an inhibitory role for V and W in genome amplification (56). However, an important step toward understanding the role of the V protein in the Sendai virus life cycle was made when it was found that, although the Sendai virus–edit minus mutant grew perfectly well in cell culture, it was avirulent for mice (148). In contrast to wild-type virus, Sendai virus–edit minus could not sustain its infection of the respiratory tract and was quickly cleared from the animal. Given that mice could restrict Sendai virus–edit minus replication so quickly, it was suggested that V functioned to counteract some aspect of the animal's innate immune system (148).

To examine whether this avirulence was caused by the loss of V, or W, or both proteins, Sendai virus–Vstop mutant, in which the V ORF is closed and expresses a W-like protein in place of V, was characterized (67,149). In 3-week-old outbred mice, Sendai virus–Vstop was almost as attenuated for virulence as Sendai virus–edit minus. In inbred mice, however, Sendai virus–Vstop was almost as virulent as wild-type Sendai virus, whereas Sendai virus–edit minus

remained avirulent. Thus, the W protein can mostly replace the V protein for counteracting host defenses in the inbred mouse strain. The W protein, however, cannot replace the V protein in the more robust outbred animals, where the cysteine-rich domain of the V protein is clearly required for virulence. The finding that the cysteine-rich domain of V protein is not essential for virulence in some mice may be relevant for hPIV-1, which does not contain a V ORF or an editing site (184). The hPIV-1 may express low levels of a W-like protein by other means, such as ribosomal frameshifting. For hPIV-3, two or more (depending on the strain) stop codons are present between the editing site and the almost perfectly conserved cysteine-rich domain, and a V-like protein has not been demonstrated biochemically in hPIV-3 infections. Nevertheless, the introduction of stop codons in both the V and D ORFs simultaneously (but not individually) attenuated hPIV-3 replication *in vivo* (76). Thus, a hPIV-3 V-like protein may be expressed at low levels after all, by some mechanism other than editing, and may contribute to viral virulence along with the D protein.

Measles virus–edit minus mutant is also attenuated compared to wild-type virus in mice with severe combined immunodeficiency disease (SCID) that have been engrafted with human thymocyte/liver as a substrate for measles virus replication. Measles virus–edit minus mutant also grows to lower titers in the lungs of cotton rats (277,279). Measles virus–edit minus is also slightly less virulent in transgenic mice that express the human CD46 receptor (195,216). Thus, Morbillivirus V/W proteins may also function in countering host defenses. On the other hand, rubulaviruses that cannot express their V protein have not been reported. It may be that the Rubulavirus V protein has a significant role in intracellular virus replication. Precisely what aspect of innate immunity the V, W, or D proteins affect remains unclear. Neither natural killer cells nor the interferon system seems to be involved for Sendai virus (96,101).

C Proteins and Rubulavirus V Proteins

Measles viruses that cannot express their single C protein are viable, and they replicate in cell culture in a manner similar to wild-type viruses (226). The hPIV-3 also expresses a single C protein, but hPIV-3-C-minus growth is clearly restricted in cell culture (76). Sendai virus, in contrast, expresses four “C” proteins (C', C, Y_1, and Y_2), and recombinant Sendai virus (rSeV), which cannot express any of their C proteins, is at the limit of recovery from DNA and grows to titers that are four logs lower than wild-type virus (159,167). The number of expressed C proteins, and their relative importance for the intracellular replication of each virus, is thus quite different, with the caveat that the “wild-type” measles virus is a cell culture–adapted mutant.

The Sendai virus C' and C proteins (but not Y_1 and Y_2) are promoter-specific inhibitors of viral RNA synthesis (24,267). Consistent with this, infections with rSeV that cannot express C' or C individually (by mutating their ribosomal start codons) accumulate more viral RNAs than wild-type rSeV infection, and cytopathic effects are seen earlier (167). However, the simultaneous absence of both C' and C paradoxically delays viral RNA accumulation and cytopathic effects, and these viruses form “pin-hole” plaques. Thus, in addition to their negative effects on viral RNA synthesis (which apparently operate later in infection when these essentially nonstructural proteins have accumulated), C' and C apparently also provide a positive function without which the onset of viral RNA accumulation intracellularly is delayed. This positive function of C is not seen when a recombinant Sendai virus infection is launched from plasmids in transfected cells. Here, the early events in the infectious process have been bypassed (by jump-starting viral replication from DNA), and only the later inhibitory effects are detected. Presumably either C' or C (but not Y_1 or Y_2) can supply this early required function in cell culture infections. Viruses unable to express either C' or C individually would have this function provided by the remaining protein and would not show a debilitated phenotype.

Mutation of residue phenylalanine 170 of the Sendai virus C protein to serine (by classic or reverse genetics) strongly reduces virulence in mice. The C protein F170S mutation was discovered as one of two mutations (the other in the L gene) in a highly virulent virus strain (Sendai virus strain M; LD_{50} of 40) that became avirulent (Sendai virus variant MVC; LD_{50} of >800,000) on adaptation to LLC-MK2 cells (137). Recombinant Sendai virus carrying the C protein F170S mutation in an otherwise wild-type background is also avirulent in mice (95), and introduction of this mutation into hPIV-3 (C protein F164S) similarly attenuated virulence *in vivo* (76). Although rSeV-C protein F170S was avirulent, it grew normally in the mouse respiratory tract at first. However, like Sendai virus–edit minus, virus was then quickly cleared. The rapidity of the antiviral response in immunologically naive mice again suggested that some aspect of innate immunity is involved. One such function has recently been identified. Infection of interferon (IFN)-competent cells with Sendai virus, or SV5, does not induce an IFN-mediated antiviral state. These infections do not affect the secretion of IFN but somehow interfere with its receptor-mediated signaling, as they prevent added IFN from inducing an antiviral state (71,96). For Sendai virus, the C gene is clearly involved, as Sendai virus-C protein F170S infection does not interdict IFN signaling (96), and C protein expression independent of virus infection prevents added IFN from activating IFN-responsive promoters (94). Consistent with this latter finding, Sendai virus-(C-minus) infection was avirulent, whereas Sendai virus-(C'-minus) was found to be as virulent for mice as wild-type virus, even though this virus overexpresses Y_1 and Y_2. Thus, the AUG_{114}-initiated C protein is specifically required for virulence in mice, or to interfere with IFN signaling (96,168). For SV5, however, it is the V protein that functions to interdict IFN signaling (71), and the SV5 V protein interferes with IFN signalling by causing the proteasomal degradation of the transcription factor, STAT-1 (72). Given that the IFN system is the first line of defense against viral infections, it is possible that the Morbillivirus C proteins (83,195,216) or one of the Pneumovirus accessory proteins, also functions to counteract the IFN-mediated cellular antiviral response.

CHAPTER 42 Parainfluenza Viruses

Robert M. Chanock, Brian R. Murphy, and Peter L. Collins

HISTORY

The parainfluenza viruses include important respiratory tract pathogens of infants and children, as well as important viruses of mammals and birds. These medium-sized (150- to 200-nm) enveloped viruses have a nonsegmented negative-strand RNA genome and belong to the family *Paramyxoviridae* of the order *Mononegavirales*, the nonsegmented negative-strand RNA viruses (240). The parainfluenza viruses that infect humans were first recognized following the application of tissue culture and hemadsorption techniques to the study of pediatric respiratory tract disease (24,28,137). The four human parainfluenza viruses (hPIV1 to hPIV4) were first recovered during the period of 1956 to 1960. They were recognized by cytopathic effects that developed in infected tissue cultures (hPIV2) or by the hemadsorption reaction in which guinea pig red blood cells become adsorbed to an infected tissue culture monolayer (24,28,137). The hPIV1, 2, and 3 were initially isolated from infants and children with lower respiratory tract disease, and hPIV4 was recovered from children and young adults with minor upper respiratory tract illness. Soon after their discovery, these viruses were shown to be a major cause of croup (hPIV1, 2, and 3) as well as pneumonia and bronchiolitis (hPIV3) (27,29,30,90,159,228). As a group, hPIV1 to 3 are second only to respiratory syncytial virus (RSV) as a cause of serious respiratory tract disease in infants and children (208).

Before the first human virus strains were isolated, a parainfluenza virus had been recovered from mice inoculated with an autopsy specimen from an infant with respiratory disease (173). This agent, Sendai virus, was later shown to be indigenous to mice and not a human pathogen. Its antigenic relationship to hPIV1 led to some confusion when it was used in serologic studies of patients with acute respiratory disease. Ultimately, Sendai virus was classified as the murine counterpart of hPIV1. Animal counterparts were subsequently identified for other human parainfluenza viruses. Simian virus 5 (SV5), a common contaminant of primary monkey kidney tissue cultures and a cause of croup in dogs, was shown to be a counterpart of hPIV2, whereas a bovine shipping fever virus was classified as the bovine counterpart of hPIV3 and designated bPIV3 (1,26,45). Simian virus 41 (SV41) also was isolated as a contaminant of primary monkey kidney cell culture and appears to be even more closely related to hPIV2 than is SV5 (314). In addition, nine distinct serotypes of avian parainfluenza virus are now recognized, of which Newcastle disease virus (NDV) is the prototype of serotype 1 (3).

The parainfluenza viruses share biophysical and morphologic properties and are unambiguously related on the basis of their gene map as well as nucleotide and amino acid sequence. They also are related antigenically, except that, of the avian viruses, only NDV and possibly avian parainfluenza virus type 2 exhibit antigenic relatedness to the other parainfluenza viruses (3,129,167,174,314,315).

Newly available methods of reverse genetics (see section Genetics and Reverse Genetics, later) have made it possible to recover complete infectious recombinant virus entirely from cDNA for a number of parainfluenza viruses, namely Sendai virus, hPIV3, bPIV3, SV5, and NDV (70,86,109,115,233). In addition, helper-dependent minireplicon systems have been developed for a number of parainfluenza viruses, providing an additional tool for molecular biologic studies. Application of the technology of reverse genetics to these viruses has revolutionized studies of their molecular biology and pathogenesis and has facilitated vaccine development.

Several of the parainfluenza viruses, namely Sendai virus, SV5, and NDV, have been used extensively in studies that have defined many of the basic biochemical and molecular biologic properties of the paramyxoviruses. This information is summarized in Chapter 41; the present chapter will provide additional detail and focus on biologic and medical aspects of the human parainfluenza viruses.

INFECTIOUS AGENT

Classification

The parainfluenza viruses are classified in the subfamily *Paramyxovirinae*, family *Paramyxoviridae* (Chapter 41), order *Mononegavirales* (the nonsegmented negative-strand RNA viruses, referred to as mononegaviruses) (240). This order contains four families: *Bornaviridae* (a family that is somewhat distinct and is not considered further here), *Rhabdoviridae*, *Filoviridae*, and *Paramyxoviridae*. The last three families share a number of properties: (a) the negative-sense RNA genome is single-stranded; (b) the genome is present in the form of a nucleocapsid, tightly bound along its entire length by the major nucleocapsid protein; (c) the virally encoded polymerase is packaged in the virion; (d) genome transcription is sequential and yields predominately nonoverlapping subgenomic mRNAs; (e) the replicative cycle is cytoplasmic; and (f) progeny virions bud at the plasma membrane. In *Paramyxoviridae*, the fusion activity is segregated on a separate, additional surface glycoprotein, the fusion (F) protein. F is active at physiologic pH and mediates viral penetration at the plasma membrane (175).

The parainfluenza viruses comprise two of the three genera of the subfamily *Paramyxovirinae*, namely Respirovirus and Rubulavirus. Mumps virus (Chapter 43) also is a Rubulavirus, but historically it is not considered to be a parainfluenza virus because its disease is not based in the respiratory tract. The other genus of the subfamily *Paramyxovirinae* is Morbillivirus (measles virus, Chapter 44). Morbilliviruses are related to the parainfluenza viruses on the basis of gene map and certain nucleotide and amino acid sequences but are distinct antigenically and in the disease they produce. The paramyxovirus family contains a second subfamily, namely the *Pneumovirinae*, represented by RSV (Chapter 45). Pneumoviruses, which are more distant relatives with limited amino acid sequence relatedness, are not related antigenically, but they share the property of being important agents of respiratory tract disease.

The segregation of the parainfluenza viruses between the Respirovirus (hPIV1 and hPIV3) and Rubulavirus (hPIV2 and hPIV4) genera is based on a number of distinguishing features (Table 1 and Fig. 1 and Fig. 2): (a) antigenic relatedness and amino acid sequence identities are greater within than between genera; (b) there are genus-specific differences in proteins, such as the presence of one or more C proteins in respiroviruses but none in rubulaviruses, the presence of an additional gene encoding the small hydrophobic SH protein in some rubulaviruses but not in respiroviruses, and a smaller P protein in rubulaviruses (see Table 1); (c) conserved sequence motifs at the 3' and 5' ends of the genome (illustrated for hPIV3 in Fig. 1) and at the ends of each gene are more highly conserved within than between genera; (d) intergenic regions of respiroviruses are conserved trinucleotides, whereas those of rubulaviruses are variable in length and not conserved (see Fig. 2); and (e) the details of RNA editing differ between the two genera (see Table 1). The rubulaviruses have more diversity in genome organization and in nucleotide and amino acid sequences than do the respiroviruses. The hPIV4 has been divided into two antigenic subgroups, A and B, based on antigenic differences detected by hemadsorption-inhibition (HI) and monoclonal antibody reactivity (169). Sequence analysis shows that these two subgroups are very closely related: For example, the NP, P, and M proteins are 93% to 97% identical between hPIV4A and B, whereas they are 33% to 49% identical between hPIV4A/B and hPIV2, SV5, or mumps virus (226).

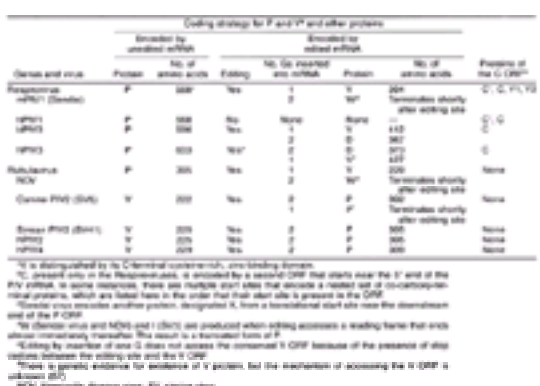

TABLE 1. *Coding strategy of the P/V mRNA of the parainfluenza viruses (PIVs) of the Respirovirus and Rubulavirus genera*

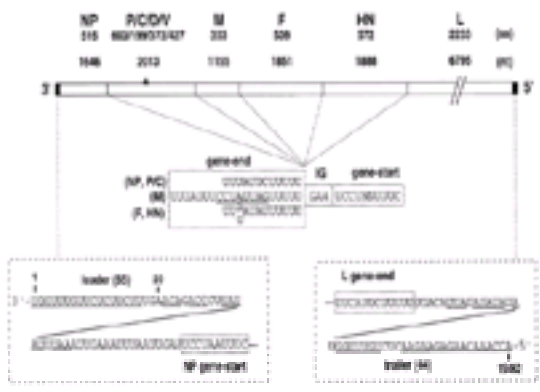

FIG. 1. Map of the RNA genome (3' to 5', negative sense) of hPIV3 (JS strain). Each *open box* represents a separate encoded polyadenylated mRNA. Above each box are the mRNA length [exclusive of poly(A) or editing] in nucleotides (*nt*), the length(s) of the encoded protein(s) in amino acids (*aa*), and the protein name(s); slashes indicate that more than one proteins are encoded by a single mRNA. The sequences of the extracistronic 55-nucleotide 3'-leader and 44-nucleotide 5'-trailer regions and adjoining NP gene-start or L gene-end transcription signals, respectively, are shown below each box. Terminal complementarity between the leader and trailer regions is indicated by *underlining.* Note that

there is an additional element, not shown here, that is conserved between the 3' ends of the genome and antigenome: namely, three conserved G residues at positions 79, 85, and 91 spaced at hexamer intervals (294,295) The gene-end, intergenic (*IG*), and gene-start sequences at the gene junctions are shown: The eight nonconsensus nucleotides that interrupt the M gene-end sequence are *underlined.* The intergenic trinucleotide is italicized, as are the last three nucleotides of the leader region and the first three nucleotides of the trailer region, which for hPIV3 and a number of other paramyxoviruses resemble intergenic trinucleotides. The editing site (nucleotides 2504 to 2508 in the complete hPIV3 sequence) is marked with an *asterisk.* (For additional review, see refs. 7,72,84,279,280,283,285.)

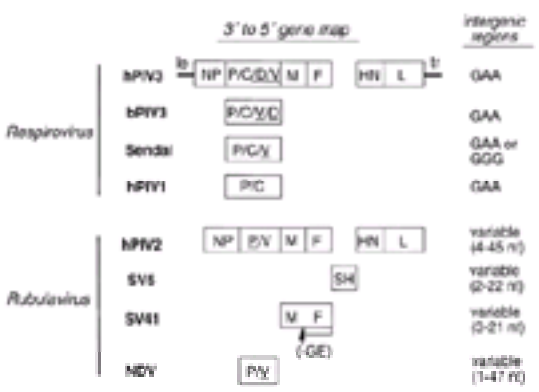

FIG. 2. Comparison of parainfluenza virus gene maps (3' to 5', negative-sense genome RNA). Encoded mRNAs are shown (*boxes*). Complete maps (not to scale) are shown for hPIV3 (Respirovirus) and hPIV2 (Rubulavirus). *le* indicates 3'-leader and *tr* indicates 5'-trailer. Gaps have been introduced to optimize alignment of mRNAs encoding analogous proteins. Gene map features are shown for the other members of each genus only if they differ from the prototype of the genus. For example, the other respiroviruses differ from hPIV3 in the proteins encoded by the P mRNA; SV5 differs from hPIV2 in having the additional SH gene; and SV41 differs in lacking a gene-end signal for the M gene (*-GE*) and in synthesizing two mRNAs from this region, an M-F readthrough mRNA and an F mRNA. The gene map of hPIV4 is very similar to that of hPIV2 and is not shown. For the P mRNAs, the protein products of ORFs fused by editing are *underlined.* The C, C', Y1, Y2, X, W, and I proteins encoded by the P mRNAs of some viruses are not shown (see Table 2). (For additional review, see refs. 61,109,154,155 and 156,171,219,262,269,270,279,285,288).

NDV is the only parainfluenza virus whose taxonomic classification within *Paramyxovirinae* is unclear. On the basis of its general gene map and other features, NDV appears to be a Rubulavirus and currently is so classified: It lacks a C protein, has a smaller P protein (albeit not as small as those of the other rubulaviruses), and has variable intergenic regions (see Table 1 and Fig. 2). However, in some other ways it resembles a Respirovirus, such as features of its RNA editing (Table 1) and closer nucleotide sequence identity at the conserved genomic termini. On the basis of overall nucleotide sequence identity, NDV does not segregate with either Respirovirus or Rubula virus and thus may represent a distinct genus (61). Amino acid sequence alignments of the various proteins generally are consistent with NDV being a somewhat distinct member of the Rubulavirus genus or, alternatively, being classified as a separate genus. NDV and the avian parainfluenza viruses are now being considered for possible reclassification as a new fourth genus within subfamily *Paramyxovirinae*.

The term *parainfluenza* was originally coined because some of its disease symptoms are influenza-like and because the virus particle, like that of influenza virus, has hemagglutination and neuraminidase activities. Indeed, information on glycoprotein processing and activities, host immunity, and viral pathogenesis of the influenza viruses can often serve as a general model for the parainfluenza viruses. However, the parainfluenza viruses and influenza viruses (the latter belonging to the family *Orthomyxoviridae*) differ in many ways. In contrast to parainfluenza viruses, influenza viruses have a segmented negative-strand RNA genome, transcribe and replicate in the nucleus, have splicing and cap-snatching activities, and lack nucleotide or amino acid sequence relatedness with parainfluenza viruses except for certain widely conserved polymerase protein amino acid sequence motifs (234). The surface glycoprotein primary and tertiary structure of influenza viruses exhibits similarities to that of parainfluenza viruses, and this hints of a distant common origin (40).

Virion Morphology and Activities

Parainfluenza viruses are pleomorphic and range in average diameter from 150 to 200 nm. Virions are bounded by a lipid bilayer membrane bearing spikelike surface projections composed of the tetrameric hemagglutinin-neuraminidase (HN) or trimeric F glycoprotein (162). These surface glycoproteins are anchored in the plasma membrane of the infected cell or in the viral envelope by a hydrophobic transmembrane domain, with most of the protein oriented extracellularly and leaving a small tail at the inner face of the membrane. This tail is thought to play a role in virus assembly through its interaction with matrix (M) protein, which, in turn, interacts with intracellular nucleocapsids (170,232,263). F protein alone is sufficient for virion assembly (287).

The surface glycoproteins execute a number of biologic activities. The hemagglutination activity of the HN protein mediates adsorption of virus to the host cell to initiate infection. This activity can be measured experimentally by the agglutination of erythrocytes by virus in suspension (hemagglutination) or by the adsorption of erythrocytes to infected cell monolayers expressing HN (hemadsorption). Late in infection, the neuraminidase activity of HN cleaves its sialic acid receptor to release progeny virions. This activity can be quantitated using sialic acid derivatives as substrates in a colorimetric or fluorimetric assay. The F protein mediates fusion between the viral envelope and the host cell plasma

membrane, an activity which can be measured *in vitro* by lysis of erythrocytes.

The RNA genome is contained within a helical nucleocapsid whose morphology is conferred by the tight association of the genome with about 2,600 molecules of the nucleocapsid protein, NP (162,176). Interestingly, the nucleotide length of genomes of respiroviruses and rubulaviruses is an even multiple of six. Mutational studies with recombinant viruses or helper-dependent mini-genomes recovered from cDNA indicated that this feature is necessary for efficient RNA replication (21,166). Called the “rule of six,” this requirement is thought to reflect a nucleocapsid organization in which each NP monomer associates with six nucleotides. It might represent a requirement for proper spacing of cis-acting RNA signals relative to the NP monomer or the genomic termini (166) (see later section Genome and Encoded mRNAs and Proteins). This rule appears to be more strict for some parainfluenza viruses than for others (211). Morbilliviruses obey the rule of six, but the pneumoviruses and rhabdoviruses do not. For parainfluenza viruses, as for all nonsegmented negative-strand RNA viruses, the genome and the antigenome (which is its positive-sense replicative intermediate) are found only in nucleocapsids and never as free RNA. Indeed, the synthesis of the genome or antigenome is tightly linked to concurrent encapsidation of the nascent RNA (325).

The nucleocapsid also contains about 300 copies of the phosphoprotein P and about 40 copies of the major polymerase subunit L (71,176). Within the virion, the nucleocapsid is wound about itself; however, when it is released by disruption of virus, it assumes a linear, flexible conformation that is approximately 1,000 nm in length (42). Nucleocapsids have been observed in several distinct morphologic states that are thought to have functional significance (71). The nucleocapsid has an RNA-dependent RNA polymerase that consists of the P and L proteins in association with NP-bound genome (105). Purified virions can be activated for cell-free transcription by disruption of the envelope with detergent, and the virion-associated polymerase contains all the activities required to transcribe the viral genome in its entirety into mRNAs. Cell-free transcription is stimulated by the addition of host-cell cytoskeletal proteins, such as tubulin in the case of Sendai virus (202) and actin in the case of hPIV3 (60). The nucleocapsids of parainfluenza viruses and other paramyxoviruses associate with the cellular cytoskeleton during synthetic and maturation steps, and it may be that the interplay between viral and cytoskeletal components is integral to viral RNA synthetic processes.

Paramyxoviruses mature by budding from the surface of infected cells at membrane sites where the viral glycoproteins and M protein have accumulated. During the process of budding, the nucleocapsid is enveloped within the extruding virus particle. Virions contain predominantly genomic (negative-strand) RNA nucleocapsids (162). Depending on the virus and cell type, a varying, but small, proportion of virions contain antigenomic genomes. Hence, at least in such cell types, there does not appear to be a mechanism for stringent selective packaging of the genomic nucleocapsid.

Genome, Encoded mRNAs, and Proteins

The Respirovirus or Rubulavirus genome is a single strand of negative-sense RNA of about 15,000 nucleotides (nts) in length (Table 2). The map of the genome of hPIV3 (see Fig. 1), the most extensively characterized human Respirovirus, is compared to other respiroviruses and the rubulaviruses in Fig. 2. Viruses of the two genera encode six nonoverlapping polyadenylated mRNAs, except for SV5 which encodes seven. Five of these mRNAs each encode a single structural protein, namely, NP, M, F, HN, or L. The additional mRNA of SV5 encodes the small hydrophobic SH protein (see Fig. 2).

Virus	Genome length	GenBank accession no.	Reference
Sendai virus	15,384	M30202 M29343	21, 269, 270
hPIV2	15,649[a]	X57559	154, 155, 171
SV5	15,246	AF052755	169
SV41	15,450	X64275	156, 219
hPIV3	15,462	Z11575	7, 285
bPIV3	15,480	D84095 AF178654 AF178655	7, 282, 288
NDV	15,186	AF077761	61

[a] 15,648 nucleotides does not conform to the rule of six (21) and is likely to be either 15,642 or 15,648 nucleotides.

SV, simian virus; NDV, Newcastle disease virus.

TABLE 2. *The length and accession number of the complete sequence of the genomes of various parainfluenza viruses (PIVs)*

The remaining mRNA, the P/V mRNA, has a complex coding strategy with considerable variability between the genera and among individual viruses. The P and V proteins are encoded by alternative forms of the mRNA produced by the novel mechanism of RNA editing described later. In Respirovirus and NDV, the exact-copy mRNA encodes P and the edited version encodes V, whereas in all rubulaviruses except NDV, the situation is the converse (see Table 1). The Respirovirus P/V mRNA contains a second 5'-proximal open reading frame (ORF) that overlaps that of P and encodes one or more C proteins. Rubulaviruses do not have this ORF.

Cis-acting sequences in parainfluenza virus genomes have been identified both by nucleotide sequence conservation within and between viruses and on the basis of direct mutational analysis using reverse genetics (see later section Genetics and Reverse Genetics). As will be described later, the cis-acting elements of parainfluenza viruses are relatively small and circumscribed. They consist of (a) a dispartite promoter contained within the 3'-terminal 90–96 nucleotides of the genome and antigenome, (b) transcription signals 10 and 13 nucleotides long at the upstream and downstream ends, respectively, of each gene, and (c) an RNA editing motif in the P/V gene. In the respiroviruses, the intergenic trinucleotide might also be a cis-acting signal. Thus, cis-acting signals occupy only slightly more than 2% of the genome. The first 13 to 14 nucleotides at the 3' end of the parainfluenza virus genome are highly conserved within and between the Respirovirus and Rubulavirus genera and are obvious candidates to be part of the promoter (61). Also,

within each Respirovirus and Rubulavirus, there is extensive sequence identity between the 3' ends of the genome and antigenome (the latter is encoded by the 5' end of the genome), which also suggests that a conserved promoter sequence is present at each end of the molecule. For example, hPIV3 has 85% identity between the 3'-terminal 38 or 39 nucleotides of the genome and antigenome (see Fig. 1), and this sequence was conserved even in PIV3 genomes that had become highly mutated during a 29-month persistent infection of cells in culture (210). These conserved sequences confer complementarity between the 3' and 5' ends of genomic RNA, and they have the potential to form a short panhandle. Such panhandles are important in RNA synthesis by influenza virus. However, studies with minireplicons indicate that panhandles are unlikely to play a role in the function of the parainfluenza viral genome or antigenome (295). Thus, these conserved ends most likely do not interact, but each contains a conserved promoter. Furthermore, it is thought that encapsidation of the genome and antigenome occurs cosynthetically and initiates at a sequence near the 5' end of the nascent molecule. Thus, the complement of each promoter, representing the 5' end of the nascent RNA, might contain an encapsidation signal.

To date, mutational analysis of promoter sequences is incomplete and has focused on sequences involved in RNA replication. Nonetheless, a common model has emerged. For Sendai virus, the genome promoter appears to consist of two elements, one contained within the 3'-terminal 31 nucleotides of the leader region, and a second contained within nucleotides 79 to 96, a region located in the leader proximal nontranslated region of the NP gene (294,295). The element represented by the first 31 positions probably involves the dense concentration of highly conserved nucleotides mentioned previously, whereas the element in nucleotides 79 to 96 appears to consist of three key C residues at positions 79, 85, and 91 (in the negative-sense 3' to 5' sequence). Interestingly, if the genome sequence is considered to consist of hexamers, each determined by association with an NP monomer according to the rule of six mentioned previously (21), the spacing of these key C residues corresponds with the first nucleotide of hexamers 14, 15, and 16 (numbered from the 3' end). Thus, the rule of six might operate to maintain certain cis-acting signals in the correct position relative to higher-order nucleocapsid structure (166). Inspection of the sequence at the 3' end of the antigenome suggests that it contains the same promoter elements, and thus the genomic and antigenomic promoters are likely to be very similar. A similar picture, differing only in details of sequence and spacing, emerged from analysis of the replication promoter of the Rubulavirus SV5 (212). Sequence alignments suggest that Sendai virus promoter is conserved among respiroviruses, whereas the slightly different version described for SV5 is conserved among rubulaviruses (212).

The sequences involved in the initiation of transcription have not been defined. It is likely that the main elements of the transcription and replication promoters involve the same nucleotides, although there also may be some differences in the cis-acting signals involved in initiating these two processes. Interestingly, a recombinant Sendai virus was made in which the first 42 nucleotides of the 55-nucleotide 3' leader end of the genome were replaced with the corresponding nucleotides of the antigenome. The resulting virus was viable and was competent for transcription and RNA replication, although it differed in some biologic properties (86). This showed that the antigenomic promoter, like the genomic promoter, is able to direct transcription as well as replication, even though in the natural situation it directs only replication.

The polymerase transcribes the parainfluenza virus genome in a linear, sequential manner guided by short conserved signals at the gene termini: a gene-start signal of approximately 10 nucleotides at the upstream end, which encodes the 5' end of the mRNA, and a gene-end signal of approximately 13 nucleotides at the downstream end, which directs polyadenylation and termination of the subgenomic mRNA (61). The polymerase remains template bound, and it reinitiates synthesis at the adjacent downstream gene. This mode of transcription is typical for mononegaviruses. The mRNAs are capped and polyadenylated. Both of these activities are directed by the viral polymerase. The gene-start and gene-end signals tend to be highly conserved among the genes of a given virus, and thay are also conserved between related viruses. The gene-start and gene-end signals of hPIV3 are illustrated in Figure 1. Note that the gene-end signal terminates with a run of U residues, which encodes the poly(A) tail of the mRNA by stuttering.

For all mononegaviruses, there is a gradient of transcription in which promoter-proximal genes are expressed more efficiently than promoter-distal genes. This is because of polymerase falloff during sequential transcription, which probably reflects an inherent inefficiency in resuming transcription at each gene junction. This is one of the major factors in the regulation of gene expression by parainfluenza viruses and mononegaviruses in general. A second major factor is that the large L gene is expressed much less efficiently than would be expected based on its position as the last gene in the map. It was demonstrated directly with recombinant SV5 that this was not the result of some deficiency in the signals at the HN-L junction, and thus it probably reflects polymerase falloff within this very long gene or sensitivity of this large mRNA to degradation (107).

Differences in transcription signals can influence gene expression. For example, there are several examples of parainfluenza viruses in which the efficiency of the M gene-end signal in directing termination is reduced because of sequence differences. In each case, this is associated with an increase in the synthesis of a readthrough of the M and F genes and a decrease in the expression of monocistronic M and F mRNAs. The M gene-end signal of hPIV3 contains an apparent eight-nucleotide insertion (see Fig. 1) (279). In SV5, a single nucleotide difference in the M gene-end signal reduces its efficiency (244). In SV41, the M gene-end signal is lacking altogether (see Fig. 2): M is expressed solely as an M-F readthrough mRNA. Interestingly, the F gene of SV41 also is expressed as a monocistronic mRNA by initiation at its gene-start signal. The manner by which this occurs is unknown, but it is speculated that some polymerases might fail to initiate at the M gene-start signal and would then be free to slide along the M gene and initiate at the F gene-start signal. The common feature of these three examples is a reduction in the synthesis of monocistronic F mRNA, which most likely is a mechanism for reducing the synthesis of this protein. One might speculate that reduced synthesis of this fusogenic factor might prolong cell viability and thereby enhance virus production. Regulation at the gene junctions was also studied with complete infectious recombinant SV5, in which the naturally occurring HN-L gene junction was replaced by each of the other naturally occurring junctions (107). This strategy evaluated the efficiency with which each junction executed the stop and restart steps of transcription. The ratios of HN to L varied over only a fourfold range. However, this was sufficient to significantly alter plaque size and the kinetics of growth of the recombinant viruses.

The paramyxoviruses of the two genera differ with regard to intergenic sequences (see Fig. 2). The genes of respiroviruses are separated by the trinucleotide GAA (or GGG) (269,270,279), which is highly conserved both within

respiroviruses and between respiroviruses and morbilliviruses. This high degree of conservation suggests that these trinucleotides, flanked on either side by the gene-end and gene-start sequences, might be a cis-acting transcription signal. In addition, an intergenic-like trinucleotide is found at the end of the leader region and the beginning of the trailer region (Fig. 1). In contrast, the intergenic regions of rubulaviruses are quite variable in sequence and length, ranging from 1 to 45 nucleotides (see Fig. 2). For SV5, a virus that has variable intergenic regions, studies in a minireplicon system indicated that alteration of the sequences in the intergenic region can influence the efficiency of termination of the upstream gene and reinitiation at the downstream gene (243). There was no evidence of a specific cis-acting signal, and intergenic length did not appear critical, but it appeared that sequence composition influenced the efficiency of termination and reinitiation.

Respiroviruses and rubulaviruses execute RNA “editing,” a feature that is also seen with morbilliviruses and filoviruses. This involves the cotranscriptional insertion of one or several G residues into the nascent P/V mRNA by stuttering of the viral polymerase at a specific site in the template midway in the P/V gene. An array of mRNAs is produced: They include the unedited, exact-copy form as well as species with one, two, or more inserted G residues. The details of editing differ between the respiroviruses and rubulaviruses, with NDV following the pattern of the respiroviruses (see Table 1). In respiroviruses (and NDV), the exact-copy mRNA encodes the P protein. Also, individual viruses can differ in the distribution of added G residues. The Respirovirus consensus editing site is 3'-UUUUUCCC (negative sense), although the nine nucleotides that lie immediately upstream of this motif also influence editing (106). The addition of a single G nucleotide (or any multiple of 3, plus 1) shifts the reading frame to access an internal V ORF, resulting in the synthesis of the V protein containing a characteristic cysteine-rich motif. In contrast, for rubulaviruses other than NDV, the situation is the converse, with the exact-copy mRNA encoding the V protein. The consensus editing site is 3'-AAAUUCUCCC. The insertion of two G residues (or any multiple of 3, plus 2) shifts the reading frame to access the internal P ORF, resulting in the synthesis of the P protein.

Additional proteins also can be made by editing. For example, for both hPIV3 and bPIV3, the insertion of two G residues accesses a second internal ORF and results in a chimeric protein called D protein. No other paramyxovirus has a D ORF. In other respiroviruses, the addition of two G residues accesses an ORF that quickly terminates and results in a protein called W, which essentially is a truncated P protein. In rubulaviruses, the addition of one G residue results in a similar truncated P protein that is called I.

There are two respiroviruses that do not conform to the pattern just described for expressing V. hPIV1 does not appear to edit, and its V ORF is interrupted by numerous stop codons (255). Thus, hPIV1 does not make a V protein. HPIV3 has an intact, conserved V ORF, but it is separated from the editing site by several stop codons (7). This makes it unlikely that an hPIV3 V protein could be translated efficiently from an edited mRNA, suggesting that it might be accessed by another mechanism, as there is genetic evidence that an hPIV3 V protein is made (67).

The spectrum of proteins encoded by the P/V mRNA of respiroviruses is increased by the presence of C ORF, which in some cases is accessed by more than one translational start codon (see Table 1).

Properties of the Proteins

All parainfluenza viruses encode the following six proteins: the two surface glycoproteins HN and F, the three nucleocapsid-associated proteins NP, P, and L, and the nonglycosylated internal protein M. These six proteins are essential for multicycle virus growth, and each is a component of the virion. The respiroviruses and rubulaviruses encode one or more additional proteins that are not essential for growth in cell culture and therefore are referred to as accessory proteins, namely V, D, W, I, X, C, and SH. These accessory proteins presumably reflect adaptation of each virus to its particular host, although the relatively wide distribution of proteins such as V and C suggests that they provide several functions useful to the virus.

Nucleocapsid Protein

The major NP is 509 to 557 amino acids in length and the amino acid sequence is relatively well conserved. The NP encapsidates genomic and antigenomic RNA, with each NP monomer associating with six nucleotides (this corresponds to 2577 and 2564 molecules of NP per nucleocapsid for hPIV3 and Sendai virus, respectively). RNA replication is dependent on cosynthetic encapsidation of the nascent RNA by NP. This protein can participate in nucleocapsid formation only when it is available in a soluble complex with P; if expressed on its own, NP self-assembles and is not available to form authentic nucleocapsids (17, 117). The N-terminal 75% of the molecule is the more highly conserved part. It is involved in forming the soluble complex with P as well as in subsequently associating with other NP monomers and with RNA to form the nucleocapsid (17, 56). The more variable C-terminal 25% of the molecule is not required to form the nucleocapsid but is essential for it to function as a template. This variable tail mediates association between the nucleocapsid and P (16).

Phosphoprotein

The P protein is an integral part of the transcriptase/replicase, but its exact functions in these processes have not been defined (14). The P protein is not highly conserved within a genus and not at all between genera. The P protein of respiroviruses (568 to 603 amino acids) is larger than that of rubulaviruses (392 to 399 amino acids) (see Table 1). In both genera, P forms a homooligomer by noncovalent association (Sendai virus) or disulfide bonds (some strains of NDV). Recent evidence indicates that this is a tetramer. The P protein consists of conserved amino- and carboxy-terminal halves separated by a divergent spacer that spans the editing site, and this division segregates the protein into two functional modules (55, 280, 305). The P protein is so named because it is phosphorylated, mainly at one or two serine residues in the N-proximal module (18, 19). Whether this serves a structural or regulatory role, or both, remains to be determined. Through its N-proximal module, P associates with soluble NP, which maintains NP in a soluble form that can participate in nucleocapsid formation (58, 117). The C-proximal module (a) contains the trimerization site (54), (b) mediates binding to the NP-RNA nucleocapsid (53, 257), and (c) mediates binding with soluble L to form the polymerase

complex (117). Thus, the N-proximal module is a chaperone for soluble NP, and the C-proximal module is essential for RNA synthesis (53). Approximately 300 copies of P are packaged in the Sendai virus particle.

C Protein

The C protein, found only in respiroviruses, is an abundant small basic protein that is not well conserved, is associated with the nucleocapsid, binds the L protein, and is packaged in small amounts in the virus particle (118,332). The C protein has been shown to inhibit transcription and RNA replication, an effect that acts mainly at the genomic promoter and might reflect a role for C in regulating recognition of cis-acting signals (20,118,293). The Sendai virus C ORF is initiated at an ACG codon to yield the C' protein, and initiation also can occur at each of the next three ATG codons to yield C, Y1, and Y2 proteins, in that order, from the 5' end (see Table 1). Also, initiation of Y1 and Y2 translational start sites occurs through a novel ribosomal shunt mechanism that does not require AUG codons (177). In comparison, hPIV1 encodes C' and C proteins and possibly Y1 protein, with C' arising from a GUG initiation codon. hPIV3 and bPIV3 encode only one C protein.

Ablation of expression of all of the C-related proteins of Sendai virus and the single C protein of hPIV3 strongly attenuated the replication of both viruses *in vitro* and *in vivo*, and point mutations in C also decreased replication *in vivo* (67,133,172). Ablation of Sendai virus C, but not C', was highly attenuating (172,177). That there would be an apparent functional difference between these two proteins was surprising, because C' contains all the amino acids of C, differing only by nine additional amino acids at its N-terminus.

Although the role that the C protein(s) plays in augmenting replication of virus *in vitro* and *in vivo* has not been defined, it might interfere with the host's innate immunity. Sendai virus C proteins interfere with the establishment of an interferon alpha- or beta-induced antiviral state, in part by inhibiting the production of the interferon-induced Stat1 transactivator protein (85,96). The Sendai virus C protein increases apoptosis when expressed intracellularly (132). The mechanism responsible for these two activities of the C proteins remains to be elucidated.

V, W, I, and D Proteins

The V protein consists of the upstream module of P attached to the cysteine-rich, conserved, carboxy-terminal V module. The V protein of the Rubulavirus SV5 is a component of the nucleocapsid and is packaged in the virion (229). In contrast, the Respirovirus Sendai virus V protein appears to be nonstructural. The V protein of Sendai virus binds soluble NP but not NP-RNA, as would be expected for a protein containing the upstream module of P. The Sendai virus V protein inhibits RNA replication, perhaps because it competes with the formation of NP-P complexes needed for encapsidation (119). The V protein of some, but not all, parainfluenza viruses also binds to the cellular damage-specific DNA binding protein, although the significance of this is unknown (181).

The W (Respirovirus) and I (Rubulavirus) proteins result when RNA editing shifts into a reading frame that terminates shortly downstream, and thus W and I essentially consist of the upstream module of P. W protein binds to soluble NP and inhibits RNA replication.

The D protein, which is found only in hPIV3 and bPIV3, is a fusion protein of the P (241 to 242 amino acids) and D (125 to 131 amino acids) ORFs (see Table 1). D is expressed from the P gene by the process of transcriptional editing in which two nontemplated G residues are added to the P mRNA at the RNA editing site.

The V protein of Sendai virus, like the C protein, is important in virus growth and pathogenesis *in vivo*. A series of recombinant Sendai viruses were constructed in which expression of V and W was ablated by inactivation of the editing site, or in which the expression of V was ablated separately by interrupting its ORF. Ablation of expression of V and W together produced viruses that were highly restricted in virus replication and in production of disease in mice (63,151,152). The effect of ablation of only V was less drastic, and a virus lacking V was not as attenuated as one lacking both V and W. This suggests that both V and W play an important role in supporting robust virus replication *in vivo*. Recombinant hPIV3 viruses were constructed in which the D or V ORFs were interrupted individually or together by introduction of translational stop codons and were assayed for replication in hamsters and primates. Silencing either ORF alone did not have an effect on replication *in vitro* or *in vivo*, but silencing both ORFs reduced replication *in vivo* by a modest but significant amount. This provides genetic evidence that both the D and V proteins are produced by hPIV3 and that they play a role in replication *in vivo*, although they clearly are not essential for replication (67).

The V protein also interferes with host innate immunity. This has been directly confirmed for SV5, where the V protein was shown to interfere with the establishment of an interferon-mediated antiviral state at the level of signal transduction (65). This indicates that different accessory proteins, namely, the V protein of the rubulaviruses and the C proteins of the respiroviruses, each function to counteract the antiviral activities of the interferon system.

X Protein

A small abundant nonstructural protein of unknown function called X, which has been identified only for Sendai virus, is generated by translational initiation at an AUG near the downstream end of the P ORF and contains the carboxy-terminal 95 amino acids of P (57).

Large (L) Protein

The L protein is a large, nonabundant protein that is the major polymerase subunit. It is a multifunctional protein responsible for catalytic steps of RNA synthesis, capping and methylation. The N-terminal half of L contains blocks of highly conserved amino acids that are thought to be functional domains. The N-terminal half of the molecule also is essential for the formation of a complex with P (225). Approximately 20 to 40 copies of L are present in the Sendai virus

particle.

Matrix Protein

The matrix protein (M) is a well-conserved, nonglycosylated protein that is located on the inner face of the virion envelope. M is thought to drive virion morphogenesis and mediate association between the nucleocapsid and the envelope. For example, intracellular expression of the M protein of hPIV1 alone can induce the budding and release of empty virus-like particles. Expression of NP and M together yields extracellular particles containing nucleocapsid-like structures (47). The Sendai virion contains approximately 3,000 copies of M.

Small Hydrophobic Protein

Among the parainfluenza viruses, only SV5 encodes an SH protein, although a comparable SH gene is found in mumps and RSV. SH is a transmembrane virion envelope protein in which the C-terminus comprises a very small ectodomain. The SH protein of SV5 can be deleted without any effect on virus growth *in vitro*, virion morphology, or fusion activity (108).

F Glycoprotein

The fusion (F) glycoprotein (Fig. 3) mediates penetration of the host cell by fusion of the viral envelope to the plasma membrane. Late in infection, when newly synthesized F glycoprotein has accumulated on the surface of the infected cell, it also can mediate fusion with contiguous uninfected cells, leading to (a) the formation of a syncytium and (b) spread of infection in the local area by this recruitment mechanism. Syncytium formation is a prominent feature of the cytopathic effect produced by viruses of the two genera in cell culture. The SV5 F protein can direct syncytium formation when expressed alone by a recombinant vector (120), but for all the respiroviruses and the other rubulaviruses studied to date, syncytium formation is insignificant unless the HN protein is coexpressed (175,197,267,268) (see later and Chapter 41). This suggests that in most instances, viral penetration requires coordinate attachment and fusion activities. Although it is thought that parainfluenza viruses attach to the host cell via sialic acid receptors, Sendai virus can also enter cells via an alternative pathway that involves binding of cleaved F_0 to the hepatocyte-specific asialoglycoprotein receptor. The significance of this alternative mechanism in pathogenesis of infection *in vivo* is not known (11).

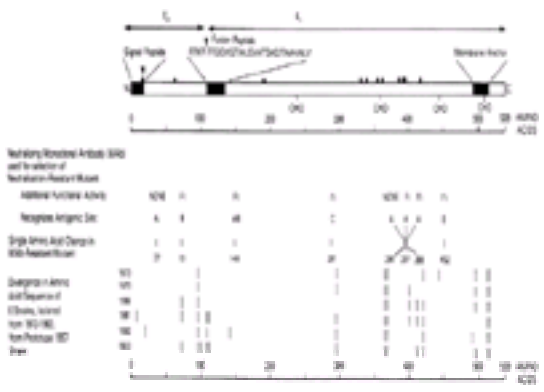

FIG. 3. Linear structure and antigenic organization of the hPIV3 fusion protein (prototype strain 47885, 1957). · denotes cysteine, *FI* denotes fusion-inhibition, and | denotes the site of amino acid difference. (From ref. 35, with permission.)

The F proteins of hPIV3 and other parainfluenza viruses are very similar in size (529 to 565 amino acids) and share a moderate level of sequence identity that is greater within the same genus, 63% for respiroviruses and 25% to 51% for rubulaviruses, than between genera, 16% to 21%. Among the different F proteins, there are two to six potential acceptor sites for N-linked carbohydrates whose number and location are moderately conserved within but not between the two genera. In optimal sequence alignments, nine of the ten cysteines present in the mature hPIV3 F protein are conserved in other viruses of the two genera. Also, proline and glycine residues, which are important determinants of folding, tend to be well conserved. Sequence alignments and structure predictions of the F proteins of the respiroviruses and rubulaviruses, as well as of the morbilliviruses and pneumoviruses, suggest that there are common features of secondary and higher-order structure (23,82,198) (Chapter 41).

The F protein is a typical type I glycoprotein (see Fig. 3). The N-terminus has a hydrophobic signal peptide of approximately 18 amino acids that mediates insertion into the rough endoplasmic reticulum during synthesis and is cleaved by signal peptidase (12). There is a second hydrophobic region near the carboxy terminus (amino acids 494 to 516 in hPIV3, the location being similar in other viruses of the two genera) that functions to anchor the protein in the membrane, and the carboxy-terminal 23 amino acids constitute the cytoplasmic tail of the F protein. The F protein alone appears to be sufficient to mediate association with the M protein and the nucleocapsid during virion morphogenesis (287). As is typical for membrane proteins, F is synthesized as an inactive precursor, F_0, in the rough endoplasmic reticulum, where the following modifications occur: glycosylation, cleavage of the signal peptide, folding, disulfide bond formation and rearrangement, and assembly into noncovalently associated homooligomers, which are probably trimers (191,198,199,201,256,266). The oligomer, which represents a single virion spike, is then transported through the exocytic pathway to the plasma membrane.

F_0 is converted into the fusogenic form following cleavage by a trypsin-like host endoprotease to yield two subunits, F_2 (amino acids 19 to 109 in hPIV3) and F_1 (residues 110 to 539 in hPIV3), which remain linked by a disulfide bond. The site of cleavage has been confirmed by direct sequence analysis of the amino terminus of F_1 of both hPIV3 and Sendai virus

(89,283). The cysteine residues of Sendai that link the two subunits are residues 70 (the only cysteine in F_2) and 199 (the N-terminal-most in F_1). Cleavage of F_0 is a prerequisite for virus infectivity, an important determinant of tissue tropism and pathogenesis. Cleavage results in a conformational change in the molecule, as assayed by changes in reactivity with monoclonal antibodies, ultraviolet circular dichroism spectrum, and detergent binding (123,165,318).

The F_1 amino terminus created by cleavage is an internal hydrophobic region of the F_0 protein called the fusion peptide (amino acids 110 to 135 in hPIV3, its location being similar in the F proteins of other paramyxoviruses). This is the most highly conserved sequence in the F protein, having exact conservation among viruses of the two genera at 12 of the first 26 positions (Chapter 41). Four lines of evidence support the view that the fusion peptide is important in fusion and probably functions by direct insertion into the target membrane. First, the high degree of sequence conservation of the fusion peptide is consistent with its having a direct functional role, and its hydrophobicity and alpha helical character are also suggestive of membrane insertion. Second, cleavage, which liberates the fusion peptide as the amino terminus of F_1, is accompanied by a conformational rearrangement of the molecule and an increase in its hydrophobicity (123,165,318). This suggests that cleavage activation is linked to the liberation of the hydrophobic fusion peptide. Third, synthetic peptides mimicking the amino terminus of F_1 inhibit fusion by Sendai virus, SV5, and the morbilliviruses measles and canine distemper viruses (253,254). Fourth, site-specific mutations that should increase the alpha helical nature of the fusion peptide of SV5 augmented its fusogenicity (120), a result that is fully compatible with the proposal that the fusion peptide is directly involved in membrane penetration.

Not surprisingly, other regions of F_1 also appear to play a critical role in the fusion process. For example, three neutralization-resistant mutants of Sendai virus selected by different F-specific neutralizing, fusion-inhibiting monoclonal antibodies did not have a mutation within the fusion peptide (238). Instead, each mutant sustained an amino acid substitution distant from this region, namely, at amino acid residue 399. One of the monoclonal antibodies bound a synthetic peptide whose sequence spanned the mutation site, confirming that it was part of the epitope. These findings suggest that a region distant from the fusion peptide in the linear sequence of the molecule either plays an important role in positioning the fusion peptide correctly or becomes located close to it in the mature folded molecule so that fusion can be inhibited directly by an antibody that binds to the distant sequence around amino acid 399. A model for F protein function has been described (175) that shows its similarities to the penetration proteins of other viruses such as influenza virus. It is now thought that two regions containing heptad repeats, one of which abuts the hydrophobic fusion peptide and the other located adjacent to the transmembrane domain, form a stable trimer of heterodimers that is required for proper folding of the mature fusion protein structure (140). This heptad repeat structure is actively being studied as a target for action of antiviral compounds.

The F proteins of the two genera fall into two groups with regard to cleavage phenotype (Table 3). The F_0 proteins of most of these viruses, including hPIV3, bPIV3, hPIV2, SV5, and virulent strains of NDV, are readily cleaved in most cell types. Cleavage is mediated by intracellular protease(s) in the Golgi compartment or trans-Golgi network of the exocytic pathway (259). This protease appears to be nearly ubiquitous, conferring a broad host range, although different cells can vary in the efficiency with which cleavage occurs, and a few cell types appear to lack the necessary protease (241). The protease (or one of several possible proteases) responsible for activation has been presumptively identified as furin, a calcium-dependent serine protease that is a component of the constitutive exocytic pathway. This is supported by the observations that cleavage of the F protein of virulent NDV does not occur in furin-defective cells (220) and that cleavage can be mediated by a recombinant vaccinia virus expressing furin cDNA in these cells (95,222). Furin cleaves on the carboxy-terminal side of the motif Arg/Lys-X-Arg/Lys-Arg, which is consistent with the cleavage sites of most of the intracellularly cleaved F_0 proteins. Following cleavage, the basic residues of the cleavage site are removed by further proteolysis (165).

TABLE 3. *Amino acid sequences of the cleavage peptides of parainfluenza (PIV) F_0 proteins*

In contrast, the F_0 proteins of Sendai virus, hPIV1, and the so-called avirulent (less pathogenic) strains of NDV are insensitive to intracellular proteases. The cleavage site of their F_0 protein consists of a single arginine residue preceding the fusion peptide, with the avirulent strains of NDV having a second arginine or lysine at position –4 (see Table 3) (13,93,310,311). A secretory endoprotease, which appears to have a primary role in activating Sendai virus and avirulent NDV *in ovo*, has been purified from eggs and identified as blood clotting factor Xa, a calcium-dependent serine protease that is secreted into the egg's allantoic and amniotic fluids (97,158,218). It cleaves on the carboxy-terminal side of arginine in the motif Glu/Gln-Gly/Ser/Thr-Arg. An activating secretory protease with a similar activity, named tryptase Clara in reference to the bronchiolar epithelium cells that produce it, has been isolated from rat lung (158,261,304). Sendai virus infection was shown to stimulate secretion of tryptase Clara (157). These same proteases are responsible for cleavage of the hemagglutinin protein of most strains of influenza A virus in most cell lines. In tissues that lack the appropriate secreted protease, infectious virus will undergo only a single round of replication because the parainfluenza

virions produced contain only F_0 and thus are noninfectious. They can be rendered infectious if F_0 is cleaved with exogenous trypsin. Analysis of Sendai virus mutants confirmed the critical role of the cleavage site in activation; mutants in which the arginine residue at the cleavage site had been replaced with isoleucine lost the ability to be activated efficiently by trypsin (131). That cleavage occurs extracellularly *in vivo* was confirmed for Sendai virus using an antipeptide antiserum specific for the cleavage region of F_0: It blocked cleavage sterically but had no effect on the activity of already-cleaved F protein. When administered *in ovo* or into the respiratory tract of rats, the antibody inhibited the production of infectious virus (301).

The presence of a furin-type cleavage site is not obligatory for intracellular cleavage. A Sendai virus mutant with the cleavage site Pro-Lys was readily cleaved intracellularly in many cell types. Other Sendai virus mutants, selected by passage *in vitro* in the absence of trypsin, gained the ability to be cleaved intracellularly as a result of amino acid changes at or near the cleavage site that did not involve arginine or lysine and included the loss of a nearby acceptor site for N-linked sugar in F_1 (299). Interestingly, sequence analysis of clinical isolates of hPIV3 revealed variation in the cleavage site sequence. Specifically, four of seven isolates similar to the prototype strain had the sequence Arg-Thr-Lys/Arg-Arg, which is consistent with furin cleavage, whereas three other isolates had the sequence Arg-Thr-Glu-Arg in which Glu at position –2 ablated the furin motif (Table 3) (322). Nonetheless, the latter strains were fully competent for replication and the production of infectious virus *in vitro* and in the respiratory tract of rhesus monkeys. This indicates that a complete furin motif is not necessarily obligatory for efficient replication *in vivo*. Also, several clinical isolates of hPIV2 showed differences in the cleavage sequence. Whereas the prototype strain has the furin motif sequence Arg-Gln-Lys-Arg, the sequence of a number of clinical isolates was Thr/Pro-Arg-Gln-Glu-Arg, which is very similar to the Glu substitution pattern described previously for hPIV3 (see Table 3). In this case, restricted growth *in vitro* was observed in simian Vero cells but not in primary cultures of primate cells. This suggests that additional unknown proteases are involved in processing the F protein of human parainfluenza viruses in primate cells. The structural requirements for cleavage and virulence can now be addressed using reverse genetics to systematically modify the cleavage site.

The efficiency with which intracellular cleavage occurs can vary among different F_0 proteins, presumably because of the subtle structural differences mentioned. Reduced cleavability is associated with reduced host range *in vitro*, presumably because of differences in protease availability among different cell types. For example, an avirulent NDV strain that had a site that should be compatible with efficient cleavage by furin (Gly-Lys-Gln-Arg-Arg) was cleaved in bovine kidney tissue culture cells but not in canine kidney cells, baby hamster kidney cells, or primary chick embryo cells (241). Thus, there is a broad gradient of “cleavability,” determined largely but not exclusively by the cleavage site sequence, which can confer differences in cell tropism *in vitro* and *in vivo*.

HN Glycoprotein

The hemagglutinin-neuraminidase glycoprotein (Fig. 4) mediates the first step in infection, namely virus adsorption, by attachment to cellular surface receptors that are sialic acid–containing glycoproteins or gangliosides (184,185 and 186). This activity is responsible for the ability of the virus to agglutinate erythrocytes, which is employed in serodiagnosis and experimental laboratory studies. HN also functions late in infection to cause enzymatic cleavage of sialic acid (neuraminic acid) residues on the virus and on the infected cell surface that must be removed to prevent self-aggregation of virus particles during release from infected cells and to prevent their reattachment to the infected-cell surface. Among the mononegaviruses, only the respiroviruses and rubulaviruses have a neuraminidase.

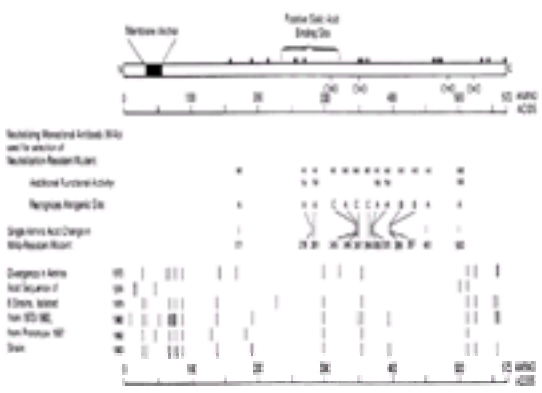

FIG. 4. Linear structure and antigenic organization of hPIV3 hemagglutinin-neuraminidase protein (prototype strain 47885, 1957). Putative sialic acid binding site refers to neuraminidase domain. · denotes cysteine; *HI* denotes hemagglutination-inhibition; *NI* denotes neuraminidase-inhibition; | denotes site of amino acid difference. (From ref. 35, with permission.)

The dual functions of HN appear to be modulated by halide ion concentration and pH (194). Hemagglutination activity appears to be favored by the halide ion concentration and pH of the extracellular environment, consistent with the role of HN in binding to extracellular receptors, whereas neuraminidase activity is optimal at lower pH and halide ion concentration, consistent with the role of HN in stripping sialic acid from newly formed viral and host-cell glycoproteins during transport to the cell surface. The depletion of sialic acid residues on cell surface proteins is thought to facilitate release of newly budded virus.

For almost all respiroviruses and rubulaviruses examined to date, the HN protein also participates in fusion (175,197,267,268) (Chapter 41). For example, syncytium formation by cells expressing the F protein is greatly augmented by coexpression of its cognate HN. The participation of HN might simply involve its attachment function, perhaps by positioning the target membrane at a precisely defined optimal distance, or a more direct role which remains

to be defined.

The hPIV3 HN protein (see Fig. 4) is typical for the viruses of the two genera. It is 572 amino acids in length, compared to 565 to 582 amino acids for the other viruses. It has four potential sites for addition of N-linked carbohydrate side chains; other viruses of the genera have five to ten sites (counting only those that are located in the extracellular domain and whose sequences are compatible with utilization), whose approximate locations tend to be similar. The amino acid sequence of HN is moderately conserved, with hPIV3 having 77%, 48%, 49%, 22%, 23%, 22%, or 23% identity, with the HN proteins of bPIV3, hPIV1, Sendai virus, hPIV4A, mumps virus, NDV, or SV5, respectively. The locations of most of the cysteine residues (of which there are 14 in the HN of hPIV3) are highly conserved in optimal sequence alignments, as are many of the proline and glycine residues. This suggests that these surface glycoproteins have a similar tertiary structure.

Amino acid sequence comparisons of the HN proteins of the two genera indicate that they share regions of linear, segmented sequence identity (40,82,139,154,198). The sequence, Asn-Arg-Lys-Ser-Cys-Ser (residues 252 to 257 in hPIV3), is conserved exactly among the other HN proteins (35,40,139). This motif is located within a 90-amino-acid region (residues 234 to 323 in hPIV3) that has been proposed to represent part of the sialic acid binding site of the neuraminidase domain (35,40,139). The predicted secondary structure of this region is similar to that identified as the sialic acid binding site of influenza A viral neuraminidase by x-ray crystallography (41). Consistent with this observation, substitutions introduced into the NDV HN cDNA involving the Asn, Arg, Lys, or the N-proximal Ser greatly decreased the neuraminidase activity of the expressed protein, and some of the substitutions reduced reactivity with monoclonal antibodies that inhibited neuraminidase activity (197). In contrast, a second conserved sequence in NDV (corresponding to positions 408 to 413 in hPIV3) was shown to be important in maturation: Substitutions did not affect its biologic functions but frequently interfered with folding (267).

The HN protein is anchored in the membrane by a hydrophobic region of about 25 amino acids in length that is located near the amino terminus. This serves as a noncleaved signal sequence that both mediates insertion into membrane and anchors the protein, leaving the amino-terminal 31 amino acids (in the case of LPIV3) cytoplasmic and the remaining amino acids extracellular (type II orientation). Folding and oligomerization into tetramers occur concurrently within the rough endoplasmic reticulum (39,191,198,201). For some (e.g., most NDV strains) but not all (e.g., hPIV3) viruses of the two genera, the oligomeric monomers are stabilized by intermolecular disulfide bonds.

The higher-order structure of the HN protein has been studied in greatest detail for Sendai virus. The HN tetramer, which presumably represents a single virion surface spike, appears to contain several domains: the cytoplasmic tail, the transmembrane anchor, a stalk that is sensitive to trypsin cleavage, and a globular head that represents most of the extracellular domain and contains most of the conserved amino acids. The globular head retains all of the biologic activities and the major antigenic sites, and the stalk probably is a support structure. When visualized by electron microscopy, solubilized Sendai virus HN tetramers (prepared by proteolytic removal of the N-terminal 131 residues) have a box-shaped head (10×10 nm) in which the four identical subunits exhibit fourfold symmetry (306). Interestingly, the shape and dimensions of the box-shaped head of HN are similar to those of the head of the influenza A virus neuraminidase tetramer. Based on this general similarity in organization and on the identification in the HN proteins of conserved amino acids corresponding to active-site-residues in the influenza virus neuraminidase, it is thought that the three-dimensional structures of the two proteins are broadly similar (40,139).

The HN protein of some avirulent strains of NDV is synthesized as a longer precursor, HN_0, in which the functions of the hemagglutinin and neuraminidase are inactive (215). Activation requires an endoproteolytic cleavage, which results in the loss of a small, 9-kd glycopeptide from the carboxy terminus and, as with F_0, a change in conformation (165,215,265,318). Like the F_0 protein of these strains, HN_0 is resistant to cleavage in most cell types and presumably is cleaved by extracellular secretory proteases, but unlike F_0 it does not have a marked preference for trypsin and can be activated *in vitro* by a variety of proteases (215). Sequence analysis suggests that HN_0 is a longer (616 amino acids), ancestral version of the shorter (571 or 577 amino acids), noncleaved HN proteins of virulent strains. The shorter ORFs of the virulent strains might have arisen by the introduction of translational stop codons into an ancestral 616-codon ORF. This was suggested by the finding that the ORFs of the virulent strains retained the apparent relic of an in-frame C-terminal extension beyond the nonsense codon(s) terminating the current ORF. The introduction of an appropriately spaced nonsense codon into an HN_0 ancestor would yield a shorter form that does not require activation. Consistent with this idea, most of the stop codons of the shorter forms line up with potential Arg cleavage sites in HN_0 (196). A counterpart to HN_0 has not been described for any other paramyxovirus, although the sequence of the HN gene of hPIV4 has been interpreted as containing a relic of such an extension (9).

Antigenic Composition and Determinants

Antibodies against most or all of the different major species of parainfluenza virus proteins can be detected in postinfection sera from animals and humans. However, the HN and F proteins are the only antigens that have been shown to induce antibodies that neutralize infectivity as measured by inhibition of plaque formation, hemadsorption, or cytopathic effects in cell culture. *In vivo*, the parenteral administration of polyclonal or monoclonal antibodies specific to Sendai HN or F mediates resistance to challenge with Sendai virus (223,224,246). Infection of rodents with vaccinia virus recombinants expressing the HN or F glycoprotein of hPIV3 or SV5 induces a high level of resistance in the lungs to challenge with the respective virus (231,282). Similarly, immunization with purified hPIV3 HN and F glycoproteins induces a high level of immunity in cotton rats, guinea pigs, and hamsters (4,74,246,247). The ability of the hPIV3 HN and F glycoproteins to induce a protective response is unaffected by deglycosylation (73). In contrast to the strong protective immunity induced by HN and F glycoproteins, immunity to the other proteins is a weaker immunity of short duration (290).

Antibodies to HN can be measured by HI and neuraminidase-inhibition (NI) assays, which are based on the ability of the antibodies to block these activities of purified virions *in vitro*. Antibodies specific to the F protein can also be measured by inhibition of syncytium formation (fusion inhibition) in cell culture, as well as by inhibition of hemolysis of erythrocytes

(hemolysis) by purified virions *in vitro*. However, HN activity, in addition to F activity, is required for efficient hemolysis and syncytium formation by most respiroviruses and rubulaviruses, so that HN-specific antibodies also inhibit these activities (168). In addition, antibodies to each of the major virus proteins can be measured by immunoprecipitation (129).

The antigenic and functional organization of the HN of hPIV3, Sendai virus, and NDV have been defined in some detail through (a) a study of the interaction of monoclonal antibodies with virus and (b) sequence analysis of spontaneous antigenic mutants resistant to neutralization by the monoclonal antibody used for their selection. Initially, a panel of 19 monoclonal antibodies was used to analyze the hPIV3 HN, presently the best understood of the human Respirovirus attachment glycoproteins (36). A topologic map of hPIV3 antigenic sites and an operational map of the epitopes within each site were derived from competitive-binding assays of pairwise combinations of antibodies (321). Six antigenic sites were defined; five of the sites (A, B, D, E, and F) did not overlap, whereas site C overlapped sites A and B. Similar analysis of Sendai virus and NDV identified four antigenic sites on the HN of each virus (127,183,217,223,237,335).

Three of the hPIV3 HN sites (A, B, and C) are of particular interest because they react with monoclonal antibodies that neutralize virus and inhibit hemagglutination (36,322). Additional information concerning the antigenic structure of the hPIV3 HN has been provided by analysis of neutralization-resistant mutants selected with these neutralizing monoclonal antibodies. The reactivity pattern of a panel of hPIV3 HN monoclonal antibodies with the mutants, as well as a collection of 38 hPIV3 strains recovered from 1957 to 1983, indicated that the six antigenic sites contain at least 14 distinct epitopes (35,36). Eleven of these epitopes are involved in neutralization; seven are present in site A, two in site B, and two in site C. Neutralizing and HI monoclonal antibodies directed at five of the site A epitopes also inhibit neuraminidase activity, although several Sendai virus HN monoclonal antibodies were described that inhibit neuraminidase activity but not hemagglutination. Thus, the sites involved in the two activities probably overlap substantially but are not exactly identical (183,235,237).

The neutralization epitopes of hPIV3 HN have been provisionally located on the molecule by sequence analysis of 13 neutralization-resistant mutants selected with monoclonal antibodies to site A, B, or C (see Fig. 4) (36). Each of the mutants sustained a single amino acid substitution that was located predominantly in the C-terminal half of the molecule. Different monoclonal antibodies directed to the same site (and in two instances to the same epitope) selected mutations widely separated on the HN molecule, suggesting that these sites and their epitopes are formed by juxtaposition of distant regions during folding of the molecule into its mature configuration (36,322). Similar observations have been made for Sendai virus HN (307). Consistent with this interpretation is the observation that boiling and reduction of hPIV3 or NDV HN markedly reduces its reactivity with a panel of monoclonal antibodies (35,127). NDV monoclonal antibodies to four distinct antigenic sites also bind very weakly to nascent HN molecules (191,217), and neutralization epitopes could not be mimicked by synthetic peptides (112), providing additional evidence that folding is required for the formation of antigenic sites. Many of the antigenic sites defined by the murine monoclonal antibodies for hPIV3 HN (and F) are recognized by antibodies in postinfection human sera (322).

The antigenic and functional organization of parainfluenza virus F glycoproteins have also been elucidated using the strategy employed for HN. Competitive-binding assay of 26 hPIV3 F-specific monoclonal antibodies identified seven nonoverlapping antigenic sites (A to F) and one site (AB) that bridged sites A and B (35). Fourteen neutralization epitopes were identified within sites A, B, C, and AB. The remaining sites each contain a single epitope that is not involved in neutralization, whereas site A also contains a single nonneutralization epitope.

Sequence analysis of antigenic mutants of hPIV3 selected by F-specific monoclonal antibodies that neutralize virus, and in some instances inhibit fusion, has provided a provisional localization of epitopes involved in these two antibody functions (see Fig. 3) (35,319). Neutralization epitopes in site A or B contain amino acid residues that are derived from both the F_1 and F_2 subunits of the molecule, suggesting that distant regions of the linear protein are folded into close proximity to create the mature antigenic sites (see Fig. 3). Consistent with this interpretation is the finding that NDV F monoclonal antibodies that neutralize virus and inhibit fusion activity fail to react with (a) nascent F or (b) mature F that has been boiled and reduced (309). The single amino acid substitution mutations that occur in fusion-inhibition-resistant hPIV3 mutants do not involve the fusion peptide (residues 110 to 135). Instead, the site of mutation is located upstream in F_2 (amino acid 73) or distantly downstream in F_1 (amino acid 287, 397, or 398) (see Fig. 3) (35). Similar observations have been made for Sendai virus and NDV F glycoproteins (238,309). The hPIV3 F antigenic site B that induces fusion-inhibiting antibodies appears to be highly conformational because a site B monoclonal neutralizing antibody selected two independent fusion-inhibition escape mutations that were widely separated on the linear protein, residues 73 (F_2) and 452 (F_1).

Early studies of sera from infants infected with hPIV1, 2, or 3 indicated that related antigenic determinants are present on their HN proteins even though these viruses are considered to be distinct serotypes (44). These relationships among the human PIV types serve to confound serologic diagnosis and seroepidemiology. Usually, the primary response to parainfluenza virus HN is relatively specific for the infecting virus serotype, whereas the response to subsequent infection by a heterotypic virus of the group (or a booster response to the same serotype) is more cross-reactive. hPIV1 is most closely related to its murine counterpart, Sendai virus, with which it shares antigenic determinants on F, NP, and M as well as HN (100,129,168). hPIV2 is also most closely related to its canine counterpart, SV5, through shared antigens on HN, F, NP, P, and M (154). hPIV3 and bPIV3 exhibit the closest antigenic relationship of any human paramyxovirus and its animal virus counterpart (1). For example, these viruses differ only fourfold in reciprocal HI tests. Their proximity, when analyzed by HI (or neutralization as well), can be explained by the fact that the viruses share 2 of the 11 neutralization epitopes present on HN (36). Three of the 14 neutralization epitopes on F are also shared (319).

Although hPIV1, 2, and 3 each appear to be monotypic, some degree of polymorphism within a serotype undoubtedly exists. This has been demonstrated most convincingly for hPIV3. Analysis of 38 hPIV3 strains recovered over a 26-year interval in widely separated locations (United States and Australia) indicated that 6 of the 11 neutralization epitopes on HN, as well as 3 of 14 such epitopes on F, were completely conserved among all strains (35,36). Two of the three neutralization sites on HN, as well as two of four such sites on F, had one or more epitopes that were completely conserved. The observed variation in HN and F neutralization epitopes did not involve progressive accumulation of

changes with time because variation detected in early isolates was not consistently conserved in later strains. Rather, it appears that the heterogeneity that exists results from random mutations that are not subject to strong immunologic selective pressure (35). Selective pressure of preexisting immunity to hPIV3 is probably much less than that observed for influenza A viruses because hPIV3 can reinfect previously infected individuals with high efficiency, thus allowing the virus to survive in nature without a pressing need for variation in protective viral antigenic sites. Sequence analysis of hPIV1, hPIV2, and NDV has documented the apparent progressive accumulation of sequence differences, resulting in distinct "lineages," but antigenic changes have been noncumulative and nonprogressive, and they do not correlate with the genetic lineages (111,113,114,168,245,260).

Infection of mice with Sendai virus induces development of major histocompatibility class I–restricted, CD8+ cytotoxic T lymphocytes (CTLs) that are associated with resistance to reinfection (122,149,150). In one inbred strain, CTLs from Sendai-infected animals lysed target cells infected with a vaccinia virus recombinant expressing NP, but not those expressing the F, HN, M, or P/C protein (150). Thus, in this particular strain and among these proteins, only NP was a significant target antigen. Assay of synthetic peptides spanning the entire NP sequence identified residues 321 to 336 as the single immunodominant epitope (150). Immunization of mice with a peptide bearing this epitope induced levels of CTL equivalent to those induced by infection with Sendai virus, and it induced a high level of resistance to virus challenge (150). It should be noted that the CTL response and the immunity it provides is usually transient, whereas immunity provided by virus-specific antibodies is considerably more durable (290). It is likely that other mouse haplotypes recognize different or additional CTL epitopes. The roles of viral proteins in inducing other components of cellular immunity remains to be explored.

Normal adult humans tested for memory CD8+ CTL against hPIV1 demonstrated strong responses to HN, P, and NP (and fragments of NP as well as the previously mentioned peptide-borne epitope), a weak response to M, and an insignificant response to F (59). In the same study, donor CTLs that had been stimulated *in vitro* with hPIV1 showed high reactivity with the closely related Sendai virus and, remarkably, lower but clearly demonstrable reactivity against hPIV3. Memory CD4+ CTLs also have been detected in humans (277), although CD4+ and CTLs were not a significant part of the response of normal mice following primary infection (122).

Propagation and Assay in Cell Culture

The human parainfluenza viruses grow well in primary simian or human kidney cell cultures, which allows efficient recovery of these viruses from clinical specimens (25,26,28,31). LLC-MK2, a rhesus kidney heteroploid cell line, and NCI-H292, a human lung carcinoma line, have also been shown to be efficient for recovery and growth of the human parainfluenza viruses (22,78). In these cells, trypsin (1 to 2 µg/mL) is added to the medium to recover hPIV1, but this is not necessary for LPIV2 or hPIV3 (22,78). Virus infection of tissue culture can be monitored either by hemadsorption or by immunofluorescence staining. hPIV2 and hPIV3, but not hPIV1, produce a cytopathic effect that is characterized by syncytium formation, particularly in heteroploid cell lines. hPIV3 can readily be quantitated by plaque assay or by limiting dilution and direct observation of cytopathology, whereas plaque production or growth following limiting dilution by the other human parainfluenza viruses usually is visualized by hemadsorption or immunostaining. Typical yields in tissue culture for hPIV1, 2, 3, 4A, and 4B are $10^{6.5}$, $10^{6.5}$, $10^{7.8}$, $10^{5.7}$, and $10^{3.7}$ tissue culture infectious dose$_{50}$ ($TCID_{50}$) per milliliter of medium, respectively (22).

Nature of Cell Injury

The nature of cell injury *in vivo* is not fully understood and seems to pursue different pathways for different parainfluenza viruses. Some viruses, particularly SV5, can cause a persistent, productive infection in primary cell culture that does not kill cells or shut off cellular RNA or protein synthesis (33,116). In contrast, syncytium formation leading to cell death is a prominent feature of infection of heteroploid cell cultures with hPIV2 or 3 (24,25,29,43). A third situation has been observed for Sendai virus, which induces programmed cell death (87,313). Interestingly, a recombinant Sendai virus was constructed that serendipitously did not induce apoptosis, and this mutant readily established persistent infection *in vitro* (87). It has been proposed that the response of the host cell membrane to a virus of either genus plays a role in determining whether that virus initiates a moderate infection, as in primary monkey cells, or induces formation of syncytia leading to cell death, as occurs in heteroploid cells (116). Syncytium formation is thought to be a major cause of cell death when tissue cultures are infected with hPIV3. Syncytium formation following infection can be blocked by treatment of the cell monolayer with neuraminidase, indicating that fusion by hPIV3 is highly dependent on its attachment function. Blocking cell fusion prevents the development of cytopathic effects and leads to the establishment of a persistent infection (200). On the other hand, in humans, the pathology of fatal parainfluenza virus disease usually does not include giant-cell formation unless the patient has a severe defect in T-lymphocyte function (2,62,135) or is profoundly immunosuppressed (326). A possible role for apoptosis as an important cause of cell death *in vivo* remains to be investigated.

Infection in Experimental Animals and Other Laboratory Hosts

Hamsters are very sensitive to infection by hPIV1, 2, or 3 (44,45,48,290). Infection is, however, usually asymptomatic, and pulmonary pathology is minimal or undetectable. Guinea pigs, cotton rats, and ferrets also undergo a silent infection with these viruses. Chimpanzees and a variety of monkeys can be infected with hPIV1-3, but only hPIV3 causes symptomatic illness that occurs in both chimpanzees and African green monkeys (34,69). The absence of significant disease manifestations in animals other than chimpanzees and the mild disease observed in the latter host species reflects reduced replication of the virus in these experimental animal models.

Some strains of hPIV1, 2, or 3 replicate in the embryonated chicken egg, whereas others do not (29). To date, eggs appear to be less sensitive for isolation of virus from patients than are monkey kidney cell cultures. Primary isolation of a parainfluenza virus in embryonated eggs has not been reported, with the exception of Sendai virus and three strains of hPIV2.

hPIV1, 2, and 3 multiply slowly after inoculation into the amniotic cavity of 7- to 8-day-old embryonated eggs; to obtain maximal titers, incubation at 34° to 36°C for 5 to 7 days is required (29). hPIV3 grows only in the amniotic cavity, whereas one strain of hPIV2 and several strains of hPIV1 have been adapted to the allantoic cavity of the egg. Adaptation of primary isolates of Sendai virus to eggs or tissue culture cells is often accompanied by reduction in virulence for mice.

GENETICS AND REVERSE GENETICS

Genetics

As a group, RNA viruses exhibit a high frequency of mutation attributable to the lack of a 3'-5' exonuclease “proofreading” mechanism in their RNA polymerase (284). This favors the development of genetically heterogeneous virus populations. For hPIV3, the frequency of a spontaneous mutant resistant to neutralization by an individual monoclonal antibody used for its selection has been estimated to be $10^{-4.6}$ to $10^{-7.3}$; for example, in one study, 10 of 13 mutants occurred at an estimated frequency of $10^{-6.0}$ or greater (321). Because the detection of such mutants is subject to the requirement that they be viable and be able to produce a plaque, the actual misincorporation rate is probably higher. For vesicular stomatitis virus (family *Rhabdoviridae*), the misincorporation frequency has been estimated experimentally to be 10^{-3} to 10^{-4} (284).

The error-prone nature of RNA synthesis provides the potential for rapid evolution, and indeed, viruses of the two genera readily “evolve” under selective pressure *in vitro*. However, these viruses appear to evolve very slowly in nature. Sequence analysis of NDV strains isolated over a 50-year period identified what appears to be a progressive accumulation of nucleotide changes, but this was not accompanied by progressive antigenic change (260). The hPIV3 F and HN glycoproteins have undergone little variation (1.5% to 2.4%) during the four decades since the first strain was recovered from humans (27,28,36). Variation has not been progressive, and the differences have been significantly less than those described for the H1 hemagglutinin of influenza A virus that had undergone antigenic drift over a 7- to 8-year interval (250).

The various viral proteins exhibit different rates of change as assayed by the extent of divergence between related viruses. For example, divergence between hPIV3 and Sendai virus is greatest for the C and P proteins (77% and 75% differences in amino acid sequence, respectively), less for F and HN glycoproteins (59% and 53% differences, respectively), and least for the NP, M, and L proteins (41%, 39%, and 38% differences, respectively) (72,83,280,283). Similarly, divergence of human and bovine PIV3 proteins is greatest for the D ORF and least for the M protein (7). Relationships among the viruses based on amino acid sequence divergence are consistent with those determined by serologic assays, though the latter method is less sensitive in revealing relatedness (94,168).

Extensive studies of nonsegmented negative-strand RNA viruses have failed to demonstrate homologous recombination (98,310,330). However, one form of recombination that involves polymerase jumping does occur. When copying the genome or antigenome RNA strand, the polymerase can disengage from the template and, with the nascent strand still attached, reinitiate elsewhere on the same or a different template and resume synthesis. This is the origin of the defective interfering (DI) genomes, which contain large internal deletions eliminating most of the viral genome as a result of the polymerase jump. DI genomes cannot supply the necessary viral proteins to support their own replication, but they can be propagated when virus is passaged at a high multiplicity of infection, conditions under which the nondefective virus supports DI genomes in trans. Because they compete for viral proteins, DI RNAs typically interfere with the replication of nondefective genomes (see Chapter 41 for a more complete description).

Initially, genetic analysis of respiroviruses and rubulaviruses was performed by chemical mutagenesis of infectious virus followed by identification of mutants that exhibited an identifiable property such as temperature sensitivity. Like other nonsegmented negative-strand RNA viruses, certain pairs of mutants bearing distinct lesions exhibited complementation during coinfection. Before the genetic map of Sendai virus had been established by sequence analysis, characterization of 10 conditional lethal, temperature-sensitive (ts) mutants suggested the existence of seven complementation groups (236). However, the exact number of viral genes defined by these complementation groups could have been less than seven because of the possible occurrence of intracistronic complementation. In most instances, later sequence analyses of these and other paramyxovirus mutants did not provide unambiguous identification of the site of mutation that specified the observed mutant phenotype. In these instances, it was difficult to differentiate such mutations from incidental silent mutations that also occurred during passage. The lack of homologous recombination was another obstacle to genetic analysis. Therefore, it was necessary to develop a method for introducing defined site-specific changes into the viral genome. This was accomplished by the recovery of infectious virus from viral cDNA.

Reverse Genetics

Recently, methods for producing infectious recombinant virus from cDNA have been developed for a number of parainfluenza viruses, including Sendai virus, hPIV3, bPIV3, SV5, and NDV (70,86,109,115,233). In the case of the parainfluenza viruses, this involves cotransfecting cells with plasmids encoding a complete genome or antigenome RNA and the NP, P, and L proteins. Expression of the plasmids is driven by bacteriophage T7 RNA polymerase, which can be supplied by a vaccinia virus recombinant or by constitutive expression in an engineered cell line. These viral components self-assemble into a nucleocapsid, which then launches a productive infection. The recovery of infectious virus typically is not very efficient, probably reflecting inefficiency of nucleocapsid self-assembly under these conditions. In natural infection, the assembly of nucleocapsids is thought to involve tight coordination between RNA synthesis and concurrent encapsidation, and it had been generally assumed that preformed genomic or antigenomic RNA would be unable to assemble into a nucleocapsid. However, this was disproved by the demonstration that Sendai virus genomic or antigenomic RNA synthesized *in vitro* could be transfected into cells expressing NP, P, and L and recovered in infectious recombinant virus (153). Whether genomic or antigenomic RNA is introduced by transfection or expressed from a plasmid, recovery of infectious virus is reliable, and, once recovered, recombinant virus can be propagated in the same

fashion as biologically derived virus.

In a second type of reverse genetics system, the cDNA-encoded genome or antigenome RNA is replaced by a minireplicon, which typically is a synthetic version of a naturally occurring DI RNA or is a truncated version of genome or antigenome RNA in which the viral genes have been deleted and replaced by one or more marker genes such as chloramphenicol acetyl transferase or luciferase. When complemented by NP, P, and L supplied by either coinfecting standard virus or transfected plasmids (21), the minireplicon is encapsidated and undergoes efficient RNA replication and transcription, which typically is monitored by Northern blot hybridization. A minireplicon system has advantages for certain studies because it is more amenable to mutational analysis and experimental manipulation *in vitro* than is complete recombinant virus.

The ability to insert predetermined changes into infectious virus makes it possible for the first time to manipulate mononegaviruses in a directed fashion, thus revolutionizing studies of molecular genetics and pathogenesis as well as efforts to develop new or better vaccines. For example, this technologic advance made possible the identification of the rule of six and permitted detailed characterization of cis-acting RNA signals (see earlier section, Genome and Encoded mRNAs and Proteins). It also made it possible to demonstrate that parainfluenza viruses can accommodate and express a foreign gene without loss of viability when the gene is placed under the control of gene-start and gene-stop signals and inserted into the viral gene order. This very likely will have important applications in vaccine development (see later section, Prevention and Control). Chimeric recombinant hPIV3 has been constructed in which the HN and F proteins were replaced with those of PIV1, or in which the NP protein was replaced with that of bPIV3 (6,291). These chimeras might also prove useful in vaccine development (see later section, Prevention and Control).

In other studies, the function of certain viral proteins has been investigated by interfering with their expression by silencing translational start sites, introducing stop codons, altering the editing site, or deleting the gene altogether. These studies showed that the accessory proteins of respiroviruses and rubulaviruses, namely the C, V, D, and W proteins, contribute to efficient replication *in vitro*, *in vivo*, or both (see earlier section, Properties of the Proteins).

PATHOGENESIS AND PATHOLOGY

The hPIVs replicate in the epithelial cells that line the respiratory tract, causing rhinitis, pharyngitis, laryngitis, tracheobronchitis, bronchiolitis, and pneumonia. Early during parainfluenza virus infection, the mucous membranes of the nose and throat are involved. Obstruction of the paranasal sinuses and eustachian tube may also occur and lead to sinusitis and otitis media. Many patients with mild disease may have limited involvement of the bronchi as well. n more extensive infections there is a tendency for hPIV1 and 2 to involve the larynx and upper trachea, resulting in the croup syndrome; such infections may extend also to the lower trachea and bronchi, with accumulation of inspissated mucus and resultant atelectasis and pneumonia (Table 4) (205,227,228). When hPIV3 produces severe disease, infection of the small air passages is likely, with the development of bronchopneumonia, bronchiolitis, and/or bronchitis (see Table 4) (227,228,328).

Illness	Number tested	Patients with evidence of infection with virus indicated (%)							
		RSV	Para 3	Para 1	Para 2	Any Para[a]	Flu A H3N2[a]	Flu A[a] H3N2	Flu B
Pneumonia	1,161–1,742	25.0	11.2	3.5	1.6	14.4	3.5	5.4	1.0
Bronchiolitis	873–1,186	43.1	9.4	2.4	1.1	10.9	0.9	2.5	0.4
Croup	586–776	9.0	18.3	23.3	12.2	41.4	7.7	24.1	1.9
Pharyngitis/bronchitis	896–1,337	10.6	11.0	3.7	2.0	14.7	2.0	4.6	0.9
Total respiratory	3,520–5,104	23.3	11.5	6.0	3.2	17.9	3.2	7.1	1.0

[d]Tested from 1968 to 1976.

TABLE 4. *Infections*[a] *caused by parainfluenza, influenza, or repiratory syncytial virus in pediatric inpatientsl*[b]

An intensive longitudinal study of infants and children in a semiclosed nursery indicated that 80% of individuals undergoing primary infection with hPIV3 developed a febrile illness; in one third of the illnesses, there was involvement of the lower respiratory tract, resulting in either pneumonia or bronchitis (29). When infants and children were studied less intensively in a family setting, the estimate for lower respiratory tract involvement during primary hPIV3 infection was 13% (92). Longitudinal nursery studies also indicated that one half of initial hPIV1 infections and two thirds of initial hPIV2 infections produced a febrile illness (29). Lower respiratory tract involvement also occurs commonly during primary hPIV1 infection; about 25% of primary infections produce bronchitis or pneumonia (92). Severe acute laryngotracheobronchitis (croup), which is the most dramatic and serious manifestation of initial parainfluenza virus infection is noted in only 2% to 3% of primary hPIV1 or 2 infections (29,91).

Until recently, little was known about the mechanisms responsible for localization of infection within the respiratory tract and the severity of human parainfluenza virus disease. This has changed because comparative information has become available from studies of animal viruses such as Sendai virus and NDV in tissue culture and embryonated eggs, as well as in their natural hosts. In addition, evaluation of live attenuated virus vaccine candidates in nonhuman primates and clinical trials has provided new insights. The extent of virus replication appears to be a major factor in pathogenesis. For example, studies of candidate live attenuated hPIV3 vaccines in experimental animals and clinical trials indicate that a mutation that reduces virus replication *in vitro* always reduces virus replication and disease symptoms *in vivo*. A second important factor in pathogenesis is the location of infection (i.e., organ tropism). Studies on tropism indicate that (a) receptors for virus attachment are widely distributed and probably do not represent a major determinant, (b) the cleavage

phenotype of the F_0 protein and tissue-specific differences in protease availability appear to be major determinants, and (c) the cellular site of budding can be an important determinant. Other viral determinants include interference with the host's innate immunity mechanisms (e.g., with its interferon response as described). The host's adaptive immunologic response plays a role in restricting the virus to the respiratory tract and in controlling and eliminating infection, and it also very likely contributes to disease manifestations.

Because the major cell receptors for parainfluenza viruses are sialic acid–containing surface macromolecules of wide distribution, they are considered unlikely to be important determinants of tissue tropism. *In vitro*, these viruses commonly infect cell lines derived from various tissue types and nonhost species with considerable efficiency. This is consistent with a ubiquitous distribution of appropriate sialic acid receptors, though there is the caveat that immortalized cell lines might not be the best predictors of host range. For example, the pneumotropism of Sendai virus is not the result of an insufficiency of receptors on other tissues, as evidenced by the ability of the virus to initiate a single round of replication efficiently in explanted slices of various organs (130,300,302). Growth of mouse-passaged Sendai virus in eggs rapidly selected for one of two specific single amino acid substitutions in HN, which in either instance altered hemagglutinin and neuraminidase substrate specificities, and this appears to be important for adaptation to chick cells (134). However, this shift in receptor specificity did not alter the pathogenesis of these viruses in mice, which was interpreted as support for the view that HN is not a major host-range determinant.

In contrast, cleavage-activation of the F_0 precursor (and, for those viruses where it occurs, the HN_0 precursor) is a major determinant of tropism in animal models and in some instances in natural infection (213,214). As described, F_0 proteins exhibit a spectrum of cleavage phenotypes, ranging from that of Sendai virus, which is insensitive to intracellular cleavage and depends on an exogenous trypsin-like protease for cleavage, to those exhibited by some of the virulent NDV strains, which are readily cleaved intracellularly in most cell types. Naturally occurring strains of NDV that have poorly cleaved F_0 proteins (and, where they occur, HN_0 proteins) exhibit reduced virulence and in some instances have been used as live attenuated vaccine virus strains. In eggs, these attenuated viruses replicate productively only in the epithelial cells of the allantoic and amniotic cavities, where the factor Xa protease required for cleavage has been shown to be localized (218); in birds, such viruses are restricted to the epithelial lining of the respiratory or intestinal tracts. In contrast, NDV strains that have a readily cleaved F_0 protein can spread and replicate in many organs of the embryo or bird with concomitantly increased virulence. Synthesis of the HN protein as an inactive HN_0 precursor appears to confer attenuation in addition to that associated with poorly cleaved F_0 protein (215,260). This initial correlation between cleavability and tissue localization and virulence was described with the caveat that there were many other sequence differences in F and other proteins between the avirulent and virulent strains that also might have contributed to differences in virulence. For example, an additional difference in almost all of the avirulent strains was the substitution of leucine for phenylalanine at the amino terminus of the F_1 subunit (“the fusion peptide”) (93,310,311). Most recently, a study performed with recombinant NDV confirmed the importance of the cleavage site of F_0 in pathogenesis. Specifically, a recombinant in which the cleavage site was of the poorly cleaved variety and was followed by leucine was confirmed to be avirulent, whereas another recombinant that was identical except that the cleavage site contained the furin motif and was followed by phenylalanine was virulent (233).

The role of F_0 cleavage in localization and virulence was also demonstrated in studies involving various mutants of Sendai virus with altered protease-activation phenotypes. Sendai virus, like the avirulent strains of NDV, is restricted in replication *in ovo* to the allantoic and amniotic membranes and, in its natural host, the mouse, to the lumenal epithelium of the respiratory tract (261,298). Mutants that sustained a single amino acid change at the cleavage site, conferring the altered phenotype of cleavage activation by chymotrypsin or elastase and resistance to cleavage by trypsin, failed to replicate productively *in ovo* even at the usual sites unless the appropriate unnatural protease was added to the allantoic fluid (125,131,264). Similarly, trypsin-resistant mutants that were grown *in vitro* and activated with the appropriate unnatural protease could execute only a single cycle of replication (yielding nonactivated, noninfectious virus) when inoculated intranasally in mice (299). This indicated that the presence of the appropriate protease was important in localization of infection. Interestingly, one elastase-activated, trypsin-resistant mutant differed from the others and from the wild type in that it gained the ability to be cleaved in Madin Darby bovine kidney (MDBK) cells, apparently by utilizing a host intracellular elastase-like protease (299). This illustrates that the potential exists for a change in host range that results from a change in protease specificity.

Analysis of the Sendai virus protease-activation mutant F_1-R and its derivatives confirmed that cleavability is important for the pantropic phenotype and identified another important determinant of this phenotype, namely, the cellular site at which budding occurs. In contrast to wild-type Sendai virus, the F_1-R mutant was shown to be readily cleaved in most cell cultures as a result of a mutation at the cleavage site and ablation of a nearby carbohydrate side chain, and it was pantropic in mice. The mutant also had an altered budding phenotype, budding in a bipolar manner rather than exclusively from the apical membrane as is the case with the wild-type parent. This altered budding phenotype was associated with two amino acid substitutions in the M protein (297,300). Whether high cleavability and bipolar budding were both required for the pantropic phenotype was addressed using (a) a series of revertants that had regained the wild-type cleavage phenotype (as a result of reversion at the cleavage site) but had retained bipolar budding (297) and (b) additional protease-activation mutants that had an F protein that had acquired the ability to be readily cleaved intracellularly (as a result of mutations at or near the cleavage site) but that retained the wild-type apical budding phenotype (300). Neither intracellular cleavability nor bipolar budding alone was sufficient to confer pantropism when mice were infected intranasally. However, intracellular cleavability alone was sufficient if the virus was administered systemically. Thus, bipolar budding appears to mediate dissemination from the respiratory tract, presumably by delivering virus into subepithelial tissues and blood. Intracellular cleavability allows subsequent productive infection of additional organs (188). Also, basolateral budding was shown to be required for fusion with neighboring cells (303). However, caution should be exercised in extrapolating these findings. For example, the site of intracellular budding does not seem to have the same significance for a Morbillivirus, measles virus, which buds apically but typically establishes a systemic infection (249).

It is tempting to speculate that an interplay between susceptibility of viral F_0 to cleavage and the capacity of host cells to

effect intracellular cleavage or elaborate the appropriate extracellular protease may be involved in localization and intensity of parainfluenza virus infection within the human respiratory tract. hPIV1 has a cleavage site identical to that of Sendai virus and requires trypsin for the production of infectious virus *in vitro* (193), whereas hPIV3 has a cleavage site consistent with intracellular processing. Thus, the fact that hPIV3 has a greater predilection to cause pneumonia than does hPIV1 might be caused in part by its possession of an F_0 protein that can be cleaved in many cell types (78,193). The significance of the heterogeneity of the cleavage site of hPIV2 and hPIV3 clinical isolates to their pathogenesis was considered earlier in the section, Properties of the Proteins.

Comparison of naturally occurring strains of Sendai virus or NDV, or studies in which virus was attenuated by passage in cell culture, also provided evidence of large differences in virulence that could not be accounted for by the cleavage phenotypes of F or HN (38,258,333). Thus, other viral determinants of pathogenesis remain to be identified. This can now be addressed by gene exchanges between different viruses using reverse genetics.

The accessory proteins of parainfluenza viruses also can affect virus growth and pathogenesis, and they appear to do so by interfering with the host's innate immune response as well as host cell biology (see earlier section, Properties of the Proteins).

Host immunity also can be an important factor in localization of virus infection. Whereas Sendai virus pneumotropism may be determined by budding site and protease availability as described, that of hPIV3 appears to be influenced significantly by host immunity. This was demonstrated experimentally by studies in which immunosuppression of hPIV3-infected cotton rats resulted in dissemination of the virus and productive infection in other organs (239). Similarly, in children with severe combined immunodeficiency disease, systemic, fatal infection with hPIV3 has occurred, with dissemination to the liver, myocardium, and cerebrospinal fluid, as well as lungs (75,80). The rare isolation of hPIV3 from cerebrospinal fluid associated with aseptic meningitis in infants and children (49), as well as the association of hPIV3 with parotitis (52), also indicates that these viruses can occasionally disseminate from the respiratory tract in humans.

A possible role of the immune response in pathogenesis is also suggested by the observation that infants and children who develop parainfluenza virus croup produce local, virus-specific IgE antibodies earlier and in larger amount than patients of comparable age with parainfluenza virus upper respiratory tract illness (327). Also, histamine is detected in nasopharyngeal secretions of croup patients more often than in secretions from patients with upper respiratory tract disease caused by the same virus (327). Based on these observations, it was proposed that more rapid and increased production of parainfluenza virus IgE antibodies mediates histamine release in the trachea and the subglottic region, which in turn produces the symptoms of croup (327). It is not clear whether a more pronounced virus-specific IgE response plays a role in pathogenesis of croup or whether it merely reflects more extensive production of viral antigens and consequent increased antibody response during severe disease. Cell-mediated immune response to parainfluenza viral antigens, as well as parainfluenza virus–specific IgE antibody response, has also been reported to be greater among infants with parainfluenza virus bronchiolitis than among infected infants who developed only upper respiratory illness (327). These observations have been interpreted as evidence for a role of immunologic factors in parainfluenza virus bronchiolitis, but the caveat cited before also applies. Infection of epithelial cells with hPIV2 was reported to increase adhesion of, and concomitant cell damage by, neutrophils, suggesting another potential factor in immune-mediated pathology (308).

Parainfluenza viruses have been used in a number of animal models to study airway responsiveness to various stimuli following infection. In the guinea pig, which undergoes a brief, self-limited, and asymptomatic bronchiolitis after intratracheal inoculation of bPIV3, hyperresponsiveness to both histamine and a choline receptor agonist, arecholine, was seen from day 4 until day 16 after infection (76). The effect lasted through the full recovery of the epithelium but was accompanied by airway hypercellularity and depletion of mucosal mast cells. Similar responses to SV5 have been observed in beagle puppies (180).

Older children or adolescents who had severe croup as infants or young children often exhibit bronchial hyperactivity following exercise or inhalation of methylcholine (100,182). It is not known whether heightened airway reactivity is a preexisting condition that contributes to the pathogenesis of croup or whether inflammatory damage during croup produces a prolonged state of increased reactivity. Clearly, an enhanced IgE and histamine response would assume greater importance if preexisting heightened airway reactivity, especially in the trachea and subglottic region, played a role in pathogenesis of croup.

Severe respiratory tract disease caused by hPIV 1, 2, or 3 generally occurs in the first 3 to 5 years of life. In addition, reinfection with hPIV3 less frequently involves the lower respiratory tract (92). These findings suggest that primary infection confers on the host a relative resistance to subsequent severe parainfluenza virus illness.

Viremia is probably an uncommon event during parainfluenza virus infection in humans (99). Nevertheless, several observations suggest that it may occur more often than we suspect. There is one report of hPIV3 viremia in humans (99) and during experimental infection in hamsters (136). There are also several case reports of meningitis in which hPIV3 was recovered from the cerebrospinal fluid (49). It should also be noted that the SV5 commonly spreads systemically in monkeys to distant sites such as the kidneys (26).

Microscopic pathology is not well defined, as very few fatal cases of parainfluenza virus disease have been studied. Syncytium formation was observed in the lungs of two infants with severe immune deficiency who died of hPIV3 pneumonia; however, giant-cell formation is not a feature of fatal parainfluenza virus disease occurring in immunocompetent individuals (2,62,66).

CLINICAL FEATURES

In children, the most common type of illness consists of rhinitis, pharyngitis, and bronchitis, usually with fever (227,228). The most common initial symptoms are cough, hoarseness, and fever. The cough may be croupy, but respiratory distress

is not present. Approximately three fourths of such ill children have a temperature above 100°F; fever usually lasts 2 to 3 days. Coarse breath sounds, rhonchi, erythema of the pharyngeal mucous membranes, and rhinitis are the characteristic physical findings. Cervical adenopathy is uncommon (228). Otitis media is seen frequently in PIV infections, and virus is present in the middle ear fluids of patients (110).

When croup develops, the initial symptoms of rhinitis, pharyngitis, fever, and cough progress. After several days, the cough worsens and becomes brassy, “seal-like,” or barking, and stridor ensues. Most children recover after 24 to 48 hours; in some children, however, air hunger develops, with cyanosis, sternal and intercostal retractions, and progressive airway obstruction. The anteroposterior (AP) radiograph of the neck (which should be obtained under carefully controlled medical supervision, if at all) shows glottic and subglottic narrowing (the “steeple sign”) and differentiates this disease from epiglottitis.

When bronchiolitis or pneumonia develops, fever persists and the cough progresses and becomes somewhat productive. It is accompanied by wheezing, tachypnea, retractions, and, in severe cases, cyanosis. The chest radiograph shows interstitial or perihilar infiltrates and air trapping. In some patients, a combined bronchopneumonia–croup syndrome occurs. There are also case reports of children who have developed severe pulmonary disease resembling the adult respiratory distress syndrome following parainfluenza virus infection (121).

As reviewed later, infection of immunocompromised patients is usually prolonged and may be severe, with a mortality of 30% in adults infected during the period immediately following bone marrow transplantation (329). This indicates that parainfluenza viruses are inherently virulent and do not require an immune response to cause severe disease.

DIAGNOSIS

Differential

In croup, other viral causes must be considered. Influenza A virus is a common cause of croup but is usually confined to epidemic periods (see Table 4). RSV is also occasionally a cause of croup. Measles virus, particularly in developing nations, may also produce severe laryngeal inflammation. Hemophilus influenzae type B causes epiglottitis, which presents the most important differential diagnosis, although with the advent of widespread immunization this has become a rarity in the United States. Epiglottitis is usually of sudden onset, without a prodrome of rhinitis, hoarseness, or cough, and is accompanied by high fever, leukocytosis, a “toxic” appearance, and drooling. The AP x-ray of the neck is characteristic, as is the cherry-red enlargement of the epiglottis, which should be examined only as part of the intubation procedure or when preparations for nasotracheal intubation have been made. Another bacterial infection that must be differentiated from viral croup is bacterial tracheitis. This disease, described first in 1979 (138), is usually caused by *Staphylococcus aureus* and may be a complication of viral croup rather than a primary bacterial infection. Intubation is frequently necessary, as well as antistaphylococcal antibiotic therapy. In bronchiolitis or pneumonia of infancy, other viruses (particularly RSV) and *Chlamydia trachomatis* are the most frequent etiologic agents to be considered. Pneumonia in older children is more commonly caused by *Mycoplasma pneumoniae.*

Laboratory

Presumptive diagnosis of parainfluenza virus infection can be made based on young age, history, clinical findings, and relation to known or characteristic prevalence of virus in the community. Definitive diagnosis, however, requires recovery of the virus from appropriate specimens taken from the respiratory tract, identification of viral antigens in respiratory tract secretions by immunofluorescence or another form of immunoassay, or detection of viral RNA in nasal secretions by reverse transcription followed by the polymerase chain reaction (29,46,88). One method for virus isolation involves spin-enhanced cultures, in which virus is detected after 2 to 7 days of culture by immunofluorescent staining with monoclonal antibodies (178,221). Serodiagnosis by HI, complement fixation (CF), or neutralization can establish that infection with a member of the parainfluenza virus group has occurred, but frequent heterotypic responses make specific diagnosis by serology difficult (25,31).

TREATMENT

Symptomatic treatment of croup usually includes humidification of air by ultrasonic nebulizer and periodic inhalation of racemic epinephrine. Large doses of systemic corticosteroids (0.3 mg/kg of dexamethasone) are considered to prevent or shorten the period of intubation in severe croup (141), and recent evidence favors the use of inhaled steroids even in more moderate disease (163).

Specific antiviral treatment is not available. However, ribavirin exhibits efficacy *in vitro*, and it may be that this drug will prove to be efficacious when delivered by small-particle aerosol, as in the treatment of influenza A virus or RSV illness (164,271).

EPIDEMIOLOGY

Morbidity, Mortality, Age

Types 1 to 4 parainfluenza viruses have a wide geographic distribution. The first three types have been identified in most areas where appropriate tissue culture and hemadsorption techniques have been applied to the study of childhood respiratory tract diseases. Thus far, hPIV4 subtypes 4A and 4B, which are more difficult to recover in tissue culture, have been isolated in fewer areas, but serologic studies suggest that they also are relatively ubiquitous.

Each of the four parainfluenza virus types can cause acute respiratory tract disease in humans. This etiologic relationship is indicated by two observations. First, each of the virus types has been recovered significantly more often

from patients with respiratory diseases than from individuals free of such illness (27,29,30,159,227). Second, types 1, 2, 3, and 4A viruses each have produced upper respiratory tract infection and illness when administered to adult volunteers (143,312,316,317).

The parainfluenza viruses as a group are exceeded only by RSV as an important cause of viral lower respiratory tract disease in young children, and like RSV they commonly reinfect older children and adults to produce upper respiratory tract disease. Reinfection of adults, as well as children, with the parainfluenza viruses has been recognized on a number of occasions, particularly with hPIV3 and hPIV1, and disease leading to hospitalization can occur in adults (187). Although the frequency of reinfection is not known, it is probable that most individuals have repeated experience with hPIV1, 2, and 3. In a series of three outbreaks of hPIV3 infection in a semiclosed nursery population, it was observed that 17% of the children infected during one outbreak were reinfected during a subsequent outbreak, although the interval between the first and last outbreaks was only 9 months (29). Reinfection of preschool children living at home also occurs with high frequency (92). Illness usually occurs less often and is less severe during reinfection than during primary infection.

In a longitudinal study of families with young children, the overall rate of parainfluenza virus infection as estimated by serology (HI and CF) was 44.4 infections per 100 person-years (77). Type-specific infection rates could not be estimated because of the high frequency of heterotypic serologic response. Parainfluenza virus infection rate varied from 59% for children 2 to 5 years of age to 40% for adults. Spread of virus within infected families was extensive, as indicated by serologic studies; following an index infection, 64% of family members developed a serum HI antibody response. Parainfluenza virus was introduced into the family primarily by preschool children (77).

There is considerable diversity in both epidemiologic and clinical manifestations of infections caused by the parainfluenza viruses, and this diversity does not always sort on taxonomic lines. Thus, although they are in the same genus (see Table 1), hPIV1 is the principal cause of croup in children, whereas the principal serious illness caused by hPIV3 is pneumonia or bronchiolitis, and hPIV3 is second only to RSV as a cause of viral pneumonia and bronchiolitis in infants less than 6 months of age (see Table 4) (27,29,30,64,227). Likewise, although they belong to different genera, hPIV2 closely resembles hPIV1 in clinical manifestations, but serious illness occurs less frequently. Infections with hPIV4 are detected infrequently, and associated illnesses are usually mild.

The parainfluenza viruses are most important as respiratory tract pathogens during infancy and childhood. In this age group, hPIV1, 2, and 3 cause a spectrum of effects ranging from inapparent infection to life-threatening lower respiratory tract disease. Studies in different parts of the world indicate that hPIV1, 2, and 3 are associated with approximately 41% of severe croup. hPIV1 is the most important of the parainfluenza viruses causing croup. In addition to croup, hPIV1, 2, and 3 are also responsible for a smaller but appreciable proportion of other acute respiratory tract diseases of infancy and early childhood.

Parainfluenza infection generally occurs very early in life. Serologic surveys indicate that at least 60% of children have been infected with hPIV3 by 2 years of age and that approximately 80% have been infected by 4 years of age (227,228). When infants and children are studied longitudinally, it is apparent that infection with hPIV3 occurs even more commonly during infancy and early childhood than is indicated by serologic survey. During a longitudinal study of 121 infants and young children, the incidence of infection was approximately 67 per 100 per year during the first 2 years of life (92). Infection with hPIV1 or 2 generally occurs somewhat later, but by 5 years of age a majority of children have been infected with hPIV2, and over 75% have been infected with hPIV1 (227,228). hPIV3 often causes illness during the first months of life, at a time when infants still possess serum neutralizing antibodies derived from their mother (251). In contrast, in young infants, maternally derived antibodies appear to prevent both infection and severe disease with either hPIV1 or 2. Severe illness caused by hPIV1 or 2 is rather rare under 4 months of age (27,29,90). After 4 months, there is a rise in the number of cases of croup and other lower respiratory tract diseases caused by hPIV1 or 2. This high incidence continues until approximately 6 years of age. After a child reaches school age, there is a much lower incidence of lower respiratory tract disease caused by hPIV1 or 2, and the occurrence of lower respiratory tract illness in individuals infected with either virus during adolescence or adult life is unusual, although this does occur on occasion (187). This reduction in infection and disease is caused by protective immunity from previous infection(s).

From 1957 to 1961, hPIV1 appeared to be endemic; infection occurred sporadically and without a definite seasonal pattern (27,29). Beginning in 1962, a different pattern developed, in which sharp outbreaks of hPIV1 occurred every 2 years in the autumn of even-numbered years. In contrast, hPIV2 caused outbreaks in the autumn of odd-numbered years (5,29,91). At present, hPIV1 and 2 epidemics are synchronous, occurring during the fall of odd-numbered years. For many years, hPIV3 exhibited an endemic pattern, with infection occurring in all seasons of the year. Within this endemic pattern, small outbreaks occurred, but there was no predictable periodicity. Within the past 10 years, there has been a shift toward yearly spring epidemics of hPIV3 infection. In the United Kingdom, hPIV3 is seen most frequently in the summer. The seasonality of hPIV1 and 2 is reflected in the seasonality of croup (64). In infants and children in the United States, the peak incidence of croup is always in the autumn, with a smaller peak in the cold months of the winter reflecting influenza and RSV as causes of the syndrome.

The parainfluenza viruses are troublesome as causes of infection in the hospital, particularly hPIV3 (204). Children who are admitted to the hospital for nonrespiratory tract illness are often infected during their hospital stay, and this is commonly associated with the development of serious lower respiratory tract disease. Nucleic acid sequence analysis has been used to analyze hospital outbreaks, and it is clear that, although outbreaks caused by a single genotypically uniform strain occur, much of the problem is sporadic spread of multiple strains within the hospital or community (145). Illness in hospital staff can occur and may be a factor in spread (272).

As mentioned earlier, there is no evidence that variation in virulence of human parainfluenza viruses plays a significant role in the epidemiology of these agents, possibly because the appropriate studies have not been performed. However, naturally circulating strains of NDV, a closely related avian Paramyxovirus, exhibit a wide spectrum of virulence for its

natural avian hosts (216,310).

There is no evidence that animal strains of PIV1 (Sendai virus) or 3 (bPIV3) infect humans in nature. Occasional reports have described the recovery of the SV5 from human specimens, but none of these observations have been confirmed. A Rubulavirus-like virus isolated 20 years ago from monkeys showed the greatest sequence and antigenic relatedness to NDV and avian parainfluenza type 2 viruses, suggesting that cross-species transmission and adaptation had occurred (174).

A number of parainfluenza viruses readily establish persistent infection in cell culture (33,87,116,200). It is possible that persistence also occurs *in vivo*, perhaps accounting for the prevalence of parainfluenza viruses in their natural host population (203). However, this is unlikely, at least for the human parainfluenza viruses. These infections remain largely localized in the respiratory tract and induce potent systemic and local humoral and cellular immune responses. It seems unlikely that the relatively small genomes of these viruses encode mechanisms to evade immune recognition and clearance by adaptive immunity, although, as mentioned before, certain animal parainfluenza viruses do appear to encode proteins that interfere with innate immunity. Instead, it is the high rate of reinfection and subclinical infection, rather than viral persistence, that maintains the virus in the population. This reflects the difficulty of maintaining solid long-term immune protection in the upper respiratory tract, caused by (a) the transient nature of local secretory IgA and cytotoxic T cells and (b) the inefficiency of transudation of serum antibodies to the lumen of the respiratory tract, particularly the upper respiratory tract. The possibility that human parainfluenza viruses might block responses to interferon, suggested in recent studies with Sendai virus and SV5, would be an additional factor aiding reinfection.

Spread and Infectivity

Transmission of parainfluenza viruses is by direct person-to-person contact or by large-droplet spread; however, the viruses do not persist long in the environment (9). The high rate of infection early in life, coupled with the frequency of reinfection, suggests that these viruses spread readily from person to person. There is evidence from studies in adult volunteers that the infectious dose of hPIV1 is small. For example, in one study, two thirds of adults who possessed a moderately high level of preexisting serum-neutralizing antibodies became infected and developed a “common cold–like” illness following intranasal instillation of 80 $TCID_{50}$ of hPIV1 (278). Also, reinfected individuals appear to be infectious. hPIV3 appears to be the most efficient of the parainfluenza viruses in its ability to spread from person to person (29). hPIV3 generally infects all susceptible individuals in a semiclosed population (such as a nursery) in a relatively short time. In contrast, hPIV1 and 2 appear to be less effective in this regard, infecting 40% to 69% of susceptible individuals in semiclosed populations (29,142). There is no evidence that infection is transmitted from humans to animals or vice versa.

During experimental infection of adult volunteers, the interval between administration of hPIV1, 2, or 3 and onset of upper respiratory tract symptoms ranges from 3 to 6 days (Fig. 5) (143,209,278,316,317). The incubation period in pediatric infections has not been defined; however, information is available concerning the interval between exposure to hPIV3 and the subsequent initial shedding of this virus. In several institutional outbreaks of infection, this interval was 2 to 4 days (29).

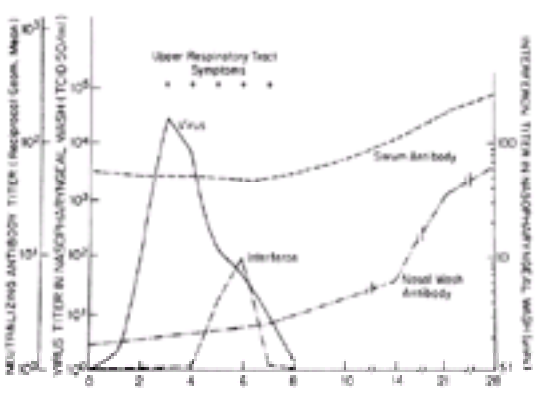

FIG. 5. Experimental infection of adults with wild-type human parainfluenza type 1 virus (*hPIV1*). Adult volunteers, all of whom had been infected previously with PIV1 under natural conditions, were administered 10^5 $TCID_{50}$ of hPIV1 by the intranasal route. *Abscissa* indicates days after inoculation (209).

The interval during which an individual infected with a parainfluenza virus can infect another person is not known. Longitudinal studies indicate that hPIV3 is usually shed from the oropharynx for 3 to 10 days (median of 8 days) during initial infection, whereas during reinfection the virus is detected during a shorter interval (29). On occasion, infants and young children may shed hPIV3 for as long as 3 to 4 weeks (79). Prolonged shedding of hPIV3 has also been observed occasionally in adults with underlying chronic lower respiratory tract disease (99). It is not clear whether chronic damage to the respiratory tract is responsible for this unusual manifestation of adult reinfection.

Immunity

Most studies of immunity to parainfluenza viruses have focused on adaptive immune responses, and in particular on secretory and serum antibodies against the virus. As described later, these are the major correlates of resistance to infection and reinfection. The contribution of innate immunity has received less attention, although parainfluenza viruses such as Sendai virus have long been known to be very efficient inducers of alpha and beta interferons. The ability of several accessory proteins of animal parainfluenza viruses to interfere with the antiviral activities of interferon was described earlier (in the section, Properties of the Proteins). The importance of interferon in parainfluenza virus infections in humans has not been defined. However, it is likely that inhibition of the interferon-induced antiviral state may

play a role in virulence as suggested by the attenuation of hPIV3 for monkeys that resulted from ablation of C protein function (67,275). A significant proportion (30%) of young patients with hPIV1 infection develop a detectable interferon response (geometric mean titer of 23.5 units) during the acute stage of illness (101). This frequency is somewhat less than that observed during influenza A virus infection of children (55%) but is decidedly greater than that observed during RSV infection of infancy and childhood (4%). If human parainfluenza viruses also interfere with the antiviral activity of interferon in their natural host, then the induction of interferon by these viruses would not necessarily be protective.

In a longitudinal study of hPIV3 outbreaks in infants and young children resident in a semiclosed nursery, preexisting serum-neutralizing antibodies correlated with resistance to infection and illness (29). However, resistance associated with serum-neutralizing antibodies was only partial. One third of infants and children with a high serum antibody level became infected. Although reinfection occurred, a partial effect of immunity from previous infection was indicated by a shorter period of virus shedding compared to that observed during primary infection. Moderate levels of serum antibody were not associated with complete protection against febrile illness, as such illness occurred approximately 40% as often as during first infection. A somewhat greater reduction of lower respiratory disease was observed during second infection with hPIV3 during a longitudinal family study (92).

Infants also appear to be partially protected from infection and disease by hPIV1 and hPIV2 serum antibodies. This protective relationship is suggested by the relative sparing of young infants from hPIV1 and 2 infection and associated disease at a time when they possess serum antibodies passively acquired from their mother. Also, the risk of infection with hPIV3 during the first 4 months of life is inversely related, in the aggregate, to the level of neutralizing antibodies present in cord serum at birth (92). However, the protective effect of passive immunity to hPIV3 is less than that observed for hPIV1 and 2, as some infants with a moderately high level of maternally derived serum antibodies become infected with hPIV3 and develop illness (92).

The ability of serum-neutralizing antibodies to confer resistance to pulmonary replication by parainfluenza viruses has been well documented in experimental animals, where parenteral administration of polyclonal or monoclonal virus-neutralizing antibodies conferred a high level of resistance to virus replication in the lower respiratory tract and a lower level of resistance in the upper respiratory tract (223,224,239,246). In addition, these studies demonstrated that significant resistance in the respiratory tract requires a high serum antibody titer. This reflects the absence of a specific mechanism for transporting serum IgG to the mucosal surface of the lumen of the respiratory tract. The transport of IgG by nonspecific transudation is driven by high serum titer and is highly inefficient.

Experimental infection of adults possessing varying levels of local nasal secretory IgA-neutralizing antibodies and a relatively high level of serum-neutralizing antibodies indicated that resistance to hPIV1 or 2 infection and upper respiratory disease was mainly a function of mucosal antibodies (278,312). Similar information is not available for hPIV3, nor is information available concerning the immunologic determinants of resistance to parainfluenza virus disease of the lower respiratory tract in adults. Also, the efficacy of IgA in mediating resistance has been demonstrated in studies in experimental animals. IgA and IgG were equally effective in providing resistance to Sendai virus challenge in mice when administered directly into the respiratory tract (190). However, in the natural situation, IgA has the advantage of being specifically transported through the epithelium to the surface of the lumen as well as being able to neutralize virus within infected epithelial cells (189). The central role of respiratory tract IgA was demonstrated unambiguously for influenza virus in mice, where resistance to influenza virus replication in the respiratory tract of previously infected immune mice was ablated by topical administration of anti-IgA antibodies (247,252). Comparable findings would be expected for the parainfluenza viruses. Studies in hamsters showed that preparations of hPIV3 glycoproteins induced a higher level of local IgA and a higher level of resistance to intranasal challenge when administered intranasally rather than subcutaneously, illustrating the importance of direct stimulation of local immunity (247).

Infection with hPIV3 stimulates the development of serum antibodies to most of the viral proteins, but only antibodies to the two viral surface glycoproteins, HN and F, have been shown to have virus-neutralizing activity *in vitro* or *in vivo* (148). Primary infection usually induces a greater antibody response to the HN protein (322). Reinfection is often required to stimulate a high level of serum antibodies to the F protein. Initial studies with SV5 in tissue culture suggested that antibodies to F might be more important than those to HN because they could both neutralize virus infectivity and prevent cell-to-cell spread of infection by cell fusion, whereas HN-specific antibodies could only neutralize virus infectivity (195). However, it is now recognized that most other parainfluenza viruses require both HN and F for efficient syncytium formation, and antibodies against HN interfere with F activity in this situation (128,237). Furthermore, evaluation of vaccinia virus recombinants expressing the hPIV3 HN or F glycoprotein, as well as purified baculovirus-produced HN and F glycoproteins in cotton rats, indicated that HN induced more effective immunity than did F (15,282).

Adults respond to reinfection by developing an increase in local nasal secretory IgA antibodies that neutralize virus infectivity (see Fig. 5) (278). In contrast, young infants undergoing primary infection produce local nasal IgA antibodies that neutralize virus infectivity poorly or not at all (334) and exhibit a decreased serum antibody response to the HN glycoprotein (144). Production of nonfunctional local antibodies, as well as a poor serum F and HN antibody response, may explain why reinfection (especially with hPIV3) occurs with considerable frequency during infancy and early childhood.

The importance of CTLs in recovery from human parainfluenza virus infection has not been formally established. Nevertheless, it is likely that this form of cell-mediated immunity is important in the recovery process because hPIV3 infection of infants or children with profound T-cell deficiency can lead to fatal giant cell pneumonia (62). Memory CTLs of both CD4+ and CD8+ subsets specific for hPIV1 have been isolated from normal adult donors, although their contribution to resistance to reinfection is not known (59,277).

The importance of class I and class II major histocompatibility complex–restricted, virus-specific T cells in recovery from pulmonary Sendai virus infection was demonstrated during a study in which mice, the putative natural host, were challenged by the intranasal route (122,149,150). Intranasal infection resulted in a rapid increase in pulmonary CD8+ CTLs, whose appearance coincided with the decrease in titer of pulmonary virus and resolution of infection (122). However, possible participation of other effectors such as secretory or serum antibodies was not defined. Immunization of

mice with a peptide bearing a major epitope for CD8+ CTLs induced a high level of resistance to virus challenge (150). Mice that had a mutant nonresponder class I restriction element failed to develop a virus-specific CD8+ CTL response upon infection, whereas serum antibody, delayed-type hypersensitivity, and natural-killer-cell responses were unimpaired. These mice cleared infection but Sendai virus had an LD_{50} that was tenfold lower than that for wild-type congenic mice. The LD_{50} for congenic nude mice that lacked all subsets of T cells but produced natural killer cells was 300-fold lower than that determined in wild-type mice (149). The survival time of infected nude mice could be increased (from 19 days) by passive administration of cloned Sendai virus-specific CD8+ cells (to 25 days), or CD4+ cells (to 34 days), or both (>100 days). In contrast, interleukin-2 alone did not provide significant prolongation (149). In a situation in which infection was not lethal, removal of CD8+ cells, either through antibody depletion or disruption of the b2-microglobulin gene, resulted in delayed viral clearance and 20% mortality (122), whereas antibody-mediated depletion of CD4+ cells inhibited antibody production but delayed viral clearance only marginally with no mortality. Removal of CD4+ cells by antibody depletion did not affect the development of the CD8+ CTL response, but removal of both subsets resulted in a failure to clear the virus and 100% mortality (122). Pulmonary virus-specific CD8+ cells exhibited efficient cell-killing activity *in vitro*, suggesting that this is a major effector function *in vivo*. CD4+ cells isolated from normal Sendai virus–infected mice did not have significant *in vitro* cell-killing activity, nor did they seem to have a critical role in promoting the CD8+ response (122). It seems likely that a major antiviral activity of CD4+ cells is to provide T-cell help for antibody-producing B cells (122,149).

Consistent with this, children and adults with various forms of immunodeficiency, usually involving both the cellular and humoral arms of the immune system, may develop particularly severe illness and can shed virus for a prolonged period (62,75,80,242). Pneumonia caused by a parainfluenza virus occurring during recovery from bone marrow transplantation carries a mortality of 30% (329), and children who are immunodeficient as a consequence of human immunodeficiency virus infection may shed parainfluenza viruses for months to years (192).

In summary, it is useful to distinguish between elements of immunity that are critical in clearing an infection, and those important in conferring resistance to reinfection. Innate immunity presumably functions in both situations. During resolution of infection, antibodies and CTLs play important independent roles. With respect to prevention and resolution of reinfection, the protection mediated by CTLs and secretory antibodies is relatively short-lived, whereas serum virus-neutralizing antibodies mediate long-term resistance, especially in the lower respiratory tract.

PREVENTION AND CONTROL

Initially, inactivated parainfluenza virus vaccines prepared from infected embryonated eggs or primary monkey kidney cell culture were developed for hPIV1, 2, and 3 and shown to be immunogenic in children, as indicated by the development of serum HI and neutralizing antibodies. Unfortunately, parenteral administration of these vaccines failed to induce resistance to parainfluenza virus disease (32,81). Perhaps this is not surprising in view of the importance of local secretory IgA antibody in resistance and the relative ineffectiveness of parenterally administered vaccines in stimulating this response. Selective inactivation of F glycoprotein by formalin may also have contributed to the ineffectiveness of inactivated vaccines, as suggested by the observation that formalin selectively destroys the antigenicity of the F glycoprotein of the related mumps virus. More recently, hPIV3 adsorbed onto immunogenicity-enhancing microcarriers was shown to protect hamsters against subsequent virus challenge when immunization was performed by the intraperitoneal route, but it was poorly protective when given by the more relevant intranasal route (248). An efficient method of immunization against parainfluenza virus disease using a killed virus vaccine remains to be developed.

Subunit vaccines have also been evaluated, namely, preparations of the hPIV3 HN and F glycoproteins isolated from purified hPIV3 or from insect cells infected with recombinant baculoviruses expressing the HN or F protein or a chimeric form of HN and F encoded by an engineered cDNA (15,102,179,246,320). The glycoproteins expressed individually in baculovirus did not appear to differ significantly from native antigens, based on their reactivity with panels of monoclonal antibodies representing the major neutralization epitopes. Parenteral immunization of cotton rats with these viral glycoproteins induced satisfactory levels of neutralizing, HI, and FI antibodies, and the immunized animals were highly resistant to intranasal challenge with hPIV3. Also, intranasal administration of the purified glycoproteins was effective in inducing a local IgA response (247). To date, none of the aforementioned strategies has been validated in nonhuman primates or in clinical trials. In a number of studies, antigens of a variety of human viruses that were highly immunogenic in small experimental animals, proved to be much less immunogenic in chimpanzees or humans (206). Also, evaluation of vaccines in a host such as the cotton rat, which is semipermissive for hPIV3 replication and thus easier to “protect,” can yield artifactually encouraging results (206). Experience gained during the development of RSV vaccines suggests that immunogenicity observed in small rodents provides an overly optimistic prediction of the response of humans to the same material. In addition, subunit vaccines have decreased immunogenicity in immunologically naive subjects, and their immunogenicity can be suppressed by passively acquired antibodies, both of which suggest decreased usefulness of such vaccines in the first 6 months of life (207). In any case, subunit vaccines might prove to be useful for boosting the response to a prior live attenuated virus vaccine, or the immunogenicity of such a vaccine might be improved through the use of novel adjuvants or methods of administration (74).

Another approach to immunization involves construction of viable viral recombinants that express parainfluenza virus protective antigens for use as live vaccines. This would have the advantage that antigens would be expressed *in situ* and thus should be conformationally unperturbed. This approach was evaluated by constructing vaccinia virus recombinants expressing the hPIV3 F or HN glycoprotein (282). Both glycoproteins appeared to be expressed in authentic, fully immunogenic form. Infection of cotton rats with either vaccinia virus recombinant, or of patas monkeys with both recombinants, induced a high level of PIV3-specific serum neutralizing antibodies, and the immunized animals developed significant resistance to challenge with hPIV3 (281,282). However, subsequent studies with replication-defective vaccinia virus recombinants, which are more appropriate for use in humans because of their greater margin of safety, were less encouraging (68,331). Replication-defective vaccinia virus recombinants that expressed the PIV3 HN or F glycoprotein were administered to rhesus monkeys by three routes simultaneously—intranasal, intratracheal, and intramuscular. Monkeys immunized in this manner were resistant to subsequent challenge with wild-type PIV3. Unfortunately, this protective effect was partially abrogated when monkeys were infused with PIV3-specific simian antibodies the day before

immunization. Significantly, this suppressive effect of a physiologic amount of passive antibodies was not observed when monkeys were immunized intranasally with a live attenuated PIV3 vaccine candidate. Suppression of immune response by maternally derived antibodies is an important issue because almost all young infants to be immunized would possess such antibodies.

Another approach to immunoprophylaxis involves development of live attenuated vaccine virus mutants suitable for administration by the intranasal route. Previous efforts at development of parainfluenza and RSV vaccines suggested that live attenuated, intranasally administered vaccine viruses represented the most effective strategy for prevention of viral lower respiratory tract infection in experimental animals. This would offer the advantage of direct stimulation of local respiratory tract immunity by all of the protective viral antigenic sites in their most authentic form. Importantly, live attenuated viruses are protective in the presence of passively acquired antibodies (68).

A novel approach to the development of live parainfluenza virus vaccines that has not been evaluated in humans as yet is illustrated by the “protease-activation” mutants of Sendai virus described previously. These mutants were selected for cleavage by elastase or chymotrypsin and, concurrently, resistance to cleavage by trypsin (124,296). Intranasal instillation of a moderate amount of mutant virus (about 10^6 plaque-forming units) induced serum virus-specific antibodies in mice as well as significant resistance to subsequent challenge with wild-type virus (124,296). Additional mutations in the cleavage site region may be required before this approach can be considered feasible for the human parainfluenza viruses, because a Sendai virus mutant with an amino acid substitution at the cleavage site (residue 116) and residue 109 was genetically unstable in mice (124).

Development of one of the initial candidate attenuated hPIV3 vaccines employed the oldest successful strategy for formulation of a live virus vaccine. First used by Jenner more than 200 years ago, this strategy for protection against a virus virulent for humans relies on immunization with an antigenically related animal virus not virulent for humans. bPIV3 and hPIV3 are approximately 25% related by cross-neutralization (1). Their HN glycoproteins share two neutralization epitopes in antigenic site A, and three neutralization epitopes are shared on their F glycoproteins (35,36,321). The two shared epitopes on HN, as well as two of the three shared epitopes on F, are completely conserved among human PIV3 isolates, whereas the third shared epitope on F is very highly conserved (97%). bPIV3 was immunogenic in cotton rats and squirrel monkeys and induced a significant level of resistance to challenge with hPIV3 (323). In addition, bPIV3 was shown to be 100- to 1,000-fold more restricted in replication in the respiratory tract of rhesus monkeys and chimpanzees than hPIV3, indicating a partial host-range restriction that would be expected to be associated with reduced virulence in humans (323). However, strains of bPIV3 grew well enough *in vivo* to induce a serum neutralizing antibody response that should, based on previous experience, provide resistance to hPIV3 infection. In clinical trials, bPIV3 was administered intranasally to 50 infants and children, 2 to 60 months of age (144,146). The candidate vaccine was well tolerated and appeared to be satisfactorily attenuated. Of seronegative children who received 10^4 or 10^5 $TCID_{50}$, 85% became infected and shed virus that retained its attenuation phenotype when tested for level of viral replication in rhesus monkeys. The candidate vaccine elicited a mean serum HI antibody titer for bPIV3 of 1:40, and for hPIV3 of 1:16, in 92% and 61% of the seronegative vaccinees, respectively. These encouraging results in seronegative infants and children indicated that bPIV3 was safe, infectious, and stable with regard to its attenuation phenotype. Furthermore, the candidate vaccine induced a level of protective antibodies that should provide significant resistance to hPIV3 infection (34,146,206). A second “Jennerian” parainfluenza vaccine candidate was recently described. Sendai virus (murine PIV1) was highly immunogenic when administered intranasally to African green monkeys, and immunized animals were completely resistant to replication of a second dose of the candidate vaccine or to subsequent challenge with hPIV1 (126).

A second type of live attenuated hPIV3 vaccine was developed by passaging a wild-type virus in cell culture at suboptimal temperature (20° or 22°C) (10,50,51). A promising vaccine candidate was identified after 45 cold-passages. This *cp*45 mutant exhibited three interesting properties: (a) cold adaptation (*ca*) (i.e., an ability to replicate efficiently at 20°C, a temperature restrictive for wild-type PIV3); (b) temperature sensitivity (*ts*) (i.e., a decreased ability to produce plaques at the high end of the normal temperature range); and (c) reduction in level of replication (“attenuation” or *att*) in hamsters, monkeys, and humans (104,147). This mutant was considered to be a promising vaccine candidate because its *ca* and *ts* phenotypes were stable after replication in cell culture, and it induced significant resistance in hamsters and monkeys to subsequent challenge with wild-type hPIV3 (104).

Evaluation of the *cp*45 mutant in rhesus monkeys showed that it was attenuated as a consequence of a mixture of *ts* and non-*ts* mutations (104). Subsequent evaluation in chimpanzees confirmed its satisfactory level of attenuation (103). Significantly, the mutant was still able to induce a high level of resistance to wild-type virus challenge. Although *cp*45 exhibited a partial loss of the *ts* phenotype during replication in chimpanzees, such partial revertants remained satisfactorily attenuated when tested in additional chimpanzees. This illustrates the importance of having multiple attenuating mutations, some of which are non-*ts* in nature, to maximize stability of the attenuation phenotype. Preliminary clinical evaluation of the attenuated *cp*45 mutant in seronegative infants and small children suggested that this candidate vaccine strain was suitably infectious and attenuated, as well as moderately immunogenic (147). In addition, each of 135 virus isolates from vaccinees retained the *ca* and *ts* phenotype.

The production and characterization of live attenuated parainfluenza virus vaccines have been greatly facilitated by the recent development of reverse genetics. For example, existing attenuated viruses can be sequenced and their relevant mutations identified by their introduction into recombinant wild-type virus. This makes it possible to differentiate attenuating mutations from incidental mutations. Novel mutations, such as those affecting the cleavage site of the F protein or genomic RNA regulatory sequences, can also be introduced. Attenuating mutations identified in these ways can then be introduced in various combinations into wild-type virus or existing attenuated mutants to produce a graded series of genetically defined vaccine viruses.

These approaches have been and are currently being used to characterize the *cp*45 hPIV3 vaccine candidate, as well as to construct derivatives of *cp*45 that might also be useful for immunization. The *cp*45 differs from hPIV3 wild-type parent (strain JS) by 20 mutations (Fig. 6) (275,286). Five of these changes are located in coding regions but are not thought to be significant because the amino acid sequence is not altered and they do not involve cis-acting signals. The remaining

15 changes include four nucleotide substitutions in the 3' leader region, one nucleotide substitution in the NP gene-start signal, and 10 amino acid substitutions distributed among six viral proteins, namely NP, C, M, F, HN, and L (see Fig. 6). These mutations, either singly or in combination, were introduced into full-length, wild-type viral cDNA and the resulting viable mutants were then analyzed to determine their *ca*, *ts*, and *att* phenotypes (275). Multiple mutations throughout the hPIV3 genome were shown to contribute to the *ca*, *ts*, and *att* phenotypes. The three L gene mutations were tested separately or together (see Fig. 6). Each of these L mutations contributed individually to the *ts* phenotype and to growth restriction in hamsters (i.e., the *att* phenotype) but did not specify the *ca* phenotype either separately or together (274). The triple L gene mutation recombinant virus was as attenuated in hamsters as the *cp*45 mutant, indicating that the L gene mutations make a major contribution to the attenuation exhibited by the *cp*45 vaccine virus. Two other proteins, namely C and F, were also identified as sites in which amino acid substitution could independently specify attenuation. It is likely that the multiplicity of mutations responsible for the *ts*, *ca*, and *att* phenotypes of *cp*45 is responsible for the observed stability of these phenotypes during replication *in vivo*. Improvement of *cp*45 hPIV3 could also be achieved by addition of other mutations imported from attenuated mutants of related paramyxoviruses of the same genus, another genus, or another subfamily. An example of the latter approach was the small incremental increase in attenuation of *cp*45 hPIV3 that was achieved by importation of an L protein mutation from the Pneumovirus RSV mutant into an analogous site of the hPIV3 mutant (273).

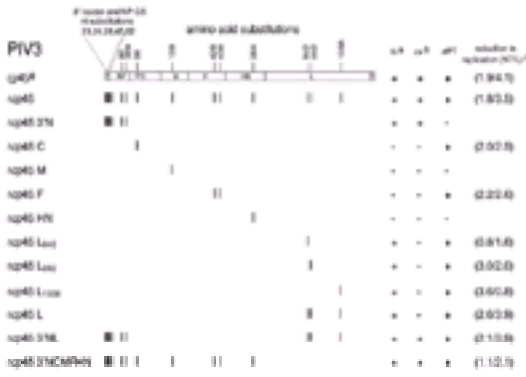

FIG. 6. Contribution of 15 nucleotide (*nt*) or amino acid (*aa*) point mutations to three laboratory phenotypes exhibited by the *cp*45 hPIV3 JS strain candidate live attenuated vaccine virus. The genome position of each nucleotide substitution in the 3' leader and the N gene-start (*GS*) signal or each amino acid substitution in the NP, C, M, F, HN, and L proteins is indicated by a *vertical line*. Each line represents the relative position of the indicated mutation in the biologically derived *cp*45 mutant or in a cDNA recombinant mutant constructed to bear that mutation. **a:** Temperature sensitivity (*ts*): A virus is defined as exhibiting the *ts* phenotype if plaque formation at 40° is more than 100-fold reduced compared to wild-type (*wt*) rhPIV3 at 40°C. **b:** Cold-adaptation (*ca*) is defined as a greater than 10-fold increase in replication at 20°C compared to that of wild-type HPIV3 at 20°C. **c:** Attenuation (*att*): A virus is defined as exhibiting the *att* phenotype when its replication in lungs or nasal turbinates of hamsters is reduced by at least 10-fold compared to wild-type rhPIV3. **d:** Reduction (log_{10}) in virus replication in the respiratory tract of hamsters compared to wild-type hPIV3 (*NT*, nasal turbinates; *L*, lungs). **e:** *cp*45 is a biologically derived virus. All the other viruses are mutant hPIV3 (JS strain) recombinants derived from cDNA.

The feasibility of increasing the breadth of immunity conferred by the *cp*45 hPIV3 vaccine candidate has been investigated by constructing a viable chimeric recombinant virus in which the F and HN ORFs of wild-type hPIV3 were replaced by the corresponding sequences of wild-type hPIV1 (291). The resulting hPIV3-1 chimera replicated as efficiently *in vitro* and *in vivo* (hamsters) as its hPIV1 parent and induced effective immunity to hPIV1. That the hPIV3-1 virus was fully viable *in vitro* and *in vivo* was remarkable, given the divergence in F and HN amino acid sequence between the two serotypes. For example, the cytoplasmic and transmembrane domains of F and HN share less than 20% amino acid identity between hPIV3 and hPIV1. Because these regions are generally thought to interact with internal proteins such as M, it might have been expected that a swap of the complete glycoproteins would have reduced viability (289), but this was not the case. Introduction of the attenuating mutations of *cp*45 into hPIV3-1 yielded a chimeric virus that was satisfactorily attenuated and highly immunogenic in experimental animals (276,292). Interestingly, the immunity induced by hPIV3-1 had two components: (a) a moderate level of resistance to hPIV3 challenge, which appeared to be mediated by cellular immunity specific for internal hPIV3 proteins and which was short-lived (290), and (b) a high level of resistance to hPIV1 challenge that was durable and was mediated by antibodies to hPIV1 HN and F (290). The finding that the hPIV3-specific response induced by the antigenic chimera was short lived suggests that reimmunization with the same hPIV3 vector bearing other antigenic determinants, such as the HN and F proteins of hPIV2, should be feasible (290). Thus, immunization against hPIV1, 2, and 3 might be achieved using antigenic chimeras constructed on the hPIV3 *cp*45 backbone.

Parainfluenza viruses also have been evaluated as a vector for added foreign genes. In this strategy, the foreign gene is placed under the control of gene-start and gene-end parainfluenza virus transcription signals and inserted into the gene order. Because of the polarity of transcription, placement in a more promoter-proximal location would provide a higher level of expression. For example, gp160 of HIV was inserted into the Sendai virus genome at a promoter-proximal location and recovered as a recombinant virus, which then expressed an additional mRNA encoding the foreign protein (336). This turns out to be a surprisingly efficient expression strategy, and foreign inserts in mononegaviruses are remarkably stable. Also, this strategy can be used to produce foreign proteins *in vitro* for use as subunit vaccines. Alternatively, the recombinant parainfluenza viruses expressing the selected foreign protein can be used to deliver the foreign antigen by infection. For example, recombinant hPIV3 has been constructed that expresses the HN or F protein of hPIV2 or the HA protein of measles virus as an additional gene (unpublished observations). The capacity for accepting additional foreign sequence in a viable recombinant is quite large and is still being explored: More than 3,900 nucleotides can be added to the hPIV3 genome with little effect on replication *in vitro* and with only a small reduction in replication in hamsters (unpublished observations). The use of viruses such as hPIV3 as vectors has several advantages. The

intranasal route of immunization is highly immunogenic. It also partly abrogates the suppressive effects of serum antibodies, and hence parainfluenza viruses can circumvent the inhibiting effects of maternal antibodies in young vaccinees as well as of preexisting serum antibodies in older vaccinees. An appropriate level of attenuation of the vector can then be achieved by reverse genetics. The existence of three serotypes of human PIV expands the range of vectors. The fact that essentially all adults and older children are seropositive for the human parainfluenza viruses and hence protected against serious disease means that the use of such a vector would not pose a biosafety risk to the general population.

An additional application of reverse genetics to parainfluenza virus vaccine development involves construction of novel attenuation mutations that do not exist in nature. One example involves Sendai virus or hPIV3 C or V protein knock-out mutations that attenuate virus growth *in vivo* (see earlier section, Properties of the Proteins). A second example involves the transfer of attenuating point mutations in related viruses such as RSV or Sendai to the corresponding sequences in hPIV3 (67,273). Another example involves the construction of virus chimeras that contain a mixture of internal protein genes of hPIV3 and bPIV3. In one construct, the NP ORF of hPIV3 was replaced by that of bPIV3. The resulting virus was fully viable *in vitro*, but in monkeys it exhibited the host-range restriction typical of bPIV3 (6).

In summary, reverse genetics provides a method for identifying the basis of attenuation of existing attenuated virus vaccine candidates. It also can produce new attenuation mutations. Desirable mutations in different viruses can be combined through a cDNA intermediate, something that is not possible in nature because of the inability of the mononegaviruses to undergo homologous recombination. This makes it possible to incrementally adjust the attenuation phenotype of a recombinant vaccine strain to accommodate information that is obtained during clinical evaluation. Finally, the ability to bring together the antigenic determinants of one virus and the attenuating internal proteins of another virus provides the flexibility needed to produce multivalent vaccines in a timely manner.

CHAPTER 43 Mumps Virus

Kathryn M. Carbone and Jerry S. Wolinsky

HISTORY

In the 5th century B.C., Hippocrates described a mild epidemic illness associated with nonsuppurative swelling near the ears and, variably, with painful swelling of one or both testes. The name *mumps* may derive from an old English verb that means to grimace, grin, or mumble (185). Hamilton, a physician of the late 18th century, is credited as being the first to associate central nervous system (CNS) involvement with mumps in his description of the neuropathology of a fatal case (87).

A number of investigations suggested that there was a filterable, transmissible agent responsible for mumps (62,79,81,107). The demonstration that mumps virus could be isolated and propagated in embryonated eggs (86) enabled the demonstration of the hemagglutinating (139), hemolytic (164), and neuraminidase (33) properties of the virus. The introduction of tissue culture as a practical alternative for the propagation and study of the virus (89) further advanced the molecular understanding of mumps virus and the epidemiology and pathogenesis of mumps.

An attenuated mumps virus vaccine was introduced in the United States in 1967 (162). This resulted in a steady decline in the incidence of reported mumps cases, from 76 per 100,000 population in 1968 to the current low level of less than one reported case per 100,000 population (37,39). However, the widespread use of mumps vaccines remains relatively restricted to more affluent countries. Therefore, mumps is likely to remain a common worldwide human viral infection for some time.

INFECTIOUS AGENT

Mumps virus is a member of the genus Paramyxovirus in the family *Paramyxoviridae* (see also Chapter 41).

Propagation and Assay in Cell Culture

Mumps virus infects various primary and established mammalian cell lines *in vitro*, including BSC-1, Vero, MDBK, and HeLa. Mumps virus can also be propagated in the allantoic cavity of embryonic chickens and in chicken embryo cells *in vitro*. The presence of mumps virus is normally detected by the presence of syncytia followed by lysis of infected monolayers. Cytopathic effects of mumps virus in culture vary considerably among isolates and host-cell systems. Cell-to-cell fusion produces massive syncytia composed of large homogeneous masses of cytoplasm enclosing numerous nuclei (91) (Fig. 1). Such cell fusion requires expression of mumps virus glycoproteins HN and F (216). The presence of serine at position 195 of the fusion glycoprotein, F, seems to be obligatory for the appearance of significant syncytium formation (217). Other cytopathic effects of various mumps virus strains include spindle formation, cytoplasmic vacuolization and inclusions, and cell pyknosis and lysis; in some instances, there is little evident morphologic change (84,151). The type of cytopathic effect produced does not appear to correlate reliably with the *in vivo* behavior of the virus.

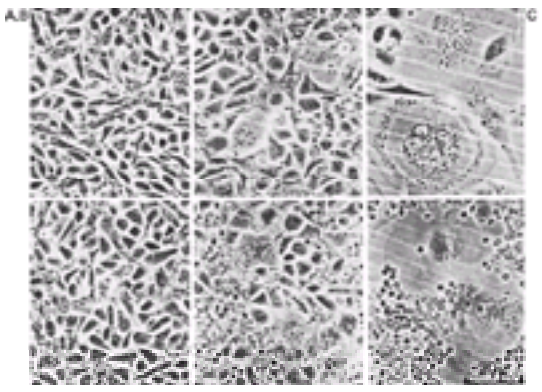

FIG. 1. Comparative cytopathic effects of avirulent O'Take (**B**) and neurovirulent Kilham (**C**) experimental mumps virus strains are illustrated in phase photomicrographs of BSC-1 cells taken 6 days after omparable low multiplicity or mock (**A**) infection. The monolayers of the *lower row* were hemadsorbed with guinea pig red blood cells. Occasional diploid cells are seen following the O'Take infection. This contrasts markedly with the syncytial-type cytopathology of the Kilham infection.

Because not all mumps virus strains produce cytopathic effects *in vitro*, mumps virus replication can be verified by hemadsorption (guinea-pig red blood cells), normally within 3 to 6 days of inoculation (201). Mumps virus–specific antiserum is then used in hemadsorption-inhibition (HI), plaque reduction neutralization (PRN) assays, and direct or indirect immunofluorescence assays. In addition, genome amplification by reverse transcriptase polymerase chain reaction (RT-PCR) and sequencing can be performed to identify unequivocally the isolate (22).

Some noncytolytic mumps virus infections are the result of persistent infection *in vitro* (90,154,224,235), and these may be instructive regarding naturally occurring, persistent Paramyxovirus infections. Factors that may contribute to mumps virus persistence *in vitro* include interferon (IFN) production, noncytopathic mutant selection, and the generation of defective interfering particles containing subgenomic RNA (70,151). Persistent replication *in vitro* has been associated with poor induction of IFN-induced 2',5'-oligoadenylate synthetase, linked to a decrease in STAT-1a (257). However, the relative contributions of these factors *in vivo*, in the presence of a host immune response, are not known.

Biologic Characteristics

Virion Morphology

Mumps virions are markedly pleomorphic (100 to 600 nm), and roughly spherical with an outer membrane that envelops an inner, coiled helical structure (Fig. 2). However, filamentous and bizarre forms are common even when virions are fixed *in situ* and examined in resin-embedded sections (Fig. 3). Multiploid mumps virions whose size and heterogeneity increase with multiplicity of infection have been reported. The envelope is studded with projections formed by the viral glycoproteins that rise 12 to 15 nm from the virion surface. The coiled inner structure or nucleocapsid is a ribonucleoprotein complex that appears to be a hollow tube with a unit length of approximately 1 µm, a diameter of 17 nm, and a central core of 5 nm (99,100,153). Full-length genomic RNA is an unsegmented, single-stranded macromolecule of negative polarity that contains about 15.3 kilobases (3).

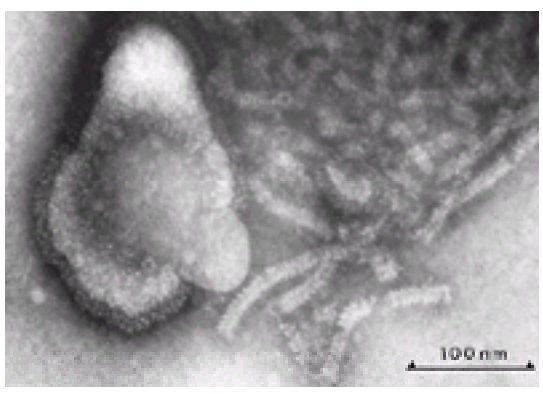

FIG. 2. Mumps virus preparation negatively stained with phosphotungstic acid, showing a typical virion studded with fine surface projections that represent the viral glycoprotein spikes. The membrane of the lower right portion of the virion has burst, allowing the escape of nucleocapsids, seen as scattered linear structures to the right of the field, that exhibit a typical herringbone pattern.

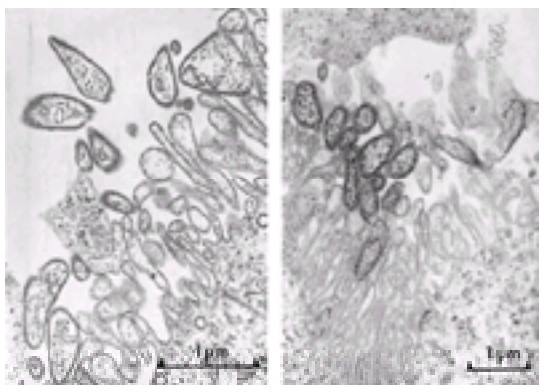

FIG. 3. Left: Pleomorphic mumps virions budding from a choroid plexus epithelial cell. **Right:** A subjacent section processed for postembedding localization of the major nucleocapsid-associated protein using monoclonal anti-NP antibody. The NP is localized by punctate, electron-dense reaction products below the surface membranes of the cell.

Key Virus Antigens

Many investigators have contributed to the delineation of the structural polypeptides of mumps virus (94,101,106,157,158,166,174,175,200). The virus contains six major structural proteins: nucleocapsid-associated protein (NP), phosphoprotein (P), and polymerase protein (L) are associated with the nucleocapsid; membrane or matrix (M) protein; and two glycoproteins, a hemagglutinin-neuraminidase (HN) and a fusion (F) molecule (Table 1). All mumps virus genes have been sequenced (55,57,58,129,237,239,250). The gene order for mumps virus is 3-*NP-P-M-F-SH-HN-L*-5 (56). There is a nontranscribed leader sequence of 55 nucleotides (215) and a trailing sequence of 24 nucleotides (170) that share inverse complementarity at their extremes. Consensus intragenic start (3'-U C C GG U N CU U U UC U) and stop (3'-A UA AU U C AU$_{6-7}$) sequences are separated by intergenic sequences of one to seven nucleotides (56). Mono-, di-, and polycistronic transcripts of these genes are variably found in mumps virus–infected cells (2).

Gene	mRNA[b]	Amino acids	MW in kd[c] Predicted	Observed	Biologic activity
NP	1,845	540	61.4	68–73	Major NC-associated protein; protects genomic RNA from cellular proteases
P	1,212	391	41.6	45–47	NC-associated phosphoprotein; forms part of the transcriptase complex
M	1,253	375	41.6	37–42	Membrane-associated protein; involved in NC alignment
F	1,721	538	58.8	65–74	Surface glycoprotein with fusion activity; mature form is a disulfide-linked complex of F$_1$ (48–51 kd) and F$_2$ (10–16 kd)
SH	310	57	6.7	6	Hydrophobic membrane-associated protein
HN	1,887	582	64	74–80	Surface glycoprotein with hemagglutinin-neuraminidase activity; disulfide-linked oligomer in native state
L	6,925	2,201	250.6	180–200	NC-associated protein, contributes to RNA-dependent RNA polymerase

[a]Composite properties from multiple studies; see text for specific references.
[b]Number of nucleotides in mRNA not including the polyadenylation tract.
[c]Approximate molecular weight in kd given first as predicted from the nucleic acid sequence and then as observed by gel electrophoresis.
NC, nucleocapsid; MW, molecular weight.

TABLE 1. *Mumps virus genes and gene product*[a]

Both mumps virus glycoproteins are membrane bound (106). The larger glycoprotein, HN, has both hemagglutinating and neuraminidase activities (106). In the native state, the HN protein is a disulfide-bonded oligomer. The F protein is composed of two disulfide-linked glycopolypeptides (F_1 and F_2) of unequal size (94,157,166,200,238,240). Both glycoproteins are acetylated (157). The HN glycoprotein mediates the adsorption of virus to host cells, and monospecific antibody against HN inhibits virus infectivity (33,173). The F glycoprotein mediates the fusion of lipid membranes at neutral pH; thus, F is required for the penetration of the viral nucleocapsid into the host cell and for hemolysis (174). Expression of both HN and F are required for efficient cell-to-cell fusion (216).

In contrast to the case for several other paramyxoviruses, the failure of some mumps virus strains to induce syncytia *in vitro* is not caused by incomplete processing of the F glycoprotein (157). However, differences in neuraminidase enzyme function of the nonfusing and fusing strains have been reported (158,240). For example, conversion from a nonfusing to a syncytium-forming phenotype was correlated with the substitution of isoleucine for threonine at HN residue 181 (236).

As deduced from the nucleic acid sequence, the HN protein consists of 582 amino acids and it has a molecular weight of about 64 kd when unglycosylated, with minor variations in predicted mass between mumps virus strains (134,237). HN appears to be held in the lipid bilayer by the hydrophobic domain of 19 residues near the amino terminal, a domain that probably also serves as a signal sequence in a manner similar to other Paramyxovirus HNs. There are nine potential N-linked glycosylation sites on HN, five of which are most likely used. The *F* gene encodes a protein of 538 amino acids with a calculated molecular weight of about 58.8 kd (57,239). At the extreme amino terminus of F_2, there is a hydrophobic signal sequence of 19 residues that is not present in the mature protein (239). The molecule is anchored into the bilayer by a stretch of 30 hydrophobic amino acids located near its carboxyl terminus. The active forms of the F protein (F_1 and F_2) are produced by cleavage of the immature protein (F_0) by a host-cell protease. This protease recognizes a sequence of five basic amino acids (Arg-Arg-His-Lys-Arg) at the carboxyl terminus of the F_2 protein. The fate of this segment after cleavage is unknown. A sole cysteine in F_2 then provides the only disulfide link with the membrane-bound F_1. The hydrophobic F_1 amino terminus is highly conserved and similar to other Paramyxovirus F_1 terminal domains. This hydrophobic domain of F_1 is presumed to be the functionally important region for fusion, initiating the fusion process by

intercalation with the lipid bilayer of target cell cytoplasmic membrane. Depending on the virus strain, there are six or seven potential glycosylation sites on F, five on F_1, and one or two on F_2 (239). Both the HN and F of mumps virus bear homology to simian virus 5 (SV5) and Newcastle disease virus (NDV). The greatest overall homology, both by sequence comparison and immunologic cross-reactivity, is with parainfluenza virus types 2 and 4 (119,126).

Mumps virus contains another membrane-associated protein called the membrane or matrix (M) protein, which is not glycosylated (106,174). M protein plays a critical role in the assembly of paramyxoviruses by mediating the alignment of the nucleocapsid under regions of virus-modified host cell membrane before the budding of the virion (149). As deduced from nucleic acid sequence data, the M protein is composed of 375 amino acids and has an estimated mass of about 41.6 kd. Its primary structure is conserved among mumps virus strains (53,57) and exhibits considerable sequence homology with that of other viruses such as NDV.

Nucleocapsids isolated from mumps virions contain the major structural protein NP and lesser amounts of P and a high-molecular-weight polypeptide, L (174). There are two closely related forms of the NP that resolve by electrophoresis. Both forms of NP are phosphorylated, and the extent of phosphorylation may affect the electrophoretic mobility of the proteins (166). Alternatively, the heterogeneity of NP may reflect limited proteolytic degradation of the protein. It is known that NP is readily susceptible to such degradation, as evidenced by the multiple NP-related polypeptide species observed when nucleocapsids are isolated from infected cells (150,200). Based on the nucleic acid sequence of the mRNA, the NP protein should contain 549 amino acids and have an estimated molecular weight of about 61.3 kd (215). This is 8 to 10 kd less than that usually observed by gel electrophoresis (150,174), even after *in vitro* transcription from cDNA constructs (215). The primary structure of NP is well conserved among phenotypically divergent mumps virus strains. Mumps virus NP is most homologous to human parainfluenza virus types 2 and 4B (215).

The virion possesses an RNA-dependent RNA polymerase or transcriptase (120), most likely involving both P and L. The P protein of mumps virus has been identified by its internal location in the virion, size, and association with nucleocapsid (150). Consistent with what is known of other paramyxoviruses, the P protein is phosphorylated (166). Three distinct mRNAs derive from the *P* gene: (a) a faithful transcript of the *P* gene virion RNA (vRNA) that encodes NS2 (also referred to as I), (b) P, and (c) NS1. The latter two are produced after RNA editing of vRNA by guanosine insertion at a G-rich region of the *P* gene (178,213). P has a predicted mass of 41.6 kd (54,213). The cysteine-rich domain of NS1 may be involved in transcription/replication of the vRNA (178). The accuracy of insertion of the nontemplated G may vary with the mumps virus strain (58). By electrophoresis, these species (P, NS1, and NS2) have apparent molecular weights of 45 kd, 28 kd, and 19 kd (94).

There is a large, virus-specific, about-200-kd polypeptide both in disrupted mumps virions and in mumps virus–infected cells (94,101,151,157). Associated with the viral nucleocapsid structure as part of the transcriptase complex, this protein is considered the L protein. The *L* gene contains 6,925 nucleotides and encodes a polyprotein of 2,261 residues with a predicted molecular weight of 256.6 kd (170). Motifs within the predicted L primary structure are consistent with the presence of an active polymerase catalytic site, an RNA template contact region, and an ATP binding site (170).

The remaining mumps gene encodes a small hydrophobic (SH) protein (56,57). The SH mRNA is found in mumps virus–infected cells and encodes a 57-amino-acid molecule. SH has an amino terminal stretch of 25 residues that could readily associate with membranes (55). Recently, detection of the SH protein was reported in the endoplasmic reticulum and perinuclear Golgi of infected cells using antisera prepared against SH oliogopeptides (214). However, the inability to identify SH in the Enders mumps virus strain indicates that the SH gene product is not required for viral replication.

Serologic Determinants

Two mumps virus antigens, S and V, are largely composed of the NP and HN proteins, respectively (106). Using polyclonal antisera in PRN assays, a broad cross-reactivity to HN from a variety of mumps strains has been demonstrated (254). Interestingly, although some type-specific anti-HN neutralizing antibody has been reported, there was no correlation found between specific changes in nucleic acid sequence with type-specific antibodies (176).

P>Monospecific polyclonal and monoclonal antibodies that react only with the glycoproteins have localized the red blood cell adsorption and neutralization sites to domains on the HN molecule that are distinct from those with neuraminidase activity (174,200,247). Similarly, the hemolytic activity of the virus resides with the F glycoprotein (174) and is distinct from red cell adsorption activity. Virus-specific antisera and mumps virus anti-NP monoclonal antibodies serologic cross-reactivity is highest between mumps virus and human parainfluenza viruses (105).

Infection in Experimental Animals

Host Range

The only natural host of mumps virus is man. Experimentally induced mumps infections have been reported in several species, most significantly, monkeys (138), adult and suckling hamsters (172), suckling mice (123), neonatal and suckling rats (187,191), and developing chick embryos (86).

Experimental Animal Models

Inoculation of mumps virus into suckling hamsters produces neurologic disease reminiscent of some features of human infection. The neuroadapted Kilham mumps virus strain, originally isolated from human breast milk, produces a severe meningoencephalitis and hydrocephalus in suckling hamsters on intracerebral inoculation (172,211). Developmental brain defects, such as a Chiari type I cerebellar malformation, have also been identified, possibly linked to the increased intracranial pressure in the setting of rapid postnatal growth of the cerebellar cortex (212).

In the 1950s, there was a report of experimental infection of young rats (187). Now there is renewed interest in the rat

experimental model, examining its value for predicting the human neurovirulence risk from mumps virus vaccine strains (191). In addition, unique evidence of neurodevelopmental damage, such as cerebellar hypoplasia, has been reported in the mumps virus–infected neonatal rat.

PATHOGENESIS AND PATHOLOGY

Virus Entry, Primary Replication, Spread

Susceptible individuals in close, but not necessarily intimate, contact are required to establish an epidemic (79). Transmissibility after nasal or buccal mucosal inoculation of virus (107) suggests that natural infection is initiated by droplet spread. During the 18-day incubation period from exposure to first clinical symptoms, the virus multiplies in the upper respiratory mucosa, spreads to draining lymph nodes, and then disseminates via a transient plasma viremia (120).

Virus is shed in saliva for as long as 6 days before the onset of parotitis (93). Termination of viral excretion in saliva correlates with the local appearance of virus-specific secretory IgA, as early as 5 days after disease onset (41). Virus-specific IgM antibodies are also present early in saliva (181). Thus, patients with mumps are capable of spreading virus by the respiratory route over a 7- to 10-day interval. Plasma viremia disappears coincident with the development of mumps virus–specific humoral antibody, which can be detected in serum as early as 11 days after induced apparent or inapparent infection of humans (93). Mumps virus preferentially infects activated human T lymphocytes (63). Animal models suggest that circulating infected lymphocytes provide a means for the spread of virus in the face of mounting humoral immunity (246).

Cell and Tissue Tropism

Parotid Gland

Initial clinical symptoms usually relate to infection of the parotid gland, but viral involvement of this gland is neither a primary nor an obligate step in the infection (121). Virus infects the ductal epithelium, producing intracytoplasmic inclusions (viral nucleocapsids) and viral antigens, with eventual desquamation of involved cells (147,242). Periductal interstitial edema and a local inflammatory reaction primarily involving lymphocytes and macrophages are also seen (242). Swelling, inflammation, and tissue damage in the parotid gland may produce elevation of serum and urine amylase levels (199).

Kidney

Virus also frequently disseminates to the kidneys, where epithelial cells of the distal tubules, calyces, and ureters appear to be primary sites of virus replication (242). Viruria, as an expression of renal involvement, can be detected in most patients, sometimes for as long as 14 days after the onset of clinical symptoms (226,228). Mild abnormalities of renal function have been described but are usually of little clinical importance (226). Although virus dissemination to, and replication in, the parotid gland and kidney can occur simultaneously, replication in renal tissue is more prolonged and continues well beyond the appearance of neutralizing antibody in serum.

Central Nervous System

The CNS is a common site of mumps virus dissemination with or without associated signs of parotid gland involvement. Virus is readily recovered from human cerebrospinal fluid (CSF) during the early phases of mumps meningoencephalitis (121). Using CSF pleocytosis as a marker of viral invasion of the brain, at least half of all infections are associated with replication of virus within the CNS (29). Symptomatic mumps meningoencephalitis is significantly more common in males than in females (19).

Viral invasion of the CNS presumably occurs across the choroid plexus (29). Blood-borne infected mononuclear cells may cross the fenestrated endothelium of the choroid plexus stroma and serve as a source for subsequent infection of the choroidal epithelium. However, direct passage of plasma virions across the endothelium of the choroid plexus to infect choroidal epithelium has not been excluded. Maturation of virus from the ventricular surfaces of choroidal cells provides progeny virions that are widely distributed through ventricular pathways and the subarachnoid space by CSF (Fig. 4).

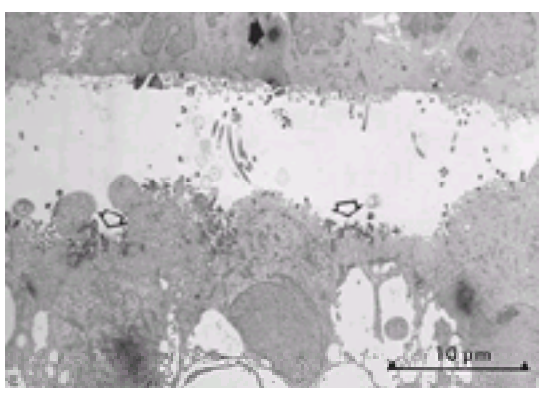

FIG. 4. Postembedding electron-microscopic immunocytochemical staining of a region of the lateral ventricle of a hamster on the fifth day following intraperitoneal infection with the Kilham strain of mumps virus. Anti-NP monoclonal antibody was used as the primary reagent. The reaction product defines nucleocapsids located below the cytoplasmic membranes at sites of virion budding along both the ependymal and choroidal (*unfilled arrows*) surfaces. Intracytoplasmic nucleocapsid inclusions are also demarcated by the reaction product in both choroid plexus and individual ependymal

(*filled arrow*) cells.

Although the specific virus genomic regions linked to mumps virus neurotropism and neurovirulence are not known, some nucleic acid sequences have been found to be associated with nervous system disease. In Japan, wild-type viruses that lacked a *Bam*HI restriction cleavage site in the *P* gene, compared to viruses that contained this cleavage site, were disproportionately associated with symptomatic meningitis (193). The presence of A in base position 1,081 of the *HN* gene is found in wild-type viruses (83), and this sequence has been proposed to be associated with increased neurovirulence of live, attenuated vaccine viruses (26). In contrast, a G in the same position was not associated with CNS disease (6). However, other sites on the mumps virus genome very likely contribute to neurovirulence [e.g., nucleotide positions 1,470 and 1,570 (amino acid positions 464 and 498, respectively) in the *HN* gene] (6).

Neurologic manifestations during mumps are usually those of meningeal infection (e.g., headache, fever, and stiff neck). Infection of the lining of the ventricles (ependymal cells) is also seen. Virus can penetrate brain parenchyma by contiguous spread from infected ependymal cells that line the ventricular cavities of the brain. However, frank encephalitis (e.g., infection of neurons in brain parenchyma leading to obtundation and other neurologic deficits) is less common. Once within neurons, virus most likely spreads along neuronal pathways, as reported in subhuman primates (138). In addition, the direct effects of mumps virus infection on neural cells may be compounded, in rare instances, by a virus-associated autoimmune attack on CNS myelin sheaths (i.e., autoimmune-mediated postviral encephalitis).

Typical CNS pathology of mumps virus encephalitis includes perivascular infiltration with mononuclear cells, scattered foci of neuronophagia, microglial proliferation, and perivascular demyelination (52,219). When seen, the selective periventricular myelin loss with relative sparing of axons is typical of parainfectious autoimmune encephalitis.

Rarely is mumps CNS infection fatal. However, a few fatalities have been reported, both in immunocompromised and in previously healthy individuals (10). Most cases of mumps meningitis resolve without sequelae. However, electroencephalographic changes, ataxia, and behavioral disturbances may take months to resolve following mumps meningoencephalitis (128). Permanent and ongoing neurologic damage may occur, such as obstructive hydrocephalus (169), deafness (142), myelitis (13), cerebellar ataxia (45,102), and, more rarely, problems from a variety of other neurologic syndromes. Hydrocephalus develops days to years after initial mumps virus infection (169). Narrowing or obliteration of the aqueduct of Sylvius, presumably the result of desquamation of infected ependymal cells (110) and/or cross-linking of ependymal cell processes by the agglutinating properties of mumps virions (244). Blockage of the aqueduct restricts the flow of CSF to normal adsorptive sites over the cerebral convexities and results in progressive enlargement of the lateral and third ventricles. Hydrocephalus can lead to progressively worsening headaches, mental status changes, and gait abnormalities. Deafness is probably the result of direct damage to the cochlea and, to a lesser extent, cochlear neurons (142).

Persistent CNS Infection

The cell-associated-virus persistence in the CNS extends well beyond the establishment of specific immune defenses (231). Persistence of inflammatory cells (pleocytosis) and oligoclonal immunoglobulin (bands) in the CSF indicate continued antigenic stimulation by persistent mumps virus (143). Such persistence, on rare occasions, has been associated with CNS diseases such as chronic encephalitis resulting in intellectual deterioration and seizures (231).

Gonads

Symptomatic gonadal involvement occurs primarily in postpubertal men and is rarely documented in women (14). Ovary infection may be underappreciated, because unless a pelvic exam is performed abdominal or pelvic pain from inflamed ovaries might be attributed to pancreatic infection. It is unclear why orchitis is less often seen in prepubertal boys. Virus has been isolated from testicular biopsies of the affected gland within the first 4 days of symptoms (17), strongly suggesting that symptomatic gonadal involvement reflects local virus replication and inflammation. The seminiferous tubules may be the primary site of viral replication, with local lymphocytic infiltration and edema of interstitial tissues.

Pancreas

Pancreatic involvement is usually expressed as mild epigastric pain, but severe hemorrhagic pancreatitis (61) and transient exocrine function abnormalities (49) have been reported. The mumps virus infects human pancreatic beta cells *in vitro* (232), and this occurs after experimental infection of hamsters (246). Viral infections have been considered a possible precipitating event leading to the onset of about one third of all cases of juvenile-onset or type I insulin-dependent diabetes mellitus (IDDM). Mumps may account for up to 8% to 22% of the preceding viral illnesses (125). Whether mumps virus causes IDDM is still unclear (48). In some cases of IDDM, autoantibodies to insulin or pancreatic islet cell antigens have been detected (189). Some epidemiologic studies (72) have reported an association between mumps and IDDM, but other studies have not (198). There is no association between mumps and type II diabetes (144).

Heart

Myocardial invasion occurs frequently in mumps, as indicated by electrocardiographic abnormalities (8). Although it is seldom symptomatic, there may be an interstitial lymphocytic myocarditis and mild pericarditis following mumps replication in cells of the myocardium and pericardium (30). Mumps virus myocarditis may lead to a rare but serious sequela of endocardial fibroelastosis (167). In contrast, mumps virus does not cause inclusion-body skeletal muscle myositis (258).

Mild to moderately severe mono- or polyarticular and, often, migratory arthritis has rarely been associated with mumps (80). Mumps virus can not be isolated from joint fluids or synovial tissues, and there is no evidence for significant immune complex deposition.

Fetus/Neonate

Mumps may produce a fetal wastage when contracted by the mother during the first trimester of pregnancy, occurring after blood-borne infection of the placenta, with or without subsequent spread of virus to involve fetal tissues directly (203,256). Mumps virus has been isolated from fetal tissues following spontaneous first-trimester abortion on the 4th day of maternal mumps (134) and from tissues derived from a planned therapeutic abortion of seronegative women 1 week after vaccination with live attenuated mumps virus (253). A proliferative necrotizing villitis with decidual cells containing intracytoplasmic inclusions has been described in the products of spontaneous and induced abortions (73).
Late-gestation intrauterine infection was reported in an infant born to a mother who developed mumps more than 4 weeks before delivery, diagnosed by RT-PCR testing of the infant's cord blood cells (249). This infant developed severe pulmonary symptoms, including hypertension and hemorrhage. Mumps virus is excreted in breast milk (122), but few cases of perinatal mumps have been described. Perinatal infection was suggested by virus recovery from an 8-day-old infant with upper respiratory symptoms whose mother developed mumps 4 days before parturition (112,135).

There appears to be a somewhat different mode of pathogenesis of mumps in newborns. In the first year or two of life, infants may have only pulmonary involvement without associated evidence of parotitis (112,249). Split immunologic recognition in the infants can follow maternal parotitis, resulting in mumps-specific, cell-mediated immune responses without concomitant humoral antibody response (1,206,222).

Immune Response

The host's immune response to mumps virus is complex but can be superficially divided into cellular and humoral responses.

Cell-Mediated Immune Response

In vitro lymphocyte-proliferative responses to mumps virus antigens are readily measured in seropositive individuals (103). Cell-mediated responses to previously recognized antigens may be diminished during and for up to 4 weeks following human infection with attenuated mumps vaccine virus (133) and, most likely, with natural mumps as well.

CD8+ and gamma-delta cytotoxic T lymphocytes have been demonstrated in blood and/or CSF following infection with wild-type or vaccine mumps virus strains (16,42,64,131). Mononuclear cell inflammation in mumps virus–infected tissues is well developed at the time of onset of clinical disease, suggesting that specific cellular responses develop during the incubation period. The presence of Ia+ T lymphocytes and specifically sensitized cells in both the blood and the CSF of some patients with active mumps meningitis supports this view (69). After immunization, peak immune responses are found 2 to 3 weeks later (42). Circulating cytotoxic T-cell responses restricted to autologous infected target cells are found within the first few weeks of mumps meningitis. Furthermore, variability in the host's cellular immune response to virus-infected cells might influence the clinical expression of the disease and contribute to the varied clinical expression of mumps.

Despite the importance of the cellular response in the recovery from most human viral diseases, there is little evidence to imply that the development of cellular immunity is crucial for resolution of mumps. However, some contribution of altered immune surveillance on the course of human mumps is suggested, for example, by a report of persistence of mumps virus antigens in lymph nodes and splenic tissues of patients with Hodgkin's disease (223).

Humorally Mediated Immune Response

The development of the complement fixation (CF) test using mumps virus antigen allowed the demonstration of (a) virus-specific antibody as a marker of prior mumps virus infection, (b) mumps cases without or prior to parotitis, and (c) correlation of seropositivity with resistance to clinical mumps (68,106,148). HI, PRN, enzyme-linked immunosorbant assays (ELISA), or radioimmunoassays (RIA) have largely supplanted the use of CF in the laboratory and in clinical studies of mumps humoral immunity (88,159,188,195). ELISA is valuable for rapid screening of large numbers of samples and typically shows more than 90% correlation with PRN tests (88). However, in a portion of the postvaccination sera, results for ELISA and PRN do not correlate (184). Thus, while the ELISA has proven quite sensitive, it appears less specific than the PRN, in part possibly because of cross-reacting antibody directed against parainfluenza viruses.

Mumps virus–specific IgM-class responses usually exceed IgG-class responses early in the infection and wane within the first 2 to 6 months (18,225). Virus-specific IgM-class antibody responses thus appear to be the most sensitive serologic indicator of acute or very recent infection and have the advantage of showing little cross-reactivity with related antigens of the parainfluenza viruses (159). Virus-specific IgG-class antibody responses do not reach maximal values until about the 3rd week of clinical disease (225), but they probably persist indefinitely. Using immunoprecipitation techniques, IgG-class antibodies that recognize HN, F, NP, and P are consistently produced following natural infections; a detectable IgG-class antibody response to M is unusual (Wolinsky and Salmi, unpublished data). The major IgG response is composed of immunoglobulin of the IgG1 subclass, with a minor contribution from IgG3 (194), suggestive of a T-helper-class type I response.

The role of humoral antibody in arresting the infection cannot be underestimated. Seropositive patients challenged intravenously with up to 10^9 plaque-forming units of mumps virus showed only transient fever, and no symptoms of reinfection developed even though an anamnestic rise in antibody titer was seen 4 to 5 days later (171). Animals are protected from otherwise lethal viral challenge by neutralizing monoclonal antibody administered several days after

primary virus inoculation (247). The development of HI and PRN antibody in the hamster model correlates well with the fall in peak virus titers in infected organs. However, in hamsters, viral antigens continue to be expressed, and clinical CNS disease actually occurs after virus titers have fallen considerably (246).

Neurovirulence

Development of a reliable *in vitro* or *in vivo* assay for understanding and predicting the pathogenesis of mumps virus strain-specific variations in neurovirulence for the human nervous system has proven a difficult and, as yet, unmet goal. *In vitro*, there are variable and contradicting reports of links between cytopathology and neurovirulence (152,191,244,246). *In vivo* model systems, such as rodents and primates, have shown variable neurotropism (i.e., ability to enter the nervous system) and neurovirulence (i.e., ability to damage the nervous system) profiles among various mumps virus strains (146,147,152,191,192,245,246). However, whereas some report correlation of wild-type strain neurovirulence in animal models with appropriate rankings of human neurovirulence in the clinical setting, other authors suggest no predictive value of the animal model for human mumps-related CNS disease. Moreover, model systems capable of reliably discriminating the subtle neurovirulence differences among attenuated vaccine strains are even more difficult to achieve. Development of an animal model that can predict the relative neurovirulence of mumps virus strains for human CNS is still an important goal. Such a model will aid in the identification of changes in virus genomic sequences responsible for neurovirulent phenotypes and development of sophisticated preclinical neurovirulence testing of candidate vaccines.

An association has been reported between specific sequences in viral genes and modulation of some of the neurovirulent phenotypes of the mumps virus strains. After *in vitro* selective pressure with HN-specific monoclonal antibodies, escape mutant strains show significantly reduced neurovirulence for hamsters *in vivo* (146). Analysis of these variants at the genomic level suggests that substitution of a cysteine for an arginine at position 360, within a postulated monoclonal antibody neutralization epitope of HN, results in attenuation (130). Subsequent studies on the HN of neurovirulent vaccine strains suggest that nucleic acid position 1,081, amino acid 335, is also associated with neurovirulence phenotype (26). The nucleotide A (Lys-335) in this position has been found in mumps virus vaccine and wild-type strains associated with CNS disease (26,83), whereas the presence of nucleotide G in this position (Glu-335) has been associated with neuroattenuated phenotype (6). In addition, the loss of a *Bam*HI restriction cleavage site in the *P* gene has also been associated with a neurovirulent phenotype in vaccine and wild-type virus strains (193). Thus, although limited information is currently available, data suggest that genomic sequences associated with neurovirulence phenotype are most likely located in multiple areas of the genome and involve more than one virus gene.

EPIDEMIOLOGY

Age

In an unvaccinated population, immunity to mumps is usually acquired between the ages of 5 and 14 years, with maximal acquisition of humoral antibody occurring between 4 and 7 years (7). In an urban population in 1978, 95% of adult women had serologic evidence of immunity, with a lower prevalence of immunity to mumps seen in rural communities. Premature infants may be particularly susceptible to mumps virus infection (77). At birth, 55% of infants born at less than 32 weeks gestation were found to be seronegative for mumps, although only 3% of their mothers were seronegative. By 3 months of age, 100% of the premature infants were seronegative for mumps virus, suggesting these infants may be susceptible to mumps well before 1 year of age.

Morbidity and Mortality

The major morbidity from mumps primarily results from complications of meningitis, encephalitis, and orchitis. These occur as age- and sex-specific hazards, with peak risk in postpubertal boys (7). Before World War II, mumps was an important cause of disability among troops and was 3 times more common than measles, the next most frequent communicable disease affecting military strength (79). Subsequent vaccine use has eliminated mumps as an important military concern. With the case fatality ratio for mumps between 1.6 and 3.8 per 10,000 (36), and with 0.5% to 2.3% of all mumps encephalitis cases being fatal (162), it is apparent that most fatal mumps cases have CNS manifestations.

Origin and Spread of Epidemics

Mumps virus, like measles virus, requires a population of about 200,000 people to sustain it. Such population densities were first achieved some four to five millennia ago (20), so it follows that mumps virus first evolved about 5,000 years ago. Presently, mumps is a geographically unrestricted disease except for its absence among a few remote tribes or isolated small island populations. In modern-day urban populations and in the absence of immunization, mumps occurs endemically, with peak incidence rates in the winter and spring months (162). The clustering of cases presumably reflects increased contact rates among susceptible children, usually attributed to the gathering of children at school (145). Mumps outbreaks are still reported even among highly vaccinated populations in developed countries (15,24,40,95). In Switzerland, after a low activity of mumps from 1986 to 1991, several outbreaks were reported in 1992 indicating an incidence of almost 200 cases per 100,000 population (75). Although primary vaccine failure (i.e., individuals who failed to develop immunity following vaccination) probably accounts for most mumps cases in vaccinated populations, there is also evidence of secondary vaccine failures (i.e., previously immune, vaccinated individuals with waning antimumps immune protection over time). For example, persons vaccinated more than 3 to 5 years before these outbreaks were more likely to contract mumps, consistent with waning immunity over time (4,24,95). Fortunately, secondary vaccine failure was rare in individuals who had received two doses of vaccine (95).

Prevalence and Seroepidemiology

Data on the incidence of mumps are complicated by the fact that approximately 30% of all mumps virus infections are subclinical (140,148). Furthermore, only one quarter of all cases are seen by a clinician, and, of these, as few as 14% are

reported to public health agencies (140). Annual incidence rates vary, with peaks every 2 to 7 years. Three-year peak cycles have been observed in England (7).

The highest incidence reported in the Unied States since 1922 was almost 250 per 100,000 population in 1941. In 1968, when mumps vaccine was introduced, the yearly incidence was 76 per 100,000 population, and it has steadily declined to just over 600 cases—that is, less than one case per 100,000 population in the United States (Fig. 5) (39).

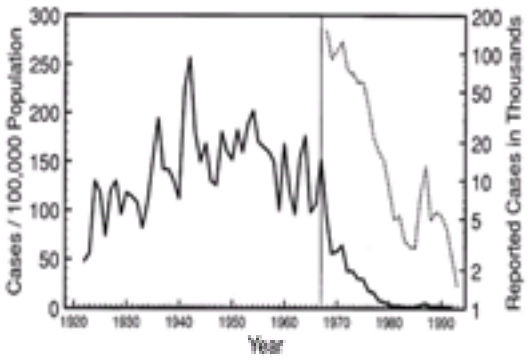

FIG. 5. Incidence of mumps in the United States from 1922, and annual reported cases reported from 1968 (37,44). The vaccine was first licensed for general usage in 1967.

Among 2- to 5-year-old children, mumps virus is a frequent cause of subclinical and symptomatic upper respiratory tract infections without parotitis (46). Parotitis occurs in only approximately 20% of all mumps infections in children under age 2. Furthermore, preschool-aged children were an important source of virus introduced into families with recent newborns (46).

In the outbreak of mumps among Eskimos on the St. Lawrence Island, where mumps was previously unknown, the epidemic evolved over 27 weeks from the time of induction of the signal case. After the epidemic, 87% of susceptible islanders had developed mumps CF antibody. Serologically defined inapparent infections were most common at the extremes of life (below age 4 and above age 60). Analysis of clinical symptoms obtained by history showed that 95% of all cases had parotitis, with 5% having orchitis without parotitis. The incidence of both mastitis and orchitis was highest among the postpubertal population.

Mumps virus was the most common cause of encephalitis in the United States until 1975 (38). In unvaccinated populations, mumps accounts for up to half of all encephalitis cases (186). In an epidemic setting, 11% of clinical mumps cases had CNS disease, 90% with meningitis and 10% with meningoencephalitis (183). Severe mumps meningoencephalitis is most common between the ages of 5 and 9 years, with a clear male predominance in all age groups (19). In adults (e.g., male military recruits), approximately 4% have symptomatic CNS involvement (156).

Once established, natural immunity to mumps is long-lived. Reinfection is distinctly uncommon. For example, reports of apparent symptomatic reinfection in individuals with preexistent CF antibody (183) may reflect known cross-reactivities of antibodies to other paramyxoviruses with mumps virus CF antigens (46).

New Epidemiologic Approaches

The most exciting molecular epidemiology advance has been RT-PCR to identify individual virus strains to group virus by related sequence. The SH gene sequence has also been used to characterize mumps virus isolates for clinical diagnosis, outbreak description, and confirmation of vaccine-induced adverse events, and to identify new virus strains (2,3,117,132,177,208,255). Although there is no uniform format for genotype groupings (118), a scheme of SH genotype categories A to F_1 has been proposed (220). In addition to geographic localization of some genotypes, there have been reported associations between the genotype clusters of mumps virus and propensity for CNS disease expression. For example, genotype A is associated with parotitis but rarely meningitis, whereas genotypes C and D are associated with meningitis, with and without parotitis (220). Final correlation of genotype group with clinical or geographic associations awaits international confirmation and agreement.

Other mumps genes have been used for strain identification. Based on restriction fragment length polymorphism, some vaccine strains can be distinguished from wild-type mumps virus strains (26,117,251). The sequence of the F gene, amplified by RT-PCR directly from clinical samples, has been reported to be useful in identifying circulating wild-type mumps virus strains (82). In contrast, the M gene sequence appears to be highly conserved between strains and of less use for strain identification (5).

CLINICAL FEATURES

The clinical features of mumps reflect the pathogenesis of the infection, as reviewed here. The incubation period is about 18 days (93,107), but approximately one third of all mumps virus infections occur without recognized symptoms (148,183). Moderate fever is present at the onset of disease, with defervescence a few days later. The feature most characteristic of mumps is salivary gland swelling (95% of all symptomatic cases), particularly the parotid glands (90% bilateral involvement) (183). Submaxillary gland enlargement and involvement of the sublingual glands also occurs. Enlargement of individual glands usually is maximal within 48 hours, at which time pain becomes most prominent, and may persist for a week or more (92). Virus is present in the saliva for several days before the onset of clinical disease

(91) and for up to 5 days later (41). The virus can be detected in urine for several weeks after the onset of mumps (228).

Various organs can be symptomatically involved during mumps. These include the testes, CNS, epididymis, prostate, ovary, liver, pancreas, spleen, thyroid, kidneys, labyrinth, eyes, thymus, heart, mammary glands, lungs, bone marrow, and joints. They are generally affected after parotitis, but their involvement may be clinically evident before, during, or even in the absence of parotid enlargement.

After mumps virus infection, about one quarter of all males develop orchitis, more frequently unilateral, and more often after puberty (183). Swelling and associated pain in the involved testes follow a time course similar to that of the parotid gland. Mumps orchitis often leads to testicular atrophy of the involved and, rarely, the clinically uninvolved gland (14). Atrophy after mumps orchitis is rarely implicated as a cause of male sterility (202). About 15% of females complain of breast swelling and tenderness. Like orchitis in men, the incidence of mastitis doubles among postpubertal women (183). Nausea and vomiting with or without epigastric or left-upper-quadrant pain are frequent features of mumps and occurred in about half of all cases during the St. Lawrence Island epidemic (183). It is unclear whether these symptoms reflect involvement of pancreas or other viscera. Some of these generalized features of the illness may reflect the effects of circulating IFN, which can be found in serum early in the clinical course of mumps (165,233).

Approximately half of mumps cases develop pleocytosis. Asymptomatic CNS involvement is common, since mumps meningoencephalitis occurs only in 10% to 20% of clinical cases (29,183,205). Mumps meningitis may precede parotitis, but it typically develops 5 days following parotitis. However, 50% of individuals with mumps meningoencephalitis do not have detectable salivary gland enlargement (111,121).

Diagnosis

The onset of mumps meningitis is usually marked by fever, and vomiting, neck stiffness, headache, and lethargy are quite common (9). Drowsiness and lethargy appear more commonly in younger patients, and meningeal signs are more readily detected in older patients. Seizures occur in 20% to 30% of patients with CNS symptoms (9,76).

In other childhood viral diseases such as measles, the electroencephalogram (EEG) is frequently abnormal even in the absence of CNS symptoms (109). In contrast, in mumps the EEG is usually normal, even when clinical seizures occur (76). However, in some deeply obtunded patients, diffuse slowing with increased voltage is seen.

About one third of all patients with CNS symptoms have either meningoencephalitis or pure encephalitis (209). Frank delirium and focal neurologic deficits are uncommon (111,162). Patients with mumps meningitis and meningoencephalitis without focal deficits, prolonged or recurrent focal seizures, or papilledema have marked clinical improvement of neurologic function within 2 to 4 days. Even with profound obtundation, patients recover with few sequelae (9,29,32).

Differential

When parotitis is present, the clinical diagnosis of mumps is straightforward, even if the disease is not epidemic. Nonetheless, other causes of parotitis should be considered: starch ingestion, iodine sensitivity, thiazide ingestion, tumors, Sjögren's syndrome, sarcoidosis, suppurative infections (including atypical mycobacteria), and other viruses such as parainfluenza types 1 and 3, influenza A, coxsackie, and lymphocytic choriomeningitis viruses. Without parotitis or with inconspicuous salivary gland enlargement, symptoms of other visceral organ or CNS involvement may predominate, and thus laboratory confirmation of the diagnosis is required, even during an epidemic.

Laboratory

Laboratory diagnosis presently rests on infectious viral isolation, appropriate serologic studies of acute and convalescent sera, or recovery of viral genome by RT-PCR. Virus isolation from saliva is most successful during the first 4 to 5 days of symptoms (42). Virus is recovered from urine for up to 2 weeks after symptoms begin (227), especially if care is taken to first clear the urine of debris, then concentrate the virus by ultracentrifugation (228). In patients with meningitis, the CSF can be expected to yield virus in, at best, about half of samples taken within 8 to 9 days of the onset of CNS disease (121,248). Samples are preferably plated fresh or held at –70°C. Monkey kidney primary or cell lines may be used for isolation, although other continuous cell lines are nearly comparable in sensitivity (182). Not all primary mumps virus isolates show characteristic syncytial cytopathic effects. Therefore, hemadsorption techniques should be applied to all cultures before they are discarded as negative. Immunofluorescence techniques not only provide direct confirmation of the isolation of a hemagglutinating virus in the culture but also, with appropriate reagents, specify the isolate as mumps virus (137). Amplification and sequencing of gene segments (e.g., SH) from cell extracts of primary isolates can provide useful epidemiologic data and virus strain identification (67). Combinations of techniques, such as amplifying live virus in clinical samples via Vero cell co-cultivation, followed by RT-PCR amplification of virus genome, can provide a sensitivity of 1 to 20 units of infectious virus per milliliter (22).

When performed on the same day, comparison of mumps-specific antibody titers from serum taken at the onset of clinical disease and a convalescent serum sample obtained 2 to 4 weeks later usually shows the anticipated rise in CF, HI, PRN, or hemolysis-in-gel (HIG) assays (68,85). Determination of virus-specific IgM and IgG levels on a single acute-phase serum provides an alternative when paired sera are not available (159,225). The current standard for relatively specific, rapid, and cost-effective serologic diagnosis is ELISA (43,88,141).

Examination of the CSF of patients with mumps virus infection shows abnormalities in the majority of cases, beginning with the onset of CNS disease (12). Cell counts peak around the third day of neurologic symptoms, averaging 250/mm ^{3} and, may exceed 1,000/mm^3 (121,143,248). The pleocytosis then wanes gradually over several weeks (69,243), up to as long as a year (230). The CSF is usually under normal pressure (32) and the protein content in the CSF is elevated in 60% to 70% of all cases (69,121). Protein levels up to 100 mg/dL can be seen; on occasion, they exceed 700 mg/dL. This appears to reflect damage to the blood–brain barrier, as indicated by elevated albumin indices that do not normalize for

several weeks to months after the onset of CNS symptoms (143). The CSF glucose content is modestly depressed to 17% to 41% of the serum value in 6% to 29% of all cases (51,111,243). About one third of all patients have evidence of intrathecal IgG synthesis and demonstrable oligoclonal immunoglobulins during the first week of CNS symptoms, and this oligoclonal antibody may persist for over 2 years (69). Over one half show increased IgG indices by the third month following mumps meningitis (69,143,231). Using sensitive ELISA or imprint immunofixation assays, up to 90% of patients with acute mumps meningitis can be shown to produce virus-specific IgG-class antibodies within the CNS compartment (143,225,231), and one half show mumps virus–specific IgM (65). In many instances of mumps meningitis, diagnosis can be confirmed by elevated CSF/serum antibody ratios from a serum sample set taken during illness (165,225), as mumps antibodies are uncommon in the CSF during other CNS infections (50).

Of all cases of mumps with symptoms severe enough to warrant hospitalization, less than 10% can be expected to show transient electrocardiograph abnormalities consistent with myocardial damage. These usually consist of ST-segment depression, but patients can show evidence of atrioventricular conduction defects, including complete heart block (8). Seldom is the cardiac involvement acutely symptomatic. However, mumps virus myocarditis can be linked to serious long-term sequelae, such as endocardial fibroelastosis (167).

TREATMENT

Treatment of mumps and its various complications is generally symptomatic. In a controlled study, adult men presenting with parotitis were alternatively given either an intramuscular injection of 20 mL of gammaglobulin prepared from human convalescent serum or simply confined to a hospital for routine, nonspecific symptomatic therapy (74). Orchitis developed in 4 of 51 antibody-treated and 14 of 51 symptomatically treated patients ($p < .01$ by chi square). No protective effect was seen with gammaglobulin obtained from a normal donor serum pool (74). This study suggests that immunotherapy with high-titer polyvalent or monoclonal antibody preparations could be useful in selected cases but should be used very early in the course of the illness. Recently, experimental treatment of orchitis with IFN-a-2B has been reported (35).

PREVENTION AND CONTROL

Control measures for mumps must be primarily directed at prevention. The high incidence of asymptomatic infection, the relatively long period of virus shedding before clinical symptoms emerge, and the infectivity of nonparotitis cases render futile any patient quarantine procedures that might be tried to stem an epidemic. The mass use of hyperimmune gammaglobulin can reduce the incidence of mumps in a community if administered very early in an outbreak (47), but such an approach has generally not been effective in clinical practice (190). Therefore, prevention through an effective vaccination program remains the only rational approach to the control of mumps.

Vaccination

Two general types of mumps virus vaccines have been used. The vast majority of mumps vaccinations are with live attenuated mumps virus preparations. Except for specific indications, killed mumps virus antigens have a more restricted value and have been largely supplanted by the more effective live attenuated vaccines.

Killed Virus Vaccine

Killed mumps virus vaccines have a limited role, as serologic evidence of immunity may wane without periodic booster injections (185). Serologic responses following immunization with either killed or live attenuated vaccines are similar (113). It is likely that the formalin-inactivated mumps vaccine can induce antibody to the HN glycoprotein, but it does not induce a response to certain F-glycoprotein configurations (168). However, most inactivated vaccine recipients generated antibody to denatured F protein (113). Furthermore, induced antibody appears to be limited to the IgG class, with no IgM class responses detected by RIA following immunization with killed vaccine (104). Finally, cell-mediated immune responses following killed vaccine appear to be delayed compared to those seen after natural infection (104).

The killed vaccine does provide effective, if not durable, protection and does not appear to predispose to later atypical mumps (180). It therefore may provide an alternative for vaccination of immunocompromised, susceptible patients. Furthermore, the rather extensive experience with inactivated mumps virus vaccine suggests that molecularly engineered component vaccines may be effective in stimulating a protective immune response to mumps virus.

Live Attenuated Virus Vaccines

The use of live attenuated mumps virus vaccines has caused a remarkable decline in the incidence of mumps and related sequelae of wild-type infection. Several different strains of live attenuated mumps virus vaccine are in international use at this time, and new vaccines are continuing to be evaluated and licensed. Many vaccines are now known to be mixtures of several related strains, including Jeryl Lynn, Urabe Am9, and Leningrad 3 (3,23,26). In general, the efficacy of mumps vaccines is good relative to their profile of safety and adverse event induction. However, at least one mumps virus vaccine strain was withdrawn from use in several countries because of an unacceptable incidence of associated meningitis (26,27).

Continuous serial passage to select for attenuation is the strategy used to develop mumps vaccines (59,93,252). At present, there is no clear distinguishing marker for attenuation of mumps virus strains apart from the failure of a passaged isolate to produce clinical symptoms in man. In addition, because of demonstrated and theoretical considerations about spread of virus to placenta and fetal tissues, administration of vaccines containing live mumps virus during pregnancy is not advised (185).

Jeryl Lynn/RIT 4385

The Jeryl Lynn B strain of mumps originated as an egg allantoic fluid isolate (34). This isolate was attenuated first by 17 serial passages in embryonated hens' eggs and chick embryo cell cultures. The Jeryl Lynn vaccine is a mixture of at least two virus strains (3,28). A predominant strain (JL5) was identified along with a second strain (JL2) in a ratio of 5:1, respectively. Recently, a new mumps vaccine (RIT 4385) derived from the JL5 component of Jeryl Lynn strain has been licensed in Europe (204).

Vaccination of susceptible children with a single subcutaneous inoculation of Jeryl Lynn vaccine does not produce serious clinical symptoms, and vaccine virus cannot be isolated from blood, urine, or saliva (60). However, some dissemination of Jeryl Lynn vaccine virus must occur, as virus has been isolated from placental tissues of two of three seronegative women immunized with attenuated live virus vaccine 7 to 10 days prior to planned induced abortion (253).

Urabe Am9

The Urabe Am9 vaccine was developed in Japan and is widely used in North America (not the United States), Europe, and Japan, proving to be an effective, immunogenic vaccine. However, recently Urabe Am9 was withdrawn from many markets because of an unacceptably high incidence of CNS adverse events (e.g., meningitis) (27,66,67,221). It is not surprising, therefore, that this vaccine appears to disseminate more widely in the vaccinee than does Jeryl Lynn. Aseptic meningitis with vaccine virus recovered from CSF complicates from 1 in 1,000 to 1 in 11,000 vaccinations with Urabe strain–containing vaccines (160). Symptoms of meningitis appear within 4 weeks of vaccination (155).

Virus recovered from several Urabe vaccinees with meningitis possessed the wild-type substitution of A for G in nucleotide position 1,081 of the *HN* gene (26). Brown and Wright also reported that the Urabe Am9 vaccine was a mixture of viruses with A or G in base position 1,081. This G to A change resulted in a Glu to Lys change at amino acid 335. Interestingly, amino acid 335 may be an important neutralization epitope (6). These data suggested that postvaccine meningitis might be associated with a virus with the wild-type sequence at position 1,081 in the *HN* gene. Furthermore, it has been suggested that this virus, capable of replication in the CNS, was one of the preexisting components of the vaccine, rather than a reversion to wild type (28). It is important to note, however, that other evidence suggests that genomic differences at other sites also contribute to the neurovirulent phenotype (6,28).

Rubini

A live attenuated virus vaccine developed from a wild type isolated in Switzerland, the Rubini strain sequence bears similarity to the Enders strain and was originally licensed based on studies showing high immunogenicity rates. Following mumps outbreaks in Switzerland and Singapore, recent reports suggest that the Rubini strain has a lower immunogenicity profile (75), possibly suggestive of primary vaccine failure (78) or waning immunity with time (4). Additional studies are needed to resolve these issues.

Serologic Response

Neutralizing antibody is usually present within 2 weeks of vaccination (60), and a serologic response to vaccination is anticipated for over 90% of vaccinees (31,88,97). While antibody titers after vaccination develop more slowly and are lower than those following natural infection, protection from natural mumps appears complete (31,60), and neutralizing antibody has been shown to persist for more than 19 years (185). Combined immunization with live attenuated measles, mumps, and rubella virus vaccines does not adversely affect either the serologic response to mumps virus or the apparent long-term protection from mumps (185,241).

Adverse Events

Millions of doses of Jeryl Lynn mumps virus–containing vaccine have been distributed in the United States, with few serious adverse effects noted (96). Most reported complications such as rash, pruritus, and purpura have been allergic in nature and are both uncommon and usually mild and self-limited (38). Approaches for the immunization of egg-allergic children have been detailed (136). A comprehensive survey of the literature by the Vaccine Safety Committee of the Institute of Medicine failed to find adequate information to establish or reject a causal relationship between the administration of Jeryl Lynn mumps virus–containing vaccines and the development of encephalopathy, encephalitis, residual seizure disorders, optic neuritis, transverse myelitis, Guillain-Barré Syndrome, IDDM, or sterility due to orchitis (for extensive reviews, see refs. 21,207).

Based on information from countries in which multiple mumps virus vaccines are licensed and utilized, there are some mumps virus strain-specific differences in adverse events. Whereas both Urabe and Jeryl Lynn vaccine strains have been associated with parotitis, with an incidence of 0.7% (11), Jeryl Lynn vaccine has not been associated causally with significant CNS disease. In contrast, in Japan at least 311 meningitis cases were reported among 630,157 recipients of the Urabe Am9 vaccine, with 96 cases being confirmed by vaccine virus isolated from the CSF (210). Urabe vaccine–associated meningoencephalitis was also documented in other countries, such as Canada and England (11,98,160). The majority of the affected vaccinees became ill within 15 to 21 days after vaccination. There was a male predominance and the meningitis was reported to be mild with no sequelae noted. Interestingly, there are suggestions of variable rates of postvaccination meningitis with Urabe vaccines from different Japanese manufacturers, raising a question of manufacturing consistency (124).

Other adverse events include orchitis and transmission of vaccine virus to siblings following Urabe vaccination (210). Although deafness, IDDM, pancreatitis, autism spectrum disorder, and inflammatory bowel disease (114,163,234) have been reported following mumps vaccination, the most current evidence does not support a causal association with the vaccine (11,179,218).

Clinical Use

The generally accepted practice is to vaccinate all children with trivalent measles-mumps-rubella vaccine between 12 and 15 months of age to avoid the presence of passively transferred maternal antibody (196). However, between 15% and 19% of children vaccinated at age 12 to 18 months may be seronegative by PRN 4 years after vaccination (161). Concerns raised by this and other studies led to the demonstration of the benefits and adoption of the two-dose regimen (25). The doses are administered at least 1 month apart; typically, children receive the first dose of vaccine between 12 and 15 months of age, and the second dose before entering elementary school at 4 to 5 years of age (38). Data suggest that administering the second dose at 11 to 13 years appears to be equally effective (38,108). Vaccination in the face of recent chemotherapy or radiation therapy is unlikely to induce adequate serologic responses and should be delayed for at least 3 months following such treatment (185). Studies of mumps virus–containing vaccines in nonimmunocompromised human immunodeficiency virus–infected patients, primarily in the form of trivalent mumps, measles, and rubella vaccines, have not documented serious or unusual adverse effects; however, in these patients the clinician needs to consider the risk–benefit ratio of vaccination and consult the current recommendations of the Advisory Committee on Immunization Practices (38). Vaccination as early as 9 months of age may be equally as effective, particularly with infants born to vaccinated mothers who have not experienced wild-type infection (115,197).

At one point, a transient reversal in the marked trend for reduced numbers of reported cases of mumps in the United States created considerable concern. A detailed analysis suggested that the observed relative increase of incidence is a reflection of the pool of susceptible children, teenagers, and young adults who were not immunized aggressively for mumps (15,24,40,44,95,116,205), especially during the first decade following introduction of the vaccine. Interestingly, theoretical models of the effects of mass vaccination programs suggest that the average age of disease can be anticipated to rise with the level of induced immunity, with the additional paradoxical result of increased relative risk of serious consequences of mumps infection (e.g., orchitis in susceptible postpubertal males) (7).

Although mumps and its complications are usually mild, most analyses of theoretical cost–benefit ratios favor an intensive vaccination program for affluent, developed nations (71,116,122,127,205).

CHAPTER 44 Measles Virus

Diane E. Griffin

Measles is a highly contagious disease characterized by a prodromal illness of fever, coryza, cough, and conjunctivitis, followed by the appearance of a generalized maculopapular rash. Introduction of measles into virgin populations and endemic transmission in populations with inadequate medical care are associated with high mortality. Despite the development of a successful live attenuated vaccine, measles remains a major cause of mortality in children, particularly in developing countries, and a cause of continuing outbreaks in industrialized nations.

HISTORY

Measles is a relatively new disease of humans and probably evolved from an animal Morbillivirus. Phylogenetically, measles virus (MV) most closely resembles rinderpest virus (RV), a pathogen of cattle (461) (Fig. 1), and it is postulated that MV evolved in an environment where cattle and humans lived in close proximity (413,458). Because large numbers of people are required to generate sufficient susceptible individuals to maintain measles in a population, measles probably evolved in the early centers of civilization in the Middle East where populations attained sufficient densities to maintain transmission (413).

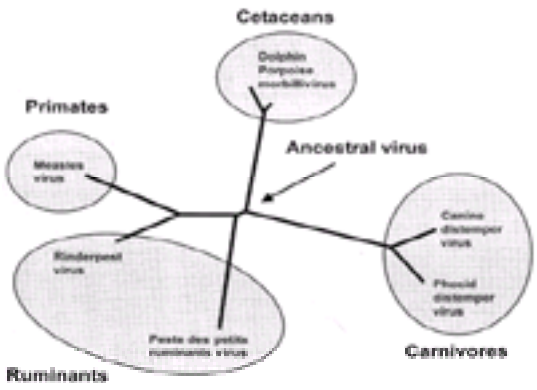

FIG. 1. Genetic relationships between morbilliviruses based on comparison of the nucleotide sequences of the N genes. The tree was derived using PHLIP, DNADIST and FITCH programs. The branch lengths are proportional to the mutational differences between the viruses and the hypothetical common ancestor that existed at the nodes in the tree. (From ref. 43, with permission.)

Abu Becr, an Arab physician known as Rhazes of Baghdad, is generally credited with distinguishing smallpox from measles in the 9th century. He dated its first description to the 6th century. Rhazes referred to measles as *hasbah*, “eruption” in Arabic, and regarded it as a modification of smallpox (281,517). One distinction noted was that “anxiety of mind, sick qualms and heaviness of heart, oppress more in the measles than in the smallpox” (517). Repeated epidemics of illnesses characterized by a rash are recorded in European and Far Eastern populations between A.D. 1 and 1200 (413). It appears that measles spread across the Pyrenees into France with the Saracen invasion of the 8th century (534). Repeated epidemics identified as measles are not recorded until the 11th and 12th centuries, and it is first

mentioned as a childhood disease in 1224 (413).

In the European literature, the name applied was “morbilli,” derived from the Italian “little diseases” to distinguish it from plague, *il morbo*, but morbilli included several exanthemata. Sanvages in 1763 defined morbilli as measles but called it rubeola [derived from the Spanish (534)], leading to a common confusion with rubella that persists to the present.

Introduction of measles into previously unexposed populations has been associated with high morbidity and mortality (67,129,534). Epidemics of rash illnesses were associated with episodes of depopulation in China, India, and the Mediterranean region. There was 26% mortality associated with introduction of measles into the Fiji Islands in 1875 (281,534). Approximately 56 million people died as a result of European exploration of the New World, largely because of the introduction of Old World diseases, notably smallpox and measles, into native Amerindian populations. Decreases in population are likely to have facilitated the transfer of Spanish culture to South America (413).

Many of the basic principles of measles epidemiology and infection were elucidated by the studies of Peter Panum, a young Danish physician who was sent to the Faroe Islands in 1846 during a large measles epidemic (481). Panum deduced the highly contagious nature of the disease, the 14-day incubation period, and the lifelong immunity present in older residents, and he postulated a respiratory route of transmission.

Complications of measles were first described in the 18th century. In 1790 James Lucas, an English surgeon, described the first case of postmeasles encephalomyelitis in a young woman who developed paraparesis as the rash was fading (384). Medical textbooks of the 19th century associated measles with the exacerbation of tuberculosis, and in 1908, while working at a tuberculosis hospital in Vienna, von Pirquet recorded the disappearance of delayed-type hypersensitivity skin test responses to tuberculin during a measles outbreak (641).

Subacute sclerosing panencephalitis (SSPE) was first described in 1933 by Dawson in a 16-year-old boy with progressive neurologic deterioration (147). Histologic examination of the brain showed eosinophilic intranuclear and intracytoplasmic inclusions in neurons and glial cells (147). Reports of paramyxovirus-like particles in the inclusions (616) were followed rapidly by documentation of elevated MV antibody in serum and cerebrospinal fluid (CSF), staining of the inclusions with antibody to MV (131), and culture of MV from SSPE brains (486).

INFECTIOUS AGENT

In 1757, measles was formally shown to be caused by an “infectious” agent when the Scottish physician Francis Home, attempting immunization, transmitted the disease to naive individuals using blood taken from measles patients during the early stages of the rash (285). In 1905, Hektoen transmitted disease to volunteers with blood “free of bacteria” taken from measles cases in the acute stage (270). In 1911, Goldberger and Anderson transmitted measles to monkeys with filtered respiratory tract secretions from measles patients and successfully passaged disease from one monkey to another (226).

Propagation and Assay in Cell Culture

Primary Isolation

The virus was first grown in tissue culture in 1954 by Enders and Peebles, who inoculated primary human kidney cells with the blood of David Edmonston, a child with measles (177). Isolates were also made from peripheral blood leukocytes or respiratory secretions inoculated onto primary monkey kidney cells (173,177). Because of problems with animal use and possible contamination of primary cells with simian viruses, continuous monkey kidney cell lines (e.g., Vero, CV-1) subsequently replaced primary kidney cell cultures for MV isolation (589). However, isolation of wild-type strains is most often successful using an Epstein-Barr virus–transformed marmoset B lymphocyte line, B95-8 (342), or human cord blood leukocytes (201). Generally, the first observable sign of virus growth is cell–cell fusion and syncytia formation (Fig. 2).

FIG. 2. Typical cytopathic effects of syncytium formation associated with measles virus replication in (**A**) Vero cells and (**B**) lung tissue of a monkey with giant cell pneumonia. (Courtesy of W. Bellini.)

Laboratory Propagation and Assay

Once MV has been isolated in culture, it can often be adapted to replicate in a variety of cells in culture. For instance, MV has been grown in primary human cells, in human cell lines, and in primary monkey kidney and testis cells, as well as monkey cell lines (173).

The process of adaptation of MV to foreign hosts, such as the chick embryo and canine and bovine kidney cells, has led successfully to the development of live attenuated vaccine strains (332,333,423,568). Mouse cell lines are generally nonpermissive, except for neuroblastoma lines where there is restricted synthesis of MV proteins and a low yield of infectious virus (386,503).

Most experimental work is done with tissue culture–adapted strains, so virus stocks are generally grown in Vero cells using a low multiplicity of infection to avoid accumulation of defective interfering particles (123). These cell lines are most useful for titration of adapted virus by plaque formation (9) using an agar or methylcellulose overlay. The virus replicates slowly, and 3 to 5 days of culture are needed before plaques become visible. Longer periods may be required to reach

the endpoint of a titration. Heat shock may increase the yield of infectious virus (482). Stocks of nonadapted strains may be assayed by syncytium formation in B95-8 or human cord blood cells. Identification of infectious foci is optimized by using immunocytochemical techniques to detect MV-infected cells.

Biologic Characteristics

Genetically, the morbilliviruses form two groups of viruses related either to canine distemper virus (CDV) or to RV (see Fig. 1). Morbilliviruses are distinct from other paramyxoviruses in that they form intranuclear inclusion bodies (Fig. 3). Virions are pleomorphic and range in size from 100 to 300 nm. The envelope carries surface projections with a length of 9 to 15 nm, which are composed of the viral transmembrane hemagglutinin (H) and fusion (F) glycoproteins (Fig. 4). The nucleocapsid (total length of 1.2 µm) is packed within the envelope in the form of a symmetrical coil (385). Virions may also contain actin from the cellular cytoskeleton, which is involved in the final steps of budding from the plasma membrane (79).

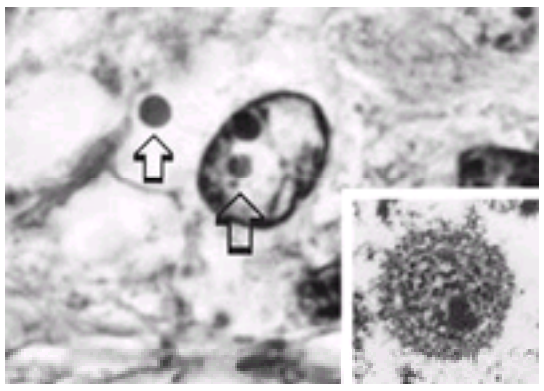

FIG. 3. Morbillivirus inclusion body formation within a canine distemper virus-infected astrocyte. By light microscopy, cytoplasmic inclusions (*small arrow*) are discrete and intensely eosinophilic, representing dense aggregates of viral nucleocapsid. The most common expression of intranuclear inclusions is an eosinophilic circular structure (*large arrow*). The ultrastructural basis for this intranuclear inclusion is the complex nuclear body (*inset*), a nucleolar derivative containing N protein. (From ref. 463, with permission.)

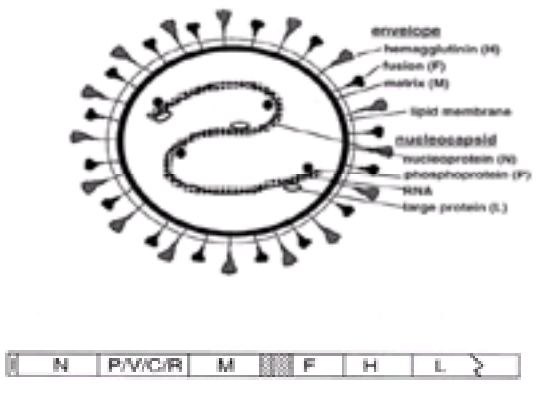

FIG. 4. Schematic diagram of measles virus and the genome and gene order. I is the leader and P/V/C/R is a multicistronic gene encoding P, V, C, and R proteins. The *shaded region* between M and F contains approximately 1,000 nucleotides of untranslated RNA.

Proteins

The proteins of MV are listed in Table 1.

Protein	Amino acids (N)	Apparent size (kd)	Infected cell	Virion	Suggested function and special features
Nucleoprotein (N)	525	60	Cytoplasm	Nucleocapsid	Most abundant of viral proteins; closely associated with full-length + and − sense RNA to form helical capsids; phosphorylated
Phosphoprotein (P)	507	70	Cytoplasm	Nucleocapsid	More abundant in infected cells than virions; likely involvement in regulation of transcription and replication; complex formation with N and L; phosphorylated
C	186	20	Cytoplasm and nucleus	Not present	Read from the same transcript as P, but a different reading frame; downregulates transcription?
V	299	45	Cytoplasm	Not present	Read from an "edited" transcript of P gene; phosphorylated; contains cell-CCCH tetrakus; function unknown
Matrix or membrane (M)	335	39	Inner leaflet of plasma membrane, cytoplasm (perinuclear inclusions)	Inner surface of membrane	Virion assembly and budding; inhibits transcription?
Fusion (F)	550	59	ER, Golgi, and plasma membrane	Transmembrane dupe N surface protein	Glycosylated; membrane fusion, virus entry, and hemolysis activity in conjunction with H; 50 kd inactive precursor F_0, mature sits F_1 and F_2
Hemagglutinin (H)	617	76	ER, Golgi, and plasma membrane	Transmembrane dupe N surface protein	Receptor binding, hemagglutination activity, disulfide-linked dimer, glycosylated
Large (L)	2,183	250	Cytoplasm	Nucleocapsid	Catalytic component of viral polymerase; least abundant protein; RNA transcriptase and replication, complex formed with P?

TABLE 1. *Characteristics of the Measles Virus Proteins*

Nucleocapsid Protein

The nucleocapsid (N) mRNA is the first transcribed from the genome, and the N protein is the most abundant of the viral proteins. N (525 amino acids) is synthesized on free ribosomes and folded in the cytoplasm (230), and it plays a central role in the replication of viral genomic RNA. N is phosphorylated, and this modification appears to regulate function. Free N is phosphorylated on serine, whereas nucleocapsid-associated N is phosphorylated on serine and threonine and, in persistently infected cells, also on tyrosine (231,569). N appears as a 60-kd band on polyacrylamide gels, but it is often cleaved by cellular proteases during extraction to 45- and 41-kd products (236). N can self-assemble but usually surrounds viral genomic and antigenomic RNAs that possess the leader sequence (108) to form the nucleocapsid structures (627). This structure is the required template for both replication and transcription and, in conjunction with the P and L proteins, comprises the ribonucleoprotein complex (510). N can be transported to the nucleus but is usually retained in the cytoplasm by binding to P (298). Amino acid sequence conservation is strong in the N-terminal portion of the protein that is required for self-assembly into nucleocapsids or interaction with P (38,230,592) (Fig. 5). There is variability in the region between residues 130 and 150 (542) and in the C-terminal 125 residues (37,117,541,542,615) that are located on the outside of the nucleocapsid structure (87). Analysis of the variable C terminus of N has been useful for identification of genotypes and analysis of the molecular epidemiology of measles (542,615).

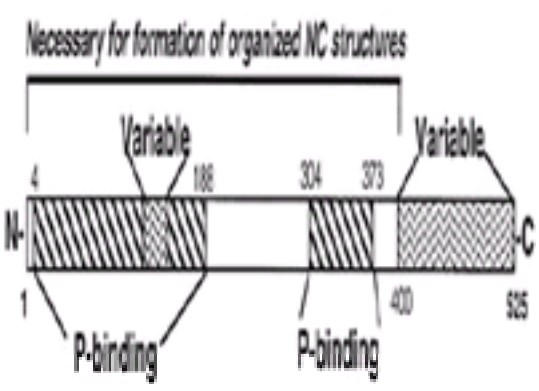

FIG. 5. The nucleocapsid (*N*) protein. Diagram showing the regions of N required for binding to the P protein and regions of sequence variability between strains.

P, C, V, and R Proteins

The P (phospho) protein (507 amino acids) is activated by phosphorylation and binds to N, L (large), and RNA to form the replicase complex (526). Serine/threonine phosphorylation of P is carried out by cellular kinases, primarily casein kinase II (144). Although the 72-kd P protein is abundant in the infected cell, only small amounts are present in the packaged virus. The N terminus is acidic and highly phosphorylated, and it binds to L, whereas the region between amino acids 204 and 321 contains the domain that binds to N (298) (Fig. 6). The P protein oligomerizes and interacts with L and N through the unique C-terminal portion of the protein (136,264,377) and modulates assembly of nucleocapsids (592).

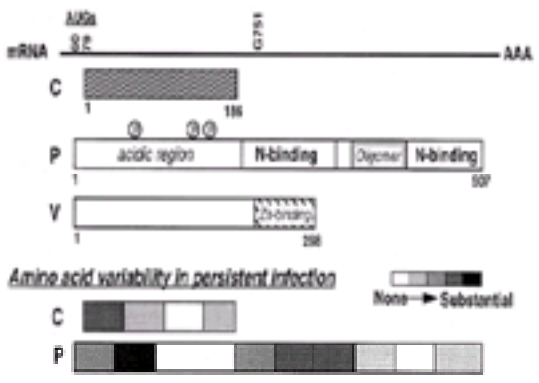

FIG. 6. The phospho (*P*), C, V, and R proteins. Diagram of the mRNAs and encoded proteins. P and C are initiated at AUGs in different reading frames. V is translated from an edited RNA with a nontemplated G at nucleotide 751. R is the truncated form of P that is produced by ribosomal frame shifting to access the V open reading frame 24 nucleotides upstream of the V stop codon.

The P gene of MV, like many members of the *Paramyxoviridae*, encodes several proteins in addition to P. The C protein is encoded by the same mRNA, but it is translated using an initiator methionine codon 19 nucleotides downstream from that for P and an overlapping reading frame (57). In contrast, the V protein shares the initiator methionine and the amino-terminal 231 amino acids of the P protein. RNA editing to add an extra non-template-directed guanosine (G) residue at position 751 following three genomically encoded Gs results in a different carboxyl terminus. The last 276 amino acids normally encoded by the P mRNA are replaced with a cysteine-rich domain of 68 amino acids (113) that has zinc-binding properties (375). Both V and C interact with cellular proteins (377). V is phosphorylated, diffusely distributed in the cytoplasm of infected cells, and affects N–P interaction (229,620,649). A fourth protein R is a truncated form of P that is produced by ribosomal frameshifting, which accesses the V open reading frame 24 nucleotides upstream of the V

stop codon (376). The C and V proteins play a role in the regulation of transcription and replication, possibly by modulating the intracellular environment for replication (377).

Neither C nor V is necessary for MV replication in Vero cells (500,563), but deletion of C decreases MV replication in peripheral blood mononuclear cells and epithelial cells of the thymus, suggesting an important *in vivo* role for the protein (180,632). In glioblastoma cells, absence of V decreases the amount of virus released and increases intracellular accumulation of viral proteins and RNAs. Overexpression of V does not alter replication in Vero cells but decreases cytopathic effect, whereas in glioblastoma cells virus production is decreased (563,620). *In vivo*, absence of V delays and prolongs MV replication in human thymic epithelial cells, whereas overexpression is associated with more rapid replication (632). Absence or overexpression of V decreases MV replication in the lungs of cotton rats (620).

Matrix Protein

The envelope of the virion consists of the matrix (M) protein (335 amino acids) and the two transmembrane glycoproteins F and H. M is a basic protein with several conserved hydrophobic regions (33,56) (Fig. 7). The mRNAs for Morbillivirus M proteins contain approximately 400 nucleotides of noncoding sequence at the 3' end of unknown function (56). In infected cells, the M protein is associated with nucleocapsids and with the inner layer of the plasma membrane (278). M appears to interact with the intracytoplasmic regions of one or both transmembrane glycoproteins, perhaps stabilizing or organizing the membrane environment in preparation for budding of virions (626). Deletion of M increases cell-to-cell fusion and decreases production of infectious virus (110). When bound to the viral ribonucleoprotein complex, M inhibits transcription (603). The ability to bind nucleocapsids and inhibit RNA transcription is often defective in M proteins from viruses that cause persistent infection (277,603).

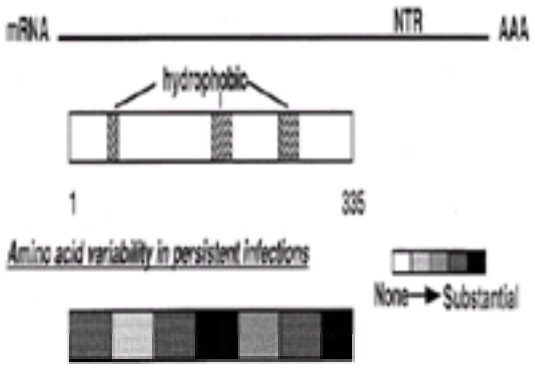

FIG. 7. The matrix (*M*) protein. Diagrams of the mRNA with its long 3' nontranslated region (*NTR*) and the protein showing the conserved hydrophobic regions. The M protein from persistent infections has frequent amino acid substitutions across the entire length. (Portions adapted from refs. 112 and 117, with permission.)

Fusion Protein

The fusion (F) protein is a highly conserved type I transmembrane glycoprotein synthesized as an inactive precursor protein (F_0) of about 60 kd. The mRNAs for Morbillivirus F_0 proteins contain unusually long (460 to 585 nucleotides), G-C–rich, 5'-nontranslated regions (NTRs) that are predicted to have extensive secondary structure and are followed by clusters of three to four AUGs (Fig. 8) (186,418,519). The 5' NTR influences the choice of AUG and enhances translation of functional F protein (109,186,674). There is a 28-residue putative signal sequence. After translation, F is glycosylated, tetramerized, and transported to the plasma membrane. In polarized epithelial cells, this transport is primarily to the basolateral surface (73,674). F_0 is cleaved by furin in the trans-Golgi to yield the 41-kd (F_1) and 18-kd (F_2) disulfide-linked activated F protein (80,261,652) (see Fig. 8). The cleavage site consists of five basic amino acids (residues 108 to 112: Arg-Arg-His-Lys-Arg). Arg 112 is a critical determinant of cleavage, as mutation results in a reduced rate of F transport to the cell surface, aberrant cleavage, and abolition of fusogenic activity necessary for infection (14,652).

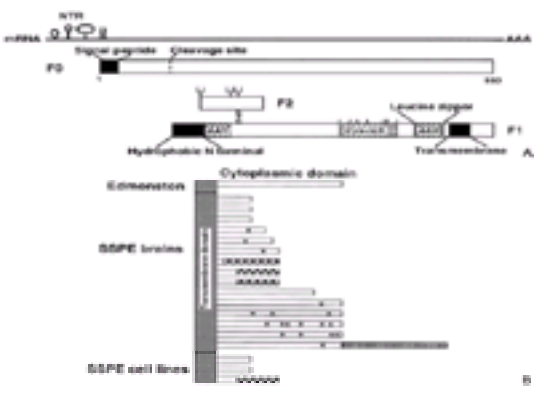

FIG. 8. Diagram of the fusion (*F*) protein. **A:** The mRNA with its long 5' nontranslated region (*NTR*) and proteins. F_0 is an inactive precursor that is cleaved into the active disulfide-linked F_1 and F_2 proteins. **B:** The truncations, point mutations (*x*), and altered reading frames ( ) found in the cytoplasmic portions of F_1 from persistent infections. (Portions adapted from refs. 558 and 60, with permission.)

Glycosylation is necessary for proteolytic processing and transport to the cell surface (555). F_2 has all the predicted N-linked glycosylation sites (residues 29, 61, and 67). Mutation of any of these asparagines, particularly Asn-29 or -61, decreases transport to the cell surface and impairs proteolytic cleavage, stability, and the fusion capacity of F, presumably by altering F_2 conformation (15,293).

F_1 contains a highly conserved stretch of hydrophobic amino acid residues at the new amino terminus. This region is postulated to play an important role in the fusion process (519). Oligopeptides identical to or nearly identical to this hydrophobic segment of F_1 inhibit fusion activity (520). However, mutants of MV resistant to the fusion inhibitory effect of these oligopeptides do not have predicted amino acid alterations in this hydrophobic region but rather in the cysteine-rich region postulated to be important for interaction with H (299). Additionally, there are two predicted amphipathic a-helices: one adjacent to the putative fusion peptide and another that contains a leucine zipper motif N-terminal to the transmembrane region. Mutagenesis of the leucines in the zipper region adversely affects fusion (88), and a synthetic peptide representing this region inhibits fusion (97,358).

Fusion requires the expression of H as well as F (665). Production of chimeric CDV-MV proteins has identified a cysteine-rich region (residues 337 to 381) within F_1 that is important for interaction with H (664). The 33-residue cytoplasmic domain is frequently altered in viruses associated with persistent infection (60,117,558) (see Fig. 8). Mutations include premature stop codons, missense mutations, altered reading frames, and nonconservative amino acid substitutions. These changes interfere with virus envelope assembly and budding and increase cell-to-cell fusion (111,116).

Hemagglutinin Protein

The hemagglutinin (H) protein (617 amino acids) is the receptor-binding and hemagglutinating (HA) protein and is an important determinant of Morbillivirus cellular tropism (597). It is a type II transmembrane glycoprotein and resides on the surfaces of infected cells and virions as a disulfide-linked homodimer (13,261). H acts in conjunction with F during fusion and entry (116,665). Residue 98 and the region between residues 244 and 250 have been implicated in functional cooperation of H with F (203). H is folded and dimerized in the endoplasmic reticulum (ER) and has 13 strongly conserved cysteines, all in the ectodomain. Cleavage studies indicate that cysteine residues at 139 and 154 are responsible for intermolecular disulfide bonding of monomeric H glycoproteins (554).

Modeling of the three-dimensional structure suggests that the N terminus forms a stem supporting and contributing to a b-propeller structure with a sialic acid binding site analogous to the HN proteins of other paramyxoviruses (Fig. 9) (359). Previously unsuspected neuraminidase activity can be demonstrated for RV and peste des petits ruminants virus but not MV (359). Mutagenesis studies suggest that cysteine residues at 287, 300, 381, 394, 494, 579, and 583 are important for oligomerization and folding (296). The structural model is consistent with disulfide bonds between cysteines at 287 and 300, 381 and 386, 394 and 494, and 570 and 579 (359). Neutralizing epitopes are located on the top loops of the b-propeller. The membrane cofactor protein (CD46) binding site maps primarily to a large loop between sheets 4 and 5, on the side of the b-propeller and away from the tetramerization site (J. P. M. Langedijk, unpublished) (see Fig. 9).

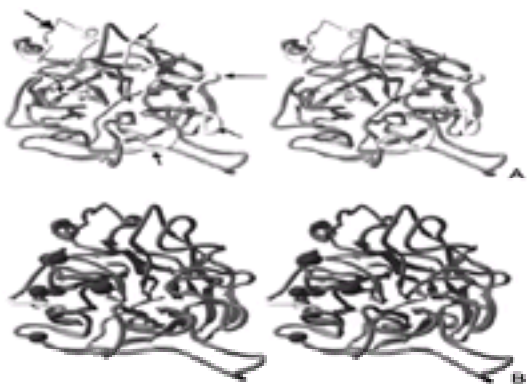

FIG. 9. Stereo ribbon diagram of the hemagglutinin (*H*) protein. **A:** The location of linear epitopes (*white ribbons marked by arrows*) according to peptide binding studies (235,236,237,238,239,240,241,242,243,244 and 245,276,277,278,279,280,281,282,283,284 and 285,309,310,311,312,313,314,315,316,317 and 318,368,369,370,371,372,373,374,375,376,377,378,379,380,381,382,383,384,385,386,387,388,389,390,391,392,393,394, 395 and 396,442,443,444,445,446,447,448,449,450 and 451, and 587,588,589,590,591,592,593,594,595 and 596) (391,392). The major antigenic site (367) is indicated with a *thick arrow.* **B:** Regions involved in CD46 binding according to peptide inhibition studies (483) indicated as *white ribbon* (468,469,470,471,472,473,474,475,476,477,478,479,480,481,482,483,484,485,486 and 487), and according to mutation studies (300,483,580) indicated as *dark spheres* (473,474,475,476 and 477,481,493,495,506, and 546). (From ref. 359, with permission.)

The H protein of the well-studied Edmonston strain of MV has five predicted N-linked glycosylation sites, and they are clustered at positions 168, 187, 200, 215, and 238 (13). The first four of these sites are used (116,294). Glycosylation at 215 is heterogeneous, which may account for the two types of H often observed on polyacrylamide gels (467). More recent MV isolates have an additional glycosylation site at residue 416, and this correlates with a loss of HA activity (548). Glycosylation is necessary for proper folding, antigenicity, dimerization, and export of H from the Golgi (294). Studies on H processing indicate that the rate of intracellular transport is relatively slow, taking approximately 30 minutes for oligomerization and an hour to reach the medial Golgi (295). In polarized epithelial cells, H is transported to both the

apical and basolateral membranes. H proteins associated with persistent infections often have mutations that affect glycosylation, oligomerization, and intracellular transport (116).

Hemagglutination of monkey erythrocytes is indicative of binding to CD46 and is dependent on the C-terminal 18 amino acids (70) of H and the regions involving residues 451 and 481 (483). Tyrosine at 481 allows binding to CD46, whereas asparagine does not (292).

Large Protein

The large (L) protein (2183 amino acids) is highly conserved and contains the Gly-Asp-Asn-Gln motif common to the RNA polymerases of negative-strand viruses (584). L protein is present in small quantities in the infected cell, interacts with and functions in association with P, and is part of the viral nucleocapsid in the cell and in the virion (594). The P binding domain has been mapped to the N-terminal 408 amino acids (288).

Cellular Receptor

The cellular receptor for wild-type MV is generally accepted to be a glycoprotein present on human and monkey cells that interacts with the H protein. Candidate receptors or coreceptors include 20-kd and 30.6-kd proteins on Vero cells identified with an antiidiotypic antiserum (346), a substance P–binding protein on neurons (263), and moesin (a membrane-organizing extension spike protein) on murine cell lines (166), subsequently shown to affect syncytium formation but not to act as a receptor (156). The only glycoprotein that clearly has been identified as a cellular receptor for MV, by demonstrating the ability to confer MV binding and replication to murine cells, is membrane cofactor protein, or CD46 (158,446,461). This receptor was identified with a monoclonal antibody that blocked Edmonston infection of HeLa cells (447) and reacted with CD46 (446). Additional evidence for the role of CD46 as receptor was provided by studies with anti-CD46 antibodies and hybrid cell lines containing human chromosome 1, the location of the CD46 gene (158).

CD46 is a widely distributed human complement regulatory protein expressed preferentially on the apical surface of polarized epithelial cells (73). It normally binds and acts as a cofactor in the proteolytic inactivation of C3b/C4b by factor I (378). Monkeys have a CD46 homolog, but such a protein has not been identified in mice (378,447,449). Multiple species of mRNA are produced by alternative splicing of CD46 transcripts. All code for proteins that contain an identical N-terminal signal peptide, four short consensus repeats (SCR) or complement-control protein domains, a transmembrane region, and an anchor (Fig. 10). Isoforms differ in the length and composition of an extracellular serine/threonine/proline (STP) domain near the transmembrane segment and in having one of two alternative cytoplasmic tails (323,544). Four isoforms are common on human cells in different tissues and all can serve as receptors for MV (218,397). SCRs 1 and 2 interact with the H protein to bind MV (436), and SCRs 2, 3, and 4 bind C3b/C4b (312). The N-linked carbohydrates on SCR-2, but not the O-linked carbohydrates on the STP domains, are important for MV binding (389,390). The H binding site involves one planar face of SCR-1 and SCR-2 (85,107,291,396,436). Increasing the distance between the MV binding domain and the transmembrane domain increases binding but decreases virus fusion (86). MV infection of cells or expression of the H protein alone of some, but not all, strains of MV leads to down-regulation of CD46 by rapid internalization from the cell surface (351,447). This alters susceptibility of the cell to complement-mediated lysis (559). In persistently infected cells, CD46 down-regulation is accomplished through a mechanism that recognizes a membrane-proximal Tyr-X-X-Leu motif in the cytoplasmic domain (675). Interestingly, CD46 is also down-regulated by the H proteins of morbilliviruses such as RV that do not use CD46 as a receptor (212). In macrophages, the cytoplasmic tail of CD46 is associated with intracellular kinases (671), and cross-linking of CD46 can alter macrophage function (279,328). Down-regulation is necessary for major histocompatibility complex (MHC) class II processing and presentation of H (525). Amino acids at positions 451 and 481 of H are important determinants of CD46 down-regulation (45).

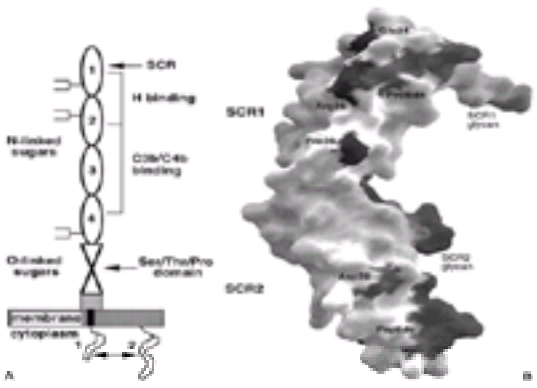

FIG. 10. The measles virus receptor membrane cofactor protein or CD46. **A:** In the diagram, the extracellular N-terminal portion contains four short consensus repeats (SCRs) with three predicted sites for N-linked glycosylation. SCR-1 is absent in CD46 from New World monkeys, and SCR-2 is mutated in baboons (290). The Ser/Thr/Pro domain near the membrane is a site for O-linked glycosylation. The C-terminus has two different cytoplasmic tails. (Adapted from ref. 378, with permission.) **B:** Molecular structure of the two N-terminal SCRs derived from the x-ray crystal structure. Regions involved in MV binding are highlighted. (From ref. 107, with permission.)

It is likely that MV entry into cells requires interaction of the virion with more than one cell surface protein. The existence of a coreceptor is suggested by a number of observations: (a) attachment to the cell occurs through H, but penetration requires F as well (128); (20) small hydrophobic peptides bind to cells and block virus penetration without affecting binding (521); and (c) L cells expressing CD46 are not susceptible to MV infection, but other murine cells are (397,446).

MV receptors in addition to CD46 may be used preferentially by some strains of MV (46,89,612). Marmosets are

susceptible to measles, and marmoset B cells are more sensitive than Vero cells for isolation of wild-type strains of MV. However, marmoset CD46 lacks the SCR-1 domain and does not render Chinese hamster ovary cells susceptible to infection with wild-type MV (437), and antibody to CD46 does not block infection of B95 cells with wild-type MV strains (292). The H gene of wild-type, but not vaccine, strains renders B95, but not HeLa or COS cells, susceptible to fusion (612). Similar observations have been made with wild-type viruses isolated on human B-cell lines (46). Ability to bind CD46 is determined, at least in part, by the amino acid at residue 481 of H (292). Recently, CD_w 150 (SLAM), a surface protein expressed on T, B, and dendritic cells, has been identified as an additional measles receptor (613a). Further characterization of wild-type strains isolated in different ways will be necessary to determine the receptor used *in vivo*.

Hemagglutination and Hemadsorption

Measles virus binds to the erythrocytes of Old World monkeys and most efficiently agglutinates red blood cells from *Cercopithecus aethiops* (African green), patas, and rhesus macaques. This is consistent with the tissue distribution of the CD46 molecule, which is not present on human red blood cells, and with the molecular characteristics of primate CD46 (290,378). Erythrocytes from other primates hemagglutinate poorly. In baboons, this is the result of a mutation in SCR-2, and in New World monkeys to an absence of SCR -1 (290). HA occurs optimally at physiologic pH and 37°C, and cells productively infected with some strains of MV can be identified by their ability to adsorb monkey erythrocytes (hemadsorption). Both HA and hemadsorption are properties of the H glycoprotein. Many wild-type MV isolates have little HA activity or require a high salt concentration. HA is improved by adaptation to growth in Vero cells (580). Many of the low HA viruses encode an H protein with an asparagine at residue 481 and/or an additional glycosylation site at residue 416 (292,549). Salt-dependent HA may be determined by the amino acid at residue 117 of the H protein (523).

Fusion and Syncytium Formation

Hemagglutination is followed within a few hours by lysis of the agglutinated erythrocytes (348). The biologic activities of hemolysis and cell fusion are properties of F, but they require coexpression of H (15,116,128,609,665). Cell-to-cell fusion occurs at neutral pH; therefore, syncytium formation occurs in infected cells *in vitro* and in infected tissues *in vivo* (177) (see Fig. 2). Syncytium formation is affected by cytochalasin B and by the presence of the actin filament–plasma membrane cross-linker moesin, suggesting a role for the cytoskeleton in fusion (53,156). Several regions of the activated F protein are important for fusion activity (see previous discussion of F).

Cytopathic Effects

Measles virus replication in cell culture monolayers results in cytopathic changes of three varieties: multinucleated giant cells (syncytia), altered cell shape, and inclusion bodies (178). Fusion of infected cells with uninfected cells may produce syncytia with 50 or more nuclei bounded by a single cytoplasmic membrane (see Fig. 2). Nuclei in the center of the syncytia have marginated chromatin (177,577) and are undergoing apoptotic cell death (182) leading to plaque formation *in vitro*. Infected cells may also change from a normal polygonal shape to a stellate, dendritic, or spindle-shaped appearance with increased refractility to light. This type of “strand-forming” cytopathic effect appears after several passages (423,570) and may be related to the production of defective interfering particles (412).

Both spindle-shaped cells and syncytial cells may contain intracytoplasmic and intranuclear inclusion bodies (see Fig. 3). Cytoplasmic inclusions are generally larger than nuclear inclusions and contain RNA encapsidated with N protein. Cytoplasmic inclusions are decorated with P and M protein, producing “fuzzy” or “granular” nucleocapsids (78,527) (Fig. 11). In CDV-infected cells, cytoplasmic nucleocapsids of two densities can be distinguished. Biologically active light nucleocapsids contain a 70-kd heat-shock protein, whereas biologically inert dense nucleocapsids do not (466).

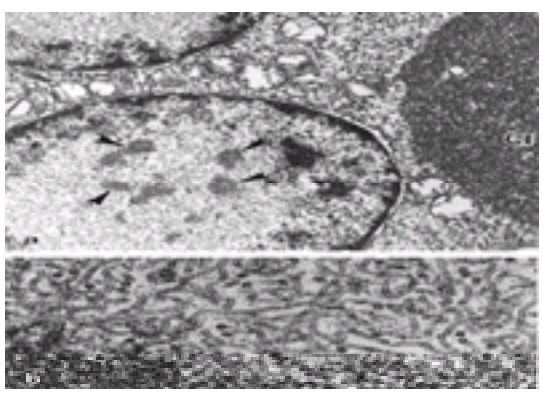

FIG. 11. Electron micrographs of MV inclusion bodies. **A:** Large cytoplasmic inclusion (*CI*) in the brain of a hamster infected with an SSPE strain of MV; the nuclei on the left contain free or aggregated smooth nucleocapsids (*arrowheads*). **B:** Detailed structure of nuclear nucleocapsids in SSPE-infected cells. (From ref. 162, with permission.)

Intranuclear Cowdry type A inclusion bodies are characteristic of morbillivirus infections and occur late in infection (504), but there is no evidence to suggest that the nucleus plays a role in replication. The frequency of development of nuclear inclusions varies with the virus strain (443,454). Electron microscopic examination of CDV-infected cells has shown that intranuclear inclusion bodies are usually complex nuclear bodies derived from nucleoli (463) (see Fig. 3). These nuclear bodies contain N and a cellular heat-shock protein associated with translocation of N from the cytoplasm to the nucleus (465). Similar nuclear bodies have been described in MV infection (478). MV N when expressed alone migrates to the nucleus (127,299,593), where it can assemble into nucleocapsids (199) that lack P, M, and viral RNA (464) and appear “smooth” by electron microscopy (78) (see Fig. 11). Coexpression and binding of P to assembled nucleocapsids is associated with cytoplasmic retention (298). It has been postulated that late in infection the amount of P protein may be

limiting, allowing N to move into the nucleus without encapsidation of viral RNA (79,298).

Antigenic Composition and Strain Variation

Measles virus has long been considered an antigenically stable monotypic virus. Antisera from individuals infected decades ago retain the ability to neutralize more current wild-type strains of MV, and vice versa. Nevertheless, variability, primarily in the N and H genes, has been recognized by nucleotide sequence analysis (523,540,542,551,615) and monoclonal antibody reactivity (62,223,579,611).

The N proteins of wild-type viruses exhibit antigenic heterogeneity in the C-terminal region (87,223), and N genes differ by up to 7% within the C-terminal 456 nucleotides (524,542,615) (see Fig. 5). The H gene nucleotide sequence is quite variable, particularly between residues 167 and 241, where the five potential N-linked glycosylation sites are located (540). The observed rate of mutation of H in virus circulating in defined geographic locations is low, estimated at 5×10^{-4} per year for a given nucleotide (523), whereas the rate of mutation during growth *in vitro* is higher, estimated at 9×10^{-5} per replication for a nucleotide (566).

Strains examined to date can be separated into eight different clades and at least 15 different genotypes (Fig. 12). Some are co-circulating, while others may be extinct (see Fig. 12). Few differences have been described among MV vaccine strains regardless of the geographic origin of the parent virus, suggesting that MV globally was quite similar when most of the parent strains were isolated (541).

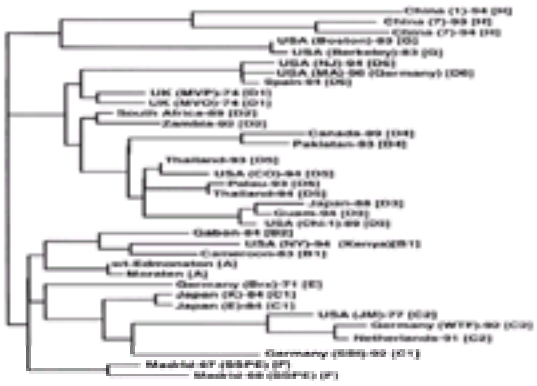

FIG. 12. Evolutionary relationships of wild-type and vaccine strains of measles virus. The phylogenetic tree is based on the complete sequence of the N gene and shows representatives of the 15 recognized genotypes designated in *square brackets* (19). Vaccines are represented by the Moraten strain. (Courtesy of P. Rota and W. Bellini.)

PATHOGENESIS AND PATHOLOGY

Classic Measles

Measles is typically a childhood infection of humans spread by the respiratory route. Disease is characterized by a latent period of 10 to 14 days and a 2- to 3-day prodrome of fever, coryza, cough, and conjunctivitis, followed by the appearance of a characteristic maculopapular rash. The onset of the rash coincides with the appearance of the immune response and initiation of virus clearance (Fig. 13). Recovery is accompanied by lifelong immunity to reinfection (481). Monkeys that have been exposed to infected humans or experimentally infected with wild-type strains of MV develop a similar disease (635), and much of our more detailed understanding of pathogenesis and sites of virus replication come from studies of nonhuman primates.

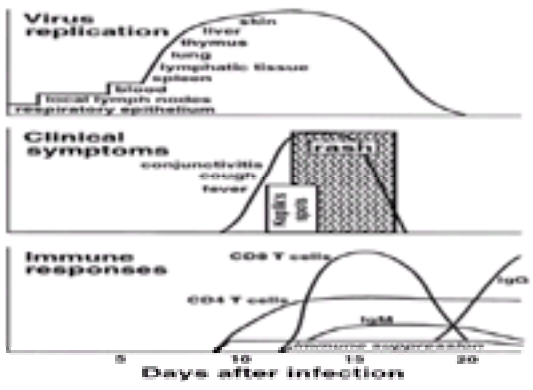

FIG. 13. Pathogenesis of measles. Virus is spread by the respiratory route; replication begins in the respiratory epithelium and spreads to monocyte/macrophages, endothelial cells, and epithelial cells in the blood, thymus, spleen, lymph nodes, liver, skin, and lung and to the conjunctivae and the mucosal surfaces of the gastrointestinal, respiratory, and genitourinary tracts. The rash appears at the time of the virus-specific immune response. Clearance of virus is approximately coincident with fading of the rash.

Entry and Sites of Primary Replication

Virus is spread by aerosol and enters by the respiratory route. Initial infection is established in the respiratory tract with virus replication in tracheal and bronchial epithelial cells (550,577). From the respiratory tract there is extension to local lymphatic tissues, perhaps carried by pulmonary macrophages or dendritic cells (326,573). MV replication in lymphoid tissue results in the appearance of lymphoid or reticuloendothelial giant cells first described by Warthin (651) and Finkeldey (195). Typically these are large cells of up to 100 µm or more in diameter that may contain 100 nuclei aggregated near the center. Inclusion bodies are not generally present. Warthin-Finkeldey cells tend to be located at the periphery of germinal centers and in submucosal lymphoid tissue.

Spread

Amplification of virus in regional lymph nodes results in the appearance of a viremia and spread of virus through the blood to infect a variety of organs. Numerous studies have documented a cell-associated viremia, present prior to and at the time of the rash (201,306,543). Only rarely has a plasma viremia been detected and then only prior to the appearance of neutralizing antibody (487), but viral RNA can be detected in plasma by reverse transcriptase polymerase chain reaction (RT-PCR). The primary cell infected in blood is the monocyte (184). Infection of monocytes and macrophage cell lines by some strains of MV increases the expression of LFA-1, an adhesion molecule that promotes adherence to endothelial cells and may contribute to virus dissemination (29,301). Leukocytes other than monocytes can be infected *in vitro* and may be infected *in vivo* as well (477). The viremia is accompanied by leukopenia (31,573).

Target Tissues and Cells

Lymphoid organs and tissues (e.g., thymus, spleen, lymph nodes, appendix, and tonsils) are prominent sites of virus replication (253,473,550) as is evidenced by the increasing numbers of giant cells in lymphatic tissue prior to the appearance of the rash (195,266,571,598,651). In the spleen, macrophage-rich areas are primary sites of MV replication. In the thymus, epithelial cells are infected (425), leading to thymocyte apoptosis and a prolonged decrease in the size of the thymic cortex. Other lymphoid tissues recover promptly (659). MV also spreads to numerous other organs, including the skin, conjunctivae, kidney, lung, gastrointestinal tract, respiratory mucosa, genital mucosa, and liver. In these various sites, the virus replicates primarily in endothelial cells, epithelial cells, and/or monocytes and macrophages (184,215,253,335,425,473,602,605). Endothelial cell infection is accompanied by vascular dilatation, increased vascular permeability, mononuclear cell infiltration, and infection of surrounding tissue (150).

The histopathology of the measles rash suggests that the initial event is the infection of dermal endothelial cells (71,338). This is followed by spread of infection into the overlying epidermis, with infection of keratinocytes in the stratum granulosum leading to focal keratosis and edema (605). Epithelial giant cells form and a perivascular mononuclear infiltrate accumulates (150,187). Koplik's spots found on the oral mucosa are pathologically similar to the rash and involve the submucous glands (150).

Pathologic examination of other tissues shows multinucleated epithelial giant cells that resemble those formed in tissue culture (see Fig. 2). Epithelial giant cells are prominent at the onset of the rash and are readily demonstrated in nasal secretions and the conjunctivae during the prodrome and first days of the rash (49,370,453,556). MV-infected epithelial cells are also shed into the urine (370,380).

Immune Responses

The immune responses to MV are important for clearance of virus and recovery from infection and are directly responsible for several of the clinical manifestations of measles. Appreciation for the roles of various components of the immune response in recovery from infection has been gained from “experiments of nature,” in which the outcome of MV infection in patients with selective deficiencies of immunologic function has been documented (232). In general, patients with hypogammaglobulinemia recover, whereas individuals with severe congenital or acquired deficits in cellular immune responses or combined deficits in cellular and humoral responses are prone to developing progressive disease.

Nonspecific host responses may contribute to control of virus replication during the incubation period, but the onset of clinically apparent disease coincides with the appearance of MV-specific immune responses. There is marked activation of the immune system (Fig. 14), which is coincident with the appearance of immune suppression. Immune suppression and immune activation continue for many weeks after apparent recovery.

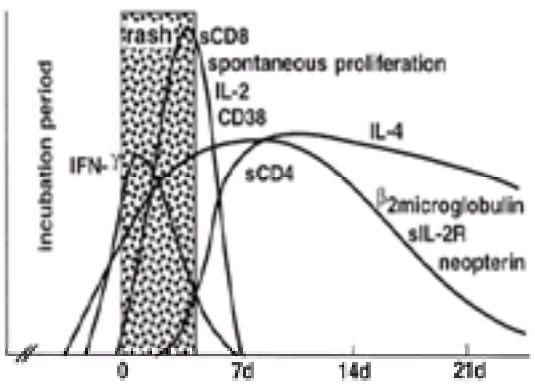

FIG. 14. Appearance of circulating cytokines during uncomplicated measles. The patterns suggest early activation of CD8 and type 1 CD4 T-cells followed by prolonged activation of type 2 CD4 T cells.

Early Nonspecific Responses

Measles virus infection of cells *in vitro* induces production of interferon (IFN)-a and IFN-b, which decrease MV replication and increase expression of MHC class I antigen on infected cells (154,315). Increased levels of IFN are present in serum 8 to 11 days after measles immunization (491), but elevated plasma levels of biologically active IFN have not been documented during natural infection (247,583). Natural killer (NK) cells constitute another potentially important early defense mechanism, but studies of NK activity indicate that NK cell function is actually lower than normal during measles (247). These studies have been performed using samples from humans collected at the time of the rash and do not exclude induction of and roles for IFN and NK cells at earlier stages of infection.

Antibody

Antibodies are first detectable when the rash appears (51,235). The isotype of MV-specific antibody is initially IgM, and in mice, IgM production depends on T cells (189). Later, the isotype switches primarily, but not exclusively, to IgG1 and IgG4 (172,403). IgG is initially of low avidity, but this increases steadily over several months 193). IgA, IgM, and IgG antibodies to MV are found in secretions (83,490). Antibodies are eventually produced to most viral proteins (235,456,623) (Fig. 15).

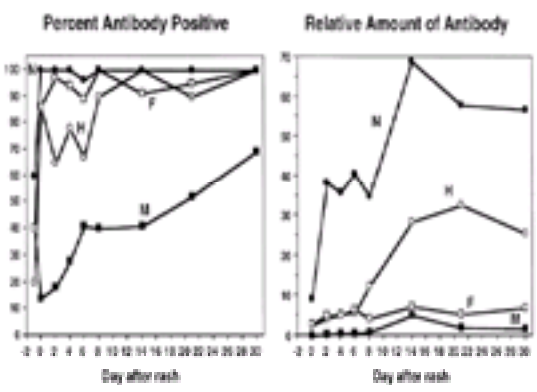

FIG. 15. Production of antibody to measles virus proteins during natural infection. **A:** Percent of individuals positive for antibody to each protein. **B:** Relative amounts of antibody to each protein. Antibody was measured by immunoprecipitation. (Adapted from ref. 235, with permission.)

The most abundant and most rapidly produced antibody is to N (235,456), and this is the primary reactivity measured in the complement fixation (CF) test (456). Because of the abundance of anti-N antibody, absence of this antibody is a reliable indicator of seronegativity. The M protein elicits only small amounts of antibody except in atypical measles (235,387).

Antibody to F is measured by inhibition of MV hemolysis of monkey erythrocytes [hemolysin inhibition (HLI)], by immunoprecipitation of F or specific enzyme immunoassay (50,456,457,674). Antibodies to F contribute to virus neutralization, probably by preventing fusion of the virus membrane with the cell membrane at the time of virus entry (395). Two regions of F induce neutralizing antibodies: one includes amino acid 73 and the other includes amino acids 388 to 402 (26,188,395). Human sera recognize linear epitopes in six to seven regions spread over much of the F protein (662), and these linear B-cell epitopes are frequently close to T-cell epitopes (434). Monoclonal antibodies (MAbs) to F may cross-react with cellular heat-shock proteins (578).

Antibody to H is measured by inhibition of the agglutination of monkey erythrocytes by MV [hemagglutination inhibition (HAI)], but these antibodies also may inhibit hemolysis and fusion (105,224,456,459). Antibodies to H can also be measured by immunoprecipitation (457) or specific enzyme immunoassays (50,674), and they are the primary antibodies measured by neutralization of virus infectivity (224,225). Four to six neutralizing epitopes have been mapped by competitive binding of MAbs and analysis of different strains and escape mutants (105,297,300,366,579). Human convalescent sera show reactivity to linear epitopes, as well as epitopes dependent on conformation and glycosylation (294,435). One of the major conformational epitopes has been localized to the region between amino acids 368 and 396 (366). In the proposed propeller model of H, essentially all of these epitopes are predicted to be on an exposed surface on top of the molecule (see Fig. 9) (359).

Antibody can protect from MV infection, may contribute to recovery from infection, and may play a role in establishing persistent infection (1,8,355,507). There is *in vivo* and *in vitro* evidence for a role in recovery. Antibody-dependent cell-mediated cytotoxicity (ADCC) correlates temporally with cessation of cell-associated viremia (202). Antibody binding to infected cells alters intracellular virus replication and may contribute to control of infection (206,207,228,562). Failure to mount an adequate antibody response carries a poor prognosis (657). The role of antibody in protection from infection is discussed in the section Immunization, and the role in establishing persistence is discussed in the section Persistent Infection.

Cellular Immunity

The ability to recover from measles was postulated by Burnet to be an indication of the adequacy of T-lymphocyte-mediated immune responses (91). There is abundant evidence that CD8 T cells are activated and expanded in response to infection. MV-specific, human leukocyte antigen (HLA)-restricted, CD8 cytotoxic T lymphocytes

(CTLs) (318,353,588,633) and proliferating CD8 T cells (646) with evidence of clonal expansion (426) are detectable in blood at the time of the rash, and in bronchoalveolar lavage fluid during pneumonitis (439). Cultures of peripheral blood mononuclear cells with autologous MV-infected cells or peptide-pulsed cells after recovery expand CD8 T cells with cytolytic activity demonstrating that CD8 T-cell memory is established by infection (318,319,444,633). Soluble CD8 and b2 microglobulin (a component of the MHC class I molecule that presents antigen to CD8 cells) are increased in plasma (245,247) (see Fig. 14). MV infection of cells *in vitro* up-regulates MHC class I expression through production of IFN-b (154). MV antigens that induce CD8+ cytotoxic T cells include the N, P, H, and F proteins (276,318,637).

CD4 T cells are also activated in response to MV infection. *In vitro*, binding of H to CD46 targets virion proteins to an endosomal compartment for efficient presentation by MHC class II proteins (219). CD4 T cells proliferate during the rash (646), although absolute numbers of circulating cells often decreases (374). Soluble CD4 becomes elevated in plasma and remains so for several weeks after recovery (244) (see Fig. 14). Classic CD4 T-cell responses, such as MV-specific proliferation and lymphokine production, are stimulated during measles (633). Lymphocyte proliferation can be induced by most MV proteins in immune individuals and is usually MHC class II restricted (58,433,492,537,637). Cytokines produced by CD4 T cells determine their function. Type 1 CD4 T cells produce IFN-g, which activates macrophages, and interleukin (IL)-2, which promotes T-cell proliferation. These are the primary mediators of classic delayed-type hypersensitivity. Type 2 CD4 T cells produce IL-4, IL-5, IL-10, and IL-13, which are important for B-cell growth and differentiation and for macrophage deactivation. In measles, IFN-g, neopterin (a product of activated macrophages), and soluble IL-2 receptor rise during the prodrome, prior to the appearance of the rash (245,246). This is followed by elevation of IL-2, soluble CD4, and soluble CD8 at the time of the rash (245,248). As the rash fades, IL-4 and IL-5 increase, and this elevation persists in some individuals for weeks (248). This pattern of cytokine production suggests early activation of CD8 (IFN-g) and type 1 (IFN-g and IL-2) CD4 T cells during the rash, followed by activation of type 2 (IL-4, IL-5) CD4 T cells during recovery.

Longevity of the Immune Response

Epidemiologic studies have documented that long-term protection from reinfection does not require reexposure (481). Immunologic memory includes both continued production of antibody (68) and circulation of MV-specific T cells (307,633,672). There is no evidence for persistence of latent virus, although intermittent reports of detection of MV RNA in the blood and tissues of normal individuals (251,560) make this a possibility. Extensive replication of MV in lymphoid tissue may maximize the interaction of viral antigen with antigen-retaining follicular dendritic cells in germinal centers, leading to long-term antibody production.

Immune Suppression

There is *in vivo* and *in vitro* evidence of immune suppression during measles (Fig. 16). Immune suppression is probably a multifactorial process and is likely to underlie the increased susceptibility to other infections characteristic of measles. *In vivo*, delayed-type hypersensitivity skin test responses to recall antigens, such as tuberculin, are suppressed prior to the rash and for several weeks after apparent recovery from infection (595,610,641,656). Production of antibody and cellular immune responses to new antigens is impaired (132). Reactivation of tuberculosis (129) and remission of immunologically mediated diseases such as nephrotic syndrome, juvenile rheumatoid arthritis, and idiopathic thrombocytopenic purpura (371,372,677) have been reported to follow measles. *In vitro*, lymphoproliferative responses to mitogens are suppressed and lymphokine production is abnormal (23,282,647). Analysis of the *in vitro* abnormalities suggests defects in the responses of both monocytes and lymphocytes.

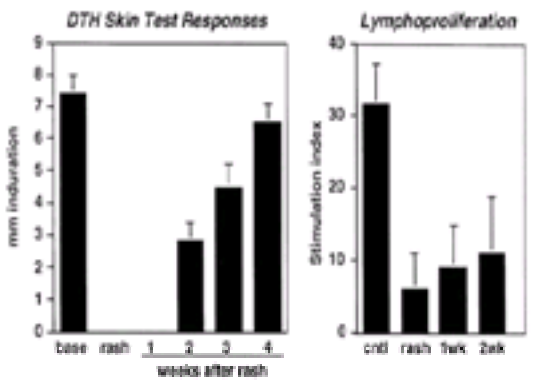

FIG. 16. Immunosuppression during measles. Changes during measles in tuberculin-induced delayed-type hypersensitivity (DTH) skin test responses in children with measles who had previously received immunization against tuberculosis and changes in proliferation of peripheral blood mononuclear cells to the mitogen phytohemagglutinin. (Data from refs. 610 and 282, with permission.)

Monocytes are infected during measles (184), and monocyte function is abnormal, with low levels of tumor necrosis factor (TNF)-a production during both acute and convalescent phases of the disease (241). Decreased TNF-a is observed when macrophage-lineage cells are infected with MV *in vitro* and monocyte production of IL-12 is suppressed by cross-linking the MV receptor CD46 (328,363).

Circulating T cells are decreased in number in most individuals during the acute phase of measles, and profound lymphocytopenia is associated with HLA-AW32 (134,143,656,660). Both normal and abnormal proportions of CD4 and CD8 T cells have been reported during measles, and it is likely that the numbers of circulating T cells are rapidly changing during the acute phases of infection (24,142,242,374,646). A greater decrease in CD4 T cells has been associated with malnutrition and more severe disease (337). Infection of thymic epithelial cells induces terminal

differentiation of these cells and apoptosis of thymocytes that are not infected. These events may have long-term consequences for cellular immune function (30,630).

One of the reasons for low T-cell proliferation to mitogens *in vitro*, especially during convalescence, is inadequate production of IL-2. Addition of recombinant IL-2 to measles lymphocyte cultures supports spontaneous proliferation and improves mitogen responses (242,645). When *in vitro* production of other cytokines is assessed, IFN-g is low to normal and IL-4 is high compared to controls (244,647), suggesting that type 2 CD4 T cells are preferentially activated. *In vitro* neutralization of IL-4 improves proliferation (244). The suppressive effects of IL-4 on type 1 CD4 T cells and macrophages may contribute to suppression of delayed-type hypersensitivity and macrophage activation during measles.

In vitro infection of leukocytes and leukocyte cell lines with the Edmonston strain of MV induces abnormalities of B-cell, T-cell, macrophage, and dendritic cell function, which may be relevant to immune suppression during measles. Resting lymphocytes and dendritic cells produce little virus unless activated (205,565). Virus production by macrophages decreases with cellular maturation (205,272,601). T-cell proliferation to mitogens and soluble antigens (405,590,683) and cytotoxic function (106), as well as B-cell production of immunoglobulin (106,406,619), are suppressed by infection. T and B lymphocytes infected *in vitro* can be activated by mitogen, but they proliferate poorly because entry into S phase and progression through the cell cycle is impaired (405,445). Failure of MV-infected T cells to proliferate is linked to poor responses to IL-2 and somatostatin (54,350). Dendritic cells lose the ability to stimulate an allogeneic response and undergo apoptosis when co-cultured with T cells (205,249). Monocytes and dendritic cells exposed to MV have impaired production of IL-12, a cytokine necessary for induction of type 1 CD4 T cells (205,328). In monocytes, increased nitric oxide and suppressed IL-12 production are the result of MV interaction with CD46 (279,328). Likewise, B-cell production of IgE is stimulated by CD46 cross-linking in the presence of IL-4 (310). Other studies suggest that CD46-independent interactions of H and F with lymphocytes and soluble factors produced by infected T cells inhibit T-cell proliferation and contribute to immune suppression (208,249,450,557).

Autoimmunity

An autoimmune demyelinating disease, postinfectious encephalomyelitis or acute disseminated encephalo-myelitis (ADEM), is an important complication of measles (422) (Fig. 17; see Table 2) and is associated with an immune response to myelin basic protein (322) similar to that seen in animals with experimental autoimmune encephalomyelitis. The similarity of these diseases and lack of MV in the brain have led to the current understanding that ADEM is an autoimmune disease (322,344) induced by measles.

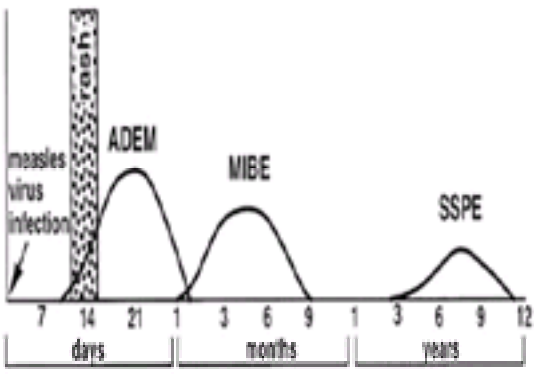

FIG. 17. Time after infection of the three neurologic complications of measles: infections or acute disseminated encephalomyelitis (*ADEM*), measles inclusion body encephalitis (*MIBE*), and subacute sclerosing panencephalitis (*SSPE*).

Disease	Host	Typical age of infection	Measles virus in brain	Incidence	Pathology	Time course
Acute disseminated encephalomyelitis (ADEM)	Normal	>2 yrs	No	1:1000 cases	Inflammation, demyelination	Monophasic, weeks
Measles inclusion body encephalitis (MIBE)	Immunosuppressed	Any	Yes	?	Inclusion bodies	Progressive, months
Subacute sclerosing panencephalitis (SSPE)	Normal	<2 yrs	Yes	1:100 cases	Inclusion bodies, inflammation	Progressive, years

TABLE 2. *Neurologic complications of Measles*

The mechanism of induction of autoimmune disease during measles is not clear. Hypotheses have included altered presentation of myelin antigens resulting from MV infection of oligodendrocytes (344), molecular mimicry of myelin antigens by MV (316), and dysregulation of immune responses (282). There is little evidence for MV infection of cells in the nervous system (217,322,425). The possibility of molecular mimicry with cross-reactivity between myelin basic proteins and MV protein has been explored using computer searches and studies of T-cell and antibody cross-reactivity. Sequence analyses have revealed areas of homology (316), but the biologic relevance of these potential cross-reactions is not known. Neither cross-reactive antibodies nor cross-reactive T-cell clones have been identified in humans or rats

with demyelinating disease induced in conjunction with MV infection (367). Genetic susceptibility to ADEM has been postulated, but the number of patients studied has been insufficient to clearly identify a link between MHC antigens or other genetic markers and disease (240,361).

Studies of immune regulation have shown that patients with encephalomyelitis differ from patients with uncomplicated disease by having a distinct pattern of immunologic abnormalities. IgE is more persistently elevated and soluble IL-2 receptor is lower in patients with encephalitis (239,245). The timing of autoimmune encephalomyelitis and the occurrence of a pathologically similar disease as a complication of treatment with IL-2 (233) suggest that immune activation and dysregulation during measles may play a role in allowing activation and expansion of autoreactive lymphocytes.

Release

Epidemiologic data suggest that infected individuals become infectious for nonimmune contacts a few days before the onset of the rash. At this time, virus can be cultured from the mucous membranes of the nasopharynx, conjunctivae, and mouth (173), suggesting that the respiratory tract is the site of virus release.

Virulence

Strains of MV can clearly differ in virulence, as attenuated vaccine strains cause little disease in humans and wild-type strains cause measles. Sequences of these strains have been compared but phenotypes have not yet been correlated with genotypes (608). A lack of animal models for assessing virulence has handicapped attempts to determine the molecular basis for changes in virulence. Monkeys (rhesus or cynomolgus macaques) develop a rash illness similar to measles in humans and are probably the most relevant model system for assessing virulence. Limited studies have shown that adaptation of wild-type MV to growth in Vero cells selects for a virus that no longer causes a rash in monkeys. This attenuation is associated with predicted amino acid changes in the *P* and *L* proteins, but the specific changes responsible for decreased virulence are not yet known (607).

A second model system that has been used to assess virulence is the study of replication of MV in human cells implanted into immunodeficient mice with severe combined immunodeficiency disease (SCID). In thymic implants, wild-type viruses grow more rapidly and to a higher titer, and they cause more extensive thymocyte apoptosis than attenuated strains (30,631). In human mononuclear cell implants, wild-type strains grow better than vaccine strains (304). Again, the regions of the genome and the specific amino acid substitutions associated with these changes in replication and tissue destruction have not yet been defined. However, the availability of a reverse genetic system for MV now makes manipulation of the genome and these more definitive experiments possible (501).

Persistent Infection

Measles virus can establish persistent infection of cells *in vitro* and *in vivo*. A number of cell lines persistently infected with MV have been established, and neurologic disease can be caused by persistent infection of neurons and glial cells.

Persistently Infected Cells in Culture

Replication of MV usually causes death of cells in culture. The elements determining persistent noncytopathic versus lytic infection are not completely understood, but properties of both the infected cell and the infecting virus contribute. Methods used to establish persistently infected cell lines include (a) passage of virus at high multiplicity with generation of defective interfering particles (522,658), (b) passage of infected cells in the presence of antibody (546), (c) cultivation of cells surviving lytic infection (192,546), and (d) co-cultivation of cells with MV-infected brain cells from patients with SSPE or from persistently infected animals (416).

Persistent noncytopathic infection is most easily established in neuronal cells (421,503), but it has also been established in lymphoid, epithelial, and glial cell lines (192,383,416,546) and is associated with down-regulation of CD46. Identified cellular factors that affect the ability of MV to establish and maintain persistent infection are expression of heat-shock proteins, IFN-inducible proteins, and possibly RNA-binding proteins (362,421,564). Increased levels of cyclic adenosine monophosphate inhibit virus replication (528) and may correlate with the restriction of MV replication associated with neuronal differentiation (421). Cellular protein synthesis is relatively unaffected by MV infection, but specific cellular proteins (e.g., cell surface receptors) and functional responses (e.g., signal transduction, expression of transcription factors) may be altered, particularly in neural cells (48,197,252,613).

Strains of MV differ in their ability to establish persistent nonlytic infection in the same host cell (192). Replication of variants likely to cause persistent infection is often temperature sensitive (234,503). Persistent MV infection is usually accompanied by a marked decrease in the amount of infectious virus released and by intranuclear and intracytoplasmic accumulation of nucleocapsids with decreased evidence of virus-induced cytopathic effect compared to lytic infection (546). Some cell lines produce no infectious virus (92): Persistent infection is apparently maintained by passage of encapsidated viral RNA to daughter cells during cell division and therefore may not require production of infectious virus. The ability to transfer infection from persistently infected cells to uninfected cells is postulated to be an important mechanism for spread of infection in SSPE and has been demonstrated in organ cultures of neural tissue (576).

Limited expression of viral proteins on the surface of persistently infected cells has led to the suggestion that defects in synthesis of viral envelope proteins may be an important component of persistent infection (416,545,678). Defects in glycoprotein expression may in part result from limited mRNA production associated with steep transcriptional gradients (115,510) and an increase in bicistronic messages (115,303). However, mutations in these genes also may lead to proteins with altered expression or function. In persistently infected HeLa cells, M was rapidly degraded and H was not properly processed in the ER (678).

Subacute Sclerosing Panencephalitis

Much is known and has been written about SSPE, but the pathogenesis remains poorly understood. SSPE is a rare (approximately 1 in 1 million) late complication of measles that is most likely to occur if the original MV infection occurred at a young age (151,314). The route of virus entry into the central nervous system (CNS) is unknown, but infection of cerebral endothelial cells is one possibility (183,340). The incubation period is usually 7 to 10 years (424) (see Fig. 17). Extensive sequence analysis of viral RNA from various parts of the brain in SSPE suggest that the virus in the CNS is clonal (34), implying that virus entered the brain at one time (presumably during the original acute infection) and then gradually spread throughout the nervous system.

Studies of Brain and Brain-Derived Cell Lines

At the time that neurologic symptoms occur, neurons and glia contain nuclear and cytoplasmic viral inclusion bodies (275), antibody responses to virus are vigorous and evident both in serum and CSF (82,622), and there is an extensive mononuclear inflammatory reaction in the CNS (148,478). Both white matter and gray matter are affected (148). Virus replication is defective and when virus can be recovered it is only by co-cultivation or explantation of brain tissue (128,486). Brain tissue from patients with SSPE contains defective interfering particles that may contribute to persistence (585). CD46 is absent and no virus is seen budding from the surface of infected cells (161,462). Nuclear inclusions are filled with “smooth” nucleocapsids (161,275). The cytoplasm contains “fuzzy” nucleocapsids that extend into neuronal processes, suggesting that virus can spread within the CNS by synaptic transmission of the ribonucleoprotein from cell to cell (311,484). The observation that strains of MV isolated from patients with SSPE are more likely than standard strains of MV to cause neurologic disease after intracerebral inoculation into small animals (468) suggests that the virus has adapted to growth in neural tissue.

Viruses capable of production of infectious virus *in vitro* are infrequently recovered from SSPE patients, but extensive sequence analysis of viral RNAs from tissue suggests that SSPE viruses are genetically distinguishable from those that cause acute measles, especially in the viral genes encoding the M, F, and H proteins (33,35,117,558,669). Studies of brain have revealed differences in the relative amounts of the various viral mRNAs and proteins (35,365,585), in the antigenicity of viral proteins (485), and in RNA sequences coding for viral proteins (35,117) between SSPE viruses and wild-type or vaccine strains of MV. It is not known for certain whether these differences represent unique features of the original infecting virus, selection for growth in the CNS, or selection for growth in the presence of a vigorous antibody response.

In general, expression of M protein is low (153,255,365). This may be the result of a lack of synthesis of M (596) or an instability of the synthesized protein (575). A variety of defects have been encountered in the mRNA encoding M extracted from SSPE brain (117). Mutations occur throughout the gene (see Fig. 6), and the frequent U to C sequence changes noted in some viruses suggest mutation of double-stranded RNA in persistently infected cells by adenosine deaminase (biased or adenosine/inosine hypermutation) (112,169,670), although the role of this enzyme has been questioned (287). M transcripts often lack initiator AUGs necessary for expression (603). When expressed, M proteins may have defects in binding to viral nucleocapsids (277) and in down-regulating transcription (603). In one study, M protein of the SSPE strain remained in the cytosol, whereas the M protein from a related wild-type strain was bound to nucleocapsid at the plasma membrane (278). Defects in M are so common in SSPE that M is likely to be dispensable for virus growth and spread in the CNS, and it is possible that abrogation of the function of M is necessary to establish persistent CNS infection.

Aberrant M protein was believed to be the hallmark of persistent MV infections in SSPE patients (255). However, further investigations of SSPE viral genomes and proteins have demonstrated that alterations in any of the MV envelope proteins that in some way interfere with assembly and budding of infectious virus can be associated with persistent infection and SSPE (35,116,117,558). H proteins are often defective in intracellular transport and protein–protein interactions important for cell–cell fusion (116). Truncations, mutations, and deletions in the cytoplasmic domain of F are almost universal (see Fig. 8). Truncations do not affect fusion but may interfere with virus budding (116,558).

Immune Responses

The possibility that the development of SSPE represents a defect in the immune response to MV has led to investigations of humoral and cellular immune responses to MV and other antigens. The antibody response to MV is accentuated with significant production of MV-specific antibody by plasma cells residing in the CNS. This antibody appears in CSF, leading to elevations in the level of CSF immunoglobulin, much of which is MV specific (138,181,621). Antibody produced in the CNS is of restricted heterogeneity, leading to the appearance of oligoclonal immunoglobulin bands on electrophoretic analysis of CSF (168,638). Antibodies against the N and P proteins present in the ribonucleoprotein complex are particularly abundant, and antibody against the M protein is particularly deficient (153,255). The antibody produced is capable of mediating complement-dependent lysis of infected cells (470), but it is ineffective in clearing virus from the CNS.

Antibody to MV has been postulated to play a role in establishing persistent CNS infection either through alteration of the induction of the primary immune response at the time of infection (507), through production of immune complexes (591), or through modulation of infection once virus is in the nervous system (206,325). Antibody can cap viral antigens from the cell surface, producing infected cells that are refractory to immune-mediated lysis (325). Antibody may also contribute to establishment of persistent infection by suppression of P and M protein production (207).

Experiments in small mammals have shown that treatment with antibody after intracerebral infection with neuroadapted strains of MV attenuates acute disease but increases the incidence of subacute or chronic encephalitis associated with persistent virus infection (506). Cases of SSPE have been associated with passive transfer of immune globulin, and

persistent infection has been induced experimentally by passive transfer of antibody (507).

Studies of cellular immunity have been less extensive. MV-specific lymphoproliferation is similar to that of healthy seropositive individuals but MV-specific cytotoxic T-cell activity is decreased (152). General measures of cellular immunity, such as skin test responses to various recall antigens and proliferative responses to mitogens, are normal (33). The mononuclear inflammatory response in the brain includes CD4 and CD8 T cells, as well as monocytes and Ig-secreting B cells (181,442). Class I and class II MHC expression is increased in brain and b2 microglobulin, soluble IL-2 receptor, and soluble CD8 are increased in CSF (414). Thus, there is no evidence for a global defect in immune responses, but there is evidence that these immune responses are ineffective in clearing virus from the CNS.

Other Chronic Diseases

In addition to having a clear role in SSPE, MV also has been implicated in the pathogenesis of Paget's disease (47,511), tosclerosis (25,411), chronic active hepatitis (529), achalasia (324), multiple sclerosis (4,16), and Crohn's disease (642). For most of these diseases, an etiologic link to measles is controversial (20,61,419), and for none has a definitive role for MV been identified.

Veterinary Correlates

Canine Distemper

Canine distemper was first described by Carré in 1905 as an infectious disease of young dogs associated with gastroenteritis, pneumonitis, conjunctivitis, and encephalomyelitis (100). Canine distemper was shown to be of viral etiology in 1926 (357), and the virus was isolated in primary canine kidney cells in 1959 (530). Canine distemper is a severe disease of canines, raccoons, ferrets, and seals, with many similarities to measles, but direct infection of the CNS and neurologic disease is more common. CDV has a broader host range than many morbilliviruses and it appears to be expanding (260). Recently, CDV has spread to large felines in the wild in Africa (533) and in zoos in North America (260). CDV is spread by aerosol and the disease is characterized by fever, coryza, conjunctivitis, gastroenteritis, and pneumonitis (164,165). CDV appears first in bronchial lymph nodes and tonsils, followed by a cell-associated viremia. Infection spreads to epithelial tissues and enters the brain by infecting endothelial cells or by infiltration of infected monocytes (21,32). Like measles, canine distemper is associated with profound short- and long-term immune suppression, and much of the mortality is caused by secondary infections (121,347). CDV replicates in CD4 T cells (313) and is cleared in most animals with the appearance of antibody to envelope proteins and lymphocyte-mediated cytotoxicity for infected cells (21,22,347,349).

Dogs, ferrets, and lions may develop neurologic complications characterized by gait abnormalities and seizures (164,165). Neurologic disease is most common in young dogs (348) and can occur either early after infection or 3 to 4 weeks later associated with infection of oligodendrocytes and demyelination (72,373). Persistence of virus in neurons and epidermal cells of the feet (21) lead to diseases known as old dog encephalitis and hard pad disease (21). Some cases of old dog encephalitis have defective virus with intranuclear inclusions in the CNS coexisting with high levels of antiviral antibody, features in common with SSPE (309,373). In other cases, virus can be isolated without co-cultivation, and the disease cannot be clearly distinguished from late-onset encephalitis (309).

Rinderpest and Peste des Petits Ruminants

Rinderpest was first recognized as a distinct clinical entity causing severe gastroenteritis in cattle during a 4th century European epizootic (493). The causal agent of this disease was reported to be filterable in 1902 (5) and was isolated in bovine embryonic kidney cells in 1957 (494). Sequence analysis suggests the existence of a second bovine morbillivirus that causes persistent infection (41).

Rinderpest is a highly contagious disease of ruminants and swine characterized by inflammation, hemorrhage, necrosis, and erosion of the gastrointestinal tract (5). RV replicates in lymphocytes and macrophages, leading to lymphoid necrosis (604), and in epithelial cells of the gastrointestinal, respiratory, and urinary tracts, and in endocrine and exocrine glands, but not in the brain or spinal cord (666). It is an important veterinary pathogen. Vaccine and virulent strains of RV have been completely sequenced and the virus has been rescued from cDNA (40,42).

Peste des petits ruminants causes a disease of sheep and goats in Africa, Asia, the Middle East, and India (574). The disease was first discovered in West Africa in 1942 and is characterized by erosive stomatitis, pneumonitis, and diarrhea (429). The etiologic agent is most closely related to RV (see Fig. 1) (220).

Morbillivirus Infections of Aquatic Mammals

In 1987, an epizootic of respiratory disease with high mortality caused by secondary infections occurred in seals in the Baltic and North Seas (640). Serology suggested infection with a morbillivirus related to CDV, and the causal agent, phocine distemper virus, was isolated in 1988 (336). This disease is characterized by fever, nasal and ocular discharge, and severe respiratory, gastrointestinal, and CNS symptoms. The primary disease is complicated by a variety of secondary viral, bacterial, and parasitic infections, suggesting the type of immune suppression seen in measles and canine distemper (475). Phocine distemper virus is most closely related to CDV (see Fig. 1) (75,137). Similar epizootics of severe respiratory disease were subsequently recognized in porpoises along the Irish Coast (409), in dolphins in the Mediterranean Sea (157), and in monk seals off the coast of West Africa (476). Distinct but related morbilliviruses were isolated from these animals (see Fig. 1) (44,157,409,476,639). Cetaceans infected with either porpoise or dolphin morbillivirus develop pneumonia and encephalitis with virus demonstrable in lung, brain, spleen, and urinary bladder.

Experimental Infection in Animals

Nonhuman primates can be infected naturally or experimentally with MV, and they provide the only experimental model for the pathogenesis of this disease in humans. Small laboratory mammals generally are not susceptible to wild-type strains of MV, although limited replication has been reported in the respiratory tract of cotton rats (673) and in transgenic mice expressing CD46 (432). Several neurotropic rodent-adapted strains of MV have been developed by repeated intracerebral passage, but these strains do not produce acute disease similar to that seen in humans but rather serve as models for neurologic diseases such as SSPE.

Primates

Natural MV infection occurs only in humans. However, a number of species of monkeys are susceptible to measles and can contract the disease by the respiratory route through contact with humans (364,515,635,655). Monkeys can also be infected experimentally by the intranasal, intratracheal, or subcutaneous routes of inoculation (31,71,635). Disease is generally similar to that seen in humans, and deaths are often caused by secondary infections (515). Experimentally infected rhesus and cynomolgus macaques have served as animal models for studies of the pathogenesis of human measles, immune suppression, and vaccine-induced protection from measles, and for analysis of virus virulence (31,71,175,342,407,634,635 and 636,680). Variations in susceptibility of different primate species may be linked to polymorphisms in the MV receptor CD46 and availability of other MV receptors used by wild-type strains of virus (292). Neurologic disease can be induced by intracerebral inoculation of cells infected with neuroadapted strains of MV (8).

Marmosets and tamarins are also susceptible to natural and experimental MV infection by the respiratory route, but they develop a fulminant disease with high mortality characterized by interstitial pneumonitis, gastroenterocolitis, and bacteremia (11,364,381). Infection with vaccine strains produces little disease (381). Intracerebral inoculation with the most virulent strains of MV produces encephalitis, but attenuated strains do not (10).

Hamsters

Of all small mammals, hamsters appear to be the most susceptible to infection with MV. Wild-type, vaccine, and SSPE strains of MV replicate, or can be adapted to replicate, in the brains of newborn hamsters (93,102,317). IFN-resistant subpopulations of viral stocks grow preferentially (102). Hamsters can also be infected using cells persistently infected with MV (600). Newborn animals develop hyperirritability leading to death within a few days. Brains from these young animals show a generalized giant cell encephalitis with intranuclear and intracytoplasmic inclusion bodies (see Fig. 11) and a polymorphonuclear inflammatory response (643). Older animals develop myoclonus with infection of cortical, thalamic, and hippocampal neurons without giant cell formation (600,643). Ependymal infection may lead to hydrocephalus (317). Cell-free virus can be easily recovered from the brains of newborn, but not older, hamsters (96). For some MV strains (e.g., HBS), there is evidence of replication outside the CNS (103) and dissemination of virus by infected monocytes (410). Demyelination is uncommon (643), but some hamsters inoculated as newborns with the LEC SSPE strain develop myelitis 5 to 50 weeks after infection (101).

Mice

Several strains of MV have been adapted to grow in the brains of newborn mice (93,99,308,404). The most extensively studied viruses have been the mouse-adapted Edmonston (MAED) (308) and the hamster neurotropic (HNT) strains (93). In newborn mice, these viruses grow well and cause fatal disease associated with lethargy and wasting within 10 days after intracerebral inoculation. Histopathology and immunocytochemical staining show neuronal and glial infection and giant cell encephalitis (243,382,448). By electron microscopy, nucleocapsid material is seen in neurons and glia (274). Virus is generally cell associated but can be assayed by plaque formation in human or primate cells (653). Inoculation by peripheral routes does not produce detectable disease or infection (448).

Infection of 4- to 6-week-old mice by the intracerebral route with MAED, HNT, or SSPE strains of MV results in a nonproductive infection of neurons in which viral proteins are produced without infectious virus (243). Infected neurons are primarily in the rhinencephalon, limbic system, and striatum without mononuclear cell infiltration, giant cells, or inclusions. The MV-antigen-positive neurons have only smooth nucleocapsid structures and no immunocytochemically detectable H, F, or M proteins, suggesting that viral replication is defective at a stage prior to assembly of virions (274,382,536). The immune response plays no identifiable role in these age-related differences in disease. It appears that maturation of CNS cells converts the production of MV from the infectious form in the newborn mouse to a primarily defective form in the 4-week-old mouse (243,274,536). Weanling mice develop severe disease consisting of hyperexcitation and seizures (243,382,508). This clinical disease is associated with production of excitotoxic amino acids and selective bilateral destruction of pyramidal cells in the hippocampus (18,382), which can be prevented by administration of N-methyl-D-aspartate-receptor antagonists (18).

The genetic background of the mouse influences the disease induced. Mouse strains vary in the amount of virus necessary to induce disease and in the rapidity with which age-dependent resistance develops; C3H/He mice are the most susceptible and SJL the most resistant (448). Weanling BALB/c mice develop fatal acute noninflammatory encephalopathy (382,508), whereas SJL mice develop little acute disease but often succumb to a chronic encephalitis associated with limbic system inflammation (508). C57BL/6 mice that survive acute disease develop chronic neurologic disease weeks to months later (122). Mice with immune deficiencies are more susceptible than immunocompetent mice (194,628).

Recently, a number of investigators have produced a variety of strains of mice engineered to provide better systems for studying measles pathogenesis. Mice with SCID have been grafted with human peripheral blood mononuclear cells (304,619) or implanted with human fetal thymus and liver, which mature to form thymic tissue (30). In thymic implants, MV shows strain-specific differences in virus growth and thymocyte apoptosis that have been useful for assessing virulence and determinants of replication *in vivo* (30,631,632). Immunologically normal mice with transplanted human leukocytes develop graft-versus-host disease and can be infected with MV (304). Transgenic mice expressing human CD46 have

been produced using genomic DNA or cDNAs with promoters designed to provide generalized or tissue-specific expression of the CD46 transgene. In general, infectious virus cannot be recovered from the mice, but evidence of MV replication is greater than in control nontransgenic mice and is enhanced by the absence of IFN (74,289,432,505). These studies have demonstrated that blocks to MV replication in mice are at multiple levels, not solely at the level of the CD46 receptor.

Ferrets

Intracerebral inoculation of ferrets with cells infected with certain SSPE strains of MV causes acute encephalitis (330,617). Subacute or chronic encephalitis is established if animals are immunized prior to intracerebral injection with infected cells (617,618). Pathologic and clinical features in animals with chronic disease resemble SSPE with cerebral inflammation, gliosis and intranuclear inclusion bodies, electroencephalographic changes, bound immunoglobulin in brain, and high titers of antibody to MV in serum and CSF (84,330,617,618).

Rats

The HNT strain can infect laboratory rats after intracerebral inoculation. The CAM strain, adapted to rat brain by serial passage, causes fatal encephalitis after intracerebral inoculation into newborn rats (366). Neurovirulence may be related to amino acid changes in the H glycoprotein (366). The type of disease produced in older rats is determined by the strain of rat. In Brown Norway rats, only 10% to 20% develop acute encephalitis, and no late disease develops in survivors. In Lewis rats, 80% to 90% develop acute fatal encephalitis, and the remainder develop subacute disease 4 to 6 weeks after infection. Infectious, cell-free virus can be recovered during acute, but not subacute, disease (368). Transgenic expression of human CD46 does not increase the permissiveness of rats for MV infection (451). Cotton rats (*Sigmodon hispidus*) can be infected by the respiratory route and develop evidence of immune suppression (450).

Rats have been used extensively to study the role of the immune response in MV-associated neurologic disease. Acute encephalitis in newborn rats can be modulated by passive transfer of neutralizing antibody to the H protein. Such antibody treatment results in a late onset of disease due to MV that has escaped neutralization by MAb (366). Prior immunization with the H, F, or N protein is protective for adult Lewis rats, and both CD4 and CD8 T cells participate in protection from CNS infection (388,513). Features of subacute disease that are similar to SSPE include an inability to recover virus by routine methods, restricted expression of MV envelope protein mRNAs in the brain and intrathecal synthesis of oligoclonal MV-specific antibody (368,561). Demyelination is not a feature of subacute encephalitis, but demyelinating disease can be more easily induced in previously infected animals (369).

EPIDEMIOLOGY

Classic Measles

In the Absence of Widespread Immunization

The study of island populations has been important in establishing many of the principles of measles epidemiology. The pioneering concepts were formulated by Panum in his observations of the transmissibility, incubation period, and lifelong immunity of measles during the 1846 epidemic in the Faroe Islands (481). These concepts were furthered by the 1883 observations of Hirsch, who noted that an epidemic ends when there are no more susceptible individuals (281).

Measles is one of the most infectious of communicable diseases. It is estimated that 76% of household exposures of susceptible persons leads to measles (286) and that the reproductive number (R_0) or average number of secondary cases produced by an infectious individual in a totally susceptible population, is 15 to 20 (427). In temperate climates, measles is more frequent in the winter and early spring, perhaps related to increased virus survival at low relative humidities (262). Transmission is most efficient through direct exposure to an infected individual, but MV can survive for hours in respiratory droplets, and direct contact is not required (76,171). Individuals are most infectious from 4 to 5 days before through 4 days after the appearance of the rash (76,129).

There is no animal reservoir or evidence of latent or epidemiologically significant persistent infection. Therefore, maintenance of MV in a population requires a continuous supply of susceptible individuals. Because older members of a community are immune through previous exposure to the virus, endemic measles is primarily a disease of childhood. If the population is too small to establish endemic transmission, the virus cannot be maintained (64).

Mathematical calculations and studies of islands and cities with populations of different sizes have shown a requirement for a population of 250,000 to 500,000 to establish measles as an endemic disease (63,334). This is approximately the population of the earliest urban civilizations in ancient Sumer around 3000 B.C., where measles is postulated to have emerged.

In large population centers, measles is endemic with occasional epidemics as the number of susceptible individuals increases. The frequency of epidemics is determined by the numbers of susceptible and immune individuals, the duration of infectiousness, patterns of population mixing, and the contributions of chaos in the system (334,472). The size of the population is also a primary determinant of the age of seroconversion (65). In developing countries with large populations, high birth rates lead to infection at an early age. The average age of infection is earlier in urban than in rural areas in both developed and developing countries (141). In small isolated populations, measles epidemics are controlled by extinction and chance reintroduction of the virus, which leads to infection at older ages on average (129,518).

Effects of Immunization

Immunization has altered the epidemiology of measles by reducing the susceptible individuals in the population, causing

an increase in the average age at infection and a lengthening of the interepidemic period (141). In countries with high rates of immunization, the average age for measles is increased, because herd immunity reduces transmission and indirectly protects children from infection (65). Very young infants are protected from measles (and from response to vaccine) by maternal antibody. The duration of protective antibody in the infant depends on the level of maternal antibody, a primary determinant of the level of antibody in the infant at birth. The source of maternal immunity (vaccine or natural measles) and gestational age at birth are determinants of the amount of antibody passively transferred, and, therefore, the length of time required for initial levels of antibody to decay to the point that an infant will become susceptible to measles (394,480). When outbreaks occur in areas of sustained high vaccine coverage, an increasingly large portion of the cases will be in older individuals who are susceptible because of primary or secondary vaccine failure.

Morbidity and Mortality

Severity of measles in a population is determined by a number of factors. Mortality is highest at the extremes of age, in those with low socioeconomic status, and in those without access to medical care (129,155,532,552). Mortality is also increased in malnourished individuals (39) and in secondary cases in a household, presumably the result of exposure to a higher dose of infecting virus (2,345). High mortality is common when the virus is introduced into virgin populations (129). Susceptibility of these populations is not completely understood, but genetic homogeneity of the populations and infection of many older individuals may be contributing factors (67,129).

Molecular Epidemiology

Sequencing of the H gene or the variable C-terminal portion of the N gene has identified several different lineages of MV that have characteristic temporal and geographic distributions (19,59,524). Some are localized to specific regions of the world and some are extinct, but most are widely distributed. Currently eight distinct clades with several genotypes are recognized (see Fig. 12) (19). Assembly of this increasingly large database of MV genotypes has aided in the identification of measles transmission pathways. Identification of the source of the MV causing disease will become increasingly important as control programs are implemented and identification of cases as imported or indigenous is necessary (59).

Subacute Sclerosing Panencephalitis

Subacute sclerosing panencephalitis occurs preferentially in boys from rural areas with a history of measles at an early age (257,314,424,681). The mean time to onset of SSPE after measles is 7 years (see Fig. 17) (424). There is no clustering of cases to suggest that the virus causing the initial infection is different from the virus causing uncomplicated disease. Several studies have identified exposure to birds as a risk factor, but the relationship to SSPE has not yet been explained (257). The incidence of SSPE has decreased dramatically since introduction of measles immunization, and there is no evidence that the vaccine virus can induce SSPE (424,681).

CLINICAL FEATURES

Classic Measles and Its Complications

Measles has an incubation period of 10 to 14 days, spanning the time from exposure to the appearance of clinical disease (see Fig. 13). The first prodromal symptoms of measles are fever, malaise, and anorexia, followed by cough, coryza, and conjunctivitis. The prodrome lasts 2 to 3 days, and during this time small, bright-red spots with a bluish white speck at the center, Koplik's spots, may become visible on the buccal mucosa, providing early diagnostic evidence of measles (343). The prodrome ends when the rash appears. Characteristically, the rash is maculopapular and appears first on the face and behind the ears and then spreads in a centrifugal fashion to the trunk and extremities. It begins to fade 3 to 4 days after it appears. Generalized involvement of lymphoid tissue may result in lymphadenopathy, mild splenomegaly, and appendicitis (215,335). In uncomplicated measles, clinical recovery begins soon after the appearance of the rash.

Respiratory Disease

The prominent respiratory symptoms are manifestations of diffuse mucosal inflammation in response to widespread infection of epithelial cells. Interstitial pneumonitis resulting from MV replication and inflammation in the lower respiratory tract is common in uncomplicated disease and frequently is detectable only by radiography or by measuring the alveolar–arterial oxygen gradient (238,273,335). Pneumonitis is more likely to be clinically severe during pregnancy (12,167). Symptomatic giant cell pneumonia (see Fig. 2) is seen primarily in immunocompromised individuals (176,200,401,502). Most of the severe pneumonia that complicates measles and leads to chronic pulmonary disease is caused by secondary bacterial and viral infections (52,238,329,430,499). Other common respiratory complications caused by secondary infections are otitis media and laryngotracheobronchitis (26,52,538). In addition to increasing susceptibility to new infections, previous viral and bacterial infections may be reactivated (129,474,599).

Gastrointestinal Disease

Measles virus replication in the liver, particularly in bile duct epithelium, is common in all ages, but clinically evident hepatitis is most frequent in adults (28,216,222,668). Diarrhea is a common complication of measles, particularly in young patients requiring hospitalization (26,237). Many epithelial surfaces are infected with MV and this may lead directly to gastrointestinal symptoms (428). However, diarrhea is frequently associated with secondary bacterial and protozoal infections (237,682). This complication often compounds the borderline nutritional status of young children in developing countries (163,256).

Myocardial Disease

Electrocardiographic abnormalities, including prolongation of the P-R interval, ST-segment, and T wave changes, can be detected in 20% to 30% of children with uncomplicated measles (227). However, symptomatic cardiac disease is uncommon and is most often related to transient conduction abnormalities. Disease may be more severe in immunocompromised individuals, and a fatal case of arteritis has been reported (606). In autopsy studies, myocardial and pericardial lesions are usually attributable to systemic bacterial infections.

Neurologic Disease

There is little evidence that the brain parenchyma is an important target tissue for MV replication during acute disease in immunologically normal individuals (173,425). However, apparently uncomplicated measles is frequently accompanied by a CSF pleocytosis (259,469) and changes in the electroencephalogram (221,259), suggesting the possibility of CNS infection. The occasional appearance of slowly progressive neurologic disease [measles inclusion body encephalitis (MIBE)] in immunosuppressed individuals (438) and the occurrence of late neurologic disease (SSPE) in immunologically normal individuals infected at a young age attests to the ability of MV occasionally to enter the brain and replicate in neurons and glial cells.

ADEM complicates 1 in 1,000 cases of measles, mostly in individuals over the age of 2 years (422). It usually occurs within 2 weeks after the onset of the rash (see Fig. 17) (379). Clinically, the disease is characterized by an abrupt onset of fever and obtundation, accompanied by seizures and multifocal neurologic signs. The majority of surviving patients have neurologic sequelae (322,370). Pathologic studies show that this is a perivenular demyelinating disease, not an inclusion body encephalitis like MIBE and SSPE (Table 2) (379). The pattern of demyelination suggests that it is immunologically mediated (217). There is little evidence for virus in the brain either as assessed directly by virus isolation or by techniques to detect viral antigen or RNA (217,425), or as assessed indirectly by the appearance of MV-specific antibody or MV-induced IFN in the CSF (322,360). There is, however, the induction of an autoimmune response to myelin basic protein (322).

Eye Disease

Measles is considered to be an important cause of childhood blindness. In India, 50% of children with measles had coarse punctate keratitis (512). In many parts of Africa, most childhood blindness is caused by corneal lesions. In areas of vitamin A deficiency, the two problems are synergistic and corneal ulceration resembling keratomalacia is a frequent complication of measles (553).

Determinants of Morbidity and Mortality

Predictors of poor outcome are severe lymphopenia (133) and poor antibody response (657). Measles modified, but not prevented, by previous immunization is associated with lower fever and decreased communicability (170). Mortality associated with measles is most common at the extremes of age and is rarely the result of uncontrolled replication of MV, except in immunocompromised individuals (39,52,425,552). There is high mortality in poor populations, particularly among children under 5 years of age with average case fatality rates in developing countries estimated at 2% to 6% (141). Risk factors for increased mortality are underlying illness, low socioeconomic status, and lack of access to medical care (155,532,552). Malnutrition increases mortality due to measles, and measles in turn increases malnutrition (163,428,552). Malnutrition affects immune responses to MV, impairs virus clearance, and may lead to lower rates of diagnosis (142,159,498). Vitamin A is a particularly important nutrient influencing the outcome of measles (39). Low serum retinol is common in severe measles because of either prior dietary deficiency or impaired mobilization from hepatic stores (77,95).

Atypical Measles

A more severe form of measles, with unusual clinical features, was seen in recipients of an inactivated measles vaccine used in the United States and Europe in the mid 1960s. Atypical measles differs from typical measles by having higher and more prolonged fever, unusual skin lesions, and severe pneumonitis (118,211,441). The rash often is accompanied by evidence of hemorrhage or vesiculation and begins on the extremities and spreads to the trunk. Pneumonitis is associated with distinct nodular parenchymal lesions and hilar adenopathy (238,679). Abdominal pain, hepatic dysfunction, headache, eosinophilia, and edema are also described. Cases of atypical measles have been reported 2 to 13 years after administration of the inactivated vaccine (254,654) and still may be occurring (200). Administration of live virus vaccine after two to three doses of killed vaccine did not eliminate subsequent susceptibility to atypical measles (124) and was often associated with severe local reactions (94,352).

Hypotheses about the pathogenesis of atypical measles included an abnormally intense cellular immune response (210), an inability of the inactivated vaccine to induce local respiratory tract immunity (55), and a lack of production of F antibody, which allowed virus to spread from cell to cell despite the development of anti-H antibody (417,455). In the rhesus macaque model of atypical measles, the formalin-inactivated vaccine induced transient neutralizing and fusion-inhibiting antibodies, but no CTL response. Subsequent infection with MV caused immune complex deposition, vasculitis, and an increase in eosinophils in blood and lungs. Antibody to most proteins appeared earlier than in unimmunized monkeys, suggesting previous priming for a nonprotective type 2 CD4 T-cell and antibody response that resulted in immune complex–mediated disease (496).

Measles in the Immunocompromised Host

Children with hypogammaglobulinemia appear to recover uneventfully from MV infection, whereas those with deficiencies in cellular immune responses may not (232). Two types of progressive disease are recognized in these individuals, giant

cell pneumonia and MIBE, often in the absence of the typical rash or other characteristic features of measles (90,176,401,586).

Giant cell pneumonia was originally described by Hecht in 1910 (269) and is characterized by increasing respiratory insufficiency beginning 2 to 3 weeks after a history of exposure to measles. Giant cell pneumonia is most frequently seen in children with congenital or acquired immunodeficiency but also has been reported in immunosuppressed adults (408). Virus can be isolated from lung tissue (176) and bronchial and nasopharyngeal washings (440). Pathology shows multinucleated epithelial alveolar and bronchiolar giant cells with intranuclear and intracytoplasmic inclusion bodies (23). There is often evidence of systemic disease, with giant cells visualized in multiple organs (23,176).

MIBE occasionally accompanies giant cell pneumonia (327) but is more often present as an isolated primary manifestation of progressive MV infection in immunocompromised individuals (see Table 2). Neurologic disease usually becomes evident 1 to 6 months after exposure to measles (see Fig. 17). Behavioral abnormalities progress to myoclonus, focal seizures, confusion, and coma (438,667). Retinopathy is occasionally present (258). Pathology shows gliosis with inclusions in glial cells and neurons. Giant-cell formation is unusual and little inflammation is present (7). MV can occasionally be recovered from brain, but the virus present is usually defective, as it is in SSPE (7,36,535,667). Viral nucleocapsids without budding particles are seen intracellularly by electron microscopy (7,535). The mRNAs for genes encoding the H, M, and F envelope proteins are reduced, and these proteins are often undetectable (36,114). MIBE may be fundamentally similar to SSPE, but clinical symptoms are manifested earlier after infection and are more rapidly progressive in the absence of an immune response (535).

Subacute Sclerosing Panencephalitis

Subacute sclerosing panencephalitis most commonly occurs in individuals under the age of 20 who present many years after measles, with mental deterioration accompanied by alterations in personality. This is followed by the appearance of myoclonus, characteristic electroencephalographic changes, and progressive neurologic deterioration marked by optic atrophy and akinetic mutism. Death occurs within months to years after onset of the disease (204). Antibody to MV is elevated in both serum and CSF, and inclusions are present in glial cells and neurons (275).

DIAGNOSIS

The classical clinical features of measles—fever, erythematous maculopapular rash, coryza, cough, conjunctivitis, and Koplik's spots—are generally sufficient to make the diagnosis, especially in the setting of a community outbreak. However, not all of these signs and symptoms may be present in measles, and many are shared with other diseases (393). The Centers for Disease Control and Prevention clinical case definition for measles includes: (a) a generalized maculopapular rash of 3 days or more, (b) fever of 38.3°C (101°F), and (c) one of the following: cough, coryza, or conjunctivitis (119). Disease manifestations are particularly likely to be modified, with absence of fever and/or rash, in very young infants, immunocompromised patients, malnourished children, and previously immunized individuals (170,393,498). The differential diagnosis of this clinical picture includes scarlet fever, rubella, parvovirus B19, human herpesvirus-6, human herpesvirus-7, meningococcemia, Kawasaki disease, toxic shock syndrome, dengue, and other causes of rash and fever (69,83,145).

Laboratory diagnostic procedures consist of isolation of virus, direct detection of the virus, viral RNA or viral antigens in secretions, detection of IgM, or low avidity IgG antibody by enzyme immunoassay (EIA) or documentation of seroconversion using HAI, CF, virus neutralization, or IgG-specific EIA on serum taken during the acute and convalescent phases.

Detection of Virus

Virus can be cultured from peripheral blood mononuclear cells, respiratory secretions, conjunctival swabs, and urine, but virus recovery is difficult and rarely used as the sole means of diagnosing acute disease. Cell lines vary in their susceptibility to infection by wild-type isolates, with primary monkey kidney cells, human cord blood leukocytes, and a marmoset B-cell line (B95-8 or B95a cells) being most sensitive (201,342).

Epithelial cells from the nasopharynx, buccal mucosa, conjunctivae, or urine can be used for direct cytologic examination for giant cells and inclusions and for antigen detection (370,589). Generally, the most useful antibody is one directed to N since this protein is most abundant in the infected cell and N antibody reactivity is retained using a wide variety of fixation methods (589). Direct examination for virus is of particular importance for diagnosis in immunocompromised individuals in whom antibody responses may not be present. The detection of MV RNA by RT-PCR using primers targeted to highly conserved regions of the N, M, or F genes has been successfully applied to a variety of clinical samples (184,321,438,582).

Detection of Antibody

The clinical diagnosis of measles is most often confirmed by serology. Samples ideally consist of acute and convalescent serum pairs, but detection of MV-specific IgM in serum or saliva or low avidity IgG in serum is diagnostic and may require only a single sample (83,193,625). IgM antibody appears at the time of the rash and can be detected by 3 days and up to 4 weeks after the onset of the rash in most individuals (271,539). MV-specific IgG peaks approximately 2 weeks after the onset of rash and gradually increases in avidity. EIA allows differential detection of IgM and IgG and is widely used because of its convenience. Plates may be coated with virus or with recombinant MV proteins (81,302). For detection of IgM, use of either the antibody capture method or preremoval of interfering IgG from serum is required for reliable results (624).

The HAI test detects antibody primarily to H and correlates well with the neutralization test (66). The major limitations of the HAI test are the requirement for fresh sensitive monkey erythrocytes, the difficulty of producing sufficient antigen for a

large number of tests, and the possible presence of nonspecific HA inhibitors in serum. The CF test has been used to determine measles immunity (51). These titers are less stable over time, and the test is more difficult to perform and is not in common use currently. The virus plaque reduction neutralization assay remains the gold standard against which other tests are measured. It is more sensitive than HAI or EIA tests (9), and it provides the best correlate for protection from infection (125) and therefore the best measure of response to immunization (1,8).

PREVENTION AND CONTROL

Treatment

There is no standard antiviral treatment for measles. Ribavirin inhibits MV replication *in vitro* (581) and may reduce the severity of symptoms (62). Immunocompromised patients with pneumonitis have shown no clear evidence of improvement after treatment with aerosolized ribavirin, but case reports suggest that intravenous ribavirin may be more efficacious (200,438).

Administration of high doses of vitamin A during acute measles decreases morbidity and mortality even in the absence of clinical evidence of vitamin A deficiency (39,135). In areas of vitamin A deficiency and xerophthalmia, supplementation prevents blindness caused by measles-induced corneal destruction. The World Health Organization (WHO) recommends high-dose vitamin A supplementation for all children with measles in countries where the fatality rate is 1% or more (661).

Numerous therapeutic agents, including amantadine, IFN, isoprinosine, ribavirin, and transfer factor, have been used for the treatment of SSPE. Evaluation of the efficacy of any of these regimens is difficult because the disease is rare, the course is variable, reports are anecdotal, and the benefits are at best short term.

Immunization

History

The earliest attempts at vaccination against measles (by Home in 1749) were based on the principles of variolation (285) with the reasoning that introduction of disease through the skin would lessen the effects on the lung. “Morbillization” was in general unsuccessful (270). Subsequent approaches between 1920 and 1940 designed to inactivate or attenuate the virus by culture in chick embryos also met with limited success (398). The isolation of MV in tissue culture opened the way for a more concerted approach to vaccine development using the Edmonston strain of virus (177). Killed virus vaccines were developed using formalin and TWEEN-ether for viral inactivation (650). Simultaneously, attenuated vaccines based on adaptation of MV to growth in chick cells were developed both in the United States and Russia (332,489). Attenuated live virus vaccine is widely used and has dramatically decreased the incidence of measles in all countries in which it has been effectively delivered (Fig. 18).

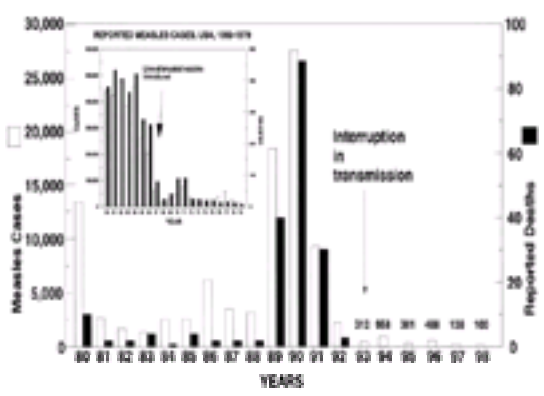

FIG. 18. Reported measles cases and deaths in the United States from 1960 to 1998. *Insert* shows data from 1960 to 1979. *Arrow* indicates documented interruption of indigenous transmission of measles in the United States. (From Centers for Disease Control and Prevention, with permission.)

The immune responses necessary for protection have not been completely defined. Successful live attenuated virus vaccines have been developed for measles (331), rinderpest (495), and canine distemper (531). These vaccines induce both neutralizing antibody and cellular immune responses (479,644). Antibody is sufficient for protection because infants are protected by maternal antibody (8,66). Passive transfer of immune serum can modify or interfere with measles immunization (583a) and partially protects children from measles after exposure. The nature and specificity of the protective antibodies have not been identified, but data from animals immunized with recombinant vaccines suggest that antibody to either H or F is neutralizing and protective (160,676).

Inactivated Vaccines

The inactivated vaccine was alum precipitated and used in a three-dose regimen (104,650). Recipients of these inactivated vaccines developed moderate levels of neutralizing and HAI antibodies and low levels of CF antibody (104,179,190). The vaccine was protective when exposure to measles occurred within several months after immunization (190,209). However, antibody titers declined rapidly, recipients again became susceptible to measles (179,209,509), and when infected they developed the more severe disease, atypical measles (441,509), as discussed previously.

Attenuated Live Virus Vaccines

The first attenuated live measles vaccine was developed by adaptation of the Edmonston strain of MV to chick embryos and subsequently to chick embryo fibroblasts after passage in primary renal and amnion cells to produce the Edmonston B virus (174,333). Inoculation of this virus produced no detectable viremia, and no spread to the respiratory tract or clinical symptoms in monkeys, but it did induce antibody and protected from subsequent challenge. This vaccine was efficacious (356) and licensed in 1963, but it was reactogenic, producing fever and rash in a large proportion of immunized children (331). These reactions could be reduced by giving antibody to MV simultaneously (514). Further passage of the Edmonston B virus in chick embryo fibroblasts by Schwarz produced a more attenuated virus that was licensed in 1965 (567). The Schwarz vaccine currently serves as the standard measles vaccine in much of the World. The Moraten strain used in the United States was licensed in 1968 and is closely related to Schwarz (541). Other Edmonston-derived vaccine strains (e.g., Zagreb, AIK-C) and attenuated strains developed independently of the Edmonston-derived vaccines using similar strategies (e.g., CAM, Leningrad-16, Shanghai-191) are also successful vaccines (280,320,489). The lyophilized vaccine is relatively stable, but the reconstituted vaccine rapidly loses titer at room temperature (415).

The recommended age of immunization has varied from 6 to 15 months and remains a subject of discussion (140,149). The probability of seroconversion and the antibody levels induced are determined by the level of persisting MV-specific maternal antibody and age of the infant (140,213,214). Therefore, the recommended age of immunization is determined by a balance between the optimal age for seroconversion and the probability of acquiring measles before that age. Both parameters show regional variation (140,394,400). In areas where measles remains prevalent, measles immunization is routinely performed at 9 months, whereas in areas with little measles, immunization is often at 12 to 15 months of age. Respiratory routes of immunization have been advocated for younger infants (547) but have proven either unsuccessful or impractical, although they may hold promise for use in older children (139).

Genetic polymorphisms in immune-response genes also affect the likelihood of seroconversion (267,268). The role of common childhood illnesses on seroconversion is unclear (354,420). Any potential decrease in seroconversion must be balanced against the loss of the opportunity for immunization and the consequent risk of the child's acquiring measles. Overall, the efficacy of a single dose of measles vaccine in infancy is estimated at 80% to 95% (250,587).

Similar compromises must be considered with respect to immunizing individuals with human immunodeficiency virus (HIV) infection (431). Progressive fatal infection has been occasionally associated with measles vaccine in severely immunocompromised children and adults. Overall, measles vaccine has been well tolerated in HIV-seropositive children and adults, but the seroconversion rate is lower. Because of the potential severity of measles in these individuals, the vaccine is recommended for routine administration to infants without respect to HIV serostatus in most countries, but it is not recommended for those with known low CD4 T-cell counts.

Administration of standard doses of live attenuated MV vaccine results in transient lymphopenia (196), suppression of delayed-type hypersensitivity skin test responses to recall antigens (196,684), decreases in antigen- and mitogen-stimulated proliferation of lymphocytes (196,283,305,684), and altered cytokine production (283,305,645). Many of these changes occur independent of serologic status (684) and are qualitatively similar to the changes that occur during measles. No evidence has been presented that this alteration of immune responses is clinically important. Adverse reactions are few and consist primarily of allergic reactions.

The dose of MV routinely used for immunization is between 10^3 and 10^4 plaque-forming units. When 10- to 100-fold-higher doses have been used, seroconversion in younger infants (4 to 6 months of age) is improved. However, subsequent follow-up of children receiving high titered vaccines in countries with high childhood mortality showed an increased mortality in girls over the subsequent 2 to 3 years (284,341). Mortality was less than in children who received no measles immunization and was not caused by measles, but rather by a relative increase in the incidence of other infections (3). The pathogenesis of delayed increased mortality after high titered vaccine is not understood but occurred primarily in those who developed a rash after immunization, and it may be related to long-term suppression of immune responses similar to that induced by measles (572,648).

The immune response to the live attenuated vaccine is similar to that induced by natural disease. However, the duration of vaccine-induced immunity appears to be more variable. In general, levels of antibody are lower after immunization than after recovery from natural disease, and these levels decay with time (130,339). Secondary vaccine failure rates have been estimated to be approximately 5% at 10 to 15 years after immunization (402), but they are probably lower when immunization is given after 12 months (17). A second dose of vaccine is recommended to provide an opportunity to immunize persons who missed or did not respond to the first dose (6,141,497). It is not clear that a second dose increases levels of antibody in individuals with waning immunity (130,399). The two-dose strategy has been credited with elimination of indigenous measles in Finland and the United States (120,488).

Experimental Vaccines

Development of new vaccines has been hampered by an incomplete understanding of protective immunity and of the enhanced disease after inactivated vaccine. Nevertheless, a number of experimental vaccines have been developed. The primary motivation for development of a new vaccine is to increase thermostability and to provide a vaccine that can be given to young infants. Immunization with the H, F, and/or N protein expressed in poxvirus, adenovirus, or Bacille Calmette-Guerin (BCG) can protect mice against challenge with MV (191,198,614,663). DNA, peptides, and MV proteins delivered with a variety of carriers can induce cellular and humoral immunity in mice (98,185,265,674). Monkeys are the most relevant challenge model, and initial studies have shown some protection against severe disease with BCG-expressed N (680). Immune stimulating complexes (Iscoms) prepared with MV envelope proteins can induce protective immunity in the presence of passively transferred antibody (634).

Prospects for Eradication

Theoretically, measles is an ideal virus for eradication through immunization: There is only one serotype, most cases are clinically identifiable, there is no animal reservoir, and a vaccine is available (516). In 1979, this was identified as a goal in the United States (516) but only recently has endemic transmission in the United States been interrupted (120). In 1989, the WHO/UNICEF Joint Committee on Health Policy declared control as the first step toward eradication (146). The highly communicable nature of the virus requires continued maintenance of very high immunization coverage to prevent outbreaks, with at least 98% antibody seropositivity needed for herd immunity (65). The role of asymptomatic infection of partially immune individuals in maintaining transmission is unclear (143). Global programs, such as the Expanded Program for Immunization, have increased vaccine coverage worldwide and have resulted in significant decreases in measles and measles mortality (141,471). However, delivery remains difficult in many areas because of civil strife, the need to maintain a cold chain for the vaccine, and the continued inability to immunize young infants. Measles remains a common infection in many parts of the world. Current strategies for eradication focus on delivery of vaccine to large numbers of individuals in a short period of time through mass campaigns (452). Eradication remains a worthy but difficult goal.

CHAPTER 45 Respiratory Syncytial Virus

Peter L. Collins, Robert M. Chanock, and Brian R. Murphy

INTRODUCTION

Human respiratory syncytial virus (RSV) is an enveloped, nonsegmented negative-strand RNA virus. RSV was first isolated in 1956 from a symptomatic laboratory chimpanzee during an outbreak of illness resembling the common cold (282). Shortly thereafter, the same virus was recovered from infants with respiratory illness, and serologic studies indicated that infection in infants and children was common (69). RSV quickly became recognized as the most important viral agent of serious respiratory tract disease in the pediatric population worldwide (14,135,142,197,232,292,320). RSV is receiving increasing recognition as an important agent of disease in the elderly and in bone marrow transplant recipients (108,115,178,416,419) as well as in the general adult population (298).

RSV lacks effective antiviral therapy or an approved vaccine, although effective passive immunoprophylaxis involving administration of RSV-neutralizing antibodies is now available for high-risk individuals (17,153,216). Worldwide, RSV remains one of the pathogens deemed most important for vaccine development (1,157). Its poor growth *in vitro* and instability and the lack of convenient animal models for authentic disease hamper studies with RSV.

CLASSIFICATION

RSV is classified in family *Paramyxoviridae,* order *Mononegavirales* (the nonsegmented negative-strand RNA viruses or mononegaviruses). Members of *Paramyxoviridae* have the following features: (a) the genome is a single strand of negative-sense RNA found exclusively in an RNAse-resistant helical nucleocapsid that also contains the viral polymerase; (b) the genome is transcribed by a sequential stop–restart mode, in which the polymerase is guided by cis-acting signals and produces subgenomic mRNAs; (c) the viral replicative cycle is cytoplasmic; (d) progeny virions acquire a lipid envelope by budding at the plasma membrane; and (e) entry into the host cell is by cell-surface fusion. Members of *Paramyxoviridae* have six genes in common (Fig. 1), encoding the RNA-binding N protein of the nucleocapsid, the nucleocapsid phosphoprotein P, the major polymerase subunit L, the nonglycosylated matrix protein M, an attachment glycoprotein G, H, or HN, and the fusion glycoprotein F. Individual *Paramyxoviridae* members have one to five additional genes that typically encode accessory proteins that enhance growth but usually are not essential.

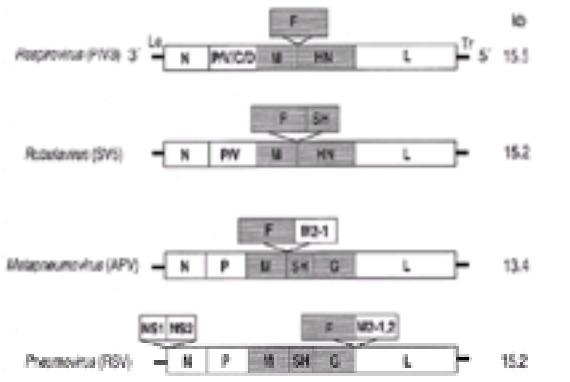

FIG. 1. Comparison of the gene maps of respiratory syncytial virus (RSV) and selected members of family *Paramyxoviridae.* Viruses: human parainfluenza virus type 3 (PIV3) and simian virus 5 (SV5) represent the respirovirus and rubulavirus genera of the Paramyxovirus subfamily, respectively; avian pneumovirus (APV) and RSV represent the

Metapneumovirus and Pneumovirus genera of the Pneumovirus subfamilies, respectively. The gene maps are drawn as 3' to 5' negative-sense genomic RNAs. Each rectangle indicates an encoded mRNA, with the encoded protein(s) identified. The envelope-associated proteins are shaded. Le and Tr, extragenic leader and trailer regions. The gene overlap between the RSV M2 and L genes is not indicated. This comparison illustrates common proteins (N, P, M, F, HN or G, and L) and species-specific proteins (NS1, NS2, SH, M2-1, M2-2), and the gene order difference between genera Pneumovirus and Metapneumovirus. Note the resemblance of the gene orders of APV and SV5.

Paramyxoviridae contains two subfamilies: *Paramyxovirinae,* which includes Sendai, measles, mumps, and Newcastle disease viruses, simian virus 5 (SV5), the human parainfluenza viruses, and others; and *Pneumovirinae,* which is represented by RSV. These subfamilies are referred to hereafter as the paramyxoviruses and the pneumoviruses. Pneumoviruses are distinguished from paramyxoviruses because (a) they are only distantly related by amino acid sequence, sharing low but significant relatedness in F and L proteins and possibly a domain in the N protein (27,65,340,366,371); (b) pneumoviruses encode eight or 10 mRNAs compared with six or seven for paramyxoviruses; (c) pneumoviruses encode additional proteins not found in paramyxoviruses: NS1, NS2, M2-1, and M2-2; (d) pneumoviruses lack RNA editing and do not follow the “rule of six” (see Chapter 41) (355); (e) pneumoviruses lack the V, D, and C proteins found in various paramyxoviruses; and (f) pneumoviruses have an unusual, mucin-like G attachment protein that is distinct structurally from the hemagglutinin–neuraminidase (HN) or hemagglutinin (H) protein of paramyxoviruses.

Pneumovirinae has two genera (see Fig. 1). Genus Pneumovirus contains human RSV as well as bovine, caprine, and ovine RSVs and pneumonia virus of mice (PVM). The second genus, Metapneumovirus, consists of avian pneumovirus (APV, formerly called turkey rhinotracheitis virus). APV differs from the RSV/PVM group on the basis of sequence divergence, the absence of NS1 and NS2 genes, and the difference in gene order for the F and M2 genes.

INFECTIOUS AGENT

Virion

The RSV virion (Fig. 2) consists of a nucleocapsid contained within a lipid envelope. When visualized by negative staining and electron microscopy, virions can appear as irregular spherical particles that range in diameter from 150 to 300 nm, similar to paramyxoviruses. Virion preparations can include a high content of filamentous forms that are 60 to 100 nm in diameter and up to 10 μm in length (Fig. 3) (37,45,347). When RSV virions are irradiated with ultraviolet (UV) light, infectivity is lost with single-hit kinetics (102). Thus regardless of structure, each infectious particle contains a single functional copy of the genome.

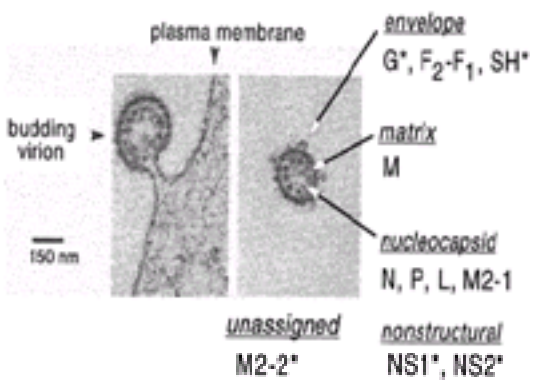

FIG. 2. Electron photomicrographs of a budding (**left**) and free (**right**) virion (from ref. 224) (original magnification, ´132,000), and virion locations of the 11 viral proteins. Note that the NS1, NS2, SH, M2-2, and G genes can each be deleted from viable recombinant virus (*asterisks*) and on that basis encode nonessential accessory proteins. From refs. 36,44,49,382,384, and 420.

FIG. 3. Electron photomicrograph of a cross section of a respiratory syncytial virus (RSV)-infected HeLa cell (from ref. 224, with permission) (original magnification, ´12,800). The changes due to infection include a large cytoplasmic inclusion (*C*), budding particles (*B*), and filamentous particles (*FP*). Microvilli (*arrows*) are not due to the infection.

The envelope consists of a lipid bilayer that is derived from the host plasma membrane. It contains three virally encoded transmembrane surface glycoproteins, the attachment protein G, the fusion protein F, and the small hydrophobic SH protein. There also is a matrix M protein that is thought to form a layer on the inner envelope face. The viral glycoproteins are organized separately into virion “spikes,” which are visualized as short (11–20 nm), closely spaced (intervals of 6 to 10 nm) surface projections. The RSV nucleocapsid is a symmetrical helix similar in appearance to that of the paramyxoviruses, except that the helical diameter is 12 to 15 nm rather than 18 nm.

Pneumoviruses lack a neuraminidase. A hemagglutinin has been reported for a single pneumovirus, involving the G protein of PVM (252). RSV has four nucleocapsid proteins packaged in the virion: the major nucleocapsid protein N, the phosphoprotein P, the antitermination factor M2-1, and the large polymerase subunit L. Polymerase activity has not yet been identified in purified virions, although partially purified nucleocapsids isolated from infected cells direct efficient transcription of the entire genome (23,199).

Proteins

Eleven RSV genes and their encoded proteins have been identified (see Fig. 2 and Table 1), accounting for all of the significant open reading frames (ORFs).

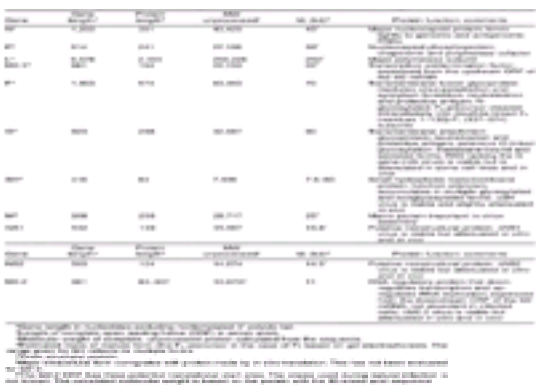

TABLE 1. *RSV genes and their encoded proteins*

Fusion F Protein

The RSV F protein (Fig. 4) directs viral penetration by fusion between the virion envelope and the host cell plasma membrane, delivering the nucleocapsid to the cytoplasm. Later in infection, F protein expressed on the cell surface can mediate fusion with neighboring cells to form syncytia. This is a prominent cytopathic effect and probably is an additional mechanism of viral spread. The pneumovirus and paramyxovirus F proteins are of similar length, are processed similarly, have generally similar structural features, and have a low but significant level of global sequence relatedness (82,366). Like the other F proteins, RSV F appears to form trimers (54). A detailed discussion of their structure and function is provided elsewhere (Chapter 41) (54,66,254).

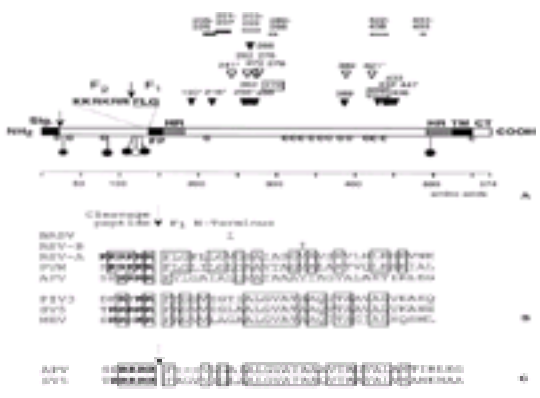

FIG. 4. Structure and antigenic map of the respiratory syncytial virus (RSV) F protein. Hydrophobic domains are *solid:* Sig., signal peptide; FP, fusion peptide; TM, transmembrane anchor. Heptad repeats (HR) are *shaded* (254). *Arrows* identify the cleavage site for the signal peptide and for generation of the F_1 and F_2 subunits: the expanded sequence shows the cleavage peptide (KKRKRR) and the first three amino acids of the FP of F_1 (*FLG*). Cysteine residues (*c*); potential acceptor sites for N-linked carbohydrate that are conserved (*stalk with solid circle*) or not conserved (*stalk with open circle*) among different RSV strains (211). Antigenic map (254): *arrowheads,* amino acid positions of point mutations determined from sequence analysis of monoclonal antibody–resistant mutants (MARMs) of the A2 (*open arrowheads*) (31,99) and Long (*solid arrowheads*) (15,254) strains. Monoclonal antibodies (MAbs) assigned to the following antigenic sites selected the following changes in strain A2: site A, single changes at positions 262, 272, 275, or 276; site B, 389; and site C, double mutations (*asterisks*) at positions 241/421. Position 266 (gray arrow) was identified in a strain A2 MARM selected using a recombinant human antibody fragment (99). MAbs assigned to the following antigenic sites selected the following changes in the Long strain: site I, 389; site II, single mutations at position 262, 268, or 272 or double mutations at 190/258 or 216/262 (*asterisks*); site IV, 429; site V, single changes at 432, 433 or 447; site VI, 436. Sites A and B correspond to II and I, respectively. Many of the site A MAbs have high fusion-inhibition titers, and many of the site A MARMs have a small plaque phenotype (31). Numbers are boxed in cases in which the selecting MAb was shown to be reactive with a short synthetic peptide (of wt sequence) spanning the position. Synthetic peptides (at top): *open boxes*, peptides that reacted with RSV-specific polyclonal antisera and/or MAbs; *solid boxes,* peptides that in

addition induced RSV-neutralizing antibodies (15,93,254,392) **B:** Comparison of the sequences of the cleavage peptide and N-terminus of the F_1 subunit of several pneumoviruses: bovine RSV (BRSV), RSV subgroup A (RSV-A), RSV subgroup B (RSV-B), PVM, and APV, and several paramyxoviruses [human parainfluenza virus type 3 (PIV3), simian virus 5 (SV5), and measles virus (MeV)]. For BRSV and RSV-B, only the assignments that differ from those of RSV-A are shown. *Boxes,* Amino acid assignments conserved among two or more of the indicated pneumoviruses or paramyxoviruses. The basic residues of the cleavage peptide are in *bold*; the cleavage site is indicated with an *arrow,* and the hydrophobic fusion peptide at the N-terminus of the F_1 subunit is *underlined.* **C:** Comparison of the sequences of the cleavage peptide and N-terminus of the F_1 subunit of APV and SV5, with gaps introduced to emphasize amino acid sequence relatedness

The F protein of RSV, like that of the paramyxoviruses, is synthesized as the precursor F_0 that is cleaved by cellular protease in the trans-Golgi compartment or network to yield the disulfide-linked heterodimer F_2–F_1. The cleavage site of the RSV F_0 precursor consists of six tandem Arg and Lys residues, and thus contains the cleavage motif for the cellular furin protease (Arg/Lys-X-Arg/Lys-Arg). The presumption that RSV F_0 is activated by this ubiquitous protease suggests that cleavability is not a limiting factor in RSV tropism or pathogenesis, in contrast to the well-known models of Sendai virus and certain strains of Newcastle disease virus (NDV). Cleavage liberates the hydrophobic “fusion peptide” at the N-terminus of the F_1 subunit, which is thought to be directly involved in membrane insertion. The amino acid sequence of the fusion peptide is not well conserved between paramyxoviruses versus most pneumoviruses (see Fig. 4B), suggesting that its function does not depend on a specific sequence. Somewhat surprisingly, however, the fusion peptide of APV shows considerable similarity to that of SV5 (Fig. 4C; see Animal Pneumoviruses, later).

Expression of RSV F by a recombinant simian virus 40 or a recombinant vesicular stomatitis virus resulted in syncytium formation in cell culture, and the latter virus gained the ability to enter cells by surface fusion (223,309). Thus RSV F can mediate entry and syncytium formation independent of the other RSV proteins. This differs from the situation with most paramyxoviruses, for which both F and its cognate HN attachment protein are necessary for syncytium formation. Although the F protein can mediate syncytium formation by itself, studies with plasmid-expressed proteins in cell culture indicate that coexpression of the G and SH proteins increased the efficiency of syncytium formation (186).

Attachment G Protein

The G glycoprotein (Fig. 5) was identified as the major RSV attachment protein because antibodies specific to G blocked the binding of virions to HeLa cells, whereas antibodies to F prevented fusion but not binding (248,401). Human RSV G is 289 to 299 amino acids in length, depending on the strain, which is only half the size of the HN or H attachment proteins of other paramyxoviruses (572–617 amino acids). The G protein lacks sequence relatedness or structural similarity with the paramyxovirus HN or H proteins, and it is difficult to imagine that they share a common ancestor (214,417). Whereas the HN and H glycoproteins consist of a folded globular head supported on a stalk, the pneumovirus G protein is a heavily glycosylated nonglobular species whose ectodomain has similarities with mucins (see later).

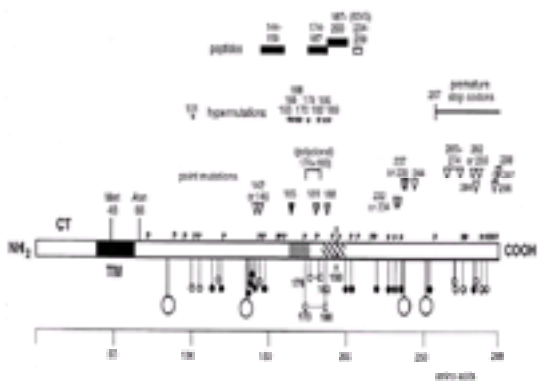

FIG. 5. Structure and antigenic map of the respiratory syncytial virus (RSV) G protein, based on strains A2, Long, and Mon/3/88 of subgroup A. TM, hydrophobic signal anchor (*solid*); CT, cytoplasmic tail. The segment of amino acid sequence that is conserved exactly between the subgroups (amino acids 164–176) is *shaded* (214). A proposed heparin binding site (amino acids 184–198) is *hatched* (123). Potential acceptor sites for carbohydrate (strain A2): serine (*stalks with small circles*) and threonine (*stalks with small solid circles*) residues predicted by sequence context (180) to be acceptor sites for O-glycosylation; potential acceptor sites for N-linked sugars (*stalks with large circles*). (P) Proline residues; (C) conserved cysteine residues, with disulfide bonding indicated (147). Met-48 is the translational start site for the secreted form (348); Asn-66 is its N-terminus after proteolytic trimming (348). The *dotted vertical line* at position 193 marks the site of the largest frame shift that gives rise to viable virus (274); hence the downstream portion of G is nonessential. Antigenic map as determined by sequence analysis of monoclonal antibody–resistant mutants (MARMs) or reactivity of MAbs with synthetic peptides (261,274): Four types of mutations were found in the MARMs: point mutations, premature stop codons, hypermutations, and frame shifts. Point mutations: certain MARMs selected with MAbs to conserved (*solid triangles*), group-specific (*shaded triangles*), or strain-specific (*open triangles*) (see the text) epitopes contained one (or two) amino acid substitutions identified by sequence position. Sometimes resistance to a given MAb was conferred by either of two closely spaced substitutions (i.e., 142 or 145) or two coordinate substitutions (265 + 274). Polyclonal monkey serum selected MARMs containing substitutions at positions 174 and 183 (375). Premature stop codons: certain MARMs, all representing strain-specific MAbs, contained mutations creating termination codons at or after position 257. Hypermutations: mutations were identified in nine different MARMs selected with four different group-specific or conserved MAbs, and those that were present in two or more MARMs are indicated with *asterisks* and identified by sequence position (261, 274, 399). Frame-shifts: MAb 63/G, representing a conserved epitope, selected MARMs containing various frame shifts (not shown, see the text) and bound to a synthetic peptide containing amino

acids 204–209. Synthetic peptides (top): peptide 187–200 induced RSV-specific neutralizing antibodies in rabbits (P.L.C., unpublished data); peptide 144–159 induced RSV-specific neutralizing antibodies in mice but was not protective; peptide 174–187 reacted with RSV-specific polyclonal antisera and MAbs and induced resistance in mice to RSV infection in the absence of detectable RSV-neutralizing serum antibodies (305,391). Peptide 204–209 bound to MAb 63/G, which selected MARMs containing frame-shifts. Note: the amino acid positions of threonine and serine residues depicted here as having O-linked side chains are threonine: 113, 119, 137, 138, 139, 141, 147, 199, 203, 219, 227, 231, 235, 253, and 282; serine: 100, 105, 117, 144, 269, 270, 275, 283, 287, 290.

G is a type II transmembrane glycoprotein with a single hydrophobic region near the N-terminal end (amino acids 38–63 in strain A2) that serves as both an uncleaved signal peptide and a membrane anchor, leaving the C-terminal two thirds of the molecule oriented externally. The G protein also is synthesized as a secreted form that arises from translational initiation at the second AUG in the ORF (amino acid 48), which lies within the signal/anchor (190,348). This truncated species apparently is then trimmed proteolytically, because amino acid sequence analysis of the secreted protein showed that it lacks the N-terminal 65 amino acids of the complete protein, and thus lacks the entire signal/anchor. There also was evidence of a second form lacking the N-terminal 74 amino acids. Secreted G was reported to compose 80% of the G protein released from infected cells 24h post infection. The significance of the secreted form is unclear, although it might function as a decoy to trap RSV-neutralizing antibody, and might influence the immune response (see Antigenic Determinants).

The G protein is heavily glycosylated with N-linked and, especially, O-linked sugars (418) and is palmitylated. Its polypeptide backbone has an M_r of approximately 32 kd. The addition of N-linked sugars increases the M_r to 45 kd. This corresponds to four N-linked side chains, which account for all of the potential acceptor sites in strain A2. The addition of N-linked sugars occurs cotranslationally, and G then assembles into homo-oligomers that probably are trimers or tetramers. The addition of O-linked sugars occurs later in the trans-Golgi compartment or trans-Golgi network, and thus the sugars presumably are added to the exterior surface of the oligomer. Mature G protein migrates in gel electrophoresis as a broad, seemingly heterogeneous band with an M_r of 80 to 90 kd, although less-glycosylated forms of M_r 45 to 80 kd can accumulate in substantial quantity.

The ectodomain of the G protein has a high content of serine and threonine residues (33–35.5%, compared with a data-base average of 13%), which are potential acceptor sites for O-linked sugars. The G ectodomain also has a high content of proline residues (10–13%, compared with a data-base average of 5%), which could contribute to an extended, unfolded secondary structure. These features of amino acid composition, together with the high content of O-linked sugars, also are characteristic of mucins. Mucins are host glycoproteins that form a protective barrier on the respiratory, gastrointestinal, and reproductive tracts.

An engineered F–G chimeric protein expressed by a recombinant baculovirus in insect cells was shown to contain 24 to 25 O-linked side chains of monosaccharides (*N*-acetylgalactosamine) or disaccharides (galactose-b-1-3-*N*-acetylgalactosamine) (410). This probably is a reasonable estimate for the approximate number of side chains in authentic G protein expressed in mammalian cells, although the composition of the side chains in mammalian cells cannot be deduced from the baculovirus material because of differences in carbohydrate processing in insect and mammalian cells. There are more than 70 serine and threonine residues in the G ectodomain, and it is not known which of these are acceptor sites for O-linked sugars. In mucins, O-linked side chains are added to serine or, preferably, threonine residues in regions of exposed and extended secondary structure with a general lack of hydrophobic and bulky residues (180). Figure 5 shows the positions of the 25 sites in the strain A2 G protein that are predicted to be the most likely to contain O-linked sugars.

The extent of G glycosylation varies among different cell lines (134), which probably reflects the existence of a number of *N*-acetyl-galactosaminyl transferases with overlapping but different substrate specificities and tissue distributions. These differences in G-protein glycosylation were shown to be associated with differences in antigenicity. It also is likely that, from molecule to molecule, there is variability in occupancy of O-linked acceptor sites and in the extent of side chain processing. This is suggested by the diffuse appearance of the G protein in gel electrophoresis. The presence of a heterogeneous sheath of host-specified sugars might partially shield this viral antigen from immune recognition.

Among the proteins, G stands out as having a high degree of antigenic and sequence diversity among strains (see Antigenic Subgroups and Diversity, and Table 3). The diversity occurs mainly in the G ectodomain, which has only 44% amino acid identity between the two subgroups, compared with 83% for the transmembrane and cytoplasmic domains. The amino acid sequence positions of potential N-linked and O-linked glycosylation sites also are poorly conserved, although the general locations of the latter are similar. Locations of proline residues are moderately conserved, and the overall hydrophobicity profile is well conserved, suggesting a general conservation of a higher-order organization (214).

Protein	RSV B1[a]	BRSV[b]	PVM[c]	APV[d]

TABLE 3. *Amino acid sequence identity (percentage) between RSV strain A2[a] (subgroup A) and the indicated pneumovirus*

However, one segment of the G protein is highly conserved in human RSV: residues 164 to 176, located midway in the ectodomain. This conserved domain, which is relatively devoid of potential acceptor sites for carbohydrate, overlaps four closely spaced, exactly conserved cysteine residues (positions 173, 176, 182, and 186) and coincides with a tight turn in the predicted secondary structure (214,244). Disulfide linkages occur between Cys^{173} and Cys^{186}, and between Cys^{176} and Cys^{182} (147), resulting in a disulfide-linked tight turn or cystine noose. Several mutant viruses that were selected for resistance to neutralization by certain G-specific monoclonal antibodies (MAbs; Antigenic Determinants) contained substitution of the cysteine residue at position 176, 182 or 186, or at both 182 and 186, showing that these particular cysteine residues are dispensable for virus replication and that either one, or both, of the two disulfide bonds similarly are dispensable (261,274,399). This conserved region is an obvious candidate to be important in attachment activity. In addition, amino acids 184 through 198, a segment that overlaps the cysteine-rich region, was suggested to be a heparin-binding site involved in attachment to cellular glycosaminoglycans (GAGs) (123).

Remarkably, the G protein is not essential for virion assembly and propagation *in vitro* or *in vivo,* although in most cases it enhances viral growth. A biologically derived virus designated B1cp-52, which was recovered after extensive Vero cell passage of the B1 strain of subgroup B, contains a spontaneous deletion of the G and SH genes (227). This virus replicated efficiently in Vero cells, to an intermediate level in cotton rats, and at a very low level in humans. This restricted growth *in vivo* likely is due to the absence of G rather than SH, because deletion of the latter gene alone from recombinant RSV had little effect on replication *in vitro* and *in vivo* (see later) (49,420). Recombinant RSV from which the G gene alone had been deleted (DG virus) has a host-range restriction: it grows efficiently on Vero cells but inefficiently on HEp-2 cells (M. N. Teng and P.L. Collins, unpublished data). One interpretation is that RSV has an alternate, G-independent mechanism of attachment whose efficiency is cell dependent.

Small Hydrophobic SH Protein

SH is a short integral membrane protein that is anchored by a hydrophobic signal-anchor sequence (amino acids 14 to 41) with the C-terminus oriented extracellularly (83). A comparable SH is found in SV5 and mumps virus but not in any other mononegavirus. Intracellularly, SH accumulates in several different forms: SH_0 is an abundant, full-length, nonglycosylated species (M_r 7,500); SH_g (M_r 13,000 to 15,000) contains in addition a single N-linked carbohydrate side chain; SH_p (M_r 21,000 to 60,000 or more) has an N-linked side chain that has been further modified by the addition of polylactosaminoglycan; and SH_t (M_r 4,800) is a nonglycosylated species that is derived from initiation at the second methionyl codon (Met-23) in the ORF. All forms associate into oligomers, which appear to be at least pentamers on the basis of chemical cross-linking (83). SH_0 and SH_p are the predominant forms in virions. This complex processing pathway is conserved among human and bovine strains, but the significance of the multiple forms and the polylactosamine is unknown.

Recombinant RSV from which the SH gene has been deleted (DSH virus) is fully viable in cell culture (49). Indeed, it formed larger plaques and had a modest growth advantage in certain cell lines, which might reflect the shorter genome length or smaller number of genes to transcribe. The DSH virus was fully competent for syncytium formation *in vitro. In vivo,* it was attenuated in the upper, but not the lower, respiratory tract of mice, and was slightly attenuated at both sites in chimpanzees (49,420). Thus, remarkably, the absence of the SH protein has little apparent consequence for infectivity *in vitro* or *in vivo.*

The function of the SH protein remains unknown. The SH protein had essentially no effect on the efficiency of formation and passage of RSV virus-like particles generated in cell culture from plasmid-expressed components (382). Syncytium formation using plasmid-expressed G, F, and SH was the most efficient when all three proteins were present (186), suggesting that SH enhanced the function(s) of one or both of the other two glycoproteins. Expression of the SH protein in bacteria increased cell permeability to small-molecular-weight compounds, an activity that seemed to be more specific than simply a consequence of the protein's being membrane associated (324). This suggested that the SH protein forms membrane channels, perhaps analogous to the M2 protein of influenza A virus. However, it is unclear what role such an activity would play for RSV.

Matrix Protein M

The RSV M protein, a nonglycosylated inner virion protein, is smaller than its paramyxovirus counterparts (256 amino acids vs. 335–375 amino acids) and lacks unambiguous sequence relatedness with these other M proteins. The M proteins do have the common feature of a hydrophobic domain in the C-terminal half of the molecule, which might mediate interaction with membrane.

The M protein of mononegaviruses is thought to have two general functions: rendering the nucleocapsid transcriptionally inactive before packaging, and mediating association of the nucleocapsid with the nascent envelope. In a reconstituted minigenome system (see Genetics and Reverse Genetics), coexpression of the RSV M protein did not inhibit RNA replication or transcription (unpublished data), suggesting that it does not function in this manner. However, M was confirmed to play an important role in the formation of virus-like particles (382).

Nucleocapsid/Polymerase Proteins N, P, M2-1, and L

The RSV N, P and L proteins copurify with nucleocapsids and are present in dense cytoplasmic inclusion bodies that are

thought to contain nucleocapsids (see Fig. 3) (133). RSV N (391 amino acids) is smaller than its paramyxovirus counterparts (489–553 amino acids). Sequence alignments of RSV N with the N-terminal 400 amino acids of the N proteins of other mononegaviruses identified three segments of similar sequence and predicted secondary structure (27). The N protein binds tightly to genomic and antigenomic RNA to form an RNAse-resistant nucleocapsid.

The RSV P protein (241 amino acids) is the major phosphorylated species. It is smaller than its paramyxovirus counterparts (391–602 amino acids). Like other mononegavirus P proteins, RSV P appears to function as a chaperonin for soluble N. This is illustrated by the observations that N expressed alone forms large aggregates and is inactive in encapsidating minigenome RNA, whereas N and P expressed together are sufficient for minigenome encapsidation (18,122). In addition, soluble N and P form stable complexes that can be immunoprecipitated.

Approximately 80% of the phosphorylation of P in RSV-infected cells involves Ser-232, and almost all the remainder involves Ser-116, Ser-117, Ser-119, and Ser-237 (25,356). Ser-232 and Ser-237 are in consensus motifs for cellular caseine kinase 2 and can be phosphorylated by this enzyme *in vitro.* However, this kinase alone did not reproduce exactly the *in vivo* labeling pattern, indicating that other kinases or factors are involved (25). Most of the phosphate of P was not essential for intracellular viral transcription and replication in a minigenome system (396). However, bacterially expressed P protein was inactive for transcription in a reconstituted *in vitro* system unless it was phosphorylated first (25). This illustrates that P also functions as a polymerase cofactor and must be phosphorylated to be functional. Polymerase reconstituted with unphosphorylated P protein produced a series of short oligonucleotide transcripts from the 3' end of the genome (106), suggesting that one of the functions of phosphorylated P is to convert newly initiated polymerase into a stable complex.

The RSV L protein is very similar in size to its rhabdovirus and paramyxovirus counterparts and contains six discrete segments that contain highly conserved residues and presumably represent polymerase motifs (371). RSV L is thought to be a close functional counterpart to the L proteins of paramyxoviruses and other mononegaviruses.

The M2-1 protein is encoded by the 5'-proximal ORF of the M2 mRNA (81). M2-1 was initially thought to be a second matrix protein but is now known to be a transcription antitermination factor that is essential for viral viability (77,80,120,181,182). Consistent with this nucleocapsid function, M2-1 can bind to the N protein, and intracellular M2-1 colocalizes with N and P in the previously mentioned cytoplasmic inclusion bodies (133). M2-1 contains a cysteine–histidine zinc finger motif near its amino-terminus that is essential to its antitermination function (183). Gel electrophoresis of M2-1 from RSV-infected cells revealed at least two electrophoretically distinct species, and the one migrating more slowly was phosphorylated (183).

N, P, and L are the viral proteins necessary and sufficient for RNA replication (80,154,433). N, P, and L also can direct transcription, but full processivity requires in addition the M2-1 protein. On a minigenome mimicking the 3' end of the genome, polymerase in the absence of M2-1 could efficiently transcribe only the NS1 and NS2 genes (120). When the M2-1 protein was coexpressed, transcription of NS1 and NS2 increased severalfold, and transcription of downstream genes occurred. M2-1 also increases the frequency of readthrough at gene-end (GE) transcription termination signals, and hence has a site-specific antitermination activity (120,181,182). Paramyxoviruses do not have a counterpart to M2-1, although the filovirus VP30 might be similar.

Nonstructural Proteins NS1 and NS2

NS1 and NS2 are detected in only trace amounts in preparations of purified virions and hence are considered nonstructural. This assignment is provisional because the RSV virion is difficult to purify and analyze. The NS1 protein has been shown to coprecipitate with the M protein (110), whereas the NS2 protein colocalizes in cells with the N protein (413) but does not coprecipitate with any viral protein (110). The NS2 protein is unstable, with a half-life in infected cells of approximately 30 minutes (110). Both proteins have been reported to form homo-oligomers (110).

In a minireplicon system complemented by plasmid-supplied support proteins, expression of NS1 was strongly inhibitory to transcription and RNA replication (18). NS2 also was somewhat inhibitory to both processes, but only at relatively high levels of expressed protein. This suggested that NS1, at least, might serve some role in RNA synthesis. NS1 and NS2, singly or together, do not appear to have an important role in the assembly or passage of virus-like particles (382).

Deletion of NS1 or NS2 alone from recombinant RSV attenuated virus growth *in vitro* and *in vivo,* and deletion of both together had an additive effect (44,383,384,420). Thus these proteins enhance growth but are not essential. Viruses lacking either or both NS1 and NS2 appear to be somewhat delayed in the accumulation of viral RNA and protein, but their roles in the viral replicative cycle remain to be defined. The V and C accessory proteins of certain paramyxoviruses have recently been shown to be pathogenesis factors *in vivo* (see Chapter 41), and also have been shown to function as antagonists of the interferon system. This raises the possibility that NS1, NS2, or any other of the RSV accessory proteins might have similar roles, or might interact with the host in some other manner. However, interferon effects alone cannot account entirely for the reduced replication of the DNS1, DNS2, or DNS1NS2 viruses *in vitro*, because this phenotype is seen in Vero cells, which lack the interferon a and b structural genes.

M2-2 Regulatory Factor

The M2 mRNA has two ORFs: the M2-1 ORF is 5'-proximal (nucleotides 10–594) in the mRNA, and the M2-2 ORF is downstream (nucleotides 563–835) and slightly overlaps the first (81). The two ORFs encode separate proteins, the 22-kd M2-1 protein and the 11-kd M2-2 protein (3,81). The M2-2 ORF is expressed by a translational termination–reinitiation mechanism. Specifically, ribosomes that complete the translation of the M2-1 ORF can reinitiate at the M2-2 ORF at any one of three (for strain A2) closely spaced AUG codons located slightly upsteam of the M2-1 termination codon (3). The abundance of the M2-2 protein in infected cells is low but increases throughout infection (2). Expression of the M2-2 gene can be ablated in recombinant virus, indicating that it is not an essential gene (36,207). The DM2-2 virus grew more slowly in HEp-2 cells than did wild-type (wt) virus, although it eventually reached a titer that was

reduced only 10-fold. Transcription by the DM2-2 virus was increased, and RNA replication was reduced compared with that of wt virus, indicating that M2-2 has a role in regulating RNA synthesis (see Replicative Cycle, later). When virus-like particles were assembled from plasmid-expressed RNA and protein, coexpression of M2-2 stimulated the production of virus-like particles severalfold (382). It is possible that, by inhibiting transcription, M2-2 depletes the genome of nascent RNAs in preparation for packaging into virions. A comparable function has been ascribed to the matrix M protein in other mononegaviruses. The DM2-2 virus was very attenuated in rodents and chimpanzees, although the virus did replicate and stimulated a strongly protective immune response (207,384).

Viral RNAs and Cis-Acting Elements

Table 2 lists the pneumoviruses for which complete genomic RNA sequences are available. The map of RSV genomic RNA is shown in Fig. 6. Antigenomic RNA, the intermediate in RNA replication, is an exact complementary copy of genomic RNA. Genomic and antigenomic RNAs are neither capped nor polyadenylated, and both are tightly associated with the N protein to form RNAse-resistant nucleocapsids. Most (90%) of genomic RNA is accounted for by the ORFs for the 11 major proteins, and less than 3% constitutes the cis-acting signals described later.

Virus	Genome length	GenBank/ accession no.	Reference
RSV strain A2 (subgroup A)	15,222[a]	M74568	79
RSV strain S2 (subgroup A)	15,150	J138402	366

TABLE 2. *Sequences of pneumovirus genomic RNA*

FIG. 6. Respiratory syncytial virus (RSV) genomic RNA (strain A2). **A:** Map of RSV genomic RNA, 3' to 5' (not to scale). The *large boxes* underneath show details of the structures of the gene junctions and 68-nt gene overlap. Nucleotide lengths are indicated. In the gene-start and gene-end signals, in cases of more than one possible nucleotide assignment at a given position, the more frequent is given uppermost. **B:** Sequences of the 3' ends of the genomic and antigenomic RNAs. *Double dots,* nucleotide identity. *Asterisk,* position 4, where substitution of C in place of G increases replication and improves recovery of recombinant virus (79,208).

RSV encodes 10 major subgenomic mRNAs. Each contains a single major ORF except for M2, which contains the M2-1 and M2-2 ORFs, as already mentioned. The RSV mRNAs are capped at the 5' end with the structure $m^7G(5')ppp(5')Gp$ (24) and are polyadenylated at the 3' end. Both modifications are thought to be mediated by the viral polymerase. Transcription also generates readthrough mRNAs because of inefficient termination at the various genes. These readthrough mRNAs are exact copies of two or more adjacent genes and their intervening intergenic regions and account for approximately 10% of total mRNA. Only the upstream ORF of a readthrough mRNA would be expected to be expressed efficiently, given the general inefficiency of eukaryotic ribosomes for initiation at internal ORFs, and so readthough has the effect of reducing the amount of translatable mRNA of each downstream gene represented in the particular readthrough mRNA.

Each gene begins with a 10-nucleotide gene-start (GS) signal 3'-CCCCGUUUA(U/C) that is highly conserved except for the L gene, which has the somewhat divergent signal 3'-CCC**U**GUUU**U**A (differences underlined). These differences do not appear to have any functional significance (240). Synthesis of each mRNA initiates at the first nucleotide of the signal. Each gene terminates with a semiconserved 12- to 13-nucleotide gene-end (GE) signal (see Fig. 6A) that directs polyadenylation and release of the completed mRNA (78,240,241). Studies with model minireplicons and recombinant viruses indicate that the GS and GE signals are independent, circumscribed signals that are largely independent of the nature of the adjacent sequences (47,48,240,241).

The first nine RSV genes are separated by intergenic regions that range in length from one to 56 nucleotides among the available sequenced strains (78,210). The intergenic regions lack consensus sequence motifs or any obvious features of secondary structure and are not well conserved among strains, although regions that are short (such as N/P) or long

(such as F/M2) in the prototype A2 strain tend to be so in other strains. The last two RSV genes, M2 and L, overlap by 68 nucleotides (84,119). Thus the GS signal of the L gene is located inside of, rather than after, the M2 gene. By this arrangement, the 68-nucleotide overlap sequence is transcribed twice, once during synthesis of the M2 mRNA, and a second time during the synthesis of the L mRNA. Overlapping genes in nonsegmented negative-strand viruses have also now been described for filoviruses, Borna disease virus, and certain rhabdoviruses.

The 3' ends of genomic and antigenomic RNA are 81% identical for the first 24 to 26 nucleotides, after which relatedness is insignificant (see Fig. 6B). This appears to represent the major element of a conserved promoter (121). Analysis of the promoter requirements in genomic RNA showed that the sequence required for efficient RNA replication (synthesis of antigenome) was contained within the first 25 nt, whereas transcription required the first 15 nucleotides as well as the GS signal of the first gene (121) (R. Fearns and P. Collins, unpublished data). The spacing of the GS signal relative to the 3' end was important, implying that initiation of transcription involves simultaneous contact between the 3'-terminal sequence and the GS signal (121).

REPLICATIVE CYCLE

Attachment and Entry

Recent studies showed that the RSV G protein binds to certain cellular GAGs, which are long unbranched polysaccharides of the extracellular matrix that consist of repeating disaccharide subunits (123,176). GAGs have been shown to be involved in interactions between cells and various viruses and other pathogens. The RSV G protein appears to bind to GAGs containing the disaccharides heparan sulfate and chondroitin sulfate B. On the one hand, this might occur by electrostatic interaction between the negatively charged GAGs and basic residues in G (123), but other work suggests that a specific GAG component, the monosaccharide iduronic acid, is important, implying a greater specificity for binding (176). It is possible that the interaction between G and cellular GAGs is the attachment step, or it might be an initial contact that is followed by a second binding step involving one or more of the three RSV surface proteins. As mentioned earlier, the biologically derived B1 cp-52 virus that lacks the G and SH genes, or recombinant RSV that lacks the G gene, can grow efficiently in Vero cells and, to a lesser extent, *in vivo.* This implies that that the remaining surface protein, F, can mediate attachment and might represent either an alternative mechanism or a second step. Although G is dispensable *in vitro,* it clearly is important for efficient infection *in vivo.*

RSV enters the cell by fusion at the plasma membrane rather than by endocytosis (369). In cell culture, the initiation of fusion by adsorbed virions appeared to be a slow step but, once started, the process was rapid (19,247). RSV fusion is inhibited below 18°C, and is efficient over a pH range of 5.5 to 8.5 (369).

The RSV F protein was recently shown to bind to the cellular protein RhoA, a small guanosine triphosphatase (GTPase) of the Ras superfamily (321,322). This interaction involves amino acids 146 to 155 in F and amino acids 67 to 110 in RhoA. A peptide containing part of this RhoA domain inhibited RSV replication *in vitro* and in the respiratory tract of mice (322), presumably by saturating the F protein of the virus. These findings suggested that RhoA might function as a receptor for the F protein, although protein-binding studies and inhibition of viral infectivity with a synthetic peptide should be interpreted with caution. Furthermore, although RhoA can associate with the inner face of the plasma membrane, it probably is not exposed extracellularly, and it is unclear how it could function as a viral receptor. Alternatively, an association between F and RhoA might be part of viral penetration. RhoA also might play a role in RSV infection through its signaling function. RhoA controls a wide array of cellular activities, including reorganization of the cytoskeleton and changes in cell morphology, adhesion, contractile responses, proliferation, and gene expression. Thus RhoA has the potential to trigger a variety of cellular responses of potential importance to virus infection, pathogenicity, and immunobiology.

All events in the RSV replicative cycle occur in the cytoplasm without nuclear involvement, and the virus can grow in enucleated cells. RSV infection results in the formation of dense cytoplasmic inclusions that appear to consist of nucleocapsids (see Fig. 3).

RNA Synthesis and Regulation

RSV transcription and replication have general similarities with the simpler prototype mononegaviruses Sendai virus and vesicular stomatitis virus (see Chapter 38 and Chapter 41). Important distinctions are that, as noted earlier, RSV transcription involves the M2-1 antitermination protein, and regulation of RNA synthesis involves the M2-2 protein and possibly the NS1 protein. RSV transcription also requires the cellular proteins actin and profilin (50,51).

UV mapping experiments confirmed that the RSV genes are transcribed by a sequential fashion from the 3' end (102). Studies with minireplicons confirmed that the polymerase does not enter the genome at internal genes (119,241).

As with all mononegaviruses, there is a polar transcription gradient such that promoter-proximal genes are transcribed more frequently than are downstream genes (85). This is the major control of gene expression. The efficiency of transcriptional stop–restart appears to vary modestly among the various RSV gene junctions, providing a second level of regulation of gene expression (181,240). Somewhat unexpectedly, this does not seem to be due to the heterogeneous intergenic regions, because they were functionally indistinguishable in a minigenome system, and deletion of the intergenic region altogether also did not affect the efficiency of transcription stop–restart (239). The conserved nature of the GS signals makes them unlikely to account for gene-specific differences in expression. The GE signals are more diverse and could be responsible for the gene-specific differences. Indeed, the NS1 and NS2 GE signals were shown to be less efficient than the others for termination and production of monocistronic mRNA (240). The basis of the effects of the different gene junctions on termination, readthrough, and reinitiation remains to be characterized fully. Gene length also appears to play a role in gene expression, because the very large L mRNA is much less abundant than the others (85). This difference might occur at the level of synthesis or stability of this large mRNA.

Minigenome experiments suggested that the M2-1 protein can reduce the gradient of transcription in a concentration-dependent fashion, increasing the efficiency of expression of downstream genes. This could occur because of its role in promoting processive transcription, as well as its role in increasing transcription across gene junctions (120,181,182). However, it is not clear whether putative regulation occurs during virus infection.

The overlap between the M2 and L genes mentioned earlier places the M2 GE signal within the L gene, 57 to 68 nucleotides from its start (84). Analysis of mRNAs synthesized during RSV infection showed that, consistent with the function of a GE signal, approximately 90% of the L gene transcripts terminate at this site to produce a short polyadenylated RNA containing the first 68 nucleotides of the L mRNA. The synthesis of full-length L mRNA thus depends on transcriptional readthrough. This illustrates one instance in which this presumed polymerase "error," readthrough at a GE signal, is necessary for the synthesis of an essential mRNA. It remains to be determined whether the efficiency of synthesis of full-length L can be increased by an increased level of M2-1 protein. Mutational analysis of a minireplicon confirmed that the overlapped gene is transcribed by sequential transcription (rather than independent polymerase entry) (119). These studies showed that, to access the L GS signal, the polymerase must first transcribe the M2 gene in its entirety and arrive at the M2 GE signal. It apparently then backtracks to the L GS signal. Indeed, the polymerase was found to be capable of reinitiating at a nearby GS signal inserted either upstream or downstream, indicating that it can scan in either direction. In the naturally occurring overlap, only the GE and GS signals appeared to be essential. The ability of the polymerase to backtrack also explains why L gene transcription is not strongly attenuated by the overlap: prematurely terminated polymerase can recycle back to the L GS signal.

Antigenomic RNA, the positive-sense replicative intermediate, is 10- to 20-fold less abundant intracellularly than genomic RNA. The two RNAs are present in virion preparations in this same proportion, implying a lack of discrimination in packaging. The synthesis of genomic and antigenomic RNAs is dependent on ongoing protein synthesis (200), probably reflecting a need for cosynthetic encapsidation. For paramyxoviruses and rhabdoviruses, cosynthetic encapsidation is thought to mediate a switch from transcription to RNA replication. However, studies with a minigenome system suggest that RSV transcription and RNA replication are not controlled by the intracellular levels of N and P protein (122). Recombinant DM2-2 virus exhibited an increase in transcription and decrease in RNA replication (36). Relative to the level of genomic RNA template, transcription was increased seven- to 18-fold. It was suggested that the intracellular concentration of M2-2 mediates a switch from transcription to RNA replication. When M2-2 is low early in infection, transcription occurs at a high level. As the level of M2-2 increases, transcription is inhibited, and replication is favored. This would be consistent with the requirements for virion formation: the early period of transcription results in high levels of viral mRNAs that are stable and continue to be translated, and the shift to replication provides progeny genome for packaging. Thus RSV is proposed to have temporal regulation of RNA synthesis involving a switch from transcription to replication mediated by a downstream product of transcription.

The expression of certain RSV genes might also be controlled at the level of translation. For example, the SH mRNA is in a suboptimal context for ribosome initiation. In addition, the first AUG codon in the G mRNA initiates a short ORF that overlaps the one for the G protein and might have the role of diverting ribosomes and down-regulating G synthesis.

RSV mRNAs and proteins can first be detected intracellularly by 4 to 6 hours after infection. The synthesis of ORF peaks at approximately 12 to 16 hours after infection and then levels off, whereas synthesis of proteins peaks at approximately 18 to 20 hours. Progeny virus can be detected as early as 8 to 10 hours after infection and reaches a peak after 24 hours. RSV has little effect on cellular macromolecular synthesis: cellular DNA and RNA synthesis diminish beginning after 11 hours after infection and are approximately halved by 18 hours, whereas protein synthesis is little affected (249). The amount of RSV macromolecular synthesis is much less than that of some of the prototype RNA viruses such as vesicular stomatitis virus but nonetheless is considerable. At the peak of protein synthesis, the major viral species can readily be detected by pulse labeling and direct electrophoretic analysis. Under optimal conditions, the more abundant viral proteins can be detected faintly among the electrophoretic pattern of total cell proteins by direct protein staining.

Virion Morphogenesis

Video microscopy showed that RSV virion maturation occurs within circumscribed regions on the cell surface, which might reflect a clustering of virus components or a dependence of budding on localized subcellular structures (19). Budding appeared to be the reverse of penetration, implying a common mechanism of membrane flow. Nascent virions also could be observed on occasion to fuse back with the host cell. Budding into intracellular vesicles also has been reported (16). The efficient replication *in vitro* of the B1cp-52 virus, lacking the G and SH genes, and of the DSH and DG recombinant viruses, indicates that F is the only viral transmembrane envelope protein required for efficient virion formation. Virus budding in polarized cells occurs at the apical surface (347), which *in vivo* might reduce systemic dissemination of the virus from the epithelium of the respiratory tract. Disruption of cellular actin filaments drastically reduced the production of infectious virus, implying a role for the cytoskeleton in assembly (50).

GENETICS AND REVERSE GENETICS

The frequency of isolation of MAb-resistant mutants (MARMs), selected with various MAbs specific to the F protein, was estimated to be 10^{-4} to 10^{-6}, which is similar to that observed with other RNA viruses (31). The actual mutation rate likely is higher, because lethal mutations would not have been recovered. Other information on the stability of RSV *in vitro* was obtained from studies designed to produce live-attenuated vaccines. In one study, 52 passages of strain A2 at progressively lower temperatures resulted in a cold-passaged (cp) RSV that had acquired only five point mutations (128,424). Detailed characterization of six temperature-sensitive (ts) attenuated mutants generated by chemical mutagenesis and biologic selection identified in each a single unique point mutation responsible for the ts and attenuation phenotype. One mutant also contained a single additional amino acid change that did not contribute to the ts or attenuation phenotype, and hence the introduction of incidental mutations into infectious virus was surprisingly rare (86,124,221,222,421,422).

The spontaneous deletion of the SH and G genes during *in vitro* passage, resulting in the B1 cp-52 virus, has already been mentioned (227). Interestingly, there was evidence for multiple independent deletion events in the virus population involving these two genes. Deletion of SH and G during this particular passage series presumably could be accommodated because neither gene is required for efficient growth in Vero cells, as mentioned previously. This propensity to delete G is puzzling because studies with recombinant RSV showed that inserts of foreign sequence are surprisingly stable, as has been found with other mononegaviruses (47,48). Point mutations accumulate in inserted foreign sequence at a low rate over multiple cycles of replication, but there was no evidence of deletion, and functional foreign protein was expressed by most recombinant RSV plaque isolates even after multiple passages.

Other types of unusual mutations also have been observed in RSV subjected to strong selective pressure *in vitro.* For example, multiple point mutations have been described in the NS2 or G genes that apparently were acquired by biased hypermutation (261,383). The finding that strain variation involves a disproportionately high frequency of A to G changes has been suggested to be evidence of hypermutation in nature (263). Frame shifting can occur at several A-rich sequences in the downstream half of the G gene, which accesses an alternative ORF. This has been detected by analysis of cloned cDNAs of viral RNA from infected cells (57), and also was identified in certain MARMs isolated *in vitro* (261) (see Antigenic Determinants). A single natural isolate had suggestive evidence of having sustained a frame shift (376), suggesting that this can occur in nature but is not common. The alternative ORF that is accessed by frame shifting is not thought to encode a functional domain. Other MARMs contained premature stop codons in the downstream end of the G ORF, and this might also occur in nature because certain natural isolates contain small C-terminal deletions (58,376). It is likely that these unusual types of mutations can be found in G because its structure is relatively tolerant of mutation.

Homologous recombination is not known to occur. Thus far, defective-interfering RSV genomes similar to those of other model mononegaviruses such as Sendai and vesicular stomatitis viruses have not been identified by molecular analysis, although there is indirect evidence for their existence (389).

Studies with RSV and mononegaviruses in general have been revolutionized by “reverse genetics,” by which complete infectious recombinant virus can be recovered from cDNA. The production of recombinant RSV requires the intracellular coexpression, from transfected plasmids, of antigenomic RNA and the N, P, L, and M2-1 support proteins (44,77,79,208). The requirement for M2-1 as a fourth support protein distinguishes RSV from the paramyxoviruses (77). This defined for the first time a correct sequence for wt RSV, and provided the means to introduce predetermined changes into infectious virus via the cDNA intermediate.

A second type of reverse genetic system involves minireplicons, which are short cDNA-encoded versions of genomic or antigenomic RNA in which some or all of the viral genes have been deleted and replaced with one or more genes encoding marker proteins such as bacterial chloramphenicol acetyl transferase or luciferase. Minireplicons usually do not contain the genes necessary for their own replication and must be complemented by viral proteins provided by cotransfected plasmids or by coinfecting standard RSV. They are useful because it is easier to perform extensive mutational and biochemical analyses with a short replicon containing only one or a few genes instead of the complete genome. The fact that the minireplicon and support proteins are encoded by separate plasmids also means that each component can be manipulated separately without affecting the synthesis of the others.

ANTIGENIC SUBGROUPS AND DIVERSITY

RSV exists as a single serotype but has two antigenic subgroups, A and B. Antigenic dimorphism among RSV strains was recognized initially by a three- to four-fold reciprocal difference in neutralization between the A2 and 18537 strains, now known to represent the two subgroups (74). Subsequent analysis of strains recovered over the past 30 years using murine MAbs indicated that isolates resembled either the A2 strain (subgroup A) or the 18537 strain (subgroup B) (10,11,192,286). Antigenic dimorphism is most evident with MAbs against the G glycoprotein. The antigenic relatedness between the two subgroups also was investigated by analysis of postinfection polyclonal antibody responses in cotton rats and infants by enzyme-linked immunosorbent assay (ELISA) with purified F or G glycoproteins. This indicated that the two subgroups are 25% related antigenically overall, with the F proteins being 50% related and the G proteins 1% to 7% related (191,213). Subgroup A strains are often thought to be associated with more severe disease (402), but in some studies, subgroup B strains appeared more virulent (198). Subgroup B viruses also replicate less well in mice and chimpanzees. The existence of antigenic heterogeneity might be a factor in the ability of RSV to reinfect (see Epidemiology).

The complete genomic RNA sequences of strains A2 and B1 of subgroups A and B have 81% nucleotide identity. As might be expected, cis-acting signals such as the genomic termini and the GS and GE signals tend to be highly conserved (90–100% nucleotide identity), whereas intergenic and noncoding gene regions are relatively more divergent (32–50% nucleotide identity) (210). The different proteins vary considerably in the extent of sequence divergence between the subgroups (Table 3). Divergence is greatest in the ectodomains of the SH and G proteins, which retain only 50% and 44% sequence identity between subgroups. The global nature of the sequence differences indicates that the two subgroups represent two lines of divergent evolution, rather than being variants that differ only at a few major antigenic sites. Within subgroups, the percentage nucleotide and amino acid identity between viruses is much higher, but otherwise follows the same pattern with regard to regions of relatively greater or lesser divergence (214,386). Within a subgroup, amino acid sequence divergence in the G protein can be as high as 20% between strains (132,376). Distinct lineages within each subgroup have been identified and shown to cocirculate during epidemics and to have broad geographic distribution (56,58,75,132,263).

During the past three decades, the two subgroups have been relatively stable antigenically and have cocirculated in most yearly epidemics studied, with subgroup A usually predominating (75,175,192,284,394). Analysis of 18 subgroup A strains and five subgroup B strains recovered from geographically diverse regions over a period of 30 years using F-specific murine MAbs that defined four antigenic sites with a total of 16 separate neutralization epitopes indicated that

seven epitopes were conserved in all but one of the strains (31). An additional unique epitope that is defined by a human RSV-neutralizing antibody Fab selected from a phage-display library also was conserved in every one of 19 RSV isolates recovered over a 30-year period from diverse locations (99). These observations indicate that subgroup divergence in protective antigenic regions on the F glycoprotein has been neither extensive nor rapid. It did not appear that mutations that confer escape from host immunity accumulated with time. Thus, if the RSV F protein undergoes antigenic drift, it does so on a much longer time scale than is the case for influenza A virus.

The G protein gene also has been examined for evidence of progressive antigenic changes. The G ectodomain is unusual because a high percentage (51–58%) of the nucleotide differences in its coding sequence within or between the two subgroup strains result in amino acid sequence changes, compared with values of 10% to 22% observed for other RSV proteins (212,263). Whereas synonymous nucleotide changes (silent at the amino acid level) in the G gene were evenly distributed, the nonsynonymous ones were clustered in the variable regions of the ectodomain (274). Considering that (a) G is one of the major protective antigens, (b) its amino acid diversity is accompanied by antigenic diversity, and (c) the genetic diversity occurs mainly in the ectodomain, this suggests that selective immune pressure operates in nature. Although immune pressure would be expected to operate similarly against F, the other major protective antigen, it likely is more evident with G because of its apparent tolerance for amino acid substitution. In contrast, the folding, processing, and function of F appear to be much more sensitive to amino acid substitutions (9). Analysis of viral isolates obtained over successive epidemics or over many years provided evidence suggestive of progressive amino acid changes in G that was associated with differences in reactivity with MAbs (58,132). This suggests that the G protein gradually accumulates antigenic differences over time, but the process is neither rapid nor extensive. Interpretation of these data is complicated by the large natural genetic and antigenic variation in the G protein and the complex pattern of G epitopes. It should be remembered that the two subgroups exhibit only a three- or four-fold difference in cross-neutralization, and relatively minor antigenic changes in G might not have a significant effect on cross-protection *in vivo*.

ANIMAL PNEUMOVIRUSES

Bovine RSV (BRSV) is a respiratory pathogen of cattle and is one of the etiologic agents of shipping fever, an economically important livestock disease. RSV and BRSV have an overlapping host range in cultured cells, with the RSV growing better in primate cells and BRSV replicating more efficiently in bovine cells (45). BRSV grows much less efficiently than human RSV in cotton rats, owl monkeys, and chimpanzees (45,325). Antibodies against BRSV or RSV recognize the N, P, M, and F proteins of the heterologous virus (21). In one study, nine of 16 F-specific murine MAbs raised against RSV had significant neutralizing activity against a bovine strain, and pooled human serum with high neutralizing activity against human RSV also efficiently neutralized BRSV (31). Antigenic analyses with MAbs suggest that BRSV has two antigenic subgroups (21,129,336).

BRSV has the same gene order as RSV, and their complete nucleotide sequences share 72.8% identity. Proteins that are relatively more, or less, conserved between subgroups A and B exhibit the same pattern between RSV and BRSV (see Table 3). The 13-amino-acid sequence in the G protein extracellular domain conserved between the two human RSV subgroups is identical for only six positions between RSV and BRSV, although the four cysteine residues and their spacing are conserved (245). BRSV and RSV GS signals and the gene overlap are nearly identical, whereas GE signals and intergenic regions are more variable.

Recombinant BRSV has been recovered from cDNA using a strategy similar to that for human RSV (44). As was the case with human RSV, BRSV NS2 was found to be a nonessential gene whose deletion attenuated the virus *in vitro.* Replacement of the 45-nt leader region of BRSV with the 44-nt leader of human RSV (82% identity) had no effect on replication *in vitro,* providing evidence of the interchangeability of cis-acting signals (44).

Ovine RSV and caprine RSV also have been isolated. The available sequences indicate that caprine RSV is very similar to BRSV, whereas ovine RSV is more distinct; for example, its G protein has 62% and 21% to 29% identity with G of BRSV and human RSV, respectively (4,257). It is thought that ovine RSV and BRSV represent two branches of ruminant RSV, with caprine RSV being grouped with BRSV (4,94).

PVM is a respiratory pathogen whose natural host appears to be the mouse and other rodents. PVM has the same gene order as RSV, although it lacks the gene overlap (64). In addition, its P mRNA contains a second ORF that is expressed as a 137-amino-acid protein and thus represents a twelfth gene not found in the other pneumoviruses (26). The N and P proteins of RSV and PVM cross-react serologically (252). Sequences have been reported for all of the PVM genes except for L (see Table 3).

APV, previously called turkey rhinotracheitis virus, causes respiratory tract disease in turkeys, chickens, and other birds (301). It is the sole representative of genus Metapneumovirus. The genomic RNA of strain CVL14/1 has been sequenced completely (see Table 2 and Table 3). Compared with RSV, APV lacks the NS1 and NS2 genes, the genome is 1.8 kb shorter, and the F-M2 genes precede the SH-G genes in APV, whereas they follow them in RSV (see Fig. 1) (251,339,432). APV has an M2-2 gene, although it might not be expressed (2). If not, APV has eight genes. The percentage amino acid identities for the proteins of APV with their counterparts from human RSV strain A2 are summarized in Table 3. Comparison between PVM and APV is not shown, but in general, these two viruses are as divergent from each other as each is from RSV. Two antigenic subgroups of APV are somewhat more divergent than are the two human RSV subgroups (220). Apart from the presence of the M2-1 gene, the gene map of APV resembles that of the rubulavirus SV5 (see Fig. 1). In addition, its fusion peptide resembles that of SV5 (see Fig. 4C). The significance of this is unclear, but it might mean that APV is an evolutionary link between the rubulaviruses and the pneumoviruses.

BRSV and PVM have the potential to serve as useful models for human RSV. Unfortunately, both grow less well *in vitro* than does human RSV. Unlike RSV, strains of PVM have been identified that differ considerably in virulence, probably because of rapid attenuation of the virus during passage in cell culture (92, 338).

PROPAGATION *IN VITRO*

RSV grows in a fairly wide variety of human and animal cells. Fresh RSV isolates do not appear to require adaptation to cell culture, and conversely, laboratory strains are virulent in chimpanzees and humans. The cell line considered to be the most efficient for virus isolation and propagation is HEp-2, which originally was from an epithelial carcinoma of the larynx but now appears to have been contaminated with and outgrown by HeLa cells, an epithelium-like cell from a cervical adenocarcinoma, which nonetheless is a good substrate for RSV. The A549 line, derived from a type II alveolar epithelial lung carcinoma, also is commonly used. Human RSV grows with reasonable efficiency in bovine cells, and even can be propagated in baby hamster kidney cells, albeit with reduced efficiency. Cell lines can lose their ability to support the growth and cytopathic effect of RSV during serial propagation in culture, necessitating frequent monitoring. Calcium and glutamine in the culture medium are important for replication and cytopathic effect (258,358). The need for calcium probably reflects the calcium dependence of the furin protease.

Up to 90% of infectious progeny RSV in cultured cells remains cell associated (19,247), reflecting either a defect in the final stage of budding or an association with cell-surface molecules as might occur in the absence of a receptor-destroying activity analogous to a neuraminidase. Much of the cell-associated virus can be released by sonication or agitation. Ten plaque-forming units per cell is a typical yield. Virion preparations commonly contain large amounts of cellular membranous material. A large fraction of released virions appear to be empty and therefore presumably noninfectious (20). The particle/plaque-forming unit ratio of two preparations of RSV grown on WI-38 human diploid lung cells was estimated to be $10^{3.5}$:1 to $10^{4.5}$:1 (52), indicative of a very high content of noninfectious particles. Surprisingly, 99% of infectivity of a preparation of BRSV was retained by a 0.45-μm filter, and all infectivity was retained by a 0.22-μm filter (317), suggesting that most of the infectious particles produced *in vitro* are aggregates or filaments. RSV rapidly loses infectivity during storage, handling, and purification: this can be partly overcome by including stabilizing agents such as buffer, sucrose, and magnesium sulfate (155), although the last agent can be toxic to cell culture and animals. Heterogeneity and lability make it difficult to concentrate RSV without considerable loss of infectivity.

Infectious virus is quantitated by plaque assay under methylcellulose or by limiting dilution. RSV plaques develop somewhat slowly, and methods have been developed for their more rapid and efficient detection by immunofluorescence or immunostaining (60,74,388).

INFECTION OF EXPERIMENTAL ANIMALS

A wide range of animal species, including cotton rats, mice, ferrets, guinea pigs, hamsters, marmosets, lambs, and a number of nonhuman primates, can be infected by administration of RSV directly into the respiratory tract (33,53,187,362). The chimpanzee alone resembles the human in being highly susceptible to infection by contact, in supporting moderate to high levels of virus replication, and in developing mild signs of disease symptoms resembling those of mild disease in humans (33), but there are severe limitations on their use because of low availability and high rate of seropositivity. The most widely used small experimental animals are cotton rats and mice. Inbred strains of mice can vary 100-fold in permissiveness for replication. The BALB/c mouse is one of the more permissive strains, but is somewhat less permissive than cotton rats, particularly for subgroup B strains (97). Infection of rodents results in a low to moderate level of virus replication that peaks on day 4 and is quickly cleared. *In situ* hybridization of lung tissue from cotton rats at the peak of virus replication showed that only scattered cells were infected (293). Rodents do not exhibit overt respiratory tract disease, although pulmonary histopathologic changes and respiratory signs that resemble mild bronchiolitis have been noted. Under some conditions, particularly with high-titered RSV inoculum, infected mice exhibit weight loss, changes in pulmonary function, and ruffled fur that are considered to be indicators of disease (53,395). The mouse model has the advantage of a wide array of immunologic reagents and genetically manipulated strains, but both the mouse and the cotton rat share the disadvantage of the uncertainty in extrapolating findings from a semipermissive inbred animal to the human. The evaluation of vaccines or antiviral agents in experimental animals in which RSV replication is semipermissive can yield overly optimistic results.

EPIDEMIOLOGY

Hallmarks of RSV are (a) it is the single most important cause of hospitalization for viral respiratory tract disease in infants and young children worldwide, (b) it infects the very young infant and even the neonate (170) despite the presence of transplacentally derived RSV-specific maternal serum immunoglobulin G (IgG), (c) reinfection is common, albeit with reduced disease and (d) it produces large yearly epidemics. Bronchiolitis or pneumonia occurs most frequently between ages 6 weeks and 9 months, and the peak incidence of lower respiratory tract disease is between ages 2 and 7 months (135,197,320). This corresponds with diminishing titer of maternally derived antibodies. The risk of serious RSV disease is increased by prematurity, young age, chronic cardiac or lung disease, immunodeficiency or immunosuppression, and family history of allergic disease. However, approximately three fourths of hospitalizations for RSV disease occur in infants and children who were previously healthy (404).

RSV is a major cause of serious pediatric respiratory tract disease. In a 13-year surveillance of infants and young children in Washington, DC, RSV infection was detected in 43% of those hospitalized with a diagnosis of bronchiolitis and in 25% of those with pneumonia (Fig. 7, and see Table 4 in Chapter 42) (232,292). Only 11% of those hospitalized with bronchitis and 10% of those with croup had RSV infection. Overall, RSV infection was detected in 23.3% of infants and children hospitalized for any respiratory tract disease, compared with 5.4% of those seen for nonrespiratory illness during this interval. A prospective survey of lower respiratory tract illness in children followed up from birth identified RSV in 39.5% of all episodes (197). In a 10-year study in Rochester, New York, RSV was associated with 50% to 80% of hospitalizations for bronchiolitis and 30% to 60% of those for pneumonia during November through April, the time of RSV epidemics (see later) (158). In the United States, RSV was recently estimated to be responsible for 73,400 to 126,300 hospitalizations annually for bronchiolitis and pneumonia alone among children younger than 1 year (359). These typical findings clearly show that RSV is the major cause of bronchiolitis, and one of the major causes of pneumonia, during the

first few years of life.

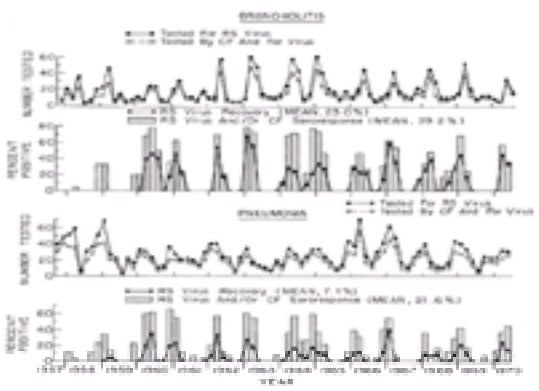

FIG. 7. Documented respiratory syncytial virus (RSV) infection in patients hospitalized with bronchiolitis or pneumonia, by 2-month intervals from October 1957, shortly after the first isolation of RSV from humans, to June 1970 (232). Serum samples were collected on admission and 3 weeks later and assayed for complement-fixing (CF) RSV-specific antibodies. Oropharyngeal swabs were collected and assayed for RSV recovery. The frequency of successful RSV isolation increased beginning in 1960 because of improved cell culture. These methods likely underreport the incidence of RSV infection: the CF antibody assay can be obscured by RSV-specific maternally derived antibodies, and virus isolation can be unsuccessful because of virus instability or insensitivity of the cell culture. Nonetheless, RSV infection was documented in 43% of patients with bronchiolitis and 25% with pneumonia. Note that the timing of the peak of the RSV epidemic can vary, sometimes occurring in the spring (1960 and 1964), and other times with a peak from November to February (1960/1961 winter).

Infection and reinfection with RSV are frequent during the first few years of life. Serologic surveys have shown that approximately one half of infants who are at risk during an RSV epidemic become infected (145,320,364). In certain settings, such as day care centers, the attack rate approaches 100% during epidemics (189). In one prospective study, the infection rate for RSV was 68.8 per 100 during the first year of life and 82.6 per 100 during the second year. All children were infected by age 24 months, and half experienced two infections. The risk of reinfection decreased to 33.3 per 100 by age 48 months (145). In a day care center, 98% of RSV-naive infants and young children were infected when exposed to RSV during an outbreak, and the frequency of reinfection during two subsequent biennial epidemics was 74% and 65%, respectively (189). Reinfection of adults also is common, particularly under conditions in which exposure to virus is heavy, and it is likely that RSV contributes considerably to respiratory tract illness in this age group (298). Several studies have shown that hospital staff on pediatric wards have an infection rate of 25% to 50% during RSV epidemics (151,163,170,297). RSV is introduced into families primarily by a young school-age child, after which infection spreads to older siblings and adults with high frequency. In one prospective study, approximately 40% of all family members older than 1 year were infected after the introduction of RSV (167). Reinfection at all ages is usually symptomatic.

Rates of hospitalization of infants for RSV disease have varied somewhat with the setting, with several developed countries having rates of one in 100 to one in 200 infections during the first year of life (73,232,315). The hospitalization rate was higher (one in 70) for heavily industrialized areas and lower socioeconomic groups (144,145). Hospitalization in middle- and high-income families is much less frequent, occurring in only one in 1,000 infections (143). Overall, the rate of hospitalization for RSV disease in developed countries is 1 to 20 per 1,000 infants younger than 1 year, with 9% of patients requiring mechanical ventilation (144,228,402). Very high rates of hospitalization for RSV can occur in certain populations, such as the rate of 53 to 249 per 1,000 infants younger than 1 year reported for Alaskan natives (228). In the U.S., RSV was estimated to be responsible for annual hospitalization costs of $300,000,000 in 1985 dollars (273).

Mortality due to RSV infection is not common in developed countries. There are no accurate determinations of the overall death rate, but a survey from the mid 1970s estimated the fatality rate at 0.5% to 2.5% of hospitalized children with RSV infection (73). In 1985, RSV was estimated to be responsible for 4,500 deaths annually in the U.S. (273), but this probably is an overestimate (359). With the advent of more effective modern intensive care, more recent estimates are as low as 0.3% to 1.0% of hospitalized children (281,300). Analysis of respiratory deaths in infants and young children reported to the Centers for Disease Control in Atlanta during the years 1975 to 1984 indicated that RSV was the virus most frequently reported in infants of ages 1 to 5 months, and influenza was the one most frequently reported in children of ages 24 to 59 months (12).

Morbidity and mortality from RSV infection is highest in infants with underlying illness. Infants with chronic lung disease (previously called bronchopulmonary dysplasia) are at high risk for prolonged, severe, or fatal illness (152). Mortality in infants with congenital cardiac or pulmonary disease was approximately 40% in the 1970s but has now declined to 3% to 4% of hospitalized patients because of improved supportive treatment (12,126). RSV infection is associated with a mortality rate of 20% to 67% in children and adults with immunodeficiency or immunosuppression. Bone marrow transplant patients are among the most severely immunocompromised and have the highest risk of fatal disease (12,108,287,353,419).

There is growing evidence that RSV is a pathogen of considerable importance in the elderly, whether infection is acquired during an outbreak in a nursing home or in the hospital or sporadically in the community (114,178,278). In one study, RSV accounted for 27% of acute respiratory illness in institutionalized elderly (115), and an overall attack rate of 40% was described (278). In another study, RSV was associated with 10% of hospitalizations of elderly for acute cardiopulmonary or influenza-like disease, with a death rate of 10%, and thus was equivalent in importance to influenza A virus in this setting (114). The clinical manifestations of the two viruses were similar, although the length of stay and

use of antibiotics and therapy for bronchospasm were somewhat greater in the case of RSV. The immunologic correlates of the susceptibility of the elderly to RSV disease are not clear, but do not appear to involve a reduced humoral response to infection (117).

RSV has a worldwide distribution. Wherever appropriate studies have been performed, RSV has been found to be the major pediatric viral respiratory tract pathogen. Serious lower respiratory tract disease occurs 30% more commonly in male than in female subjects (320); in urban centers in the U.S., the various forms of lower respiratory disease associated with RSV infection are seen more frequently in nonblack infants (320). Hospitalization for RSV disease is required more frequently for children from families with lower socioeconomic status (73,142,364).

RSV has a clear seasonality in temperate zones of the world. In urban centers, epidemics occur yearly in the late fall, winter, or spring but not during the summer (see Fig. 7) (232,285,425). In the Northern Hemisphere, the virus is rarely isolated during August or September, although isolation of RSV throughout the year was reported in the southeastern U.S. (177). Each RSV epidemic lasts approximately 5 months, with 40% of infections occurring during the peak month in the temporal center of the outbreak (39). The peak may occur as early as December or as late as June in the Northern Hemisphere. Most outbreaks peak in February or March. It is not know why the virus disappears in the spring, nor from where it reemerges in the fall and winter. In tropical or subtropical areas, epidemics usually occur during the rainy season (59) and have also been reported during gatherings such as for religious festivals (195).

A number of studies indicate that subgroup A and B viruses can alternate in prevalence during successive years (283,323,406). One interpretation is that reinfection with the heterologous subgroup is favored because it can partially evade previously induced immunity. Consistent with this view, a subgroup shift was not evident when the initial infection occurred in children younger than 6 months, a time when immune responses are reduced because of maternal antibodies and immunologic immaturity (406). However, as indicated earlier, the two subgroups differ only three- to four-fold based on neutralization with convalescent serum, which is about the same as that seen between successive antigenic variants within an influenza A virus subtype. Furthermore, many reinfections involve virus of the same subgroup as the previous infection (283). Thus antigenic dimorphism probably contributes to the high incidence of initial reinfection during early childhood, but its effect appears to be modest.

RSV is spread by infected respiratory secretions. The major mode of spread appears to be by large droplets or through fomite contamination rather than through droplet nuclei or small-particle aerosols (159,162). Spread requires either close contact with infected individuals or contamination of the hands with fomites from surfaces to which infected respiratory secretions have been introduced by mechanical means and subsequent contact between fingers and nasal or conjunctival mucosa (self-inoculation). When adult volunteers were inoculated with cell culture–grown virus, infection was easily accomplished if virus was introduced either onto the conjunctival sac or into the nose but not into the mouth (164).

RSV is a major cause of nosocomial infection (151,163). The rate of hospital-acquired infection for infants and children during an RSV season was reported to range from 26% to 47% in newborn units and from 20% to 40% for older children. Hospital staff appear to play a major role in nosocomial spread of RSV infection. The likelihood that an individual infant or child will acquire nosocomial RSV infection increases with the duration of stay and the number of individuals housed in his or her room (163).

Attempts to control such outbreaks through the use of gowns and masks have been unsuccessful. However, recent studies suggest that nosocomial spread in nurseries and pediatric wards can be reduced by a combination of measures: (a) limitation of visitors, (b) active surveillance for RSV infection among patients and new admissions, (c) cohorting of RSV-infected patients and their caregivers, and (d) institution of various barriers to virus spread. Precautions that appear to be effective include strict observance of hand washing and the use of gloves and gowns, with some possible additional protection when eye–nose goggles are worn. These measures are thought to reduce passive transfer of RSV-containing respiratory secretions to patients and also are thought to protect the staff from becoming infected by self-inoculation onto the conjunctiva or nasal mucosa (131,151,255,297).

CLINICAL FEATURES

In the normal infant who encounters RSV for the first time at age 6 weeks to 9 months, RSV infection usually causes upper respiratory symptoms. In 25% to 40% of such infections, however, the respiratory tract below the larynx also becomes involved (145,225). Bronchiolitis and pneumonia are the primary manifestations of lower respiratory tract disease, and probably represent a continuum of increasing severity of disease. Asymptomatic infection in this young age group is probably uncommon. In those infants in whom lower respiratory tract signs develop, there is a prodromal phase of rhinorrhea sometimes accompanied by a decrease in appetite. Cough may appear simultaneously, but it occurs more often after an interval of 1 to 3 days. At that time, there also may be sneezing and a low-grade fever. Soon after the cough has developed, the child may begin to wheeze; if the disease is mild, the symptoms may not progress beyond this stage. Examination usually shows moderate tachypnea, diffuse rhonchi, fine rales, and wheezes. There is profuse rhinorrhea, intermittent fever, and frequently otitis media (185). At this stage the chest radiograph is usually normal. In most instances, uneventful recovery occurs after an illness of 7 to 12 days.

In more severe cases, the coughing and wheezing progress, and the child becomes dyspneic. Hyperexpansion of the chest is evident, and there may be intercostal and subcostal retractions. The child refuses feedings. Severe tachypnea is common, even in the absence of visible cyanosis; and in advanced disease, as the child tires and hypoxia becomes more extreme, listlessness and respiratory failure occur. The chest radiograph often shows a combination of air trapping (hyperexpansion) and peribronchial thickening or interstitial pneumonia. Segmental or lobar consolidation, usually involving the right upper lobe, also is occasionally seen (343). Pleural effusion is rare. Late bacterial superinfection is unusual (173) and is probably less frequent than simultaneous bacterial–viral coinfection (318,385). Severe lower respiratory tract illness is most common in patients younger than 9 months. Bronchiolitis may occur in older infants and children, but beyond the age of 18 months, it is usually seen in children with recurrent wheezing who carry the diagnosis

of asthma.

Many infants who require hospitalization are hypoxemic on admission (169) and remain so for a prolonged period (up to several weeks), even though recovery has ensued. This hypoxemia is probably due to an abnormally low ventilation/perfusion ratio. Hypercarbia has been observed in some studies but not in others (169).

In infants with underlying cardiac or respiratory disease, the progression of symptoms may be rapid. This is particularly true of those with cyanotic congenital heart disease or chronic lung disease (152,272). In these instances, respiratory failure requiring intubation and ventilation may develop on the second or third day of illness. In children younger than 2 years with cystic fibrosis, the consequence of RSV infection may be prolonged respiratory morbidity (193).

In the newborn infant, most RSV infections produce only upper respiratory symptoms (41,170), reflecting the protective effects of maternal RSV-specific serum antibodies against disease in the lower respiratory tract. Bronchiolitis is rare, and severe infection is more often characterized by lethargy, irritability, and fever or temperature instability than by specific respiratory signs (170). In infants who were born prematurely, and sometimes in normal infants younger than 6 weeks, apneic spells may occur in response to RSV infection (271). This is often seen even in the presence of minimal respiratory signs and may be the predominant symptom bringing the infant to medical attention. Such apneic spells, although often recurrent during the acute infection, are usually self-limited and rarely cause neurologic or systemic damage. Exceptions to this occur, however, and such episodes should be an indication for hospitalization and careful medical supervision.

RSV has been detected in the lungs of a percentage of children dying suddenly and unexpectedly (sudden infant death syndrome, SIDS). However, there is no statistically significant association between RSV and SIDS, and the detection of RSV in some SIDS cases likely reflects its prevalence as well as the peak incidence of both RSV infection and SIDS in winter months (100).

Abnormalities in pulmonary function appear to be common after RSV bronchiolitis or pneumonia (or disease due to other respiratory viruses) and may persist for 7 to 10 years or even into adulthood (63,218,229,259,265). One investigation of 18 infants who had been hospitalized for bronchiolitis (half of which was due to RSV) identified only one individual with normal pulmonary function 1 year later (373). Ten had increased airway resistance, two had increased thoracic gas volumes, and five had both abnormalities. Another study of 23 children 10 years after bronchiolitis found that although all were symptom free (a criterion for admission to the study), 20 had some measurable physiologic abnormality of lung function or arterial blood gases (230). Recurrent wheezing may be common after RSV bronchiolitis or pneumonia and has been reported in 10% to 50% of former patients (63,337,363), but it is rarely of great severity. A large case–control study of 200 children hospitalized for bronchiolitis or pneumonia (half of which was due to RSV) showed that 7 years later, there was a significant tendency toward decreased pulmonary function, recurrent cough, wheezing, school absenteeism, asthma, and bronchitis in both of the previously hospitalized groups (279). Postexercise or pharmacologically induced bronchial lability is also increased, despite an absence of symptoms (156,363); furthermore, long-term hypoxia has been identified in several studies (168,230). The pulmonary function deficit is partially responsive to bronchodilators, indicating a bronchospastic component (63).

It remains unclear whether infection with RSV (or other respiratory viruses) causes subsequent abnormal pulmonary function, or whether the abnormalities observed existed before infection and indeed contributed to disease. Both possibilities might occur. A cause-and-effect relationship between RSV infection and subsequent long-term pulmonary abnormalities has not been demonstrated. The development of an effective RSV vaccine or highly effective antiviral agent for general use would help resolve this question. One study implicated RSV infection as a risk factor in the development of asthma (361), but other studies suggest that viral infections are not a major factor in the development of allergic airway disease (259,372,431). There is increasing support for the view that severe RSV infection with subsequent chronic or recurrent respiratory tract sequelae can be due to preexisting deficiencies. For example, Martinez et al. (260) measured pulmonary function in infants at birth or shortly thereafter and found a strong correlation between prior reduced function and the development of bronchiolitis with wheezing on RSV infection. This correlation persisted in children in whom at least one further lower respiratory infection developed during the first 3 years of life (260). A comparable independent study yielded similar conclusions (431). In another study, elevated peripheral blood eosinophil counts during RSV bronchiolitis were generally predictive of wheezing at age 7 years, implying the contribution of a preexisting immunologic anomaly (107). It is likely that respiratory disease and recurrent abnormalities in children are due to multiple factors including prior underlying anatomic or functional abnormality that might predispose to initial and recurrent acute bronchiolitis; a tendency to asthma or airway hyperreactivity that might predispose to recurrent wheezing; and infection, by RSV or other airway pathogens, as well as other environmental factors such as family smoking, that might trigger episodes of lower respiratory dysfunction and aggravate long-term or recurrent airway pathology. Most pulmonary abnormalities associated with prior respiratory tract infection resolve by age 8 to 12 years.

Acute RSV infections are common in normal adults, particularly in medical personnel or in individuals caring for small children (163,167). Such episodes are usually characterized by rhinorrhea, pharyngitis, cough, bronchitis, constitutional symptoms of headache and fatigue, and fever. Disease usually lasts about 5 days but may be more prolonged. In older persons, particularly those with underlying disease, severe pneumonia may occur, leading to hospitalization and the development of adult respiratory distress syndrome (ARDS), requiring intubation and ventilation.

RSV infection in severely immunocompromised individuals usually starts with an upper respiratory tract infection for 5 or 6 days, with symptoms similar to those of a normal host. There is a higher incidence of lower respiratory tract disease, and infection progresses to pneumonia in more than 50% of subjects, with patients manifesting sinusitis, cough, wheezing and dyspnea, and giant cell pneumonitis (416,419). The mortality rate associated with RSV pneumonia in adults with profound immunosuppression due to leukemia or bone marrow transplant can be as high as 80% to 100% (419).

DIAGNOSIS

Differential Diagnosis

The differential diagnosis of RSV infection in infants younger than 6 months must include all other causes of acute lower respiratory tract illness in this age group. This includes parainfluenza viruses, particularly parainfluenza virus type 3, adenoviruses, influenza viruses, rhinoviruses, and enteroviruses. In infants younger than 4 months, this also includes *Chlamydia trachomatis* (32). *Chlamydia trachomatis* causes interstitial pneumonia with cough and, in some cases, wheezing, although fever is usually absent in this syndrome. In immunodeficient children, *Pneumocystis carinii* infection must be considered. Differentiation from bacterial pneumonia may at times be difficult, although wheezing is usually not present, and infants with bacterial pneumonia may also have systemic illness associated with bacteremia.

In the newborn, other causes of listlessness, lethargy, and apnea include bacterial infections and metabolic diseases. In older infants, infections with RSV must be differentiated from other causes of mild respiratory tract infection as well as causes of acute bronchospastic disease, including inhalation of environmental allergens and aspiration of a foreign body.

In adults, RSV infection should be suspected in any older patient (with or without underlying cardiopulmonary disease) who has acute bronchitis or pneumonia accompanied by low-grade fever, particularly when such an event occurs as part of a cluster of cases in the winter season.

Presumptive diagnosis of RSV infection in infants can often be made on the basis of the clinical syndrome combined with the time of year and other epidemiologic features. It is common to observe that many members of the family have respiratory illness at the time of, or just preceding, an episode of RSV bronchiolitis or pneumonia in an infant. Usually the infant has far more serious illness than other members of the family (167).

Laboratory Diagnosis

Definitive diagnosis depends on the laboratory. The gold standard is isolation of virus in cell culture. Specimens are best obtained by aspiration or gentle washing out of nasal or nasopharyngeal secretions or by nasal swab (22,266). The lability of the virus requires that samples be kept cold without freeze–thawing and be inoculated as quickly as possible into cultured cells that have been confirmed to be sensitive to RSV. The development of RSV cytopathology requires 3 to 7 days or more, but detection can be made more rapid and efficient by immunofluorescence or immunostaining and the use of shell vial cultures (60,219,388,407).

Early diagnosis is advantageous because it allows implementation of measures to limit spread, such as in a hospital setting or nursing home, and early implementation of antiviral therapy, which should increase its effectiveness. Rapid methods involve the detection of viral antigen or nucleic acid in secretions collected as described earlier (219,407). In the direct immunofluorescent assay (DFA), exfoliated cells are reacted with fluorescent RSV-specific antibody and examined by microscopy. In the enzyme immunoassay (EIA), the sample containing respiratory secretions is incubated briefly with RSV-specific antibodies that are immobilized on plastic, and antigen thus captured is detected by reaction with a second, enzyme-linked RSV-specific antibody. The two methods are similar in sensitivity, but DFA has the advantage that the pattern of immunofluorescence can be evaluated, providing additional confirmation of specificity. DFA also requires specialized equipment (fluorescent microscope) and greater expertise. More recently, assays based on reverse transcription and polymerase chain reaction are commercially available. These can equal or exceed the sensitivity of cell-culture or antigen-based assays, and the inclusion of appropriate additional primers allows simultaneous assay for multiple pathogens (109,118,378).

Serologic methods are used less frequently. In older children and adults, an increase in complement-fixing (CF), neutralizing, or ELISA serum antibodies is a fairly sensitive index of reinfection with RSV. Asymptomatic infections are usually undetectable serologically. Serologic tests in infants are less sensitive, particularly in those younger than 4 months, with ELISA being the most sensitive assay (344). Serologic assays have been improved using ELISA with purified viral proteins or synthetic peptides (242,429), permitting the sensitive identification of immunoglobulin isotype or subclasses of RSV-specific antibodies.

PATHOLOGY AND PATHOGENESIS

The incubation period from time of infection to onset of illness for RSV is 4 to 5 days (209,225). Virus replication initiates in the nasopharynx, commonly reaching a titer of 10^4 to 10^6 $TCID_{50}$ (50% tissue culture infectious dose) per milliliter of nasal secretion in young infants (160,161) and a somewhat lower titer in experimentally infected adult volunteers (128,276). In infants hospitalized with RSV disease, virus titer usually is at a level of $10^{3.5}$ to 10^5 $TCID_{50}$ per milliliter and decreases gradually during hospitalization (161,163,171,270,407). Some infants continue to shed virus for as long as 3 weeks after initial hospitalization. In one series of studies, clinical recovery often occurred despite the persistence of viral shedding from the upper respiratory tract (160,161), although in other studies, clinical recovery was usually coincident with the end of virus shedding (269,270). It is generally thought that there is a positive correlation between the level of virus replication and the severity of disease.

RSV replicates primarily in the superficial layer of the respiratory epithelium (136,302). It also infects macrophages and monocytes and appears to interfere with some of their functions (105). Viral spread from the upper to the lower respiratory tract likely involves aspiration of secretions or spread via the respiratory epithelium. The virus also can spread from cell to cell by fusion without emergence into the extracellular fluid, although the importance of this mechanism *in vivo* is unclear. Lower tract signs usually appear 1 to 3 days after the onset of rhinorrhea, and it is assumed that this reflects the timing of viral spread into the bronchi and bronchioles. The titer of virus in the lower respiratory tract is not known, but based on studies in chimpanzees, it likely is similar to that in the upper respiratory

tract.

Although RSV is pneumotropic, it is not strictly limited to that site. In several cases of fatal RSV infection of severely immunocompromised infants or adults, virus did spread to other organs, including kidney, liver, and myocardium, although this spread was not thought to be the cause of death (125,277). Similar findings have been made in immunosuppressed experimental animals (215,426). Although viremia has not been described during infection of normal infants and children, RSV antigens have been detected in circulating mononuclear leukocytes of such individuals (105), and viral genomic RNA and mRNA have been detected in cells from arterial blood, but not in cerebrospinal fluid (306).

The pathology of severe RSV infection in infants is similar to that of bronchiolitis and pneumonia resulting from other respiratory viruses. During bronchiolitis, there is necrosis and proliferation of the bronchiolar epithelium and destruction of ciliated epithelial cells (1,302). A peribronchiolar infiltrate of lymphocytes, plasma cells, and macrophages develops, with migration of the lymphocytes among the mucosal epithelial cells. Submucosal and adventitial tissues become edematous, and secretion of mucus is excessive, which combines with cell debris and inflammatory cells to obstruct the bronchioles and alveoli, causing either collapse or emphysema of distal portions of the airway. In those instances in which pneumonia occurs, the interalveolar walls thicken as a result of mononuclear cell infiltration, and the alveolar spaces may fill with fluid. There is usually a patchy appearance of these pathologic changes, even though disease may be widespread. Immunostaining identified virus-infected cells in the bronchial, bronchiolar, and alveolar epithelium, and identified numerous syncytial cells (302). RSV antigen can be relatively abundant in lower respiratory tract disease, although the staining is usually focal, and in some cases of fatal RSV bronchiolitis, antigen was present only in small amounts (136,302). There is little information about the microscopic pathology of milder cases of bronchiolitis or pneumonia resulting from RSV infection. It is assumed that, in most instances, infection is predominantly in the small bronchioles, with inflammation of the peribronchiolar tissues and, to some extent, the interstitium.

The relative lack of direct information on the development of pathology in the infected human infant has been supplemented by studies of experimental or natural infection of calves and lambs with BRSV (42,43,264,427). Experimental administration of BRSV usually involved a large inoculum and sometimes multiple doses. Under these conditions, significant disease is observed by 3 to 7 days in all animals. At necropsy, gross lesions were observed with consolidated and emphysematous areas involving up to 70% of the affected lobe or complete lung (264,427). In the bronchiolar epithelium, the virus replicated in both ciliated and nonciliated cells, with syncytium formation, necrosis, desquamation, and considerable ciliary damage. Loss of ciliated and nonciliated cells and the degeneration of the epithelium also were observed in the nose, trachea, and main bronchi. In the alveolar epithelium, both type I and type II pneumocytes were infected, with the latter seeming to be a more important target. Lymphocytes and neutrophils accumulated in the subepithelial zone, and bronchiolar and alveolar lumina were filled with an exudate containing mucus, desquamated epithelial cells, neutrophils, lymphocytes, and macrophages. Necrosis, syncytium formation, hyperplasia, and hypertrophy also led to considerable occlusion of bronchiolar and alveolar lumina. Neutrophils were frequently found in association with infected cells, suggesting that they are important in the early inflammatory response. Virus-induced lesions resolved by 10 to 30 days after infection.

Direct virus-mediated cytopathology is an important component of RSV pathogenesis. RSV infection results in considerable damage to the epithelium and, importantly, to the bronchiolar ciliary apparatus (390). This interferes with the removal of mucus and cell debris, facilitating the collection of exudate in the bronchioles and alveoli. An important factor contributing to the frequency of severe lower respiratory tract disease in the young infant is the small diameter of the bronchioles, which obstruct easily in the face of necrosis and edema (196). As described later, it also is likely that host immunity contributes to RSV disease. However, RSV is an inherently pathogenic virus, and severe RSV disease is not dependent on the adaptive immune response. For example, RSV replicates to an increased level and causes severe pulmonary pathology in immunosuppressed cotton rats (426). Severely immunocompromised bone marrow transplant recipients also are at high risk for fatal RSV disease.

The mechanism of RSV-mediated cell death is not known and probably involves an accumulation of damage resulting from viral infection, with one possible example being perturbation of the cell membranes due to the expression of the highly fusogenic F protein. RSV infection of A549 cells *in vitro* induced the transcription factor IRF-1, which controls an apoptotic pathway (377). However, only a modest increase in apoptosis was observed in one study (306), and not at all in another study (377). As mentioned previously, RSV does not appear to interfere specifically with host-cell macromolecular synthesis.

The temporal concurrence of maternally derived, RSV-specific serum antibodies in young infants and the peak incidence of severe RSV disease initially suggested that RSV antibodies might mediate an immunopathologic reaction (268). For example, antigen–antibody complexes have the potential to induce injury by triggering the classic or alternate complement pathways or by activating granulocytes (113). Possible effects due to IgE are discussed later. However, although some contribution to pathology cannot be ruled out, several lines of evidence indicate that by far the major effect of RSV-specific antibodies is protective rather than pathogenic: (a) there is a relative sparing of serious RSV disease during the first 5 to 6 weeks of life, when maternally derived antibody titers are highest; (b) some prematurely born infants develop bronchiolitis in the absence of measurable acute-phase RSV-neutralizing antibodies; (c) there is an association between low umbilical cord blood RSV antibody titer and serious RSV disease; and (d) parenteral administration of RSV-neutralizing antibodies to experimental animals and, more recently, to high-risk infants provides protection rather than enhancement of RSV infection or disease.

It has been suggested that RSV-specific IgE is involved in the pathogenesis of RSV disease. In some studies, the level of free IgE in secretions from infants during convalescence from RSV infection was higher in individuals with asthma and wheezing and was correlated with the severity of hypoxia during acute disease (46,415). Moreover, increased levels of histamine and leukotrienes were detected in secretions of patients with bronchiolitis or RSV-induced asthma but not in those of patients with either RSV pneumonia or upper respiratory illness (397). These soluble factors are mediators of bronchoconstriction and presumably were released during the interaction of IgE, RSV, and mast cells in the respiratory epithelium. However, other studies did not find convincing evidence of increased IgE expression or mast cell

degranulation (111,387), and thus a general role for IgE in RSV pathogenesis remains uncertain.

The inflammatory response that is initiated by RSV infection (see Immunity) contributes to some pathologic manifestations of RSV disease. For example, granulocytes that are recruited into RSV-infected airways by proinflammatory chemokines can mediate direct destruction of virus-infected cells (405), which helps resolve infection but also damages tissue. Granulocytes also release degradative enzymes and, in the case of eosinophils and basophils, soluble effectors such as leukotrienes. Analysis of bronchial lavage and nasopharyngeal secretions of infants hospitalized with RSV bronchiolitis identified neutrophils as the predominant leukocyte (76% in bronchial lavage and 93% in nasopharyngeal secretions), with lymphocytes (9% and 5%) and monocytes (10% and 2%) being less abundant, and eosinophils being detected only in bronchial lavage (1%) (112). It should be noted that this method samples cells in the lumen and not in the entire lung and that prevalence of a specific cell type does not necessarily indicate its contribution to pathogenesis. Another study demonstrated elevated levels of eosinophil cationic protein, a cytotoxic protein found in eosinophil granules, in nasopharyngeal secretions of infants with RSV bronchiolitis (137). The local inflammatory response likely contributes to edema in the RSV-infected lung.

Studies in mice provided evidence that RSV-specific $CD8^+$ major histocompatibility complex (MHC) class I–restricted, $CD8^+$ cytotoxic T cells (CTLs) may play a role in the pathogenesis of RSV disease. Passively transferred, *in vitro*–stimulated RSV-specific $CD8^+$ CTLs can clear virus from the lungs of persistently infected, gamma-irradiated mice (61). However, under these experimental conditions, acute pulmonary damage occurs, and affected mice often die. Similarly, $CD8^+$ CTLs or CTL clones accelerate clearance of RSV from the lungs of infected immunocompetent mice, but clearance is accompanied by acute, and sometimes fatal, pulmonary disease. In mice treated from birth with anti-mu antibody to deplete B lymphocytes, the cellular immune response mediated both viral clearance and disease (148). Studies using mice in which $CD4^+$ or $CD8^+$ cells were selectively immunodepleted indicated that both subsets contributed to recovery as well as to a pathologic reaction, but that $CD8^+$ cells were more potent in both functions (149). These observations suggest that a balance exists between the protective and disease-producing effects of $CD8^+$ CTLs.

Another factor suggested to play a role in RSV pathogenesis is the level of stimulation of the Th1 and Th2 subsets of $CD4^+$ T lymphocytes, which are distinguished by increased expression of interferon-g versus interleukin 4 (IL-4) and IL-5, respectively. Immunization of BALB/c mice with a vaccinia virus recombinant expressing the G protein, or with formalin-treated RSV, induces a $CD4^+$ T-cell response with an increased Th2 component (5,150). Subsequent challenge with RSV results in enhanced pulmonary histopathology and eosinophilia, a response that could be ablated by depletion of either $CD4^+$ T cells or the Th2 cytokines IL-4 and IL-10 before challenge (89,91). A Th2-biased $CD4^+$ T-cell response might augment disease by chemotaxis and activation of leukocytes such as eosinophils, as suggested by the eosinophilia observed in the BALB/c mouse (357), or by other mechanisms such as IL-4–mediated class switching to IgE production and enhanced airway mucus production (76). These findings have clear relevance to situations in which G is expressed alone, such as in a subunit vaccine, and this paradigm also is relevant to the enhanced RSV disease observed with a formalin-inactivated RSV vaccine that was evaluated in the 1960s (see Vaccines later). However, it probably is less relevant in a natural infection in which Th2 $CD4^+$ T cells appear to be down-regulated by natural killer (NK) cells and $CD8^+$ T cells (201,203,367) Another weakness of this paradigm is that “disease” in this mouse model depends on a prior sensitization step that does not have a counterpart in the natural RSV disease. On the contrary, natural RSV disease is most severe in RSV-naive (unsensitized) infants and is rapid rather than delayed in its onset, and reinfection is associated with reduced rather than enhanced disease. However, some features of the immature immune system are intriguing with regard to a possible role of Th2 $CD4^+$ T cells in RSV pathogenesis. For example, the $CD4^+$ T-cell response in neonates and infants is transiently biased toward a Th2 response, and the young infant has a reduced CTL response (71,342). RSV-specific peripheral blood mononuclear cells from infants hospitalized with RSV disease exhibited a Th2-biased recall response (352), whereas cells from somewhat older children and adults secreted predominantly Th1 cytokines (13). Whether this is significant for RSV disease and immunology remains to be determined.

Mice with a targeted disruption of surfactant A, a collectin, were shown to have a reduced ability to restrict RSV, which could be restored by exogenous surfactant (246). Collectins are sugar-binding proteins secreted by type II epithelial cells of the respiratory tract that opsonize virus and facilitate phagocytosis by macrophages. Surfactant A appears to act by specifically binding to the F protein (141). Infants with severe RSV disease were found to have a reduction in surfactant concentration and function, although whether this is an effect or a cause (a predisposing host factor) of serious disease is not known (101,231).

The genetic background of the host is likely to be an important determinant in pathogenesis. This is evident from the differences in RSV replication and extent of pulmonary pathology exhibited by different strains of inbred mice (202,368). It is reasonable to suppose that, in the young infant, numerous factors ranging from surfactant expression to predisposition to reactive airway disease help determine whether an infection progresses to serious disease.

ANTIGENIC DETERMINANTS

The F and G glycoproteins are the major protective antigens of RSV. Immunization with either or both proteins, whether by RSV infection, a recombinant vector, or purified protein, confers long-lasting (although frequently incomplete) resistance to reinfection and lower respiratory tract disease that is mediated by neutralizing antibodies.

B Lymphocytes

Postinfection sera of humans or experimental animals contain antibodies against the various virion structural proteins. However, only antibodies against the F or G glycoprotein neutralize infectivity *in vitro* and confer resistance to RSV infection when transferred passively to experimental animals (379,403). Studies in which rodents were immunized with a series of recombinant vaccinia viruses, each of which expressed an individual RSV protein, confirmed that only the F and G proteins induce a significant RSV-neutralizing antibody response as well as a long-lived protective immune response

(87).

The antigenicity and immunogenicity of the F protein is highly dependent on its folded structure (254). A large fraction of F-specific MAbs efficiently neutralize infectivity, many inhibit fusion, and many are reactive with both antigenic subgroups and with BRSV. Competitive binding between MAbs identified at least four major antigenic sites on the F protein, and epitopes within these sites were defined by analysis of naturally occurring antigenic variants and of MARMs. Sequence analysis of MARMs showed that escape from neutralization by each of the various MAbs involved one or two amino acid substitution(s) each (see Fig. 4A) (15,31,99). Each position thus identified either constitutes part of the respective epitope or is important to its structure. All of the changes lie within the F_1 subunit, and none involves the fusion peptide directly, likely because this hydrophobic sequence usually is not accessible. In some cases, the view that the identified residue is part of the epitope was confirmed by reactivity of the MAb with a corresponding synthetic peptide, providing a second method for antigenic mapping (15,93,253,254,392). Certain F-specific peptides also have been shown to induce neutralizing antibodies in experimental animals (93,392). However, it is likely that most of the neutralization epitopes on F are conformational in nature and cannot be mimicked efficiently by synthetic segments. The repertoire of F-specific antibodies induced by RSV infection in humans has been assayed by recombinant cDNA cloning of lgG Fab fragments, expression, and phage display. Approximately half of the Recombinant antibodies that neutralized infectivity efficiently were specific for fully mature F protein on the cell surface and virions. The other half of the antibodies had low neutralizing activity and appeared to be specific for intracellular F protein, and thus were probably raised against immature F protein released from lysed cells (354).

In contrast to F, MAbs against the G protein react with denatured protein on Western blot, and thus reactivity is not highly dependent on a properly folded structure (261,274). Individual MAbs against G generally are not efficient in neutralizing infectivity, although neutralization can be achieved with mixtures of MAbs (262) or with G-specific polyclonal antiserum (213). Because of the considerable antigenic diversity of G, it is more useful to describe G-specific MAbs on the basis of reactivity with natural strains. The MAbs fall into three groups: (a) a small number react with viruses from both antigenic subgroups and thus recognize “conserved” epitopes; (b) a larger number react broadly within but not between subgroups and are “group specific”; and (c) a yet larger number react with some strains but not others within a subgroup and are “strain specific” (261). The conserved and group-specific MAbs often react with nonglycosylated G, whereas strain-specific MAbs often react only with glycosylated G (261).

Sequence analysis of MARMs selected with G-specific MAbs revealed an interesting variety of mutations, summarized in Fig. 5 (261,274). Some of the MARMs selected with strain-specific MAbs each contained one or two closely spaced amino acid substitutions located mostly after amino acid 232. Others contained premature stop codons that truncated the protein by up to 42 amino acids. Thus epitopes for the strain-specific MAbs mapped to residues near the C-terminus of the molecule. Synthetic peptides containing sequence from the C-terminal 84 amino acids reacted with convalescent human sera from primary infection and, interestingly, altering the peptides to include point mutations found in nature reduced antigenicity (55). However, vector-expressed G protein lacking the C-terminal 68 amino acids was as immunogenic and protective as the complete G, suggesting that this region is not needed for a protective response (310).

Epitopes for the group-specific and conserved MAbs involve the central region of the molecule containing the conserved domain and flanking cystine noose (amino acids 164–186). A few of the MARMs that were selected with group-specific or conserved MAbs, or with nonhuman primate antiserum, had one or two point mutations in this region (261,375). A number of MARMs contained multiple amino acid substitutions that likely arose from biased hypermutation: as many as 20 A-to-G transitions and up to 13 amino acid changes were involved, and many changes fell within the conserved/cystine noose domain (261). Another “conserved” MAb selected MARMs that each contained a frame-shift mutation. These MARMs each contained a single nucleotide deletion in either of two runs of As that shifted the reading frame at codon 193 or 205 into an alternative ORF. Thus the mutations had the effect of replacing as many as 106 amino acids from the C-terminus of G with as many as 81 amino acids encoded by the alternative frame. This MAb reacted with a synthetic peptide containing amino acids 204 to 209, thereby mapping a major element of its epitope. Synthetic peptides containing sequence from the central region of the G ectodomain have been shown to react with MAbs, and one that represents amino acids 174 to 187 was protective in mice and calves (28,29,392). Similarly, several peptides spanning amino acids 152 to 204 reacted with MAbs and induced resistance to RSV in mice (327), confirming the importance of this central region in immunogenicity and antigenicity.

T Lymphocytes

In seropositive humans, the N, SH, F, M, M2, and NS2 proteins have been shown to stimulate RSV-specific memory $CD8^+$ CTLs (70). There was no apparent association between MHC haplotype and protein specificity. In BALB/c mice, the F, N, and M2-1 have been shown to induce primary and memory $CD8^+$ CTL responses, and the response to M2-1 was specific to MHC haplotype $H\text{-}2K^d$ (237,313). In particular, infection with a vaccinia recombinant expressing a peptide containing amino acids 82 to 90 of M2-1 induced levels of RSV-specific $CD8^+$ CTLs in BALB/c mice comparable to those induced by RSV infection (236). In contrast, although G is one of the two major protective antigens, a significant G-specific MHC class I–restricted CTL response has not been detected in humans or experimental animals.

The RSV proteins differ in their pattern of priming $CD4^+$ T lymphocytes in the BALB/c mouse. F protein expressed from a recombinant vaccinia virus induced a $CD4^+$ T-cell response that was biased toward the Th1 subset, whereas the G protein induced a Th2-biased response (5). In the mouse model, increased sensitization of Th2 $CD4^+$ T cells followed by challenge with RSV results in an immunopathologic response marked by pulmonary eosinophilia. The effect observed with complete G could be mimicked by a synthetic peptide containing amino acids 184 to 198 of the G protein or by a vaccinia virus recombinant expressing that sequence (365,380).

One interpretation is that the G protein, and the 184 to 198 G peptide in particular, contain one or more epitopes that preferentially stimulate Th2 $CD4^+$ T cells. However, other studies indicated that the $CD4^+$ T-cell response is controlled by factors that are not epitope specific. First, the form of the antigen was found to be important, with soluble proteins favoring a Th2-biased response. For example, the secreted form of the G protein was observed to give an enhanced

stimulation of Th2 CD4$^+$ T cells, and F protein that had been engineered to be secreted was associated with a shift toward a Th2-biased response (35,217). Second, the concurrent stimulation of RSV-specific CD8$^+$ T cells was shown to down-regulate the Th2 CD4$^+$ T-cell response, probably through secreted lymphokines such as interferon-g. For example, when the strong CD8$^+$ T-cell epitope described earlier for the M2-1 protein was coexpressed with G, there was a marked down-regulation of the immunopathogenic response (367). Conversely, expression of the F protein in a CD8$^+$ T cell–deficient mouse primed for an eosinophilic response on subsequent RSV challenge (201,367). This might explain why soluble antigens often induce a Th2-biased CD4$^+$ T-cell response: such antigens typically are inefficient in stimulating CD8$^+$ T cells. The Th2-biased CD4$^+$ T cell response associated with the G protein also is consistent with the inability of G to induce a significant CD8$^+$ T-cell response. Third, the route of immunization was important: administration of vaccinia-G by the intradermal route primed for eosinophilia, whereas the intraperitoneal route did not (34). The basis for this difference is not understood, but indicates that local immune factors are important. Finally, the genetic background of the host is important (202), particularly elements of the genetic background that lie outside of the MHC locus (368). These elements have not been defined, but could include genes such as those involved in the local inflammatory response or cytokine network. Although the host and viral determinants of the CD4$^+$ T-cell response to RSV are complex, these studies provide the unifying concepts that CD8$^+$ T cells are important in regulating the RSV-specific CD4$^+$ T-cell response, and that the form, composition, and mode of administration of an RSV vaccine can greatly influence the immune response.

IMMUNITY

The adaptive immune system has the primary role in recovery from RSV infection and resistance to reinfection (95,289). For example, immunodeficient children fail to clear RSV and shed virus for many months rather than the typical interval of 1 to 3 weeks (67,172). Severely immunocompromised adults, such as bone marrow transplant recipients or individuals with leukemia, have a very high incidence of RSV infection leading to serious disease and death.

In the BALB/c mouse, pulmonary NK cells appear in the first few days after RSV infection, followed in turn by pulmonary CD8$^+$ CTLs and secretory and systemic antibody. In addition to being direct effectors against virus-infected cells, NK and CD8$^+$ T cells can modulate the immune response by secretion of lymphokines, especially interferon-g (201,203,367). Clearance of virus was temporally associated with the increase in CD8$^+$ CTLs (8). Athymic nude mice shed virus persistently, which could be cleared by adoptive transfer of primed T cells (62). Studies in which the CD4$^+$ and CD8$^+$ T-lymphocyte subsets were depleted individually or together showed that both are important in clearing a primary infection (149). Studies in which mice were depleted of B lymphocytes showed that RSV-specific antibodies are not required for clearance of virus during a primary infection, but are very important in restricting replication and disease on reinfection (148). Passive administration of antibodies to RSV-infected cotton rats or primates at the height of infection greatly reduced virus replication, showing that antibodies can be effective in restricting a primary infection (187,330). However, CD8$^+$ CTLs appear to be required to eliminate virus completely (316). The relatively minor role played by antibodies in clearing primary infection in the mouse model might reflect the rapid clearance of a semipermissive infection and the relatively slower kinetics of appearance of antibody compared with cellular immunity. In human infants, where infection is more robust and longer in duration, the decrease in virus shedding in nasal secretions was associated with the appearance of RSV-specific IgA antibodies (269). RSV-specific cytotoxic cells, thought to be CD8$^+$ T lymphocytes, have been detected in peripheral blood mononuclear cells from infants with RSV disease (71,204). It is reasonable to assume that, as in experimental animals, they are important in resolving RSV infection in humans. Thus both cellular and humoral immunity contribute to resolving RSV infection.

With regard to resistance to reinfection, immunization of BALB/c mice with recombinant vaccinia viruses that each express an individual RSV protein showed that F and G are the only proteins that induce RSV-neutralizing antibodies and long-lived resistance to challenge RSV replication (87). Immunization with antigens that stimulated RSV-specific CD8$^+$ CTLs but not neutralizing antibodies (the M2-1 and N proteins) conferred resistance to subsequent infection, but this was short lived and had largely waned by 28 days (87,90,130,236). Thus antibodies mediate long-term resistance to reinfection, whereas memory CD8$^+$ CTLs induced by primary infection did not augment resistance to reinfection, at least not in the BALB/c mouse.

RSV infection does not induce significant levels of type I interferons (a and b) in nasal secretions (165,166,267), although in some cases, low or moderate levels have been reported (299). The low and inconsistent detection of interferon is in contrast to parainfluenza and influenza virus infections. *In vitro,* RSV typically does not induce interferons and is not sensitive to their antiviral effects, although more recent work indicated that RSV can induce interferon-b (17,72,138,346). Thus it appears that type I interferons, or at least interferon-a, play a minor role in restricting RSV replication *in vivo.* Whether RSV expresses an interferon antagonist, such as have been described for influenza and parainfluenza viruses, is not yet known.

Newborn term infants typically possess transplacentally derived maternal RSV-specific serum IgG (344). This appears to provide a relative sparing of incidence and severity of RSV disease during the first 5 to 6 weeks of life, when the titer of passive antibodies is highest. The protective effect observed during this period is inversely proportional to passive antibody titer (144,170,197,320). Breast-feeding might also be a source of passive protection against RSV disease, although its impact is not great and remains controversial (127,197).

Serum and secretory antibodies to both the F and G proteins are produced to high titer in response to RSV infection by most older infants and young children in whom maternal antibodies had declined to a low level (68,269,290,344,412). However, the response of 1- to 8-month-old infants to RSV infection is blunted, with fewer infants mounting a response, and the levels of F and G antibodies achieved are only 15% to 25% those of older subjects. The diminished antibody response of young infants reflects two factors, immunologic immaturity and a suppressive effect of maternally transmitted antibodies (290,291). In experimental animals, passive transfer of RSV antibodies decreased the frequency and magnitude of the antibody response to F and G proteins expressed by vaccinia recombinants and also decreased the neutralizing activity of the antibody that was induced (291). Animals manifesting this diminished antibody response

exhibited decreased resistance to challenge with RSV. Additional information on the antibody response of infants to RSV infection has come from clinical trials of live-attenuated RSV vaccines (429). These studies showed that (a) the predominant antigen recognized by the 1- to 2-month-old infant was the G glycoprotein, with 82% of the vaccinees responding to this glycoprotein compared with 40% to F; (b) the response was best measured by using reagents to detect RSV-specific serum IgA antibodies; (c) a serum IgG response to F and G was readily detected in RSV-naive 6- to 24-month-old children but was rarely detected in 1- to 2-month-old infants, in part because this response was masked by the presence of maternally derived IgG antibodies; (d) RSV-specific IgA antibodies were detected infrequently in nasal washes; and (e) infection of the 1- to 2-month-old infant induced nearly complete resistance to replication of a second dose of vaccine, which correlated directly with the previously mentioned RSV G protein–specific serum IgA response. Thus the very young human infant appears to be capable of mounting a protective immune response to RSV, and this appears to be focused on the G protein.

Secretory antibodies play an important role in resistance to reinfection, although the effect is not long-lasting after primary infection. The secretory antibodies produced by infants in response to RSV infections often fail to neutralize the virus *in vitro* (269), and this defect may be at least partially responsible for the incompleteness of natural immunity after infection during infancy and early childhood. As individuals grow older, however, multiple reinfections induce higher levels of IgA antibody and a more sustained secretory immune response (189,414). Studies of experimental infection of adult volunteers with wt RSV have shown that immunity to infection correlates better with the level of nasal RSV-neutralizing IgA antibodies than with serum RSV-neutralizing antibodies (276,411). Nevertheless, secretory IgA antibodies are only partially protective, because volunteers could still be infected and become symptomatic even when such antibodies were present at a low to moderate level.

Serum RSV-neutralizing antibodies persist at higher titer for a much longer duration than do secretory IgA antibodies. However, serum IgG antibodies gain access to the respiratory tract primarily through the relatively inefficient process of passive transudation (289). The relative inefficiency with which serum antibodies protect the respiratory tract was demonstrated in cotton rats, where the therapeutic effect of RSV-neutralizing serum-derived antibodies was 160-fold greater when administered topically versus parenterally (332,334). In addition, serum antibodies are less efficient in conferring protection in the upper respiratory tract compared with the lower respiratory tract. Serum antibodies in the respiratory tract neutralize RSV independent of complement or the Fc portion of the molecule (331). The ability of serum antibodies to confer effective resistance to RSV is indicated by the observation that the susceptibility to RSV of staff caring for pediatric inpatients correlates inversely with RSV-specific serum antibody level (297). This point also is demonstrated by the effectiveness of parenterally administered antibodies in RSV immunoprophylaxis of high-risk infants (see Prevention and Control). In contrast to the inefficiency with which serum antibodies conferred resistance in the nasopharynx of cotton rats, infection of this region by RSV provided a high level of resistance to reinfection. Thus both local immune mechanisms and serum antibodies contribute to protection against reinfection, and serum antibodies appear to be the longer lived but less efficient component.

RSV infection of the epithelial cells and macrophages of the respiratory tract induces the transcriptional activation of a network of cellular genes involved in inflammation, immune responses, and apoptosis (139,377). This appears to be a generalized mucosal response to infection or injury, and it is not yet known whether there are unique aspects in the response to RSV in addition to the poor induction of type I interferons. RSV infection of epithelial cells and macrophages results in the induction or increased production of overlapping sets of proinflammatory lymphokines, including IL-6, IL-8, RANTES (regulated on activation, normal T-cell expressed and secreted), tumor necrosis factor a (TNF-a), and others (311,319,390,393). Other molecules that increase in response to RSV infection include cell adhesion molecules that can mediate adherence of infiltrating leukocytes to infected epithelial cells, MHC molecules that can enhance the adaptive immune response, and Fas (CD95) that can sensitize RSV-infected cells to apoptosis mediated by cytotoxic T cells (138,307,370).

Lymphokines can have direct antiviral activities. Pretreatment of cells *in vitro* with TNF-a inhibited RSV replication, and mice that had been depleted of TNF-a and subsequently infected with RSV exhibited an increase in the magnitude and length of disease symptoms (304). In BALB/c mice, pulmonary expression of interferon-g from a DNA vector reduced RSV replication (238). Lymphokines also are important in attracting and activating specific leukocyte subsets, including macrophages, neutrophils, eosinophils, T lymphocytes, and NK cells. These cells can help resolve infection but in some cases can damage tissue, either by direct attack on infected cells or through the release of additional lymphokines and degradative enzymes (205,405). In particular, eosinophil degranulation releases the vasoactive compounds histamine and leukotriene C4, which are potential mediators of bronchospasm (312). Two of the granular enzymes, eosinophil cationic protein and eosinophil-derived neurotoxin, are RNAses that have direct, but weak, antiviral activity (103). Soluble mediators also can augment the inflammatory response and can have other effects such as stimulating mucus secretion.

Analysis of nasal wash and tracheal aspirates from RSV-infected individuals confirmed the presence of elevated levels of inflammatory cytokines and chemokines including IL-8, RANTES, MIP-1 a, IL-6, TNF-a, IL-1b, and others (30,184,360). Leukocyte numbers in respiratory washes were increased substantially. In summary, the inflammatory response contributes to controlling RSV infection through elaboration of antiviral molecules and recruitment of effector cells and also contributes to stimulating and regulating the adaptive immune response.

RSV is unusual in its ability to infect in the presence of moderate titers of maternal antibodies and to readily reinfect persons of all ages, with some infections occurring within a short interval after the previous infection (174,189). This is in contrast to other viruses of the respiratory tract such as influenza virus and rhinoviruses. For example, although influenza viruses and RSV alike infect respiratory tract epithelium, influenza virus infection provides very strong long-term immunity, whereas immunity to RSV is much less complete. Reinfection with influenza viruses is largely the result of antigenic variation in the hemagglutinin and neuraminidase protective antigens, whereas reinfection with RSV does not require antigenic drift. The reasons for the difference in duration of immunity between RSV and influenza viruses, and the ability of RSV to readily cause symptomatic reinfection, remain undefined but might involve the following factors. First, RSV is a highly infectious and transmissible virus capable of infecting almost all susceptible subjects in close contact with an infected individual (174,189). Second, the course of infection is relatively rapid, which likely outpaces the secondary immune response, as exemplified by the lack of effectiveness of memory $CD8^+$ CTLs in protecting against

reinfection (87,90,236). Third, the tropism of the virus for the epithelium of the respiratory tract allows it to replicate at a site in which the major mediator of resistance, the secretory IgA response, is relatively short lived and protection by serum IgG is relatively inefficient. However, most of these factors are shared by influenza and RSV. Fourth, RSV exists as two antigenic subgroups, and there is considerable antigenic diversity even within subgroups, especially in the G protein. This antigenic diversity might be particularly important in the young infant, which appears to respond more strongly to the G protein than to the F protein (429). Fifth, the G protein is an unusual antigen that, perhaps because of the many sugar side chains and unusual nonglobular structure, induces antibodies that are poorly neutralizing on an individual basis. Sixth, the secreted form of G might act as an antibody decoy and also might preferentially induce an immunopathogenic component of the $CD4^+$ T-cell response. Seventh, RSV infection of monocytes and macrophages might impair certain of their functions, and the production of IL-1 inhibitor and IL-10 could dampen the overall immune response (319). Finally, specific RSV gene products might interfere with the immune response. For example, the cysteine noose of the G protein has structural similarity to a subdomain of the TNF receptor and might be a TNF antagonist (243).

Host-specific factors also contribute to the ability of RSV to reinfect. As mentioned earlier, secretory and systemic antibody responses in the very young are reduced because of immunologic immaturity and the immunosuppressive effects of maternal antibodies. Cell-mediated immunity also might be diminished in the very young infant (71). Hence failure to achieve effective protection against the first reinfection could reflect this diminished primary immune response. Although protection is incomplete and is often overcome under natural conditions, cumulative immunity from repeated reinfections protects older children and adults against more serious forms of infection, particularly disease involving the lower respiratory tract.

TREATMENT

Treatment of severe RSV disease of the lower respiratory tract requires considerable supportive care: mechanical removal of secretions, proper positioning of the infant, administration of humidified oxygen, and, in the most severe cases, respiratory assistance (for recent reviews, see 206,235,266,275, and 349). The use of bronchodilators is controversial but may be beneficial in older infants if wheezing is an important symptom. Corticosteroids are commonly used as antiinflammatory therapy, although there is a general lack of data demonstrating efficacy. Improvements in supportive care have clearly made a major impact on mortality from severe bronchiolitis or pneumonia. Although this is difficult to document precisely, it is illustrated by the improvement in the mortality rate for infants and children with congenital heart disease and pulmonary hypertension: a decrease from 44% to from 3% to 4% (126,300). Advances in general pediatric intensive care may well be similarly responsible for the overall low mortality rate for children hospitalized with RSV disease (152,272,281,300,374).

The nucleoside analog ribavirin (1-b- D-ribofuranosyl-1,2,4-triazole-3-carboxamide; Virazole) was approved in 1986 for treatment of RSV infection (12,349). Ribavirin has antiviral activity in cell culture and in cotton rats, although its mode of action remains unclear. Clinically, it is administered as a small-particle aerosol using a tent, mask, or mechanical ventilator, delivered for 12 to 18 hours daily for a period of 3 to 7 days. Alternatively, it can be administered at a higher dose for 2 hours 3 times daily. When delivered as an aerosol, it appears to have little or no acute systemic toxicity and is not associated with long-term adverse effects, although there are concerns over possible hazard to caregivers and family. Initial trials indicated a modest but consistent beneficial effect on both virus shedding and clinical illness (12,275). Conversely, evidence is lacking that ribavirin decreases mortality, the duration of hospitalization, or the need for supportive therapies or that it improves long-term pulmonary function (12,341). In some studies there were trends suggesting that therapy was beneficial, although not statistically significant. The American Academy of Pediatrics has changed its recommendation that ribavirin “should be used” to “may be considered” for RSV-infected infants and children with congenital heart disease, chronic lung disease, immunosuppressive disease, prematurity, or severe disease (12). In such cases, treatment should be initiated as promptly as possible (as soon as the diagnosis of RSV infection is proven or strongly suspected). Studies are now in progress for high-risk groups such as bone marrow transplant recipients in which ribavirin is given by the aerosol or intravenous routes, or both, with or without RSV-neutralizing antibodies (see later), and anecdotal reports indicate improved benefit.

The success of parenterally administered RSV-neutralizing antibodies for RSV immunoprophylaxis of high-risk infants and young children (see Passive Immunoprophylaxis, later) suggested that RSV-antibodies also might be effective as antiviral therapy against established infection. The passive parenteral infusion of serum-derived RSV-neutralizing antibodies into cotton rats or primates at the peak of RSV infection strongly reduced virus replication without evidence of any immunopathologic effect (187,332). Direct administration of RSV-neutralizing antibodies into the respiratory tract, rather than by parenteral inoculation, also was effective in reducing pulmonary virus replication, and a comparable therapeutic effect was achieved by using a 160-fold smaller quantity of antibodies (330). Intravenous infusion of RSV-neutralizing antibodies into previously healthy or high-risk infants and children hospitalized for RSV disease substantially reduced the level of virus shedding, to levels comparable to those achieved with ribavirin, but produced little or no improvement in clinical outcome (188,256,350,351). Initial studies of the aerosol route of administration provided similar findings (345), but additional evaluation is needed. As indicated earlier, combination therapy with antibodies and ribavirin also is being evaluated.

A number of other candidate anti-RSV therapeutic agents are under preclinical evaluation (104). In some cases, efficacy *in vitro* or in small experimental animals was reported to equal or exceed that of ribavirin. However, experience with ribavirin and antibody therapy, as described earlier, indicates that achieving a substantial reduction in virus replication in an infant or small child experiencing serious RSV disease does not necessarily improve the clinical outcome, perhaps because at that late time, pulmonary pathology cannot be effectively countered simply by reducing viral replication (as with ribavirin) or neutralizing free virus (as with antibodies). Other experimental therapeutic approaches include intratracheal administration of surfactant (398) or modification of the production of inflammatory cytokines and chemokines (38). Topically administered interferon is generally considered to be ineffective (194). Vitamin A therapy, which reduces morbidity and mortality associated with measles virus, did not appear to benefit RSV-infected children (40).

PREVENTION AND CONTROL

Passive Immunoprophylaxis

Infusion of RSV-neutralizing antibodies into experimental animals confers substantial resistance in the respiratory tract to a subsequent RSV challenge (187,333). These findings led to development of a successful strategy for passive immunoprophylaxis of high-risk individuals (17,275). RSV intravenous immunoglobulin (RSV-IVIG, or RespiGam) consists of fractionated human IgG prepared from sera prescreened for high RSV-neutralizing activity. RSV-IVIG is administered to infants and children at high risk for serious RSV disease in monthly intravenous infusions of 750 mg/kg, given for 4 or 5 months during the RSV season. Given prophylactically, RSV-IVIG reduced the frequency of hospitalization and duration of stay by approximately 55%, and decreased the number of days spent in intensive care by 97% (12,153). However, there is as yet no evidence that mortality due to RSV was reduced (280). More recently, an RSV-neutralizing, F-specific murine MAb was humanized by recombinant methods by transferring its complementarity-determining regions onto a human IgG1 backbone, resulting in the antibody called Synagis (previously referred to as MEDI-493 or palivizumab) (14,216). The original murine MAb, designated 1129 (31), efficiently neutralizes almost all members of RSV antigenic subgroups A and B. Its epitope involves amino acid 275 of the F protein (99). Synagis is 50- to 100-fold more effective on a weight basis in neutralization than is RSV-IVIG, and thus the total amount of immunoglobulin administered could be reduced. This permits administration by a monthly intramuscular injection (15 mg/kg) rather than an intravenous infusion that takes several hours. Its efficacy was comparable to that of RSV-IVIG. This strategy is now in use for immunoprophylaxis of premature infants or those with chronic lung disease (14). Passive immunoprophylaxis also is beginning to be evaluated in bone marrow transplant recipients.

Vaccines

Because the peak incidence of serious RSV disease is at age 2 to 7 months (197,320), a pediatric RSV vaccine must be capable of stimulating effective resistance before the second month of life. Obstacles to successful immunization during the first month of life include immunologic immaturity and the immunosuppressive effects of maternally derived serum RSV-neutralizing antibodies (71,291,429). The second major target population for an RSV vaccine is the elderly, in whom it has been projected that an RSV vaccine would be cost effective (140,178). Efforts to develop a vaccine for either target group include live-attenuated and subunit RSV candidates. Live-attenuated vaccines that are satisfactory for use in RSV-naive infants likely would be overattenuated for the elderly (146).

A vaccine consisting of formalin-inactivated, concentrated RSV was evaluated in infants and children in the mid-1960s. This vaccine induced an immune response that was not protective and, on subsequent natural infection, increased the frequency and severity of RSV disease (226,233). This appeared to be a more frequent and more severe form of the natural disease, rather than an altered disease, as was associated with a formalin-treated measles virus vaccine (329).

A number of factors likely contributed to the lack of protection. Because the formalin-inactivated vaccine was administered parenterally, it probably failed to induce appreciable local respiratory tract RSV-specific secretory IgA antibodies. In addition, retrospective analysis showed that the vaccinees had an altered, weakened systemic antibody response compared with that induced by natural infection (294,296). Specifically, vaccinees developed a high titer of serum antibodies, particularly to the F glycoprotein, but these were not effective in neutralizing RSV. It is likely that the formalin treatment denatured protective epitopes on the F and G proteins. The absence of strong local and systemic RSV-neutralizing antibody responses left vaccinees susceptible to subsequent natural infection, whereupon the expression of viral antigens initiated an immunopathologic response. Critical to this understanding was the development of experimental animal models in which immunization with formalin-inactivated RSV vaccine, followed by intranasal challenge with RSV, results in enhanced pulmonary histopathology, a surrogate of the enhanced disease observed in the vaccinees (150,314,335,367,409). In cotton rats, passive transfer of serum from animals immunized with formalin-RSV, followed by RSV challenge, did not result in disease enhancement (88). This indicated that the immunopathogenic effect was not mediated by antibodies induced by the vaccine, but rather was mediated by immune cells.

Peripheral blood lymphocytes from vaccinees exhibited an exaggerated proliferative response to RSV antigens *in vitro* compared with that observed after natural RSV infection (234). Reagents were not then available to identify the specific lymphocyte subset involved. More recent experiments in mice and cotton rats indicated that the inactivated vaccine induced an increased level of virus-specific $CD4^+$ T lymphocytes but did not induce RSV-specific $CD8^+$ T lymphocytes, which are important antiviral effectors and regulators of the cellular immune response to RSV (367). Furthermore, immunization with inactivated RSV induced a greater stimulation of the Th2 $CD4^+$ T-cell subset than did infection with RSV (150,314,409). As already mentioned, this immunopathogenic response could be abrogated by depletion of $CD4^+$ T cells or the Th2 cytokines IL-4 and IL-10 before challenge (89,91). It is not clear whether an increased number of sensitized $CD4^+$ T cells, or the disproportionate stimulation of the Th2 subset, or both, was most important in the immunopathologic response. In any case, sensitization by formalin-RSV resulted in exaggerated proliferation and activation of RSV-specific memory $CD4^+$ T cells on subsequent infection. The detailed mechanism of the immunopathology remains speculative, but might involve increased cellular infiltration and secretion of cytokines and chemokines in the infected lungs, which in turn would recruit other inflammatory cells in an exaggerated response.

Also the serum RSV-neutralizing antibody response of vaccinees to RSV infection was observed to be significantly reduced compared with age-matched, unvaccinated controls (294). This diminished antibody response would be expected to retard resolution of infection, thereby increasing severity of disease. Vaccinees continued to exhibit an exaggerated *in vitro* lymphocyte-proliferation response to RSV antigens even after a subsequent natural infection, suggestive of a lingering imbalance in the cellular immune response (234). However, enhancement of RSV disease was not observed during subsequent episodes of reinfection.

A number of other vaccine strategies are being investigated, including synthetic peptides (28); recombinantly derived viral antigen (308,328), “DNA vaccines” (250); replication-defective recombinant vaccinia virus (430); recombinant

vesicular stomatitis virus (223); live-attenuated RSV (see later); and a protein-subunit vaccine based on F and G protein purified from RSV-infected cells (381,400). The subunit vaccines have focused on the F and G glycoproteins based on their identification as the major protective antigens. So far, clinical trials have been reported only for live-attenuated RSV and the infected-cell protein vaccine.

Protein subunit vaccines can induce disease enhancement in experimental animals resembling that described earlier for the formalin-treated vaccine (179,295,303), although this was not observed in another study (328). The nonreplicating nature of these vaccines likely will not induce the strong $CD8^+$ T-cell response that appears to be important for regulating cellular immunity to RSV antigens (203,367). It may be that unique features of certain of these recombinant proteins (328) or the use of various adjuvants (381) will overcome this limitation and make them suitable as pediatric vaccines. In addition, RSV protein vaccines may find use in seropositive children and the elderly, where the safety issue of primary immune priming is obviated because of previous natural infection (116,326,408). Maternal immunization is another potential use for a protein vaccine (288).

A vaccine based on the intranasal administration of live-attenuated RSV has the advantage of mimicking natural infection, which has never been shown to prime for enhanced disease (408). In addition, in experimental animals, the topical route of administration induces strong local and systemic immune responses and is partially resistant to the immunosuppressive effects of passively transferred maternal antibodies (98). A live-attenuated RSV vaccine readily replicated and immunized 1- to 2-month-old infants despite the presence of maternal antibodies, which indicates the feasibility for the use of this type of vaccine in the target population (429).

Studies beginning in the 1960s produced a series of attenuated, immunogenic RSV cp or ts mutants, but these proved to be underattenuated, overattenuated, or genetically unstable (128,428). It became clear that it would be difficult to produce a genetically stable virus with the appropriate balance between attenuation and immunogenicity. It was then decided to use the cp-RSV virus (128) as the substrate for the introduction of ts mutations by chemical mutagenesis. Cp-RSV, which is not ts, had been shown to be attenuated in chimpanzees, adults, and older RSV-naive infants, but was insufficiently attenuated in RSV-naive younger children. Mutant derivatives of cp-RSV exhibited varying degrees of temperature sensitivity and restriction of virus replication *in vivo.* Two of the more restricted mutants were subjected to another cycle of chemical mutagenesis, which yielded mutants that were more ts and more restricted in replication in mice and chimpanzees (96). Mutants were obtained that exhibited complete or almost complete restriction of virus replication in the lower respiratory tract of chimpanzees, stability of the ts phenotype, and moderate immunogenicity, and they induced almost complete protection against infection by wt RSV. A similar strategy also was pursued by another research group (386). A number of these vaccine candidates have been evaluated clinically, with successive testing in seropositive adults, seropositive children, RSV-naive children, and RSV-naive infants of age 1 to 2 months, the latter being the target population. Only the most attenuated of the biologically derived vaccine viruses, one designated cpts248/404, progressed to the final group (429). This virus was immunogenic and protective against a second vaccine dose, but induced mild nasal congestion, indicating the need for a small amount of additional attenuation (429).

The ability to recover infectious recombinant RSV from cDNA has greatly facilitated the characterization and further development of live-attenuated viruses (79,86,208). For example, cp-RSV and six of its ts derivatives were sequenced and their attenuating mutations identified by their insertion, individually and in combination, into the wt recombinant RSV. The majority of attenuating mutations was found to involve single amino acid substitutions in the L protein; interestingly, however, the most attenuating mutation involved a nucleotide substitution in the M2 GS signal (86,221,421). It was then possible to recreate biologically derived viruses such as cpts248/404 and attenuate them further by the addition of one or more attenuating mutations from a different virus (422). Deletion of the NS1, NS2, SH, or M2-2 gene, individually or in combination, also represents another type of attenuating mutation, one that should be particularly refractory to reversion (36,384,420).

It also is possible to expedite the development of a subgroup B-specific RSV vaccine by using reverse genetics. The G and F glycoproteins of several attenuated subgroup A vaccine candidates were replaced by their subgroup B counterparts, resulting in a panel of live-attenuated vaccine candidates bearing the subgroup B antigenic determinants (423). Alternatively, the subgroup B G gene can be inserted into a subgroup A virus as an extra gene creating a single virus with dual specificity (208).

BRSV has been considered as a live “Jennerian” vaccine for use in humans based on its antigenic similarity with human RSV, especially in the F protein, and its attenuation due to host range restriction in primates. Unfortunately, BRSV does not replicate efficiently in chimpanzees, and as a consequence, does not induce resistance to RSV challenge (45). The genes of recombinant BRSV are now being systematically replaced by their counterparts from human RSV to develop a chimeric virus bearing the antigenic determinants of human RSV in a backbone that is attenuated by one or more BRSV genes (45).

CHAPTER 46 *Orthomyxoviridae:* The Viruses and Their Replication

Robert A. Lamb and Robert M. Krug

The *Orthomyxoviridae* are enveloped viruses with a segmented single-stranded RNA genome that has been termed "*negative stranded*" because the viral messenger RNAs (mRNAs) are transcribed from the viral RNA segments; by convention, mRNA is positive stranded. The genomic RNA of negative-stranded RNA viruses has to serve two functions: first as a template for synthesis of mRNAs and second as a template for synthesis of the antigenome positive strand. Negative-stranded RNA viruses encode and package their own RNA-dependent RNA transcriptase, but mRNAs are only synthesized once the virus has been uncoated in the infected cell. Viral replication occurs after synthesis of the mRNAs and requires synthesis of viral proteins. The newly synthesized antigenome positive strand (for influenza virus, often termed *template RNA* or *complementary RNA* [cRNA]) serves as the template for further copies of the negative-stranded genomic RNA.

Among the RNA viruses, influenza virus is special in that all of its RNA synthesis—transcription and replication—takes place in the nucleus of the infected cell. The nucleus provides the environment for the synthesis of influenza virus mRNAs by an unusual process: initiation requires m^7GpppX^m-containing capped primers that are generated from a subset of host cell RNAs by an influenza virus–encoded cap-dependent endonuclease. In addition to stealing the capped 5' end of host mRNAs, influenza virus uses another aspect of the host cell nuclear function, namely the splicing machinery. The mRNAs synthesized by influenza virus and by one other virus, bornavirus (see Chapter 51), provide the only known examples of splicing of RNA that is not transcribed from DNA by RNA polymerase II.

In recent years, a remarkable catalog of mechanisms has been identified by which eukaryotic cells have expanded their genome-coding capacity beyond the linear array of nucleotide sequences usually thought to encode a protein. Such coding strategies create diversity by increasing the number of proteins encoded and, in addition, provide a means by which the expression of these proteins can be regulated. Eukaryotic viruses have usually provided the prototypic example of molecular mechanisms that serve to maximize coding potentials. Indeed, the compactness of the viral genome may be an important factor contributing to the success of a virus as a cellular parasite. The influenza viruses provide some remarkable examples of genome diversity: spliced mRNAs and overlapping reading frames, bicistronic mRNAs and overlapping reading frames, and coupled translation of tandem cistrons. The variety of mechanisms used for the synthesis of proteins by influenza virus provides a paradigm of successful exploitation of a genome.

CLASSIFICATION

The family *Orthomyxoviridae* (from the Greek *orthos,* meaning "standard, correct," and *myxa*, meaning "mucus") contains four genera as defined in the seventh report of the International Committee for the Taxonomy of Viruses: influenza A, B, and C viruses, and thogotovirus (sometimes called influenza D viruses). Influenza viruses were named *Orthomyxoviridae* because of their ability to bind to mucus (hemagglutination) and to distinguish them from another family of enveloped negative-stranded RNA viruses (*Paramyxoviridae*). Influenza is from the Italian form of Latin *influentia*, meaning "epidemic," originally used because epidemics were thought to be due to astrological or other occult influences.

The influenza A, B, and C viruses can be distinguished on the basis of antigenic differences between their nucleocapsid (NP) and matrix (M) proteins. Influenza A viruses are further divided into subtypes based on the antigenic nature of their hemagglutinin (HA) and neuraminidase (NA) glycoproteins. Other important characteristics that distinguish influenza A, B, and C viruses are as follows:

1. Influenza A viruses infect naturally a wide variety of avian species, humans, and several other mammalian species, including swine and horses. Influenza B virus appears to infect naturally only humans, and influenza C virus has been isolated mainly from humans but also from swine in China.
2. The surface glycoproteins of influenza A viruses (HA and NA) exhibit much greater amino acid sequence variability

than their counterparts in the influenza B viruses. Influenza C virus has only a single multifunctional glycoprotein, the hemagglutinin-esterase-fusion protein (HEF).

3. As discussed later, there are morphologic features that distinguish influenza A and B viruses from influenza C viruses.
4. Although influenza A, B, and C viruses possess similar proteins, each virus type has distinct mechanisms for encoding proteins.
5. Influenza A and B viruses each contain eight distinct RNA segments, whereas influenza C viruses contain seven RNA segments.

Little is known about the genus *Thogotovirus,* which comprises tickborne viruses that are structural and genetically related to influenza A, B, and C viruses (190) and contain a single glycoprotein (218). Because of space limitations and the need to discuss basic principles, these viruses are not considered further.

VIRION STRUCTURE

The *Orthomyxoviridae* are composed of about 1% RNA, 70% protein, 20% lipid, and 5% to 8% carbohydrate (reviewed in 51). The lipid envelope of influenza viruses is derived from the plasma membrane of the host cell in which the virus is grown (reviewed in 51). Influenza A and B virions are morphologically indistinguishable, whereas influenza C virions can be distinguished from the other genera because the glycoprotein spike is organized into orderly hexagonal arrays (51). Influenza A or B virions grown in eggs or in tissue culture cells have a fairly regular appearance in the electron microscope, with particles that are 80 to 120 nm in diameter. In contrast, virus strains isolated from humans or animals and propagated by single passage in culture exhibit greater heterogeneity and pleomorphism. The morphologic characteristics of influenza A viruses are a genetic trait (153) but also depend on the cell type in which the virus is grown (285). Although the genes that specify spherical morphology have not be identified, the trait segregates independently of the HA and NA proteins (155).

The most striking feature of the influenza A virion is a layer of about 500 spikes radiating outward (10 to 14 nm) from the lipid envelope. These spikes are of two types: rod-shaped spikes of HA and mushroom-shaped spikes of NA. The ratio of HA to NA varies but is usually 4:1 to 5:1. Influenza A, B, and C viruses also encode another integral membrane protein, the M_2, NB, and CM2 proteins, respectively. Biochemical evidence indicates these proteins are only present in a few copies in virions (13,24,337,395). The viral matrix protein (M_1) is thought to underlie the lipid bilayer and to associate with the ribonucleoprotein core of the virus. M_1 is the most abundant virion protein (Table 1). There is no evidence for the existence of a stable lipid-free “core” structure other than the ribonucleoprotein (RNP).

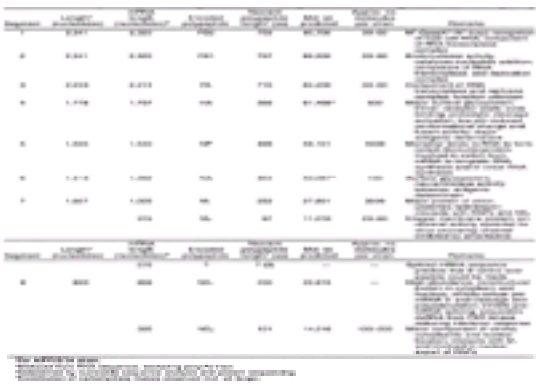

TABLE 1. *Influenza A virus genome RNA segments and coding assignments*

Inside the virus, observable by thin-sectioning of virus or by disrupting particles, are the RNP structures, which can be separated into different size classes (68) and contain eight different segments of single-stranded RNA. (Fig. 1 presents a schematic diagram of virion, and Fig. 2 shows electron microscopy photographs). The RNPs have the appearance of flexible rods (272); depending on the salt concentration during sample preparation or method of staining, the flexibility of the RNPs appears to vary (52,109,272). The RNP strands often exhibit loops on one end and a periodicity of alternating major and minor grooves, suggesting that the structure is formed by a strand that is folded back on itself and then coiled on itself to form a type of twin-stranded helix. Larger helical structures, interpreted to be formed by the orderly aggregation of the smaller segments, have occasionally been seen in partially disrupted virions (5,220). These structures might represent ordered complexes of the eight separate RNPs.

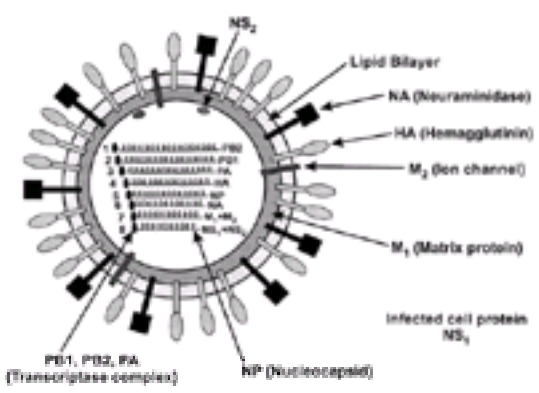

FIG. 1. A schematic diagram of the structure of the influenza A virus particle. Three types of integral membrane protein

—hemagglutinin (HA), neuraminidase (NA), and small amounts of the M_2 ion channel protein—are inserted through the lipid bilayer of the viral membrane. The virion matrix protein M_1 is thought to underlie the lipid bilayer but also to interact with the helical ribonucleoproteins (RNPs). Within the envelope are eight segments of single-stranded genome RNA (ranging from 2341 to 890 nucleotides) contained in the form of an RNP. Associated with the RNPs are small amounts of the transcriptase complex, consisting of the proteins PB1, PB2, and PA. The coding assignments of the eight RNA segments are also illustrated. RNA segments 7 and 8 each code for more than one protein (M_1 and M_2, and NS_1 and NS_2, respectively). NS_1 is found only in infected cells and is not thought to be a structural component of the virus, but small amounts of NS_2 are present in purified virions.

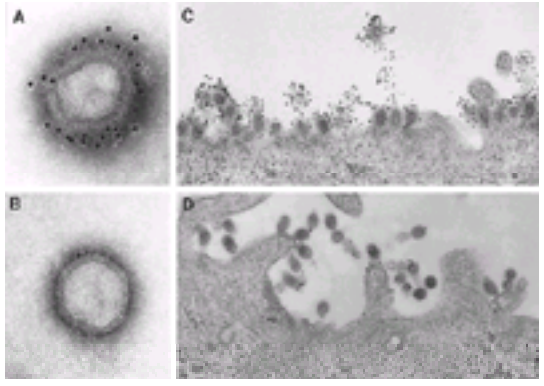

FIG. 2. Electron micrographs of purified influenza virus virions and virions budding from the surface of MDCK cells. **A:** Influenza A/Udorn/72 virus negatively stained with hemagglutinin (HA) decorated with 10-nm gold. **B:** Influenza A/Udorn/72 virus negatively stained with M_2 decorated with 10-nm gold. **A** and **B,** Final magnification ×227,500. **C:** Thin section of an influenza A/Udorn/72 virus-infected MDCK cell with HA decorated with 10-nm gold. **D:** Thin section of an influenza A/Udorn/72 virus–infected MDCK cell with HA decorated with 10-nm gold. **C** and **D,** Final magnification ×58,000. (Data from George Leser, Northwestern University.)

The RNPs consist of four protein species and RNA. NP is the predominant protein subunit of the nucleocapsid and coats the RNA: about 20 nucleotides per NP subunit. Associated with the RNPs is the RNA-dependent RNA polymerase complex consisting of the three P (polymerase) proteins, PB1, PB2, and PA, which are present at only 30 to 60 copies per virion (133,176). The RNA in the RNP complex remains sensitive to digestion by RNAase, and the RNA can be displaced by polyvinylsulfate (reviewed in 171). This suggests that the structure of the influenza virus RNP is very different from that of the RNAase-insensitive *Paramyxoviridae* RNP (see Chapter 41). The polymerase proteins in the RNP complex carry out the cap-binding, endonuclease, RNA synthesis and polyadenylation reactions described later (194,265,266,267 and 268).

The NS_2 protein (named as the second protein encoded by RNA segment 8) is present at 130 to 200 molecules per virion and forms an association with the M_1 protein (282,388), which is thought to be an essential interaction in the virus life cycle for export of the RNP complex from the nucleus (236) (see later). It has been suggested that NS_2 be renamed NEP for nuclear export protein (236).

INFLUENZA VIRUS GENOME ORGANIZATION AND ENCODED PROTEINS

Influenza A and B viruses each contain eight segments of single-stranded RNA (ssRNA), and influenza C viruses contain seven segments of ssRNA (influenza C viruses lack an *NA* gene). The early evidence for a segmented genome of influenza viruses has been extensively reviewed (172). The major step forward in understanding the structure of the influenza virus genome came from the electrophoretic separation of the virion RNAs on polyacrylamide gels (10,214,246,247,271,283,284). The assignment of specific RNA segments to virus polypeptides was made in three ways:

1. One method depended on the apparent differences between strains in the electrophoretic mobility of the RNA segments on polyacrylamide gels and the ability to distinguish proteins between strains, either by immunologic methods for HA and NA or by differences in the gel mobility of polypeptides. Reassortants were prepared between two parental strains, with comparisons made of the mobilities of the RNA segments and polypeptides between the parental types and each recombinant. From the analyses, gene assignments were made (reviewed in 244).
2. A hybridization strategy was dependent on base-sequence homologies between corresponding RNA segments of different strains and temperature-sensitive (ts) mutants (302).
3. A direct method of hybrid arrest of translation of individual influenza virus mRNAs using purified vRNA segments (173,174).

The gene assignment for influenza A virus is as follows: RNA segment 1 codes for PB2, 2 for PB1, 3 for PA, 4 for HA, 5 for NP, 6 for NA, 7 for M_1 and M_2, and 8 for NS_1 and NS_2 (see Table 1). The complete nucleotide sequence of influenza A virus PR/8/34, and many RNA segments of other subtypes, was obtained by 1982 (reviewed in 171); today, the complete sequence of many influenza A and B viruses and one influenza C virus has been obtained. The PR/8/34 strain of influenza A virus contains 13,588 nucleotides. In this chapter, for space considerations, no attempt has been made to cite the original publication of the several hundred influenza virus nucleotide sequences obtained and deposited in the EMBL/GenBank database.

The Polymerase Proteins and Their Genes

The three largest RNA segments encode the PB1, PB2, and PA proteins (apparent M_r 96,000, 87,000, and 85,000, respectively) (133,176). Because of anomalous migration of influenza virus RNA segments on gels, the proteins encoded by RNA segments 1 and 3 from different subtypes are different. Therefore, the proteins are named after their behavior on isoelectric focusing gels: two P proteins were found to be basic (PB1 and PB2) and one acidic (PA) (125,343,383). RNA segments 1 and 2 are both 2,341 nucleotides in length and code for proteins of 759 amino acids (PB2) and 757 amino acids (PB1), respectively; PB1 and PB2 are basic proteins at pH 6.5, with a net charge of +28. Because the sizes of the two polypeptides PB1 and PB2 are very similar, the ability to separate them on polyacrylamide gel electrophoresis must be due to factors such as differential binding of SDS. RNA segment 3 is 2,233 nucleotides in length and codes for a protein of 716 amino acids that has a charge of –13.5 at pH 6.5. The three P proteins form a complex in the cytoplasm and nucleus of cells that is largely resistant to disruption by normal immunoprecipitation buffers and the complex sediments on sucrose gradients at 11S to 22S (63). After synthesis in the cytoplasm, the P proteins are transported to the nucleus, possibly as a complex. However, expression of the individual P proteins from cDNA has shown that each P protein migrates to the nucleus and each contains a karyophilic signal (1,139,324). A description of the known functions of the PB2, PB1, and PA proteins in RNA synthesis is presented later.

Influenza B and C viruses also encode three P proteins that show extensive sequence identity and homology to those of influenza A virus, and it is presumed these proteins have similar roles and properties such as those of influenza A virus.

The Nucleocapsid Protein and Its Gene

NP is the major structural protein that interacts with the RNA segments to form RNP. NP is also one of the type-specific antigens; that is, it is distinct for each of influenza A, B, and C viruses. NP is also the major target of cross-reactive cytotoxic T lymphocytes generated against all influenza virus subtypes in mice and humans (reviewed in 391). It is encoded by RNA segment 5 of influenza A virus and is 1,565 nucleotides in length. NP contains 498 amino acids with a predicted M_r of 56,101, and the protein is rich in arginine residues and has a net positive charge of +14 at pH 6.5 (384). Unlike what might be expected for a protein that interacts with the acidic phosphate residues of RNA, however, there are no clusters of basic residues. This implies that many regions of the NP molecule may contribute to RNA bindings. After synthesis in the cytoplasm, NP molecules are transported to the nucleus. Nuclear targeting of NP is an intrinsic property of the protein (199,295). Two nuclear localization signals (NLS) have been localized to NP: residues 198 to 216 (360) and residues 1 to 38 (230,355). Thus, NP may interact with several members of the importin family, soluble protein receptors involved in nuclear import. NP residues 327 to 345, originally thought to be an NLS (59), are now thought to be cytoplasmic retention signal (64). Late in virus-infected cells, NP of influenza A virus is cleaved from a 56-kd protein to a 53-kd protein by a cellular caspase, but it is not known whether NP cleavage is merely a marker for the onset of apoptosis in infected cells or has a specific function in virus–host interaction (400).

Influenza B virus NP contains 560 amino acids and is 47% homologous to influenza A virus NP, and the influenza C virus NP protein contains 565 amino acids and has several regions of homology with the NP of influenza A and B viruses (reviewed in 171).

The Hemagglutinin Protein and Its Gene

Introduction

The hemagglutinin was originally named because of the ability of the virus to agglutinate erythrocytes (116,213) by attachment to specific sialic acid–containing receptors. HA has three known roles during the influenza virus replicative cycle:

1. HA binds to sialic acid–containing receptors on the cell surface, bringing about the attachment of a virus particle to the cell.
2. HA is responsible for penetration of the virus into the cell cytoplasm by mediating the fusion of the membrane of the endocytosed virus particle with the endosomal membrane, the consequence of which is the viral nucleocapsids are released into the cytoplasm.
3. HA is the major antigen of the virus against which neutralizing antibodies are produced, and influenza virus epidemics are associated with changes in its antigenic structure.

HA is encoded by RNA segment 4 and is synthesized on membrane-bound ribososmes and translocated into the lumen of the endoplasmic reticulum (ER) of infected cells as a single polypeptide HA_0 (M_r about 76,000). The HA spike glycoprotein is a homotrimer (375,380) of noncovalently linked monomers. Each HA polypeptide chain (H3 subtype) consists of an ectodomain of 512 residues, a carboxyl-terminal proximal transmembrane domain of 27 residues, and a cytoplasmic tail of 10 residues (347). HA is cotranslationally modified by the addition of up to seven oligosaccharide chains added to the ectodomain, and three palmitate residues are added via a thioether linkage to the three C-terminal proximal cysteine residues (223,224,301). Depending on the virus strain, host cell type, and growth conditions, HA exists either in an uncleaved precursor form (HA_0) or in a cleaved form consisting of two disulfide-linked chains (HA_1, M_r about 47,000; and HA_2, M_r about 29,000). Cleavage is a prerequisite for the virus to be infectious and hence is a crucial determinant in pathogenicity and in the spread of infection (reviewed in 329). The newly liberated N-terminus of HA_2 (fusion peptide) is hydrophobic, is highly conserved among HAs of different influenza virus strains, and is an essential participant in HA fusion activity.

RNA Segment 4: Gene Structure and Hemagglutinin Amino Acid Sequence

The first gene of influenza virus to have its nucleotide sequence determined was HA (274). Since then, the nucleotide

sequence of RNA segment 4 of all 15 known HA antigenic subtypes and many variants within a subtype have been determined. RNA segment 4 ranges from 1,742 to 1,778 nucleotides and encodes a polypeptide of 562 to 566 residues. The HA_1 chain is from 319 to 326 residues, and HA_2 is from 221 to 222 residues. Depending on the HA subtype, the number of residues lost on proteolytic cleavage between HA_1 and HA_2 ranges from one to six residues. The deduced amino acid sequence of the influenza B/Lee/40 HA has 24% homology to HA_1 and 39% homology to HA_2 of A/PR/8/34, suggesting a close evolutionary relationship between influenza A and B virus HAs (169,170).

Three-Dimensional Structure of Hemagglutinin

Although intact HA "spikes" can be isolated from purified influenza virions and infected cells by detergent solubilization of membranes, when the detergent is removed, the hydrophobic transmembrane domains aggregate and HA "rosettes" form. However, bromelain treatment of virus releases an antigenically and structurally intact trimeric ectodomain of HA (BHA), which is water soluble and contains all of HA_1 and the first 175 of the 221 residues of HA_2 (23,376). BHA of influenza virus A/Aichi/68 H3 subtype crystallized, and from x-ray diffraction data, the three-dimensional structure of both cleaved and uncleaved HA was determined (39,376,380) (Fig. 3).

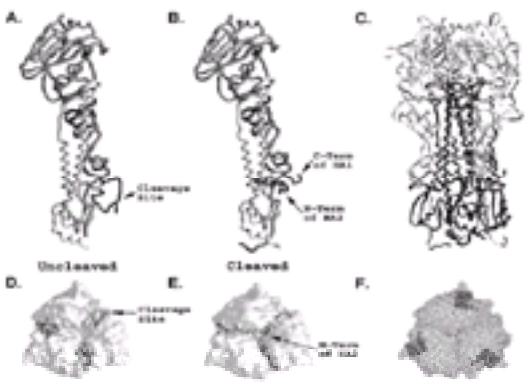

FIG. 3. Schematic diagram of the three-dimensional structure of the uncleaved hemagglutinin (HA) trimer and the cleaved HA trimer as determined from x-ray diffraction data. **A:** Side view of uncleaved HA monomer. **B:** Side view of cleaved HA monomer. **C:** Side view of cleaved HA trimer. **D:** Top down view of uncleaved HA trimer. **E:** Top down view of cleaved HA trimer. For **D** and **E,** shown in *dark gray* are the residues of the C-terminus of HA_1 and the N-terminus of HA_2 that change their position on cleavage. Note that the fusion peptide on cleavage becomes burried in the interior of the trimer. **F:** Top down view of the HA trimer. The residues that make contact with the HA receptor, sialic acid, are shown in *dark gray.* This figure was produced using Protein Data Bank (http://www.rcsb.org/pdb/) coordinate files 1HGF, 1HA0 and 1HGG.

HA_0 and cleaved HA_1 + HA_2 are superimposable in structure except for 19 residues, in a sequence bracketing the cleavage site. The HA trimer extends 135 Å from the membrane and is composed of two predominant regions: (1) a long fibrous stem extending 76 Å from the membrane, which forms a triple-stranded coiled-coil of a-helices and is derived from HA_2 residues; and (2) the globular head of the molecule, which is derived from HA_1 residues and consists predominantly of an antiparallel b-sheet (see Fig. 3). In uncleaved HA_0, eight residues that immediately surround the cleavage site, including five hydrophobic residues of HA_2, project away from the molecules into aqueous solvent. HA_0 contains a deep cavity, which is partially filled by the C-terminus of HA_1 and which swings out of the way on cleavage. This permits filling of the cavity by residues 1 to 10 of the hydrophobic fusion peptide (the newly generated N-terminus of HA_2). Cleaved HA contains the fusion peptides buried in the subunit interfaces of the stem of the trimer (see Fig. 3) and is presumed to exist in a metastable form. Uncleaved HA cannot undergo the low-pH–induced refolding events associated with HA-mediated membrane fusion. It is not known whether it is the positioning of the fusion peptide in the cavity that sets the trigger or whether the covalent bond that links HA_1 to HA_2 restricts the movement of the fusion peptide. However, the localized structural rearrangement on cleavage causes nonpolar residues of the fusion peptide to bury ionizable residues located in the cavity, residues that have been implicated in the low-pH–induced refolding event (39).

The HA receptor-binding site is a pocket located on each subunit at the distal end of the molecule (see Fig. 3). The pocket is inaccessible to antibody, and the residues forming the pocket (Tyr-98, Trp-153, His-183, Glu-190, Leu-194) are largely conserved among subtypes (380; reviewed in 321 and 370). Confirmation that the pocket is the receptor-binding site was obtained by isolating HAs with single–amino acid substitutions at residue 226 that conveyed an altered specificity for sialic acid linked to galactose by either a2,6 or a2,3 linkages (288,367). Because the receptor-binding specificities differ among human trachea (a2,6), avian intestine (a2,3), and pig tracheae (a2,3 and a2,6) (134), the number of types of HA molecules that can transfer successfully from one species to another may be restricted.

The three-dimensional structure of HA indicates that five of the six carbohydrate chains on HA_1 and one carbohydrate chain on HA_2 lie on the lateral surface. The only exception is one carbohydrate chain on HA_1, which appears to stabilize the oligomeric contacts between globular units at the top of the structure (380). Although there is no known required function for carbohydrate on the native HA molecule, addition of carbohydrate is needed for the correct folding of HA in the ER (reviewed in 66).

Five antigenic sites have been mapped on the three-dimensional structure of HA by determining the location of amino acid changes in HAs of natural influenza virus isolates and in HAs of antigenic variants selected by growth in the presence of monoclonal antibodies (376). The regions of antigenic variation cover much of the surface of the globular head of HA, including residues around the antibody-inaccessible receptor-binding pocket. Monoclonal antibodies to each

of the five antigenic sites neutralize the infectivity of the virus.

The Low-pH–Induced Hemagglutinin Conformational Change

Exposure of HA to low pH (299,371) triggers a progression of irreversible conformational changes that ultimately lead to fusion of the viral and cellular membranes. The low pH found in endosomal compartments is the physiologically relevant trigger to release the hydrophobic fusion peptides. However, heat and urea treatments can also induce this change (36,293). Thus, native (pH neutral) cleaved HA is considered to be in a metastable state, and the low-pH–induced form is in a more stable form.

The HA low-pH–induced conformational change, in which HA_1 remains largely unchanged but HA_2 undergoes a refolding event, has been studied extensively. Low pH treatment of HA makes the protein susceptible to digestion by several proteases (58,65,318), and the single disulfide bond that links the HA_1 and HA_2 subunits becomes exposed (97). Furthermore, new antigenic epitopes are revealed with the concomitant loss of others (57,363,372). Despite these changes, x-ray crystallographic analysis indicated that the monomeric HA_1 globular head is virtually unaltered in structure after low-pH treatment (15). Nonetheless, rational engineering of cysteine residues into the head of HA_1 indicates that partial dissociation of the most distal region of the trimer occurs (90).

The x-ray crystallographic structure of proteolytic fragments of the low-pH–induced form of HA has been determined (33,40) (Fig. 4). In part, the structure fits with a model predicted for the low-pH–induced form (37). The x-ray structure shows that a protein refolding event occurs in which the fusion peptide is relocated more than 100 Å toward the target membrane (see Fig. 4). This refolding can be seen by comparison of the neutral-pH form with the low-pH–induced form. In the neutral-pH form, HA_2 residues 76 to 126 form a long a-helix, residues 56 to 75 form an extended loop, and residues 38 to 55 form a short a-helix (380). In comparison, in the low-pH–induced conformation, HA_2 residues 40 to 105 form a triple-stranded a-helical coiled-coil extending 100 Å. The N-terminal coiled-coil is terminated by a four-residue (HA_2 residues 34 to 37), threefold annular N cap structure that prevents the a-helix from propagating further toward the fusion peptide. Residues 106 to 112, which in the neutral structure are a-helical, uncoil to form an extended loop; the membrane proximal region of HA_2 swings up to pack against the long coiled-coil, running antiparallel to the N-terminal a-helix, packing in the groove between a-helices in the coiled-coil (see Fig. 4). The N- and C-terminal residues of HA_2 form an extensive set of interactions that fix the N-terminal and C-terminal residues of the molecule together at one extreme end of a thermally stable rodlike structure (33,40). The refolding event that moves the fusion peptide toward the target membrane is an essential step in bringing the two bilayers together. The mechanism by which two bilayers of two opposing membranes are fused together is not known, but some important observations have been made:

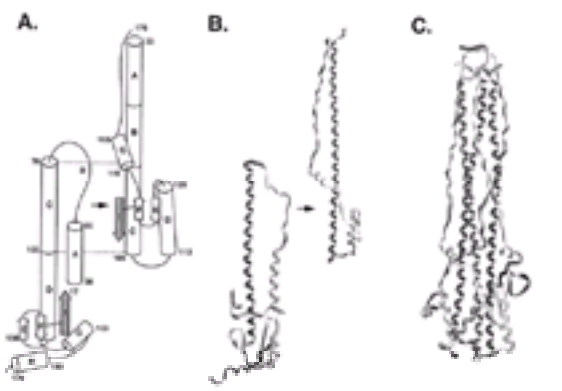

FIG. 4. The three-dimensional structure of the influenza virus HA after low-pH-induced protein refolding. **A:** Schematic diagram drawn from analysis of the x-ray crystallographic data of a proteolytic fragment of HA ($TBHA_2$) in the low pH-induced conformation. Only a monomer is shown. The long a-helix, extending 100 Å from near the proteolytic cleavage site at HA_2 residue 38 to HA_2 residue 105, participates in forming a triple-stranded coiled-coil in the trimer. In addition, the membrane-proximal portion of HA_2 swings up to pack against this long coiled-coil; residues HA_2 106 to 112, helical in the neutral pH structure, form an extended loop. (Redrawn from data of refs. 33 and 40). **B:** The atomic structure of a proteolytic fragment of the low-pH–induced form of HA_2 monomer. **C:** The atomic structure of a proteolytic fragment of the low-pH–induced form of HA_2 trimer. (This figure was produced using coordinate files available from Protein Data Bank coordinate file 1HTM and http://www.crystal.harvard.edu/wiley/coordinate_files.html.)

1. The conformational change in HA has to occur at the right time and in the right place because premature release of the HA fusion peptide causes oligomers to aggregate (294; reviewed in 319), and the refolding of HA_2 to its final and energetically most stable form is irreversible (40).
2. The fusion peptide can intercalate into lipid bilayers (reviewed in 30).
3. Several trimers are required to form a competent fusion pore (72).
4. HA requires its transmembrane domain for complete fusion to occur. A genetically engineered HA anchored to membranes with a glycosyl phosphatidylinositol anchor promotes hemifusion but not complete fusion (150).
5. It has been hypothesized that the free energy released on refolding of HA_2 may be used in the process of membrane fusion (40).

Cleavage Activation of Hemagglutinin and Its Correlation with Pathogenicity

As discussed previously, cleavage of the HA_0 precursor to HA_1 and HA_2 is a prerequisite for the conformational change to the low pH form and hence is a prerequisite for virus infectivity (158,187). Those HAs that contain the sequence

R-X-K/R-R in the connecting peptide are cleaved intracellularly by furin, a protease resident in the trans-Golgi network (TGN) (330; reviewed in 157). Those HAs with a single arginine residue in the connecting peptide (including all three known antigenic subtypes of human influenza) are not cleaved when grown in tissue culture cells (except for strain A/WSN/33; see later), but these HAs can be cleaved by addition of exogenous trypsin. When grown in embryonated eggs, influenza viruses with HA that have a single arginine residue at the cleavage site are cleaved, probably by a factor Xa–like protease (93). After cleavage, the basic residues are lost from the cleavage site, suggesting that two enzymes, the protease and an exopeptidase of the carboxypeptidase B type, are involved in activation of HA (67,87).

It was proposed that the cleavage site would correlate with the virulence of the virus and that virulent strains would contain the furin recognition motif, whereas the avirulent strains would contain only a single arginine residue (18,148); there is experimental support for this notion derived from work done with avian influenza viruses (reviewed in 157 and 329). However, there are complexities to this simple correlation: some avirulent H5 influenza virus strains have a furin recognition site. These avirulent H5 virus HAs contain an oligosaccharide chain positioned near the cleavage site, which is thought to alter accessibility of a protease to the cleavage site, whereas the virulent H5 virus HAs lack this oligosaccharide (146,147).

Among human influenza viruses, only A/WSN/33 (H1N1) can replicate in a variety of cultured cells without addition of trypsin (44), and genetic studies indicate that WSN NA is essential for WSN HA cleavage (303). It has been determined that WSN NA binds and sequesters the serum protease precursor plasminogen (92), a protease previously implicated in HA cleavage in tissue culture cells (189). Presumably, the binding of plasminogen by NA leads to a higher local concentration of the protease precursor. The structural basis for WSN NA binding plasminogen is thought to be the presence of a C-terminal lysine residue, and the absence of an oligosaccharide side chain found on all other N1 subtype NA molecules (92,196).

Influenza C Virus Glycoprotein, HEF

Influenza C virus contains only a single glycoprotein that has three activities: hemagglutinin, esterase, and fusion (HEF). The HEF protein has receptor-binding activity for 9- *O*-acetyl-*N*-acetylneuraminic acid, a fusion activity, and a receptor-destroying activity, which is a neuraminate- *O*-acetyl esterase (and not a neuraminidase) (113,348). The atomic structure of a protease-released form of HEF has been determined (289) (Fig. 5). Although HEF and HA have only about 12% sequence identity, the overall structure and details of the protein folds are quite similar. HEF is a polypeptide of 655 residues and consists of three domains: (1) an elongated stem active in membrane fusion that is closely related to the structure of HA_2 of influenza A virus, (2) a receptor-destroying esterase domain, and (3) a receptor-binding domain. The receptor-binding domain is inserted into a loop of the (esterase) domain, and the esterase domain is inserted into a loop in the stem. The esterase domain of HEF is related in structure to the esterase of *Streptomyces scabies* and a brain acetylhydrolase. HEF is cleaved by a trypsin-like protease (with a concomitant gain of low-pH–induced fusion activity and infectivity) to two disulfide-linked subunits (111,239). The structure of HEF is such that it can be anticipated that HEF will undergo a low-pH–induced conformational change similar to that known to occur for HA. The principal difference is that, unlike HA, the hydrophobic fusion peptide of HEF is not at the immediate N-terminus but instead is located six residues from the N-terminus of HEF. The hydrophobic fusion peptide tucks into the trimer, and the six N-terminal residues of HEF loop back out.

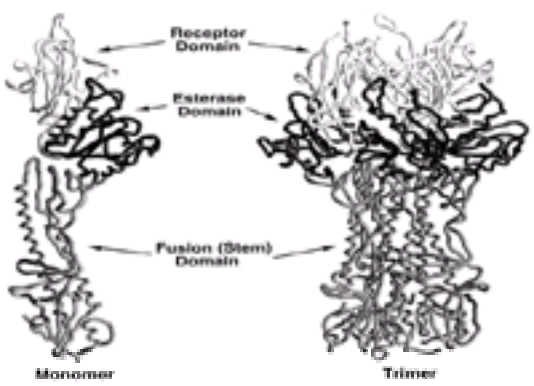

FIG. 5. The structure of the influenza C virus HEF glycoprotein. (**Left:** monomer. **Right:** trimer. Fusion, esterase, and receptor domains are indicated. (This figure was derived from atomic coordinates available from http://www.crystal.harvard.edu/wiley/coordinate_files.html .)

At one time, it was thought possible that intracellular transport of HEF might require the expression of a second viral protein. However, expression of biologically active HEF of influenza C virus strains C/Ann Arbor/1/50 and C/Taylor/1223/47 indicated their cell surface expression did not require coexpression of another viral protein (257).

The Neuraminidase and Its Gene

Introduction

The NA integral membrane protein is the second subtype-specific glycoprotein of influenza A and B viruses. The NA is a homotetramer (M_r about 220,000) containing a head domain that is enzymatically active and a stalk region that is attached to the membrane. NA is important both for its biologic activity in removing sialic acid from glycoproteins and as a major antigenic determinant that undergoes antigenic variation. Neuraminidase (acylneuraminyl hydrolase, EC 3.2.1.18) catalyzes the cleavage of the a-ketosidic linkage between a terminal sialic acid and an adjacent D-galactose or D-galactosamine (94). The role of NA in the influenza virus life cycle is still unclear. Influenza viruses containing a ts

mutation in NA aggregate at the surface of infected cells at the nonpermissive temperature, suggesting that one function of NA is the removal of sialic acid from HA, NA, and the cell surface (248). NA may also permit transport of the virus through the mucin layer present in the respiratory tract, enabling the virus to find its way to the target epithelial cells. Some avian neuraminidases (N1–3, N5–9; N4 not tested) also have a receptor binding site that causes hemagglutination, although the role of this receptor binding function in the influenza virus life cycle is not clear (103,160,186).

RNA Segment 6: Gene Structure and NA Amino Acid Sequence

The nucleotide sequence of all nine NA subtypes has been obtained (reviewed in 47 and 171). For the A/PR/8/34 subtype, RNA segment 6 is 1,413 nucleotides in length and encodes a polypeptide of 453 residues. The NA polypeptide contains only one hydrophobic domain sufficient to span a lipid bilayer, which is located near its N-terminus (residues 7 to 35). This domain acts as a combined uncleaved signal and anchor domain that both targets NA to the membrane of the ER and brings about its stable attachment in the membrane. Thus, NA is oriented with its N-terminus in the cytoplasm, and it is a prototype class II integral membrane protein (Fig. 6). There are five sites for the potential addition of N-linked carbohydrate.

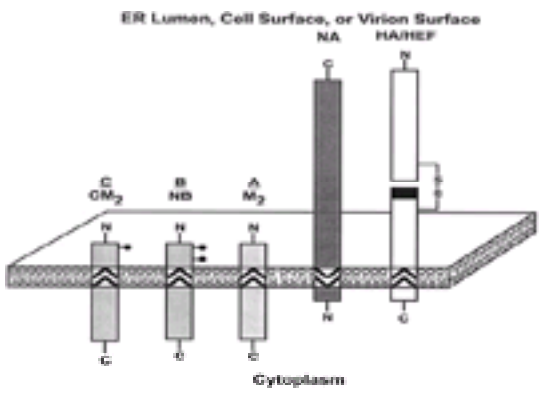

FIG. 6. Schematic representation of the orientation of the influenza A, B and C virus integral membrane proteins HA (HEF), NA, M_2, NB, and CM2.

Comparison of NA sequences among the nine subtypes of influenza A virus and influenza B virus reveals varying degrees of homology for the cytoplasmic tail, transmembrane (TM) domain, stalk, the head overall, and the catalytic active site. The cytoplasmic tail N-Met-Asn-Pro-Asn-Gly-Lys is conserved among influenza A subtypes (perhaps for a role in viral assembly; see later) but not between type A and B viruses. The TM domains of the A virus subtypes and B viruses share only the common property of hydrophobicity and not sequence homology. The stalks show a great deal of variability even between influenza A virus subtypes both in amino acid sequence and in length (62 to 82 residues, and the A/WS/33 stalk is 24 residues). The head domain shows extensive homology (42% to 57%) between influenza A virus subtypes and some homology (29%) between the type A and B viruses.

Influenza B virus RNA segment 6, in addition to containing the open reading frame (ORF) which encodes NA (466 residues), contains a second ORF of 100 residues (NB) that overlaps the NA reading frame by 292 nucleotides (309). The initiation codon used to initiate NA is the second AUG initiation codon from the 5' end of the mRNA. The NB initiation codon is the first AUG codon from the 5' end of the mRNA, and it is separated from the second AUG codon by 4 nucleotides (309). NB and NA proteins accumulate in virus-infected cells in a 0.6:1 ratio, suggesting that about 60% of ribosome preinitiation complexes scanning the NB/NA mRNA do not initiate protein synthesis at the first AUG codon but continue scanning to the second downstream AUG codon (378).

Three-Dimensional Structure of Neuraminidase

NA molecules lacking their TM domain and part of the stalk region can be obtained by pronase digestion. The isolated heads of the molecules retain enzymatic activity and antigenic properties. The protease-released neuraminidases of A/Tokyo/3/67, A/RI/5+/57, A/Tern/Australia/75, and B/Beijing/87, among others, have been crystallized, and from x-ray diffraction data, the three-dimensional structure has been determined to high resolution (19,34,48,49,345) (Fig. 7). The box-shaped head (100 Å × 100 Å × 60 Å) has circular fourfold symmetry stabilized in part by calcium ions believed to be bound on the fourfold axis of symmetry among a cluster of eight acidic groups. Each monomer of NA folds into six topographically identical, four-stranded, antiparallel b-sheets arranged in the manner of the blades of a propeller (345). The amino acids involved in the active site of NA were identified based on locating the substrate sialic acid in the molecule and obtaining an electron density difference map (49). The substrate-binding site was identified as a large pocket on the surface of each subunit rimmed by charged residues and consisting of nine acidic and six basic residues that are conserved between influenza A and B viruses. Mutagenesis of these conserved residues indicate that changes in these sites result in a loss of enzymatic activity (193).

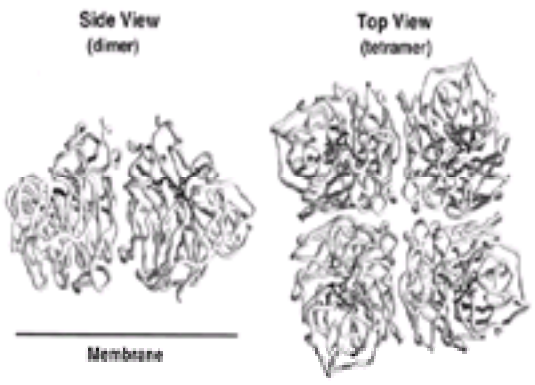

FIG. 7. Structure of the influenza A virus neuraminidase. **Left:** Side view of NA dimer. **Right:** Top down view of NA tetramer. (This figure was produced using Protein Data Bank coordinate file 7NN9.)

The HA activity reported for the N9 subtype of NA is associated with a second sialic acid (Neu5Ac)-binding site on the surface of NA separate from the enzyme active site (362). The x-ray structure of a complex of Neu5Ac with N9 NA indicates Neu5Ac binds in the second site in the chair conformation in a similar way to which Neu5Ac binds to HA (344).

In a manner analogous to that done for HA, antigenic sites were mapped on NA by analysis of changes in naturally existing strains and in variants selected with monoclonal antibodies. Four antigenic sites were identified in influenza A virus NA, each consisting of multiple epitopes (364), and these cluster into the distal surface loops that connect the various strands of b-sheet. Note that antibodies to NA are not neutralizing but rather inhibit plaque size enlargement when incorporated into the overlay medium (154).

The Influenza B Virus NB Glycoprotein

The NB ORF on influenza B virus RNA segment 6 encodes the NB glycoprotein (Fig. 8). NB is an integral membrane protein that is abundantly expressed at the plasma membrane of influenza B virus–infected cells (308), and genetic and biochemical data have indicated that NB is oriented in membranes with an 18-residue N-terminal ectodomain, a 22-residue TM domain, and a 60-residue cytoplasmic tail (377). NB lacks a cleavable signal sequence but instead contains a single hydrophobic domain that is thought both to target NB to membranes and to anchor NB in a stable manner. The N-terminal ectodomain of NB contains two N-linked carbohydrate chains attached to residues 3 and 7 (377). These carbohydrate chains are further modified by the addition of a number of repeating units of galactose b1®4-*N*-acetylglucosamine b1®3 (Gal b1®4-GlcNAc b1®3) attached to a (mannose) $_3$ (GlcNAc)$_2$ core oligosaccharide, known as *polylactosaminoglycan modification* (377,379). Originally, NB was thought to be lacking from virions, but recent analysis of virions, after endo-b-galactosidase digestion to remove polylactosaminoglycan, suggests that NB is a component of virions present at about 100 copies per virion (13,24). The function of NB in the influenza virus life cycle is not known. The influenza B virus NB glycoprotein has the same uncommon membrane orientation (type III integral membrane protein) as the influenza A virus M_2 protein encoded by RNA segment 7 (see later and Fig. 6). The influenza A virus M_2 protein has ion channel activity, but influenza B virus lacks a direct M_2 counterpart. However, because the replication strategies of the influenza type A and B viruses are similar, there has been considerable speculation that the influenza B virus NB protein may have ion channel activity (reviewed in 184). NB has been expressed in bacteria and the purified NB protein incorporated into planar bilayers. Electrophysiologic recordings from these preparations indicated an ion channel activity (335). However, the lack of a selective inhibitor makes it difficult to assign definitively an ion channel activity to NB.

RNA Segment 7 of Influenza Virus

Introduction

RNA segment 7 of influenza A virus encodes two known proteins, the matrix protein M_1, which lies inside the lipid envelope and constitutes the most abundant polypeptide in the virion, and the M_2 protein, which is a minor component of

virions and has ion channel activity. Three mRNA transcripts have been identified that are derived from influenza A virus RNA segment 7: a colinear transcript encoding M_1 protein, a spliced mRNA encoding the M_2 protein, and an alternatively spliced mRNA ($mRNA_3$), which has the potential to encode a 9–amino acid peptide, but it has not been identified in virus-infected cells. Influenza B virus RNA segment 7 encodes two polypeptides using tandem cistrons: the matrix protein M_1 and the 109-residue BM_2 protein of unknown function. The equivalent RNA segment in influenza C virus (RNA segment 6) is transcribed into a colinear mRNA that encodes the p42 protein. A portion of the colinear transcripts are spliced to form the mRNA encoding the matrix protein. The p42 precursor protein is translated from the colinear mRNA and subsequently processed to yield p31 and CM2 proteins.

RNA Segment 7 Gene Structure and Encoded Proteins

Influenza A Virus

RNA segment 7 of influenza A virus encodes two known proteins, M_1 and M_2. The gene is 1,027 nucleotides in chain length and has one large ORF of 252 residues that encodes the M_1 protein (2,180,382) (Fig. 9). A colinear transcript mRNA encodes the M_1 protein, whereas the M_2 protein is encoded by a spliced mRNA (183). The M_2 mRNA contains a 51-nucleotide virus-specific leader sequence, a 689-nucleotide intron, and a 271-nucleotide [excluding poly(A) tail] body region. The leader sequence of the M_2 mRNA body region encodes 88 residues in the +1 reading frame and overlaps the M_1 protein by 14 residues. A second, alternatively spliced mRNA ($mRNA_3$) has also been identified; it has a 5' leader sequence of 11 virus-specific nucleotides and shares the same 3' splice site as the M_2 mRNA. No evidence has been obtained to indicate that $mRNA_3$ is translated, but if it is, it would yield a 9-residue peptide identical to the C-terminus of the M_1 protein (183).

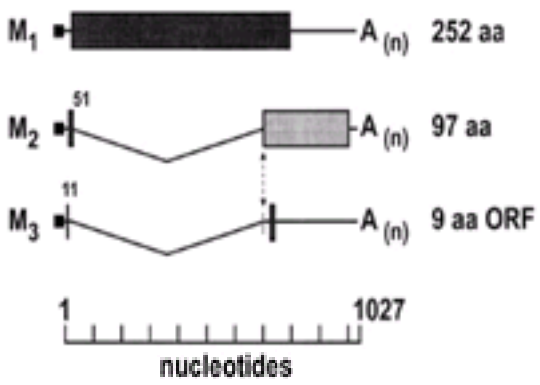

FIG. 9. Schematic diagram of the influenza A virus M_1, M_2, and $mRNA_3$ and their coding regions. Thin lines at the 5'- and 3'-termini of the mRNAs represent untranslated regions. *Shaded* or *hatched areas* represent coding regions in 0 or +1 reading frames, respectively. The introns are shown by the V-shaped lines. Rectangles at 5' ends of the mRNAs represent heterogeneous nucleotides derived from cellular RNAs that are covalently linked to viral sequences. No evidence has yet been obtained that $mRNA_3$ is translated *in vivo.* (Adapted from ref. 182, with permission.)

The M_1 protein contains 252 residues (M_r, 27,801) and is a type-specific antigen of influenza virus, and comparison of its predicted amino acid sequence among influenza A virus subtypes indicates it is highly conserved (reviewed in 171).

Influenza B Virus

RNA segment 7 of influenza B virus encodes two known proteins, M_1 and BM_2. The gene is 1,191 nucleotides in length and contains two ORFs (Fig. 10). The first ORF in the 0 reading frame begins at AUG codon nucleotides 25 to 27 and continues to a termination codon at nucleotides 769 to 771. This ORF encodes the 248–amino acid M_1 protein, 63 residues of which are identical to those of the influenza A virus M_1 protein (27). A second ORF in the +2 frame, and overlapping the M_1 protein ORF by 86 residues, has a coding capacity of 195 residues and is designated BM_2 (27,126). A polypeptide, BM_2, derived from the BM_2 ORF, was identified in cells infected with influenza B virus by using an antisera generated to a b-galactosidase–BM_2 ORF fusion protein (126). The BM_2 protein appears to be a soluble and cytoplasmically located protein of unknown function. A mutational analysis indicates that the BM_2 protein initiation codon overlaps with the termination codon of the M_1 protein in a translational stop-and-start pentanucleotide UAAUG, and that expression of the BM_2 protein requires termination of M_1 synthesis adjacent to the 5' end of the BM_2 coding region; thus, termination of translation and the reinitiation event are tightly coupled (126) (see Fig. 10). In prokaryotes, coupled tandem cistrons with the termination codon of one gene overlapping the initiation codon for a downstream gene is a common situation for coordinating regulated bacterial genes (e.g., *trp* operon; reviewed in 234); however, it is uncommon in eukaryotes.

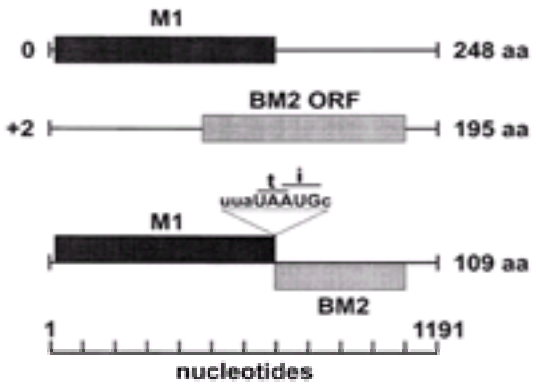

FIG. 10. Schematic representation of the open reading frames (ORFs) in influenza B virus RNA segment 7. **Top two lines:** The ORF encoding the M_1 protein contains 248 residues, and the BM_2 ORF consists of 195 residues (27). **Third line:** the extent of the BM_2 ORF used to translate the BM_2 protein found in influenza B virus–infected cells. The pentanucleotide at which M_1 translation termination (*t; UAA*) and BM_2 translation initiation (*i; AUG*) is shown in capital letters. (Data from ref. 126, with permission).

Influenza C Virus
