Interferon therapy of recurrent respiratory papillomatosis has been less successful than that of genital warts. In one randomized national study, children with severe disease were treated either with surgery plus parenterally administered interferon-a or with surgery alone (135). Complete response was achieved in 3 of 28 patients who received surgery plus interferon, but in none of 28 patients who received only surgery. In another large study, children receiving surgery plus parenterally administered human leukocyte interferon (for 1 year) were compared with children receiving surgery alone (115). In the first 6 months of the treatment, the papilloma growth rate in the interferon group was significantly lower than that in the control group; however, in the second 6 months, this difference diminished and was no longer significant. No complete responses were seen.

Depending on the setting, treatment of cervical dysplasia may be surgical, with cryotherapy, by loop electrosurgical

excision repair, or by laser. Most successfully treated cases became negative for HPV DNA, whereas incompletely treated cases may remain positive (22).

PREVENTION

Interruption of Transmission

As noted previously, the epidemiology of various forms of HPV infection may differ drastically. Therefore, approaches to control genital HPV infection would be distinct from those to control nongenital infections. Pap smear screening can prevent most cervical cancers, which represent the most serious public health consequence of HPV infection. However, current efforts to prevent HPV infection have not been particularly successful.

Epidemiologic findings, discussed earlier, suggest that most cases of laryngeal papillomas that arise in infants and young children have been transmitted from exposure to the mother's HPV during vaginal delivery (137,277). This hypothesis raises the possibility that the use of cesarean section for the delivery of infants of mothers with known genital HPV infection would reduce the risk for HPV exposure. However, the incidence of genital HPV infection is high, whereas that of laryngeal papillomas is low, which means that many cesarean sections would be needed to prevent each case of laryngeal papillomas. These considerations suggest that the morbidity and mortality risk to the mother associated with cesarean section may, in most situations, be greater than the risk of laryngeal papillomas to the baby, which argues against the widespread use of this procedure to prevent laryngeal papillomas. However, because the risk for papillomas is greater in younger women and in first pregnancies, there may be a subset of HPV-positive women for whom the cost-benefit analysis might favor cesarean section (277).

Public health efforts that can prevent other sexually transmitted infections should, in principle, also be effective in preventing genital HPV infection. Indeed, decreased sexual promiscuity on the part of both sexual partners should reduce the likelihood of exposure to genital HPVs. It would also seem reasonable to expect that condoms would be able to reduce the incidence of genital HPV infection. However, such protection has been shown for transmission of external genital warts to men but has not yet been clearly established for internal or external genital lesions in women (121), perhaps because epidemiologic studies have not focused specifically on this issue. In the absence of specific treatment that would eradicate the infection, investigation of sexual partners of infected individuals would not be expected to have much impact on HPV transmission, although it may help identify infected individuals who otherwise might not realize that they are infected. Although likely, it is not known definitively whether eradication of visible lesions lowers the transmission rate of genital HPV infection.

Vaccine Prospects

The important public health consequences of genital HPV infection make it highly desirable to develop an effective vaccine against those HPV infections associated with cancer, especially cervical cancer. Natural history studies support the conclusion that protective immune responses occur regularly in most cervical infections (65,310). These responses appear to confer type-specific protection, although the critical viral determinants have not been established. Because the same HPV types are also implicated in most other genital cancers and in oral cancers associated with HPV infection, these less common malignancies might also be prevented by a vaccine targeted to the HPVs implicated in cervical cancer. Experimental vaccine studies in animal papillomavirus models have identified several possible vaccine targets, including L1, L2, E1, E2, E6, and E7 (38,163,178,271). Intradermal injection of a vaccine composed of formalin-inactivated COPV virions was shown to protect against COPV-induced oral lesions under field conditions (16). This result demonstrates that systemic immunization can induce protective immunity against a mucosal PV infection under natural conditions. The L1 neutralization epitopes were present in the vaccine, but the viral determinants that conferred protection were not definitively identified.

Most studies have focused on prophylactic vaccine strategies, although immune reactivity against certain viral proteins may have some therapeutic potential (reviewed in 30,70,86, and 183). The chronicity of HPV infection, combined with the fact that serious pathologic sequelae arise after many years of infection, provides a highly desirable setting for developing an HPV vaccine with activity against established infection. The continuing challenge of this goal is that there is no precedent for an effective therapeutic vaccine. In addition, from a public health point of view, protective immunity must be of long duration. The neutralizing antibodies induced by most prophylactic vaccines represent the traditional cornerstone of preventive activity, in part because these antibodies can persist for years after vaccination. The activity of therapeutic vaccines would probably depend primarily on their induced cellular immune reactivity, whose duration remains unknown. However, the approach itself is feasible. For example, HPV-16 E7 is immunogenic, and immunization with E7 peptide can induce protection in mouse studies against challenge with a tumorigenic cell line that expresses E7 (45,82). The immunogenicity of E7 can also be enhanced by various manipulations, such as by redirecting the protein to a class II pathway (176), increasing its rate of class I presentation by a mutation that increases the degradation rate of the protein (281), or fusing it to heat shock protein 70 (44).

Several prophylactic vaccine studies in animal papillomavirus models have emphasized the potential of L1 as an immunogen because it contains the immunodominant neutralization epitopes. When expressed at high levels, L1 can self-assemble into VLPs, which are empty capsids that closely resemble those of authentic virions morphologically and immunologically (144). As with authentic virions, systemic immunization of animals with L1 VLPs has been found to induce high titers of neutralizing antibodies that are conformationally dependent and type-specific. In cutaneous (CRPV) and oral mucosal (COPV and BPV-4) PV models, systemic immunization with L1 VLPs can confer 95% to 100% protection against experimental high-dose challenge with the homologous virus (31,48,145,306). Protection is type-specific and can be passively transferred with immunoglobulin G, implying that most of the protective effects are mediated by the neutralizing antibodies. An interesting feature of papillomavirus VLPs is that adjuvant is not required for eliciting protective immunity. An L2 neutralization epitope that is broadly cross-reactive against genital-mucosal HPVs has been identified, but its immunogenicity is lower than the type-specific L1 neutralization epitopes (140,248).

Evidence that cellular immune reactivity against certain nonstructural viral proteins can induce some protection in animal models has also led investigators to incorporate peptides from these proteins into VLPs by fusing the peptides to L1 or L2, to form “chimeric” VLPs. When L2 is coexpressed with L1, it coassembles with L1 to form L1 and L2 VLPs. The L1-to-L2 ratio in these VLPs is close to the 30:1 that is found in virions isolated from papillomas. Polypeptides several hundred amino acids in length can be incorporated into VLPs by fusing them to L2. Alternatively, shorter peptides, up to about 60 amino acids in length, can be fused to a truncated C-terminus of L1 without eliminating the ability of L1 to self-assemble into VLPs. Although fewer amino acids can be incorporated than with L2 fusions, L1 fusions have the advantage of being present in greater abundance in VLPs. Protection against a tumorigenic mouse cell line transformed with HPV-16 E7 has been shown for chimeric VLPs composed of a C-terminally truncated L1 fused to an E7 peptide and for chimeric VLPs composed of full-length L1 and of L2 fused to full-length E7 (103,232).

Early-phase human clinical trials have been carried out for L1 VLPs and for some vaccines that contain nonstructural viral proteins. The vaccine studies in humans have confirmed that the human immune responses are similar to those seen in animals (111,337). It remains to be determined what approaches may be effective prophylactically or therapeutically.

CHAPTER 67 The Viruses and Their Replication

Thomas E. Shenk

Adenoviruses were first isolated and characterized as distinct viral agents by two groups who were searching for the etiologic agents of acute respiratory infections. In 1953, Rowe and colleagues (333) observed the spontaneous degeneration of primary cell cultures derived from human adenoids. The pathogenic changes proved to result from the replication of previously unidentified viruses present in the adenoid tissues. In 1954, Hilleman and Werner (172) were studying an epidemic of respiratory disease in army recruits, and they isolated agents from respiratory secretions that induced cytopathic changes in cultures of human cells. The viruses discovered by the two groups were soon shown to be related (188), and, in 1956, the agents were named *adenoviruses,* after the original tissue (adenoid) in which the prototype viral strain was discovered (99). Epidemiologic studies confirmed that adenoviruses are the cause of acute febrile respiratory disease among military recruits (90,122). It soon became clear, however, that adenoviruses are not the etiologic agents of the common cold; they are responsible for only a small portion of acute respiratory morbidity in the general population and for about 5% to 10% of respiratory illness in children. Besides respiratory disease, adenoviruses cause epidemic conjunctivitis (196), and they have been associated with a variety of additional clinical syndromes—perhaps most notably, infantile gastroenteritis (450). Today, more than 100 members of the adenovirus group have been identified that infect a wide range of mammalian and avian hosts. All of these viruses contain a linear, double-stranded DNA genome encapsidated in an icosahedral protein shell.

In 1962, Trentin and colleagues (398) made a seminal discovery: human adenovirus type 12 induces malignant tumors after inoculation into newborn hamsters. This was the first time that a human virus was shown to sponsor oncogenesis. No epidemiologic evidence has been reported linking adenoviruses with malignant disease in humans; extensive searches have generally failed to find adenovirus nucleic acids in human tumors (144,254). Nevertheless, the ability to induce tumors in animals and to transform cultured cells has established adenovirus as an important model system for probing the mysteries of oncogenesis.

As the interest in adenoviruses as tumor viruses intensified, their virtues as an experimental system became evident. The prototype human adenoviruses are easily propagated to produce high-titer stocks, and they initiate synchronous infections of established cell lines. Further, the viral genome is readily manipulated, facilitating the study of adenovirus gene functions by mutational analysis. Studies of adenovirus-infected cells have made numerous contributions to our understanding of viral and cellular gene expression and regulation, DNA replication, cell cycle control, and cellular growth regulation.

Perhaps the signal contribution to modern biology of the adenovirus system has been to host the discovery of messenger RNA (mRNA) splicing. Studies on the biogenesis of viral mRNA first demonstrated that many mRNAs are produced from a large nuclear transcript (17,421), and subsequent analysis of the structure of adenovirus mRNAs revealed the existence of introns (30,65). Today, the utility of adenovirus as a vector for gene therapy is the subject of intense exploration. This chapter overviews the structure of the adenovirus particle, the adenovirus replication cycle in human cells, its ability to oncogenically transform cells, and its interactions with host cells and host organisms. Details of adenovirus transformation are also considered in Chapter 10, and a discussion of the pathogenesis, clinical syndromes, epidemiology, techniques for diagnosis, modes of treatment, and utility of adenoviruses as vectors follows in Chapter 68.

CLASSIFICATION

The adenoviruses constitute the *Adenoviridae* family of viruses, which is divided into two genera, *Mastadenovirus* and *Aviadenovirus* (297). Whereas the *Aviadenovirus* genus is limited to viruses of birds, the *Mastadenovirus* genus includes human, simian, murine, bovine, equine, porcine, ovine, canine, and opossum viruses. Although there is antigenic cross-reactivity among members within each genera owing to conserved epitopes located on the hexon protein of the virion (296), there is no known antigen common to all adenoviruses.

Forty-nine human adenovirus serotypes (Table 1) have been distinguished on the basis of their resistance to

neutralization by antisera to other known adenovirus serotypes. Type-specific neutralization results predominantly from antibody binding to epitopes on the virion hexon protein and the terminal knob portion of the fiber protein (296). Hypervariable regions have been identified on the hexon that make up serotype-specific loops on the surface of the protein (75). The various serotypes are classified into six subgroups (see Table 1) based on their ability to agglutinate red blood cells (330). The central shaft of the viral fiber protein is responsible for binding to erythrocytes, and the hemagglutination reaction of an adenovirus is inhibited by antisera specific for viruses of the same type but not by antisera to viruses of different types. A variety of additional classification schemes have been explored, including subgroupings based on oncogenicity in rodents, relatedness of tumor antigens, electrophoretic mobility of virion proteins, or genome homologies. The various schemes produce reasonably concordant groupings (see Table 1), suggesting that the widely used classification based on hemagglutination is a reasonable standard.

Subgroup	Hemagglutination group	Serotypes	Oncogenic potential		Percentage of G+C in DNA
			Tumors in animals	Transformation in tissue culture	
A	IV (little or no agglutination)	12, 18, 31	High	+	48–49
B	I (complete agglutination of monkey erythrocytes)	3, 7, 11, 14, 16, 21, 34, 35	Moderate	+	50–52
C	III (partial agglutination of rat erythrocytes)	1, 2, 5, 6	Low or none	+	57–59
D	II (complete agglutination of rat erythrocytes)	8, 9, 10, 13, 15, 17, 19, 20, 23–30, 32, 33, 36–39, 42–48	Low or none (mammary tumors)	+	57–61
E	III	4	Low or none	+	57–59
F	III	40,41	Unknown

TABLE 1. *Classification schemes for human adenoviruses (mastadenovirus H)*

VIRION STRUCTURE

Adenoviruses are icosahedral particles measuring 70 to 100 nm in diameter (177) (Fig. 1). The particles (virions) contain DNA (13% of mass), protein (87% of mass), no membrane or lipid, and trace amounts of carbohydrate because the virion fiber protein is modified by addition of glucosamine (143,191). Virions consist of a protein shell surrounding a DNA-containing core. The protein shell (capsid) is composed of 252 subunits (capsomeres), of which 240 are hexons and 12 are pentons (125). As suggested by their names, penton and hexon subunits are surrounded by five and six neighbors, respectively. Each penton contains a base, which forms part of the surface of the capsid, and a projecting fiber whose length varies among different serotypes (295).

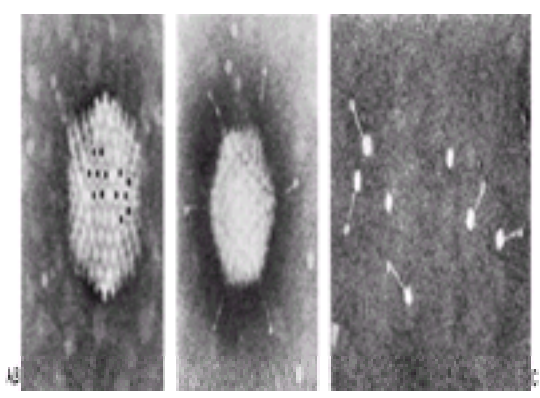

FIG. 1. Adenovirus type 5. **A:** The virion is an icosahedron. One of the 240 hexon capsomeres surrounded by 6 hexons and one of the 12 penton capsomeres surrounded by 5 hexons are marked (*dots*). **B:** Six of the 12 fibers that are present on each virus particle are shown projecting from penton capsomeres located at the vertices of the icosahedral capsid. **C:** Free penton capsomeres containing penton base and fiber (×285,000). Virion Polypeptides and DNA

Most of the structural studies of adenoviruses have focused on the closely related adenoviruses type 2 and 5 (Ad2 and Ad5). Electrophoretic analyses of purified virions disrupted with sodium dodecylsulfate was employed initially to identify structural polypeptides (191,407). Comparison of electrophoretic results with genomic open reading frames (ORFs) suggests there are probably 11 virion proteins. These proteins are numbered by convention (255), with no polypeptide I because the moiety originally designated I proved to be a mixture of aggregated molecules.

The outer shell or capsid of the virion is composed of seven known polypeptides. Polypeptide II (967 amino acids) is the most abundant virion constituent. The hexon protein is composed of three tightly associated molecules of polypeptide II (179), and this trimeric protein is referred to as the *hexon capsomere.* Polypeptides VI (217 amino acids), VIII (134 amino acids), and IX (139 amino acids) are associated with the hexon protein after various isolation procedures (107). All three polypeptides likely stabilize the hexon capsomere lattice, and polypeptides VI and VIII probably bridge between the capsid and core components of the virion. Five copies of polypeptide III (571 amino acids) associate to form the penton base protein (407), which is found at each vertex of the icosahedral particle. Polypeptide IIIa (566 amino acids) is associated with hexon units that surround the penton after pyridine dissociation of virions, and it appears to link adjacent facets of the capsid and bridge between hexons and polypeptide VII of the core (106). Polypeptide IV (582 amino acids)

forms the trimeric fiber protein (407), which projects from the penton base at each vertex of the icosahedron. The combination of penton base plus fiber is called the *penton capsomere.* All human adenoviruses examined to date encode a single fiber protein with the exception of Ad40 and Ad41, which encode two fiber proteins and incorporate both polypeptides into their virions (205). Because the fiber interacts with a cellular receptor protein, the incorporation of two fiber proteins might extend the range of cell types to which these viruses can bind. Hexon and penton capsomeres are the major components on the surface of the virion, and their constituents, polypeptides II, III, and IV, contain tyrosine residues that are exposed on the virion surface and can be labeled by iodination of intact particles (106).

The core of the virion contains four known proteins and the viral genome. Polypeptides V (368 amino acids), VII (174 amino acids), and mu (19 amino acids) are basic, arginine-rich proteins (181,335) that contact the viral DNA (6,56). The function of the mu protein is unknown (181). Polypeptide VII is the major core protein, and it serves as a histone-like center around which the viral DNA is wrapped (56,272). Polypeptide V can bind to a penton base (106), and it might bridge between the core and capsid, positioning one relative to the other. The fourth protein in the core is the *terminal protein* (671 amino acids), which is covalently attached to the ends of the viral DNA. It was first identified indirectly by its ability to mediate circularization of the viral DNA through a protease-sensitive, noncovalent interaction (327). The circularizing agent was shown to be a 55-kd protein covalently attached to each 5' end of the viral DNA (324), and the protein was subsequently visualized on viral DNA by avidin-biotin labeling (110a). The linkage between DNA and protein is a phosphodiester bond formed between the b-hydroxyl group of a serine (residue 562 of terminal protein) and the 5' hydroxyl of the terminal deoxycytosine residue (83,360). The protein is not evident in electrophoretic analyses of virion proteins because it is present in only two copies per particle. The terminal protein serves as a primer for DNA replication (49,52,236,382), and it mediates attachment of the viral genome to the nuclear matrix (36,115,342).

Ad2 DNA was the first adenovirus genome to be completely sequenced (326), and it includes a total of 35,937 base pairs (bp). Ad5 (67), Ad12 (365), murine adenovirus (268), canine adenovirus (279), and avian adenovirus genomes (62,312) have also been sequenced. The DNAs of different adenoviruses have inverted terminal repeat sequences ranging in size from about 40 to 160 bp (12,119,396). The inverted repeats enable single strands of viral DNA to circularize by base-pairing of their terminal sequences, and the resulting base-paired panhandles are thought to be important for replication of the viral DNA.

Capsid and Core Three-Dimensional Structure

X-ray crystallography, electron microscopy, and combinations of the two methods have been used to generate a fairly refined picture of the adenovirus capsid (reviewed in 372). The x-ray structure of the major capsid protein, the hexon, has been determined to a resolution of 2.9 Å (13,325). The hexon protein, which is also referred to as the hexon capsomere, is a trimer composed of three interwoven hexon polypeptides. As described first for the picornaviruses, a b-structure stabilizes the association of the three subunits into a larger structure consisting of two domains: a triangular top facing the outside of the capsid and a hexagonal base with a central cavity. Group-of-nine hexons (“ninemers”), which can be isolated from each triangular face of the virion by treatment with 10% pyridine (313), provided insight to how interactions between hexons are stabilized. The structure of these ninemers was examined by subtracting an array of nine projected x-ray–determined hexons from scanning transmission electron microscopic images (116). The resulting two-dimensional difference image revealed density from a minor protein component extending along the hexon–hexon interfaces. Biochemical analysis had previously identified this component as polypeptide IX (407), a minor capsid constituent involved in stabilization of the capsid (69). Its carboxy-terminal domain is exposed on the surface of the capsid (3).

The three-dimensional structure of the complete adenovirus particle was determined to 21 Å resolution by image reconstruction from cryoelectron micrographs (63,371,372). A density map of the virion was generated from multiple images of the particle in different orientations. The reconstruction process relied on the known icosahedral symmetry of the virion to align the individual images. This work provided the first detailed visualization of the vertex proteins, including the penton base and its protruding fiber; it confirmed the earlier placement of protein IX; and it located minor capsid polypeptides at the edges of triangular facets, bridging hexons in adjacent facets. The three-dimensional structure of the virion has been refined by subtracting 240 copies of the crystallographic hexon from the cryoelectron microscopic image reconstruction (372). The difference map revealed more precisely the positions of several capsid proteins (Fig. 2). A less abundant stabilizing protein is located at each specialized position in the hexon assemblage. The penton complex fills the large gaps at the vertices, polypeptide IX stabilizes hexon–hexon contacts within a facet, polypeptide IIIa joins hexons of adjacent facets, and polypeptide VI anchors the ring of peripentonal hexons on the inside surface of the capsid and connects the capsid to the core. The structure of the particle has been further refined by employing constrained maximum entropy tomography (359).

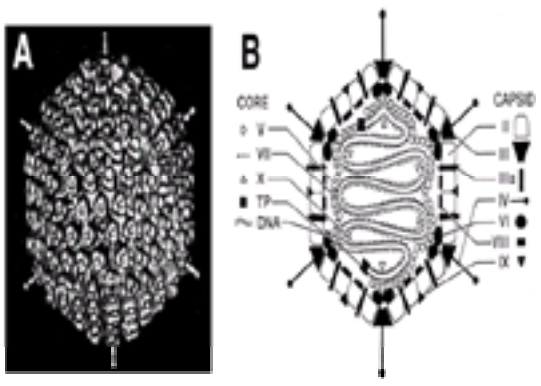

FIG. 2. Models of the adenovirus virion. **A:** Three-dimensional image reconstruction of the intact adenovirus particle viewed along an icosahedral threefold axis. **B:** Stylized section of the adenovirus particle based on current understanding of its polypeptide components and DNA. No real section of the icosahedral virion would contain all components. Virion constituents are designated by their polypeptide numbers with the exception of the terminal protein

(*TP*). A from ref. 371, with permission; B from ref. 370, with permission.)

The fiber protein that projects from each vertex of the particle is composed of three copies of polypeptide IV (334,407). The amino-terminal 40 residues of each subunit are embedded in the penton base (84,423). A central extended shaft is composed of repeating motifs about 15 amino acids in length, and the number of repeat units differs among adenovirus serotypes (145). The carboxy-terminal 180-residue segment of each subunit composing the fiber protein contributes to formation of a terminal bulb (84). The structure of the terminal bulb has been determined at 1.7 Å resolution (442), and a three-dimensional model of the fiber shaft has been proposed (375), predicting that its constituent polypeptide chains form a left-handed, triple helical structure composed of short b-strands interspersed with extended loops that follow the overall helical path. This model fits reasonably well with the cryoelectron microscopic results (372) and mutational studies (173).

The adenovirus core is composed of the linear, double-stranded DNA and four virus-coded proteins. Unlike cellular chromatin, which yields discrete mononucleosomal DNA fragments of about 146 bp on digestion with micrococcal nuclease, the adenovirus core yields a heterogeneous population of DNA fragments ranging from about 50 to 300 bp in length (74,272,410,411). These fragments are associated with polypeptide VII (272,410). Although the reason for the variability in DNA length is not understood, it nevertheless seems clear that adenovirus chromatin is organized into unit particles composed of DNA and polypeptide VII (272,410). The notion that adenovirus chromatin is arranged in a repeating unit is consistent with electron microscopic visualization of particles within the adenovirus core (41,411) and with x-ray scattering patterns obtained with cores (85). Digestion of cores with limiting amounts of nuclease fails to produce a ladder-like series of DNA fragments on electrophoresis, as would be predicted for an oligomeric structure, and this might be due to the fragile and unstable nature of the core after release from virions (411).

The higher-level organization of the core remains obscure. Psoralen cross-linking of viral DNA within partially disassembled virions indicates that the linear molecule is organized into eight supercoiled domains (440), in agreement with earlier electron microscopic studies suggesting that the core is organized into 8 to 12 domains (41). It is intriguing to note that the eight-domain organization places most of the viral transcription units into independent supercoiled domains (440).

GENOME ORGANIZATION

All human adenovirus genomes that have been examined to date have the same general organization; that is, the genes encoding specific functions are located at the same position on the viral chromosome. Avian adenoviruses differ in that they lack several of the early genes identified in the human viruses and contain ORFs of unrelated sequence in their place (62,312). The linear genome contains two origins for DNA replication. The two origins are identical, and one is present in each terminal repeat. The genome also includes a cis-acting packaging sequence (135,155,166,168) that must be located within several hundred base pairs of an end of the chromosome to direct the interaction of the viral DNA with its encapsidating proteins (165).

The viral chromosome carries five early transcription units (E1A, E1B, E2, E3, and E4), two delayed early units (IX and IVa2), and one late unit (major late) that is processed to generate five families of late mRNAs (L1 to L5), all of which are transcribed by RNA polymerase II (reviewed in 308) (Fig. 3). Families of mRNAs were initially localized on the adenovirus map by hybridization to restriction enzyme–generated fragments of the viral DNA (351), and transcription units were defined by ultraviolet light–mapping experiments (32,439). The chromosome also carries one or two (depending on the serotype) virus-associated (VA) genes transcribed by RNA polymerase III. By convention, the map is drawn with the E1A gene at the left end. Both strands of the viral DNA are transcribed with the so-called rightward reading strand on the conventional map coding for the E1A, E1B, IX, major late, VA RNA, and E3 units and the leftward reading strand coding the E4, E2, and IVa2 units.

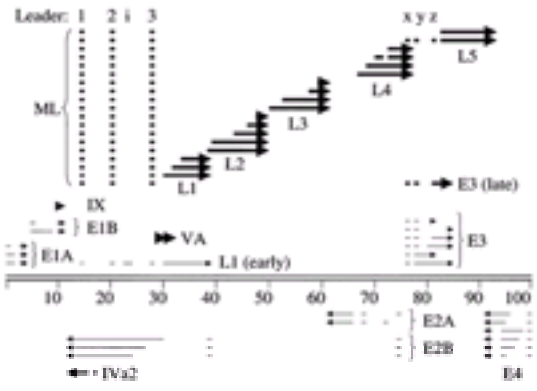

FIG. 3. Transcription map of adenovirus type 2. The early mRNAs are diagrammed with their exons represented by *thin arrows,* late mRNAs are drawn with *heavy arrows,* and delayed early mRNAs (*1Va2* and *IX*) are designated with *arrows of intermediate thickness.* Most late mRNAs originate at 16.3 map units and contain the tripartite leader whose components are labeled *1, 2,* and *3.* Some of the late mRNAs also contain leader segments *i, y,* or *z* polypeptide. Introns are indicated by gaps in the lines comprising the *arrows.*

Little is known about the functional and evolutionary considerations that have led to the current organization of the transcription units on the viral chromosome. Their arrangement might serve a timing function. Viral cores have an

organized structure (41,440), and they are converted from a more compact to a more open structure as the early phase of infection progresses (41,440). Perhaps RNA polymerase initially interacts with promoters exposed at the ends of the chromosome, and transcription of the terminal units drives further opening of the core structure. This proposal predicts that the terminal E1A and E4 transcription units would be the first to be expressed, and this is the case. Thus, the location of a transcription unit on the chromosome could influence the order in which it is expressed relative to other units during the early phase of the infectious cycle.

The activation of transcription units can also be influenced by their location relative to other units on the chromosome. Insertion of a strong transcriptional termination sequence between the E1A and E1B units inhibits activation of the E1B unit, suggesting that transcriptional read-through from E1A to E1B contributes to the activation of E1B (108). One might also imagine that transcription units embedded within the major late unit would be influenced in cis by its very active expression late after infection. However, different viral molecules could serve as templates for early and late transcription units, avoiding complications that might arise from overlapping transcription units. Further, initiation is rate limiting; hence, even if opposing and overlapping units were transcribed from the same template, transcription complexes would seldom meet on the chromosome.

Each of the adenovirus genes transcribed by RNA polymerase II gives rise to multiple mRNAs that are differentiated by alternative splicing and in some cases by the use of different poly(A) sites. The structures of mRNAs were defined by a variety of procedures, including electron microscopic heteroduplex analysis (64,66) and S1 nuclease mapping (32); 5' ends were localized by primer extension analysis (464). As mentioned earlier, the analysis of adenovirus mRNA structure led to the discovery of splicing (30,65) (Fig. 4).

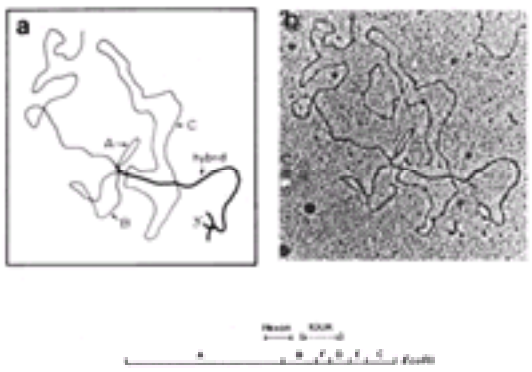

FIG. 4. Detection of adenovirus hexon transcripts processed by splicing near their 5' ends. When hexon mRNA was hybridized to viral DNA, it formed a duplex structure with three short DNA loops (labeled *A, B,* and *C*), which correspond to introns removed from the mRNA by splicing. **A:** Diagram of duplex molecules. **B:** Electron micrograph of the RNA:DNA hybrid. The position of the hexon and L4 100-kd protein coding regions are displayed on the EcoR1 cleavage map of adenovirus type 2 (*bottom*). (From ref. 30, with permission.)

Some of the protein products generated from the same transcription unit are partially related in their sequence (e.g., the two major polypeptides encoded by the E1A unit); others have no sequence in common (e.g., the two major E1B-coded polypeptides). Unfortunately, no consistent terminology has been adopted for naming viral proteins: the E1A proteins are named for the sedimentation coefficient of the mRNAs that encode them; E1B and E3 proteins are designated by their molecular mass; E2 proteins are named for their functions; E4 proteins are named for ORFs; and the structural proteins encoded by the late transcription unit are termed II to IX. The various historical names of viral polypeptides are used in this chapter, generally preceded by the name of the transcription unit or family of late mRNAs that encodes them (e.g., E1A 13S, E4orf6, L5-IV).

Many of the individual adenovirus transcription units encode a series of polypeptides with related functions. As discussed later, the E1A unit encodes two proteins that activate transcription and induce the host cell to enter the S phase of the cell cycle; E1B encodes two proteins that block apoptosis; E2 encodes three proteins that function directly in DNA replication; E3 encodes products that modulate the response of the host to infection; and the late family of mRNAs is concerned with the production and assembly of capsid components. Only the E4 unit encodes an apparently disparate set of functions. E4 products mediate transcriptional regulation and mRNA transport and modulate DNA replication and apoptosis. One might speculate that an ancestral adenovirus encoding fewer gene products evolved to generate a modern virus in which many of the ancestral genes have given rise to groups of more specialized products that remain functionally related. The grouping might also be driven in part by the advantage of using a single transcriptional control element to regulate the expression of multiple polypeptides that are needed simultaneously to execute a function such as DNA replication. Further, it might be useful to group closely the coding regions for products that interact physically or functionally to reduce the frequency with which they can be separated by recombination. Otherwise, recombinant variants, which could be defective because they encode products unable to function well together, might be generated at high frequency.

GENETIC SYSTEM AND RECOMBINATION

Adenovirus mutants have proved invaluable as reagents for the study of viral physiologic processes. Most genetic studies have used Ad2 or Ad5. Initially, physical and chemical mutagens were employed to generate variants that could be recognized on the basis of their growth phenotype. Subsequently, mutants have been produced by the targeted manipulation of viral DNA. The ability to propagate mutant viruses is currently the only limitation to their production. Many variants have proved viable, often growing more poorly than their wild-type parent, but growing sufficiently well for the production of useful virus stocks. Other mutants have been selected for conditional growth. These include

temperature-sensitive as well as host range variants. Host range mutants have played an especially important role in adenovirus genetics. E1A and E1B mutants can be propagated in 293 cells, a human embryonic kidney cell line that contains and expresses the Ad5 E1A and E1B genes (136); the physiologic consequences of the mutations can then be analyzed in standard laboratory host cells such as HeLa cells. Similarly, complementing cell lines have been developed for propagation of viruses with mutations in the E2, E4, and L5 genes (5,212,221,415,425).

Recombination between adenoviruses contributes to the evolution and diversity of viral serotypes. It is well established that recombination occurs among adenoviruses of the same subgroup. Homologous recombination occurs with high efficiency during growth in co-infected cultured cells (127,437), and comparison of field strains with disparate neutralization (hexon) and hemagglutination (fiber) serology (170) indicates that such exchanges also occur in nature. Recombination between viruses of different subgroups appears to have given rise to Ad4, the sole member of subgroup E adenoviruses. Ad4 exhibits sequence similarity in its E1A (0 to 5 map units) and E2 regions (62 to 66 map units) to group B adenoviruses (209,392), and its hexon gene (51 to 61 map units) is immunologically related to group B viruses (298), whereas the Ad4 fiber gene sequence (146) and immunologic characteristics (296) are most similar to group C viruses. Thus, the simplest model for the origination of Ad4 posits a single recombinatorial crossover event somewhere between the E2 coding region of a group B virus and the fiber coding region of a group C virus (146).

Efficient adenovirus recombination requires viral DNA replication (453), but the virus does not appear to encode any gene products that function specifically to facilitate recombination (103). Rather, it appears that single strands of DNA produced during the viral replication process, which can pair with each other or invade duplex DNAs, are the driving force behind recombination (111).

Although adenoviruses have never unambiguously been shown to integrate into the chromosomes of permissive host cells, integration does occur during the process of transformation. No specific motifs have been identified in the cellular DNA sequences at adenovirus integration sites.

REPLICATIVE CYCLE

Studies of the human adenovirus replication cycle have focused primarily on the closely related Ad2 and Ad5 viruses. These serotypes have been favored because they are easily grown in the laboratory, and an extensive collection of Ad2 and Ad5 mutant viruses have been developed. When other human serotypes have been studied, their growth strategies have proved similar to the paradigm established for the prototypes. Most studies of adenovirus growth have been performed by infection of HeLa or KB cells at fairly high multiplicities of infection (more than 10 plaque-forming units per cell). High multiplicities of infection have been used so that all cells in the culture are synchronously infected, allowing the ordered series of biochemical events during the infectious cycle to be observed in a time-wise fashion. HeLa and KB cells have been favored as hosts because they are easily propagated in large quantities, and the viruses grow in them rapidly and to high yield. These tumor cells support more rapid viral growth than human diploid fibroblasts, in which the replication cycle is substantially prolonged.

The replication cycle is divided by convention into two phases that are separated by the onset of viral DNA replication (Fig. 5). Early events commence as soon as the infecting virus interacts with the host cell. These include adsorption, penetration, movement of the viral DNA to the nucleus, and expression of an early set of genes. Early viral gene products mediate further viral gene expression and DNA replication, induce cell cycle progression, block apoptosis, and antagonize a variety of host antiviral measures. In HeLa cells infected at a multiplicity of 10 plaque-forming units per cell, the early phase lasts for 5 to 6 hours, after which viral DNA replication is first detected. Concomitant with the onset of viral DNA replication, the late phase of the cycle begins with expression of late viral genes and assembly of progeny virions. The infectious cycle is completed after 20 to 24 hours in HeLa cells. At the end of the cycle, about 10^4 progeny virus particles per cell have been produced, along with the synthesis of a substantial excess of virion proteins and DNA that are not assembled into virions (141). Cells infected at high multiplicity seldom divide; hence, at the completion of the replication cycle, the DNA and protein content of the infected cell has increased by a factor of about two.

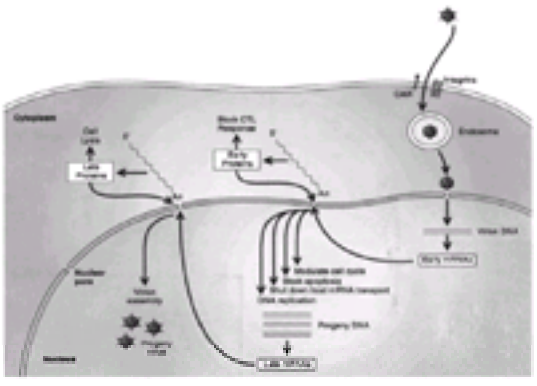

FIG. 5. Cartoon of the adenovirus life cycle.

Although *early* and *late* are convenient terms for description of events that occur during the replication cycle, the functional distinction between early and late events is often blurred. Early genes continue to be expressed at late times after infection, and the promoter controlling expression of the major late transcription unit directs a low level of transcription early after infection. The viral genes encoding proteins IVa2 and IX begin to be expressed at an intermediate time (308) and thus form a *delayed-early* category.

Adsorption and Entry

Attachment of Ad2 to cells is mediated by its fiber protein (246). The distal, carboxy-terminal domain of the fiber protein terminates in a knob that binds to the cellular receptor (84). The CAR (coxsackievirus and adenovirus receptor) protein, which belongs to the immunoglobulin superfamily, is an adenovirus receptor (29,395). It serves as a high-affinity receptor for human adenoviruses from subgroups A, C, D, E, and F, but not subgroup B (329). The class I major histocompatibility complex (MHC) a_2 domain has also been reported to serve as a receptor for Ad5 (174).

The observation that Ad2 binds to some cells but does not efficiently enter them (357) raised the possibility that a second protein–protein recognition event might be needed for internalization, and a second interaction has been identified. The penton base protein binds to members of a family of heterodimeric cell surface receptors, termed *integrins* (436). The a_vb_3- and a_vb_5-integrins and perhaps other integrin family members interact with the viral protein. The interaction occurs through an arg-gly-asp (RGD) sequence present in each of the five polypeptide III molecules that compose the penton base, the same sequence motif present in a number of extracellular adhesion molecules that bind to integrins. RGD-containing peptides can block internalization of Ad2 (436), and Ad5 variants with mutations that alter the RGD sequence in polypeptide III exhibit a delay in the onset of viral DNA synthesis under certain conditions, consistent with a reduced efficiency of internalization (20). The structure of a_vb_5-integrin bound to virions has been determined at 21 Å resolution by cryoelectron microscopy (63).

It seems likely that the fiber–receptor interaction serves to bring the virion to the cell surface, facilitating the critical integrin–receptor interaction. Consistent with this view, insertion of an RGD motif into the Ad5 hexon partially overcomes the need for a fiber–receptor interaction (414).

The tropism of adenoviruses is influenced by the availability of cellular receptors for fiber and penton. Airway epithelial cells lack both receptors (128,455). This deficiency might reflect evolutionary pressure to block a port of entry for respiratory adenoviruses, and it has frustrated efforts to use adenovirus as a vector to introduce therapeutic genes to the lungs.

After adsorption, Ad2–receptor complexes diffuse into coated pits, and they are internalized by receptor-mediated endocytosis (54,55,110,409). The process is triggered by the penton–integrin interaction because purified penton but not fiber protein is rapidly internalized by cultured cells (436). The process requires dynamin (419), a protein that specifically regulates clathrin-mediated endocytosis; and it requires activation of the lipid kinase phosphotidylinositol-3-OH kinase (230), which induces reorganization of actin filaments. The internalization of adsorbed virus is remarkably efficient (140). Eighty to 85% of virus that binds to the surface of a susceptible cell is internalized, and penetration occurs rapidly, with half of the adsorbed virus moving to endosomes within 10 minutes. About 90% of the virus within endosomes successfully moves to the cytosol with a half time of about 5 minutes. The movement to the cytosol is triggered by the acidic pH of the endosome (349,379), and the penton base is believed to play an essential role in the process. The rapidity of the movement to the cytosol suggests that the virus escapes from the endosomal unit, known as the *early endosome,* before formation of a lysosome (270). The endosome appears to be substantially disrupted because DNA–protein complexes that enter the endosome together with virus particles—but not physically attached to virions—also escape to the cytosol with high efficiency (451). Virus particles are transported across the cytoplasm to the nucleus by a process that involves microtubules (76,378). *In vitro* studies have shown that virions can attach to microtubules through the hexon, and some drugs that interact with microtubules can inhibit adenovirus infection (76). About 40 minutes after penetration, virus particles are seen at nuclear pore complexes by electron microscopy. After 120 minutes, about 40% of internalized particles have released their DNA free from hexon proteins, although it is not known what portion of this released DNA is localized to the nucleus (140). Inhibitors of nuclear import block the accumulation of adenovirus DNA in the nucleus, indicating that it enters through the nuclear pore (138).

During the internalization process, there is a sequential disassembly of the virion (140). The disassembly occurs by selective dissociation and proteolytic degradation of virion constituents. First, the proteins at the vertices of the particle are lost. Polypeptide IV that trimerizes to form the fiber, polypeptide IIIa located near the peripentonal hexons linking adjacent facets of the capsid, and polypeptide III that forms the pentameric penton base are substantially lost by 15 minutes after penetration of the cell. Polypeptides IV and IIIa dissociate somewhat more rapidly than III, and this could reflect a need to free the penton base for a role in escape from the endosome. Polypeptide VIII dissociates from the particle as the penton capsomeres are lost, and, shortly after entry of the particle to the cytosol, polypeptide VI is degraded by the virus-coded protease (139). Both polypeptides VI and VIII bridge from the DNA core to the capsid, and their loss prepares the particle for release of its DNA. Somewhat later, polypeptide IX, which stabilizes hexon facets, exits from the infecting particle; finally, the DNA-containing core is freed from hexons. Thus, the virion, which is very stable outside the cell, is dismantled by an ordered elimination of structural proteins on entry to the cell so that it can deliver its DNA to the nucleus.

The events that signal disassembly are mostly unknown. Acidification induces exit of the infecting particle from the endosome to the cytosol, but disassembly of the vertex constituents can occur in the absence of acidification (140). It seems likely that the signal for the initial dissociation of the fiber from the penton is a determining event that initiates a cascade in which each sequential disassembly event is driven by changes in the structure of the virion that result from previous events.

A DNA–protein VII complex reaches the nucleus (138). The viral DNA has been reported to convert into a structure that can be digested with a low concentration of DNase I to generate DNA fragments that form a ladder pattern similar to that of cellular chromatin on electrophoresis (384), suggesting that cellular histone proteins might replace polypeptide VII, the major core constituent, before the infecting DNA is transcribed. However, using sensitive assays, others have been unable to detect nucleosomal particles composed of viral DNA and cellular histones (410). It is possible that the viral genome is expressed as a chromosomal structure containing protein VII rather than cellular histones. When the viral DNA reaches the nucleus, it associates with the nuclear matrix through its terminal protein (36,115,342). DNAs from

mutant Ad5 variants with lesions in their terminal protein genes fail to become tightly associated with the nuclear matrix, and they also fail to be efficiently transcribed (342). This correlation between nuclear matrix association and activation of transcription suggests the two events are functionally interrelated. Apparently, the terminal protein, which arrives with the infecting genome, is the first viral gene product that functions within the nucleus to initiate the program of viral gene expression.

Activation of Early Viral Genes

There are three main goals of early adenovirus gene expression. The first is to induce the host cell to enter the S phase of the cell cycle, providing an optimal environment for viral replication. As discussed later (see Interactions with the Host), E1A, E1B, and E4 gene products play roles in this process. The second is to set up viral systems that protect the infected cell from various antiviral defenses of the host organism. The E3 and VA RNA genes contribute to these defenses, and these are also discussed later (see Interactions with the Host). The third is to synthesize viral gene products needed for viral DNA replication. All three of these goals depend on the transcriptional activation of the viral genome, and the principal activating proteins of adenovirus are encoded by the E1A gene.

E1A is the first transcription unit to be expressed after the viral chromosome reaches the nucleus. Transcription of the E1A unit is controlled by a constitutively active promoter, and it encodes two mRNAs during the early phase of infection (Fig. 6). Three additional E1A mRNA species accumulate later in the infectious cycle (369), but no distinct function has been described for their products. The two early mRNAs contain identical 5' and 3' ends, differ internally owing to differential splicing, and encode proteins that are identical except for an additional 46 amino acid segment that is present in the larger polypeptide. The two polypeptides are commonly referred to as the 12S and 13S E1A proteins. The primary E1A translation products undergo extensive phosphorylation that is mediated, at least in part, by cyclin-dependent kinases (256) and mitogen-activated protein kinase (430).

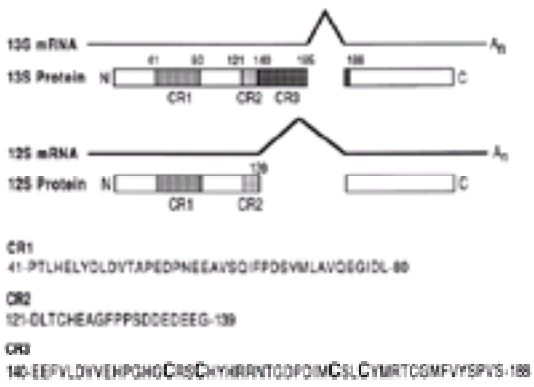

FIG. 6. Diagram of E1A mRNAs, the polypeptides they encode, and the amino acid sequence of conserved domains. 13S and 12S mRNA exons are represented (*lines*), as are introns (*carets*) and poly(A) sequences (A_n) The polypeptides encoded by the 13S and 12S mRNAs are designated (*rectangles*). Domains in the proteins that are conserved among adenovirus serotypes are identified as conserved regions 1 to 3 (CR1, CR2, CR3), and the amino acids at the boundaries of conserved regions are indicated (*above rectangles*). The amino acid sequences of the conserved domains are displayed at the bottom of the figure, and the cysteines composing the zinc finger motif in CR3 are marked (*enlarged bold letters*).

When the amino acid sequences of the E1A proteins encoded by a variety of human serotypes are compared, the E1A products prove to be constructed of three conserved regions (CR1, CR2, and CR3) (see Fig. 6) separated by less highly conserved domains (278,290,408). The E1A proteins do not exhibit sequence-specific DNA binding; rather, they bind to cellular proteins and modulate their function. The three conserved regions in the E1A proteins mark domains that play major roles in protein–protein interactions.

The ability of E1A proteins to activate expression of the other adenovirus transcription units was discovered when viral mutants were examined that carried either a single base-pair substitution (31) or a deletion (198,353) within the E1A coding region. These mutant viruses, which could be grown in transformed human cells expressing the E1A and E1B genes (293 cells) (136), failed to accumulate early viral mRNAs with normal kinetics when grown in HeLa cells that were unable to complement the defect. Compared to wild-type virus, they accumulated reduced quantities of early mRNAs only after a long delay. Subsequent analysis demonstrated that E1A proteins acted to increase the rate of transcription (289). Since the E1A proteins can activate other genes in trans, they are often referred to as *trans-activators.*

Initially, attempts to identify a promoter element that is responsive to the E1A proteins proved frustrating. In a number of studies, it was possible to mutate any specific DNA element without blocking the ability of E1A to activate test promoters, provided that basal transcription was not eliminated. The reason for the promiscuous activation is now clear. The E1A proteins activate transcription by binding to a variety of cellular transcription factors and regulatory proteins (Table 2). The E1A proteins can interact directly with auxiliary factors that mediate basal transcription, with activating proteins that bind to upstream promoter and enhancer elements, and with regulatory subunits that influence the activity of DNA-binding factors. All three conserved domains of E1A mediate protein–protein interactions that activate transcription.

E1A-binding protein	Binds to		Other proteins in complex
	12S E1A	13S E1A	
pRB	+	+	Unknown
p107	+	+	Cyclin A, cdk2/cyclin E
p130	+	+	Cyclin A, cdk2/cyclin E
p300	+	+	Unknown
TBP	−	+	Unknown
hTAF(II)135	−	+	Unknown
SUR-2	−	+	Unknown
Dr1	+	+	Unknown
ATF-2	−	+	Unknown
YY1	+	+	Unknown
Sp1	?	+	Unknown
MAZ	?	+	Unknown
STAT1	+	+	Unknown

Note: This listing contains only those cellular proteins that have been shown to bind directly to E1A proteins, and it is limited to binding partners for which there is evidence that the interaction is biologically relevant.

pRB, retinoblastoma susceptibility protein; cdk2, cyclin-dependent kinase 2; TSP, TATA-binding protein; TAFs, TBP-associated factors.

TABLE 2. *Cellular E1A binding partners*

E1A proteins activate transcription through the TATA motif (142,441), an element found 25 to 30 bp upstream of transcriptional initiation sites in many viral and cellular genes. The activation is believed to result in part from the ability of the 13S E1A protein to bind directly to the TATA-binding protein (TBP) (175,226), which is the DNA-binding subunit of the auxiliary transcription factor IID (TFIID), the first auxiliary transcription factor to interact with TATA-containing promoters. The interaction between TBP and E1A is mediated by the 13S-specific CR3 domain of the E1A protein (226), and this helps to explain why the 13S E1A protein activates transcription through TATA motifs more efficiently than the 12S protein. Part of the mechanism by which the 13S E1A protein activates transcription as a result of binding to TBP appears to involve the cellular tumor suppressor protein, p53, which can bind to TFIID (244,350) and repress transcription (350). The two proteins bind to overlapping domains on TBP, and the E1A protein can displace p53 from TBP and relieve p53-mediated repression (176). The 12S E1A protein can also activate through a TATA motif (219), but more weakly than the 13S protein. This activation event involves Dr1, a factor that can bind to TBP and inhibit transcription (190). The 12S and 13S proteins bind directly to Dr1, preventing it from associating with TBP (218). Thus, both 12S and 13S proteins can activate transcription through TATA motifs by binding to cellular factors and relieving transcriptional repression. E1A also has been reported to bind to several TAF subunits of TFIID (121,265) and to the rap30 subunit of TFIIF (242).

Recently, the 13S-specific CR3 domain of E1A has been shown to bind to the human SUR-2 protein (38). This interaction is very likely to be functionally significant because point mutations in CR3 that block transcriptional activation also block the interaction with SUR-2. SUR-2 is a constituent of a large protein complex known as *Srb/Mediator* or *TRAP.* The complex contains about 30 polypeptides and functions as a transcriptional coactivator or corepressor. The herpesvirus VP16 and p53 activation domains also interact with this complex, but through a different subunit (38,192).

In addition to interactions with the basal transcriptional machinery, E1A proteins can activate transcription through the binding sites for factors that bind well upstream of the basal promoter. The best-studied activation event occurs through E2F-binding sites. This transcription factor is named for the first promoter where it was found to bind, the adenovirus E2 promoter (214). E2F forms a complex with the cellular retinoblastoma tumor suppressor protein, pRB, and pRB inhibits transcriptional activation by E2F. The 12S and 13S E1A proteins activate transcription through E2F-binding sites (215,445,456), and both E1A proteins bind to pRB (435) through CR1 and CR2 (96,189), dissociating it from E2F (18,19,21). The strong correlation between the dissociation of the E2F–pRB complex and transcriptional activation by E1A proteins argues that E1A activates transcription by dissociating pRB from E2F. The activation of E2F by E1A not only affects the expression of viral genes but also influences the expression of cellular genes, dramatically affecting cell cycle progression (see Activation of the Host Cell).

E1A activates transcription by binding directly to several additional cellular factors. All of the early adenovirus promoters, with the exception of the E1B promoter, contain binding sites for the ATF (also termed *CREB*) family of transcription factors. E1A activates transcription through ATF-binding sites (243), presumably in part because the 13S E1A protein can bind to ATF-2 (1,239,243). The interaction occurs between the DNA binding domain of ATF-2 and CR3 of E1A. Different subdomains of CR3 mediate E1A binding to ATF-2 and TBP, raising the possibility that E1A functions as an adapter, bridging between ATF-2 bound at an upstream site and TBP (226). The SUR-2–containing complex, discussed previously, might also participate in the bridging. Such a bridging function might stabilize the initiation complex at the promoter.

E1A proteins can also activate through YY1 recognition sites (354). YY1 represses transcription when bound upstream of a transcriptional initiation site. The E1A proteins bind to YY1 through an amino-terminal sequence of E1A, and, in the case of the 13S E1A protein, the interaction is stabilized by CR3 (229). This binding correlates with the relief of repression mediated by YY1. The murine *c-fos* promoter provides a specific example of YY1-mediated repression that is relieved by E1A (462). This promoter contains both YY1- and ATF/CREB-binding sites, and YY1 binds to ATF/CREB, inhibiting its ability to activate transcription. E1A binds to YY1, blocking its interaction with ATF/CREB and relieving the repression. YY1 also interacts with p300 (see Activation of the Host Cell), and E1A potentially influences the activity of the YY1–p300 complex through its ability to bind to p300 (224).

E1A proteins have been reported to both activate and repress through the transcription factor AP1. These activities involve an amino-terminal domain and the CR1 domain of E1A (101,299). E1A can repress the action of AP1 through its consensus binding sites in the collagenase and stromelysin genes (299) and enhance the ability of AP1 to activate through the ATF sites (to which AP1 can bind) of adenovirus early genes (100,157). The AP1 transcription factor is a dimeric molecule that is generally composed of *c-fos* and *c-jun* family members, although *jun* family members can also heterodimerize with members of the ATF family (27). E1A repression appears to result from a block to DNA binding by *c-fos/c-jun* heterodimers (151), and activation by E1A through AP1 occurs, at least in part, by an indirect mechanism. E1A proteins cooperate with cyclic adenosine monophosphate (cAMP) to induce the level of AP1, which activates

transcription of viral genes (284). The E1A-mediated induction of AP1 activity results from transcriptional activation of the *c-fos* and *junB* genes through their TATA motifs (211), and the *c-jun* gene has been shown to be induced through an ATF-like element in its promoter, which probably responds to a *c-jun*/ATF-2 heterodimer (402). Hence, E1A can activate transcription indirectly through AP1-binding sites by inducing AP1 activity, and E1A can activate through ATF-binding sites either directly by binding to ATF-2 or indirectly by inducing AP1 activity. A second adenovirus protein contributes to the induction of AP1 activity. The E1B 19-kd protein activates the *c-jun* N-terminal kinase (JNK) (347), which strongly induces *c-jun*–dependent transcription.

Expression of the adenovirus VA RNA genes is induced by the E1A proteins (358,452). These genes are transcribed by RNA polymerase III, and it appears that the amount of the 110-kd subunit of transcription factor IIIC2a is increased by the E1A proteins (358). RNA polymerase III–sponsored transcription is repressed by pRB (434); hence, E1A might act through pRB to induce the synthesis of the 110-kd subunit.

Besides the E1A proteins, two additional early gene products have been shown to activate adenovirus promoters. The E4orf6/7 polypeptide binds to the cellular transcription factor E2F, with two molecules of the E4 protein apparently bridging between a pair of E2F molecules and causing them to bind cooperatively to the pair of E2F-binding sites within the E2 promoter (156,187,318). The E2 DNA-binding protein can activate a variety of early adenovirus promoters as well as the major late promoter (53), but the mechanism by which it stimulates transcription is unclear.

Individual adenovirus early promoters are activated by multiple mechanisms. For example, the E2 promoter can be activated by E1A through its TATA motif, ATF site, or E2F sites. In addition, the E4orf6/7 protein contributes to activation at the E2F sites, and the E2 promoter can also be induced by the E2 DNA-binding protein. Perhaps the activation pathways function with different efficiencies within various cell types, and these apparently redundant activation mechanisms have evolved to ensure that early viral promoters will be efficiently activated in a variety of different cell types as the virus spreads within its infected host.

Generally, adenovirus early genes remain active throughout the viral replication cycle, although the rate at which they are transcribed slowly declines. In part, the decline results from cell death. However, there are three known down-regulatory events, and in each case, it appears that a viral protein, which accumulates in response to an activation event, subsequently acts to inhibit continued transcriptional stimulation mediated by one or more early promoter elements. First, the E1A proteins can repress the activity of a variety of known enhancers, including the enhancer residing upstream of the E1A gene itself. This down-regulatory function correlates with the ability of the E1A protein to bind to a cellular protein, p300 (368), and the consequences of this protein–protein interaction are considered later (see Activation of the Host Cell). Second, whereas the E2 DNA-binding protein activates some promoters (53), it inhibits transcription from the E4 promoter (293) by an unknown mechanism. Third, the induction of AP1 activity by E1A and cAMP is transient (284). It is antagonized by the E4orf4 polypeptide, which accumulates in response to the E1A-mediated activation of the E4 gene (283). Mutant viruses unable to produce E4orf4 protein are viable but are more cytopathic than the wild-type virus, a counterintuitive result because expression of E4orf4 in the absence of infection induces apoptosis (222,356). E4orf4 binds to protein phosphatase 2A, and phosphatase activity is essential for the down-regulatory event (211).

Once early mRNAs have been synthesized, they are translated on polysomes together with cellular mRNAs. Initially, they do not appear to enjoy a competitive advantage, but as the infection enters the late phase, cellular mRNAs are excluded from polysomes (see Activation of Late Gene Expression and Host Cell Shutoff).

Activation of the Host Cell

Adenovirus infection has long been known to induce quiescent cells to enter the S phase of the cell cycle, creating an environment optimally conducive to viral replication. Modulation of the cell cycle is primarily a function of the E1A proteins, and the modulation is mediated by their CR1, CR2, and nonconserved amino-terminal domains. The key to understanding how E1A proteins manipulate cell cycle regulation came from the observation that a set of cellular proteins can be co-immunoprecipitated with the E1A proteins (158,446). The most abundant coprecipitating cellular polypeptides have molecular weights of about 33, 60, 80, 90, 105, 107, 130, 300, and 400 kd (Fig. 7); several of these polypeptides have been shown to interact directly with E1A proteins (see Table 2). The 105-kd moiety was the first to be identified (435). It is the retinoblastoma tumor suppressor protein, pRB, which, as discussed earlier (see Activation of Early Viral Genes), regulates the ability of the E2F cellular transcription factor to activate transcription. The human papillomavirus E7 protein and the large T antigens of papovaviruses also bind to pRB, underscoring its importance as a target of oncoproteins encoded by DNA tumor viruses. Although E2F sites are present in the adenovirus E1A and E2 promoters and contribute to their activation, neither papovaviruses nor papillomaviruses have E2F binding sites in their genome. Therefore, tumor virus oncoproteins must target pRB for reasons other than to influence E2F function at their own promoters.

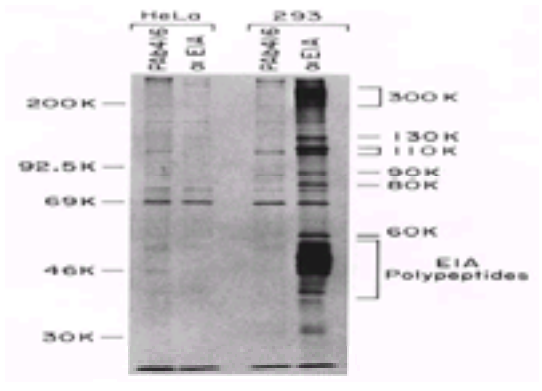

FIG. 7. Co-immunoprecipitation of cellular polypeptides with E1A proteins. Radioactively labeled polypeptides were

immunoprecipitated from lysates of HeLa or 293 cells with a monoclonal antibody specific for SV40 T antigen (PAb416) or a mixture of antibodies specific for E1A proteins (aE1A), and immune complexes were analyzed by electrophoresis. The size (kd) of marker proteins is indicated (*left*), and the size of polypeptides coimmunoprecipitated with E1A proteins, as well as the location of E1A polypeptides, is indicated (*right of autoradiogram*). (From ref. 158, with permission.)

Overexpression of pRB inhibits cell cycle progression, causing cells to arrest in middle to late G_1 phase, and growth arrest correlates with the ability of pRB to bind to E2F and block E2F-dependent transcriptional activation. pRB activity is regulated by cyclin-dependent kinases. Hyperphosphorylation of pRB inhibits the formation of the pRB–E2F complex, and it reverses the ability of pRB to arrest cell growth. These observations are consistent with the fact that hyperphosphorylated pRB and free E2F accumulate as growing cells reach late G_1 and enter S phase. The strong correlation between the ability of pRB to bind E2F and to block progression from G_1 to S phase supports the conclusion that pRB regulates cell cycle progression through its interactions with E2F. pRB inhibits E2F function: it likely masks the E2F activation domain, and it binds to histone deacetylase. Deacetylation of histones inhibits transcription, consistent with the observation that the E2F–pRB–deacetylase complex actively inhibits the transcription of E2F-responsive genes. Free E2F activates a series of genes important for S phase and cell growth that contain E2F-binding sites in their promoters (e.g., dihydrofolate reductase, DNA polymerase a, *cdc2,* cyclin E, and *c-myc.* Indeed, ectopic expression of E2F induces quiescent cells to enter the S phase of the cell cycle.

The CR2 domain is primarily responsible for the interaction of E1A proteins with pRB, and the amino-terminal portion of the CR1 domain plays an auxiliary role, stabilizing the interaction (96,189). CR2 contains the sequence Leu-X-Cys-X-Glu (where X is any amino acid), which is present in other viral and cellular proteins that bind to pRB. The E1A-binding domain on pRB is often referred to as the *pocket,* and it is composed of two essential sequences, termed A and B, separated by a spacer region (184,199). E2F also binds to the pocket domain; hence, E1A binding competes with E2F for access to the pRB pocket. As a result, E2F can be liberated from pRB by E1A (18,19,21), and the free E2F can then activate cellular genes that facilitate cell cycle progression. This accomplishes what appears to be a common goal of DNA tumor viruses: to move the infected cell into the S phase, creating an environment favorable for efficient viral DNA replication. Mutant E1A proteins that fail to bind pRB are unable to activate transcription through E2F or modulate cellular growth.

Two additional cellular pRB family members have been identified that interact with E2F—p107 and p130—and E1A can bind to them (see Fig. 7), dissociating E2F. As is the case for pRB, the interaction is mediated by the E1A CR2 domain, and E1A–p107 binding is stabilized by interactions within the CR1 domain (418). The proteins p107 and p130 associate with cyclins and cyclin-dependent kinases. E1A can be found in complexes that include kinase activities (169,210), and the phosphorylation state of p107 and p130 in these complexes is substantially elevated (22). Whether these complexes represent nonfunctional byproducts of the release of E2F or whether the complexes that include E1A, p107 or p130, cyclin and cyclin-dependent kinase (p60 and p33) (see Fig. 7) perform an active, E1A-modulated function is unknown. Not only are there multiple pRB family members present in E2F complexes, but there are also multiple E2Fs. The E2F transcription factor is a heterodimer composed of one of six known E2F family members and one of three DP family members. In summary, the E1A proteins disrupt a series of complexes that contain different pRB family members and multiple E2F subunits, forcing quiescent cells to begin DNA synthesis.

In addition to disrupting pRB–E2F complexes, E1A blocks the action of a cyclin-dependent kinase inhibitory protein. Cyclin-dependent kinases target pRB family members and regulate their activities. Hyperphosphorylated pRB does not bind E2F, allowing the transcription factor to stimulate S-phase entry. Cyclin-dependent kinases are themselves regulated by several mechanisms, including association with cyclin-dependent kinase inhibitory proteins, such as $p27_{kip1}$. Overexpression of $p27_{kip1}$ blocks cell cycle progression in the G_1 compartment. E1A antagonizes the inhibitory activity of $p27_{kip1}$ (4,257), preventing G_1 arrest and favoring progression to the S phase.

The E1A proteins facilitate cell cycle progression through a second pathway by binding to the closely related p300 and CBP proteins (see Fig. 7). Their binding site on E1A includes the poorly conserved amino-terminus and the carboxy-terminal half of CR1 (418). E1A mutants lacking CR2 and unable to bind pRB family members can nevertheless stimulate cellular DNA synthesis, provided their p300/CBP-binding site remains intact. Thus, the E1A proteins contain two independent domains, either of which can stimulate cells to progress from G_1 to S phase (183,240,459). The p300/CBP proteins serve as coactivaters for a number of transcription factors, including CREB, STATs, and nuclear receptors. The coactivaters are brought to the promoter through their interaction with DNA-binding factors. The p300/CBP proteins exhibit intrinsic histone acetylase activity, and they interact with a factor termed *P/CAF* that is also a histone acetyltransferase. Acetylation of histones is believed to weaken their interaction with DNA, producing a chromatin structure that is more conducive to transcription. Thus, p300/CBP is thought to function, at least in part, by modifying chromatin structure. When E1A binds to p300 or CBP, it simultaneously displaces P/CAF and inhibits the intrinsic acetyltransferase activity of the coactivator (48,154,307,444). The inhibition of p300/CBP acetyltransferase activity can explain the earlier observation that E1A inhibits the function of some enhancer elements (328,368,418).

S-phase entry is facilitated by the ability of E1A to inhibit p300/CBP function. The p53 tumor suppressor protein is one target of this activity. The *p53* gene is the most commonly mutated gene in human tumors, and the loss of p53 function or its alteration by mutation can contribute to tumor progression. Consistent with its frequent loss in tumor cells, high-level expression of p53 promotes cell cycle arrest or apoptosis. The p53 protein is a DNA-binding transcription factor, and p300/CBP serves as a coactivator for p53. By inhibiting p300/CBP activity, E1A proteins antagonize p53 function (238,362). Although inhibition of p53 will relieve a block to cell cycle progression, it does not by itself stimulate progression into S phase. It is likely that there are unidentified genes whose expression is modulated by the interaction of E1A with p300/CBP, inducing the cell to synthesize DNA. Alternatively, the domain on E1A that mediates its interaction with p300/CBP might interact with another unidentified target. Indeed, this domain binds to p400, the largest protein known to interact with E1A. Although p400 and p300/CBP are related in their amino acid sequences (22), the function of

p400 is unknown.

Two separate regions of the E1A proteins can induce cells to move from G_1 to S phase through two independent mechanisms: binding to pRB family members and binding to p300/CBP. Presumably, E1A proteins employ two mechanisms because together they function more effectively than either alone or because there may be cells in which one pathway works more efficiently than the other. Further, although the E1A domains mediating binding to either pRB family members or p300/CBP can induce DNA synthesis in quiescent cells, both regions are required to pass the G_2- to M-phase checkpoint and progress to mitosis (182,183,417,459). This could be an important function in animal hosts, in which infections are likely to proceed much more slowly than in cultured cells. Without the ability to divide, cells that pass completely through S phase would be stuck in G_2; if the cells can divide, they can continue cycling and return to S phase, during which viral replication is most efficient. Possibly, the simultaneous inhibition of both the pRB family and p300/CBP by E1A binding somehow enables the infected cell to pass through the G_2- to M-phase checkpoint. Alternatively, E1A proteins might alter the function of these regulatory proteins rather than simply inhibit them. E1A has been reported to bind simultaneously to a pRB family member and p300/CBP (22), and this new complex might influence passage through mitosis. It is also possible that E1A proteins bind to additional, as yet unidentified, proteins to antagonize this checkpoint.

The level and activity of p53 are induced in response to a variety of stresses, including the presence of E1A proteins (79,248,337). E1A activates p53 through a pathway that includes the p19 ^{ARF} tumor suppressor protein (78). This protein can associate with p53 to alter its level and activity. E1A induces p19 ^{ARF} through the same domains required for the induction of p53, and E1A fails to induce p53 in cells lacking p19 ^{ARF}. Although E1A inhibits the p53 transcriptional coactivator p300/CBP, p53 nevertheless acts to limit its oncogenic potential. As noted previously, high-level expression of p53 promotes cell cycle arrest at the G_1- to S-phase boundary or apoptosis. Although the transcriptional activation function of p53 mediates its block to cell cycle progression and apoptosis, p53 can induce apoptosis through a second pathway that does not depend on its ability to stimulate transcription. This helps to explain why adenoviruses have evolved additional mechanisms to counter p53 function.

The Ad5 E1B 55-kd protein binds to p53 within infected cells (339), and it can block transcriptional activation by p53. Analysis of mutant E1B 55-kd proteins has revealed a strict correlation between the ability of E1B to block p53-mediated transcriptional activation and its ability to cooperate with E1A in the oncogenic transformation of cells (447). The E1A and E1B proteins of adenovirus are oncoproteins (see Oncogenesis), and they cooperate to transform cultured cells. Oncogenic transformation is a manifestation of the ability of these proteins to interfere with the normal function of tumor suppressor proteins. Thus, the correlation between a block to transcriptional activation and transforming activity of the viral protein suggests that the E1B 55-kd protein antagonizes the ability of p53 to block cell cycle progression and induce apoptosis by inhibiting its activation function. The E1B 55-kd protein binds to the amino-terminal, acidic transcriptional activation domain of p53 (200), and this suggests that the viral protein might simply mask the activation domain. Steric hindrance might contribute to the ability of the E1B 55-kd protein to block activation by p53, but it is not the entire mechanism. The E1B 55-kd protein can inhibit transcription if it is artificially anchored to a promoter, indicating that it can actively repress transcription (448). Not only does the interaction of the E1B 55-kd protein with p53 serve to bring the viral protein to the promoter, but also the E1B 55-kd protein increases the affinity of p53 for its DNA-binding site (261). In conjunction with an as yet unidentified corepressor (261), the E1B 55-kd protein not only blocks the activation function of p53 but also actively represses transcription. Thus, like E1A, the E1B 55-kd protein binds to a tumor suppressor protein, antagonizes its normal activity, and helps to deregulate cell cycle progression.

In contrast to E1A, expression of the E1B 55-kd protein alone is not sufficient to stimulate quiescent cells to enter the S phase of the cell cycle. This is consistent with the observation that deletion of both p53 alleles does not directly lead to the loss of regulated cell division (93). Nevertheless, p53 is targeted by a variety of tumor virus oncoproteins: SV40 large T antigen binds to p53, blocks its DNA-binding activity, and interferes with its ability to activate transcription; and human papillomavirus type 16 E6 protein complexes with p53 and cooperates with cellular proteins to promote its degradation. Presumably, then, the E1B 55-kd protein collaborates with E1A to activate quiescent cells more effectively. Further, because E1A causes p53 to accumulate, E1B must contribute to the activation of quiescent cells by preventing the implementation of a cell cycle block or apoptosis by elevated levels of p53.

The E1B 55-kd protein also enables the virus to overcome a restriction to its replication imposed by the cell cycle (131) independently of the presence of wild-type p53 (132). Mutant viruses unable to express the E1B 55-kd protein fail to produce progeny efficiently unless cells are infected in the S phase of the cell cycle. The mechanism by which the E1B 55-kd protein mediates this intriguing function is uncertain. Mutant viruses that fail to express E4orf6 protein exhibit a similar cell cycle phenotype as E1B mutants (133). A complex of the E1B and E4 proteins controls the transport of viral and host mRNAs from nucleus to cyto plasm (see Activation of Late Gene Expression and Host Cell Shutoff), but this function does not appear to underlie the effect of the E1B 55-kd and E4orf6 proteins on the cell cycle restriction.

It is noteworthy that the Ad12 homolog of the Ad5 E1B 55-kd protein can inhibit p53-mediated transcriptional activation and cooperate with E1A to transform cells (447), even though it shows no indication of p53 binding (137,458). Also, the Ad5 E1B protein can sequester a substantial portion of the cell's p53 in a discrete cytoplasmic structure outside of the nucleus (457), whereas the Ad12 protein cannot (458). This has been taken as further evidence that the Ad12 protein does not bind to p53. The Ad12 E1B protein might bind weakly to p53, and the resulting complex might not be sufficiently stable to be detected by the assays that have been employed. The p53 protein is stabilized in Ad12 transformed cells, and the stabilization is dependent on expression of the E1B protein (403). Stabilization is often observed for mutant p53, but the p53 present in the Ad12 transformed cells is wild type. Further, although the Ad5 E1B protein inhibited transformation by *myc* plus *ras,* the Ad12 E1B protein, like mutant p53, enhanced the number of foci produced by *myc* plus *ras.* If there is no direct interaction between the Ad12 E1B protein and p53, these observations suggest that the Ad12 protein somehow causes wild-type p53 to be modified, perhaps by association with another cellular protein, so that it behaves in some respects like mutant p53.

In addition to the E1B 55-kd protein, the E4orf6 protein can bind to p53 and block its transcriptional activation function (92). Like the E1B 55-kd protein, E4orf6 inhibits the interaction of p53 with the TAF31 subunit of TFIID; however, unlike

the E1B 55-kd protein, which binds to the amino-terminal activation domain of p53, E4orf6 binds within its carboxy-terminal region. The E1B and E4 proteins cooperate to shorten markedly the half life of p53 (276,287,331,366). Given its ability to antagonize p53, it is not surprising that E4orf6 can cooperate with E1A in cell transformation assays (see Oncogenesis).

E4or6, but not the E1B 55-kd protein, can bind to p73 and inhibit its function (171,367). The p73 protein is a member of the p53 family that is able to activate transcription through p53 response elements. Thus, E4orf6 antagonizes the function of both p53 and p73, blocking their potential inhibitory effects on viral replication.

Inhibition of Apoptosis

E1A proteins trigger apoptosis through both p53-dependent and p53-independent mechanisms (386). The p53-independent apoptosis is an indirect effect of E1A. It results from the E1A-mediated expression of the E4orf4 protein (222,356). E4orf4 might induce apoptosis as a consequence of its ability to bind to protein phosphatase 2A and inhibit its activity (211). This phosphatase targets Bcl-2 and caspase 3, which are known to regulate and mediate apoptosis, respectively. Apoptosis is not observed when E4orf4 functions in the context of an infected cell.

As has been found for other viruses, adenoviruses encode proteins (E1B 55-kd, E1B 19-kd, and E4orf6) that block apoptosis. As discussed previously, the E1B 55-kd and E4orf6 proteins bind to p53 and inhibit its function, blocking p53-dependent apoptosis. The E1B 19-kd protein is a member of the Bcl-2 family of proteins and can block p53-dependent or p53-independent apoptosis (316). In this respect, it is similar to Bcl-2, which resides in the outer mitochondrial membrane and inhibits the translocation of cytochrome c from mitochondria to the cytoplasm. When cytochrome c enters the cytoplasm, it facilitates activation of caspase-9, provoking an apoptotic response.

Adenovirus mutants that fail to produce a functional E1B 19-kd protein induce extensive degradation of host cell and viral DNA, enhanced cytopathic effect, and reduced virus yield when grown in cultured cells (310,380,433). Presumably, the inhibitory effects of premature cell death on viral propagation would be even more severe in natural infections, in which the viral growth cycle is slower than in cultured HeLa cells. Thus, apoptosis is an example of a cellular response to infection that has the potential to inhibit viral growth and block its spread within the infected organism.

Adenoviruses encode additional proteins (E3 gp19-kd, E3 14.7-kd, E3 14.5-kd, and E3 10.4-kd) that block the induction of apoptosis by cytotoxic T lymphocytes (CTLs) and macrophages, and their mode of action is discussed later (see Viral Antagonists of Cytotoxic T Lymphocytes and Tumor Necrosis Factor-a).

Viral DNA Replication

As E2 gene products accumulate, the stage is set for viral DNA replication. Ad2 or Ad5 DNA replication begins between 5 to 8 hours after infection of HeLa cells at a multiplicity of 10 plaque-forming units per cell, and it continues until the host cell dies.

The inverted terminal repeats of the viral chromosome serve as replication origins. *In vivo* studies support a model in which adenovirus DNA replication takes place in two stages (223) (Fig. 8). First, synthesis is initiated at either terminus of the linear DNA and proceeds in a continuous fashion to the other end of the genome. Only one of the two DNA strands serves as a template for the synthesis; thus, the products of the replication are a duplex consisting of a daughter and parental strand plus a displaced single strand of DNA. In the second stage of the replication process, a complement to the displaced single strand is synthesized. The single-stranded template circularizes through annealing of its self-complementary termini, and the resulting duplex “panhandle” has the same structure as the termini of the duplex viral genome. This structure allows it to be recognized by the same initiation machinery that operates in the first stage of replication, and complementary strand synthesis generates a second completed duplex consisting of one parental and one daughter strand. Adenovirus DNA was the first eukaryotic template to be replicated *in vitro* (50), and increasingly, defined cell-free systems have allowed the analysis of replication in considerable detail.

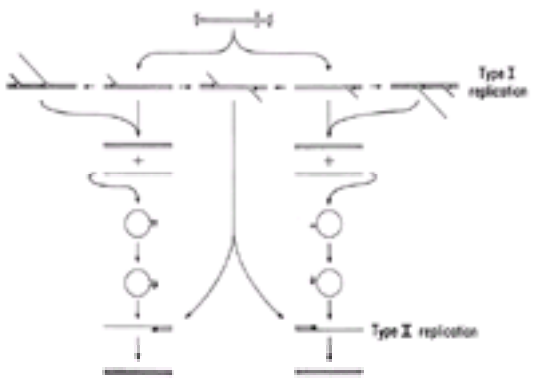

FIG. 8. A model for adenovirus DNA replication. Replication begins at either end of the duplex adenovirus DNA molecule, displacing one of the parental strands and subsequently replicating the displaced strand. Type I replication refers to replication on duplex templates, and type II replication refers to replication initiated on a single-stranded molecule. (From ref. 223, with permission.)

The cis-Acting sequences composing the replication origins are located within the inverted terminal repeats of the viral chromosome. Three functional domains have been defined within the terminal 51 bp of the repeats. Domain A consists of the first 18 bp of the viral DNA, and it functions as a minimal origin of replication. This domain is required for replication

but supports only limited replication on its own. The sequence between base pairs 9 to 18 (5'ATAATATACC-3') is conserved among different human adenovirus serotypes, and a complex of two viral proteins binds here (59,281,385): the preterminal protein (pTP) and the DNA polymerase. The E2-coded terminal protein (TP) is synthesized as an 80-kd polypeptide (pTP) that is active in initiation of DNA replication (49,373) and, as discussed previously, is found covalently attached to the 5' ends of the viral chromosome. It is subsequently processed by proteolysis during assembly of virions to generate a 55-kd fragment (TP) that is covalently attached to the genome (51), but it appears that the entire protein with cleaved peptide bonds remains associated with the genomic termini (342). The E2-coded polymerase is a 140-kd protein with biochemical properties distinct from other known DNA polymerases (102,109). It contains both 5'-to-3' polymerase activity and 3'-to-5' exonuclease activity, which probably serves a proofreading function during polymerization (109). The pTP and the polymerase form a heterodimeric complex in solution (102,235,374,385) and thus would be expected to bind to the origin as a unit.

Domain B consists of base pairs 19 to 39, and domain C includes base pairs 40 to 51. These two elements are not absolutely required for adenovirus DNA replication, but they substantially enhance the efficiency of the initiation reaction. Cellular factors bind to these elements: nuclear factor I (NFI) binds as a dimer in domain B, and nuclear factor III (NFIII) binds in domain C. NFI interacts with the DNA polymerase, stabilizing the pTP–polymerase complex at the origin (37,59,282). The binding of NFI at domain B appears to be stimulated by the third viral protein that functions in DNA replication, the E2-coded single-stranded DNA-binding protein (68,376). NFIII binds to the pTP and helps to stabilize the pTP–polymerase complex at the origin (406). NFIII binding induces DNA bending, and this might also contribute to its function (413). NFI and NFIII are also transcription factors. NFI is a member of the CTF family of transcriptional activators (197), and NFIII is also known as Oct 1, a member of the family of proteins that contain POU DNA-binding domains (302,315).

There is flexibility in the requirement for the B and C domains in the replication origin. A mutant Ad5 lacking domain C grows well, with sequences adjacent to the inverted terminal repeat compensating for the lack of an NFIII-binding site (162). Ad4 1acks domain B, the binding site for NFI, and its replication appears to require only domain A (159,163). Possibly, the Ad4 pTP–polymerase complex has an intrinsically higher affinity for its binding site in the minimal origin than is the case for the complex encoded by other adenoviruses, and this could bypass the need for the stabilizing function of NFI.

A cloned adenovirus terminal sequence will support the initiation of replication if it is cleaved to produce an end near the normal terminus (382). However, a natural template with a molecule of TP attached at its 5' end is replicated at much higher efficiency. The activity of the cloned template can be substantially increased if it is treated with a 5'-to-3' exonuclease. Thus, the production of a single-stranded 3'-terminus can compensate for the absence of an attached molecule at the 5'-terminus, and this suggests that TP bound to the template DNA normally helps to open the terminal duplex. The pTP–polymerase complex can bind in a sequence-specific fashion to the double-stranded form of the A domain of the replication origin (385), and it also can bind to single-stranded DNA (59,204). A sequential interaction of the pTP–polymerase complex, first with the duplex terminus and subsequently with a single strand, could help to unwind the terminal duplex DNA.

The pTP interacts with the nuclear matrix (36,115,342) and serves as a primer for DNA replication. Within the nuclear matrix, pTP appears to contact CAD, a multifunctional pyrimidine biosynthesis enzyme (9). This interaction might anchor adenovirus replication complexes in the vicinity of useful cellular factors.

As a primer, pTP preserves the integrity of the viral chromosome's terminal sequence during multiple rounds of DNA replication. The priming reaction begins with the formation of an ester bond between the b-OH of a serine residue in pTP and the a-phosphoryl group of deoxycytidine monophosphate (dCMP), the first residue at the 5' end of the DNA chain (49,236). The pTP–dCMP interaction requires the presence of polymerase and is template dependent (52,236,382), suggesting that it occurs after the pTP–polymerase complex is properly positioned on the template. The 3'-OH group of the pTP–dCMP complex then serves to prime synthesis of the nascent strand by the DNA polymerase. The study of mutant templates in a reconstituted replication system has revealed that pTP–dCMP first primes the synthesis of a pTP–CAT initiation intermediate by copying the second three mononucleotides of the template, and then the newly synthesized complex jumps back to base pair at the terminus (207). This jumping mechanism succeeds because the sequence starts with a repeated trimer: 3'-GTAGTA. After the synthesis of the first three or four nucleotides of the new DNA strand, the polymerase separates from pTP (206). The dissociation coincides with a change in its sensitivity to inhibitors and in its K_m for deoxynucleoside triphosphates, as the polymerase becomes a more efficient elongation enzyme.

Chain elongation requires two virus E2-coded proteins, the polymerase and single-stranded DNA-binding protein, and a cellular protein, nuclear factor II (NFII). The virus-coded DNA-binding protein is a 59-kd phosphoprotein that migrates in SDS-polyacrylamide gels with an apparent molecular weight of 72 kd. It binds tightly and cooperatively in a sequence-independent fashion to single-stranded DNA (404). The role of the DNA-binding protein in DNA replication was first revealed by analysis of an adenovirus temperature-sensitive variant carrying a mutation within the E2 gene; its ability to replicate DNA is exquisitely temperature dependent (405). The three-dimensional structure of the DNA-binding protein has been determined (400), and it contains a terminal extension that hooks onto an adjacent DNA-binding protein monomer. This drives the formation of long, multimeric protein chains bound to single-stranded DNA. If the carboxy-terminal extension is removed from the DNA-binding protein, strand displacement on a double-stranded template no longer occurs (81). This indicates that the polymerization of the DNA-binding protein on single-stranded DNA drives strand separation, consistent with the lack of a requirement for a DNA helicase to unwind the double-stranded template in reconstituted adenovirus DNA replication reactions. In the presence of the DNA-binding protein, the polymerase is highly processive (109,241) and can travel the entire length of the chromosome after it has separated from pTP. NFII copurifies with a cellular DNA topoisomerase activity (285), and mammalian topoisomerase I will substitute for it in an *in vitro* replication reaction. NFII does not significantly enhance the synthesis of nascent chains up to 9,000 nucleotides in length; hence, it must be needed to overcome a DNA structural problem that arises only after extensive replication.

In summary, a set of proteins has been identified that mediates the initiation of adenovirus DNA replication (pTP,

polymerase, NFI, and NFIII) and chain elongation (polymerase, DNA-binding protein, and NFII). These polypeptides, together with a template containing an adenovirus replication origin, are sufficient to reconstitute the complete viral DNA replication reaction *in vitro.* The adenovirus E4 gene encodes one or more products required for efficient DNA replication (39,153,426), but their role in the process is almost certainly indirect (266).

Activation of Late Gene Expression and Host Cell Shutoff

Adenovirus late genes begin to be expressed efficiently at the onset of viral DNA replication. The adenovirus late coding regions are organized into a single large transcription unit whose primary transcript is about 29,000 nucleotides in length (105,291). This transcript is processed by differential poly(A) site utilization and splicing to generate multiple distinct mRNAs (see Fig. 3). These mRNAs have been grouped into five families, termed L1 to L5, based on the use of common poly(A) addition sites (66,291,463). Expression of this large family of late mRNAs is controlled by the major late promoter. This promoter exhibits a low level of activity early after infection, and it becomes several hundred-fold more active on a per DNA molecule basis at late times (352). It is strongly activated by the E1A proteins through its TATA motif and Sp1/MAZ binding sites (E1A binds to the Sp1 and MAZ transcription factors) (306), but this does not account for the delayed kinetics of the activation event. There appear to be at least two distinct components that contribute to the delayed activation of the major late promoter: a cis-acting change in the viral chromosome, and induction of at least one virus-coded transacting factor.

The time-dependent cis-acting modification of the adenovirus chromosome was revealed by the sequential infection of cells with two closely related adenovirus strains whose late products could be distinguished (389). Although the first virus to reach the nucleus was actively expressing its late products, the second viral chromosome did not express late gene products until it had completed the early phase and had begun DNA replication. Thus, gene products from the first virus did not act in trans to initiate late expression from the second virus.

There are several possible explanations for this observation. It might be necessary to alter the constituents of the viral chromatin during the process of DNA replication to activate the major late promoter. Unreplicated viral chromatin appears to be associated with a different set of proteins than replicated chromatin (56,82). Viral DNA might remain associated with virus-coded core proteins until cellular histones bind during replication. Such an exchange could be required to activate the major late promoter. However, this proposal seems unlikely. Adenovirus DNA does not appear to be associated with histones (410), and papovaviruses exhibit a DNA replication–coupled early-to-late switch even though they package their DNA in cellular histones. Perhaps the replication process allows transcription factors to gain access to the promoter. Histones or histone-like proteins are displaced and then reassemble on DNA during replication, and this could provide an opportunity for transcription factors to compete for binding to the DNA. Alternatively, a newly arriving viral core might simply require a period of time to decondense and become available to the transcription machinery. Chromosomal domains could become accessible to the transcriptional machinery in a defined order, and the promoter responsible for most late gene expression might become accessible only after a delay. The major late promoter is active at a low level early after infection, but this might reflect early activation by a relatively minor subset of the total infecting population of viral chromosomes. It is also possible that the viral chromosome might establish a compartmentalized environment in the nucleus, and it might take a period of time to recruit cellular factors to its defined environment that are needed for late gene expression. Discrete viral centers at which replication and transcription occur have been observed in the infected nucleus by electron microscopy (262,280).

Whatever the underlying mechanism, *in vivo* footprint analysis has revealed that a transcription factor, termed *USF* or *MLTF* (45,273,341), binds to its upstream site in the major late promoter after the onset of DNA replication but not before (397). This factor activates transcription when it is bound to its recognition sequence in the major late promoter. However, a point mutation that blocks binding of USF/MLTF does not prevent the normal activation of the major late promoter (319,320). Hence, if it normally plays an important role in the late activation process, there must be redundant activators that can work in its absence, or USF/MLTF might be brought to the promoter through a protein–protein interaction in the absence of its binding site. Nevertheless, the demonstration that a factor gains access to the major late promoter only after the onset of DNA replication suggests that the time-dependent cis-acting modification to viral chromatin likely involves changes that permit access of transcription factors to the template.

The second component that contributes to activation of the major late promoter is a virus-coded transcription factor. In addition to the upstream region with USF/MLTF-, CAAT-, Sp1/MAZ-, and TATA-binding motifs, the region between +85 and +120, downstream of the initiation site, contributes to activation of the promoter (227,259). This downstream domain contains binding sites for at least two factors that can cooperate with the upstream USF/MLTF element to activate transcription (274,275). One of these factors is coded by the adenovirus *IVa2* gene (399). The *IVa2* gene has been classified as a delayed early gene because it is activated somewhat later than the standard early genes. Its promoter also contains important downstream elements (43,201), and these elements include the binding site for a factor that represses *IVa2* transcription (58). The mechanism by which repression is relieved is not yet known, but it seems likely that an early gene product plays a role. One can build a model in which a cascade of events leads to activation of the major late promoter: early transcription is activated; an early gene product relieves repression of the IVa2 promoter; and the IVa2 protein binds downstream of the major late start site and contributes to its induction. This model is attractive because the sequential nature of these events can serve as a timer, and this clock, together with the requirement for DNA replication, delays the synthesis of the late mRNAs until their products are needed for virus assembly. The IVa2 protein might work in concert with the L1 52/55-kd protein to activate the major late promoter because the two proteins have been reported to interact (149).

Adenovirus encodes a second delayed early gene product, protein IX. It activates transcription in transfection assays but does not exhibit specificity for the major late promoter (250).

Accumulation of late mRNA not only requires activation of the major late promoter but also depends on the alleviation of premature termination by RNA polymerase as it traverses the 29,000-bp late unit. Premature termination occurs at two positions within the unit. The first termination occurs close to the start site. During the late phase of infection, 80% of the RNA chains initiated at the major late promoter terminate before elongation has proceeded 500 nucleotides

(104,114,348). This termination primarily mitigates against late mRNA accumulation because prematurely terminated transcripts with 3' ends in this region are not detected early after infection (114). The second termination event occurs early after infection when molecules of polymerase fail to transcribe beyond the end of the L2 coding region (292); later, the polymerase transcribes through all of the late coding regions to the end of the genome (113). The molecular basis for the termination at early but not late times remains a mystery. Among other possibilities, it could result from cis-acting changes in the structure of adenovirus chromatin.

When DNA replication begins and all the late mRNAs are synthesized, the cytoplasmic accumulation of cellular mRNAs is blocked (26). Synthesis and processing of cellular transcripts continue, but the mRNAs fail to accumulate in the cytoplasm, suggesting that their transport is blocked. The block to cellular mRNA accumulation is mediated by the E1B 55-kd polypeptide (15,311) and by the E4 34-kd polypeptide (153,426), which exist in a complex (338). The same E1B and E4 proteins are required for efficient cytoplasmic accumulation of viral mRNAs late after infection (16,153,311,426). Thus, a complex that includes two viral proteins inhibits accumulation of cellular mRNAs and facilitates cytoplasmic accumulation of viral mRNAs. Analysis of late viral mRNA metabolism in cells infected with a mutant virus unable to synthesize the E1B 55-kd protein indicated that a block occurred immediately before movement of the mRNA from the nucleus to the cytoplasm (228). As discussed previously, the E1B 55-kd protein also binds to p53, but there is no evidence that p53 plays a role in the mRNA transport function mediated by the complex formed between the E1B and E4 proteins.

How does the E1B–E4 complex move mRNAs from the site of synthesis? The E4orf6 protein shuttles between the nucleus and cytoplasm (91,134). E4orf6 contains a nuclear export sequence, a motif first identified in the human immunodeficiency virus (HIV) rev protein, that would be expected to mediate its interaction with the cellular nucleocytoplasmic shuttling apparatus. How does the E1B–E4 complex interact with RNAs to be transported? The E1B 55-kd protein has been reported to exhibit intrinsic RNA-binding activity (178), and the viral protein interacts with a cellular protein termed *E1B-AP5* (117). E1B-AP5 is a member of the heterogeneous nuclear ribonucleoprotein family of RNA-binding proteins, it contains an RNA-binding motif, and its overexpression overcomes the block to host cell mRNA cytoplasmic accumulation in adenovirus-infected cells. A complex of the E1B and E4 proteins with their cellular partners transports newly synthesized viral mRNAs to the cytoplasm.

The discrimination between host and viral mRNAs for transport to the cytoplasm within virus-infected cells is not based on the identity of individual mRNAs. Cellular genes expressed from recombinant viral chromosomes accumulate in the cytoplasm late after infection as if they were viral mRNAs (120,167). Further, mRNAs are transported to the cytoplasm when encoded by cellular genes, such as the *hsp70* gene, that are transcriptionally induced within infected cells (277,443). Immunoelectron microscopy revealed that the E1B–E4 protein complex is localized within and surrounding intranuclear inclusions believed to represent viral transcription and replication centers (304). Together, these observations suggest a model in which the E1B–E4 complex relocalizes to viral transcription centers a cellular factor required for transport of mRNAs (304). This proposal can explain the simultaneous inhibition of host and activation of viral mRNA transport because a transport factor would be moved from the many sites of host transcription and processing to the viral centers.

In addition to their facilitated transport from the nucleus, viral mRNAs are preferentially translated when they reach the cytoplasm late after infection (461). During this period, when viral mRNAs constitute about 20% of the total cytoplasmic pool (381), they are translated to the exclusion of host mRNAs (14,449). Host mRNAs are not degraded; if they are extracted from the infected cell, they can be translated with normal efficiency in a cell-free extract (387). The translational block is not dependent on the inhibition of host cell mRNA accumulation in the cytoplasm. In contrast to most host mRNAs, b-tubulin mRNA continues to accumulate in the cytoplasm, but it is not translated (277). Also, 2-aminopurine can prevent the inhibition of translation without relieving the block to accumulation of host mRNAs (185).

Several regulatory components cooperate to facilitate selective translation of viral mRNAs late after infection. The first involves the cellular protein kinase R (PKR), which is activated by double-stranded RNA that accumulates within adenovirus-infected cells (260,301). After activation, it can phosphorylate the eukaryotic initiation factor-2a (eIF-2a), inactivating the initiation factor and blocking translation. Translation of host cell mRNAs is not inhibited after infection of cells deficient in PKR activity (185,300), suggesting that the kinase, and presumably inactivation of eIF-2a, are key components of the block to host cell translation. The adenovirus-coded VA RNAs (see Viral Antagonists of Interferon-a and -b) inhibit activation of the cellular PKR. These small RNAs have been shown to copurify with viral mRNAs (263); as a result, they might protect viral but not cellular protein synthesis, providing a functional compartmentalization.

Inactivation of eIF-4F also contributes to selective translation in adenovirus-infected cells (186). This initiation factor binds to the cap of mRNAs and facilitates scanning of the 40S ribosome from the cap to the AUG through its intrinsic helicase activity. eIF-4F is normally activated by phosphorylation, and it becomes substantially inactivated by dephosphorylation late after adenovirus infection when cellular mRNAs are not translated. The five families of mRNAs encoded by the adenovirus major late transcription unit all contain the same 200-nucleotide 5'-noncoding region, which has been termed the *tripartite leader sequence* (30). This 5'-noncoding region is important for translation of mRNAs late but not early after infection (33,245). Tripartite leader–containing adenovirus mRNAs continue to be translated late after infection because the 40S ribosome can scan from cap to AUG by a process termed *ribosome jumping* (454), without the need for a helicase as eIF-4F activity becomes limiting. In contrast, most cellular mRNAs are no longer translated in the absence of eIF-4F because they require the helicase to permit scanning through the more extensive secondary structure at their 5' ends.

Finally, there is a selective activation of late viral protein synthesis by the 100-kd protein encoded by the L4 family of late mRNAs (164). A mutant virus expressing defective L4 100-kd protein fails to translate its late mRNAs efficiently, but it is nevertheless able to block host cell translation. The L4 100-kd protein can bind to mRNA (2), suggesting it may function at the polysome to facilitate translation.

Virus Assembly and Release from the Cell

The replication of viral DNA, coupled with the production of large quantities of the adenovirus structural polypeptides, sets the stage for virus assembly. Trimeric hexon capsomeres are rapidly assembled from monomers after their synthesis in the cytoplasm (180). Assembly of the hexon requires the participation of a second late viral protein (the L4 100-kd protein), the same protein that stimulates late viral translation. Biochemical experiments indicate that a multimeric complex of the L4 100-kd protein binds to hexon monomers (47), and genetic analyses have demonstrated that mutations in the L4 100-kd protein can block assembly of the hexon capsomere (237,303). Apparently, the L4-coded protein acts as a scaffold to facilitate assembly of trimers, but the mechanism underlying the process is unknown. Penton capsomeres consisting of a pentameric penton base and trimeric fiber assemble somewhat more slowly in the cytoplasm (180). Pulse-chase experiments indicate that the penton base and fiber assemble independently and subsequently join to form a complete penton capsomere (180,412). After their production, hexon and penton capsomeres accumulate in the nucleus, where assembly of the virion occurs.

Mutations within a variety of viral genes can interfere with the assembly process. As would be expected, alterations in structural polypeptides that comprise the hexon or penton base can prevent accumulation of mature virions as well as subassemblies, such as empty capsids (87,97,336). Alterations in the polypeptide forming the fiber, polypeptide IIIa, or in the L1 52/55-kd protein can prevent assembly of virions and lead to the accumulation of incomplete capsid-like particles (57,86,87,97,336). Finally, a mutant virus with a defective L3-coded protease accumulates noninfectious virion-like particles with a set of unprocessed polypeptides (420).

Studies of mutant viruses, combined with analysis of the kinetics with which polypeptides are incorporated into capsids and mature virions, have provided a rough outline of the adenovirus assembly process. Assembly appears to begin with the formation of an empty capsid (309,377). Subsequently, a viral DNA molecule enters the capsid. The DNA–capsid recognition event is mediated by the packaging sequence, a cis-acting DNA element that is centered about 260 bp from the left end of the viral chromosome (135,155,165,390). Several cellular proteins have been reported to bind at the packaging sequence (343), but their role in the interaction between DNA and capsid is unclear. The packaging element can function only when it is positioned near an end of the viral chromosome, raising the possibility that proteins interacting at the terminal replication origin might contribute to its function. This could explain the ability of mutations in the virus-coded DNA polymerase to interfere with assembly (87). No empty capsids accumulate in cells infected with a mutant adenovirus containing a partially defective packaging sequence, even though all of the known constituents of the capsid accumulate (160,166). This suggests that capsid assembly does not occur spontaneously in the absence of an interacting DNA; rather, it is probably initiated in association with a viral DNA, an association mediated by the viral packaging sequence. Encapsidation of the chromosome is polar, beginning with the left end of the viral DNA (390), as one might anticipate given the location of the packaging sequence. The mechanism by which the viral DNA enters the capsid is controversial (87,160,422). Some experiments favor the possibility that viral DNA replication and encapsidation are coupled; that is, that the viral DNA enters the capsid as it is replicated. Other work suggests that ongoing viral DNA replication is not required and that replication and encapsidation occur in separate nuclear compartments. The L1 52/55-kd protein, which is composed of two differentially phosphorylated forms of a 48-kd precursor polypeptide, facilitates the encapsidation process (148,160,161). The L3-coded proteinase, a cysteine proteinase that requires DNA and a fragment of another viral polypeptide as cofactors (89,258,391,424), functions late in the assembly process. It cleaves at least four virion constituents, generating the mature VI, VII, and VIII and terminal protein moieties. These cleavages stabilize the particle and render it infectious.

There appear to be at least two viral systems that facilitate the escape and spread of progeny virus. The first involves disruption of intermediate filaments, which are components of the cytoskeleton. Vimentin is cleaved rapidly after infection, reportedly both by a reaction initiated by the adsorption process that does not require viral gene expression (24) and in response to the E1B 19-kd protein (431,432). As a result, the extended vimentin system collapses into the perinuclear region (80,460). Late in the infectious cycle, the L3 proteinase cleaves the cellular cytokeratin K18 (61). The cleavage event occurs at amino acid 74 of the cytokeratin, creating a “headless” protein that is not able to polymerize and form filaments; rather, it accumulates in cytoplasmic clumps. A normal intermediate filament system helps to maintain the mechanical integrity of cells, and perturbations to the network would be expected to make the infected cell more susceptible to lysis. The second system that facilitates the release of progeny virions involves the E3 11.6-kd protein. This protein, which is also referred to as the *adenovirus death protein,* kills cells as it accumulates during the late stage of infection (394). The mechanism by which it kills is not known.

INTERACTIONS WITH THE HOST

Adenovirus can maintain a long-term association with its human host, persisting for years after an initial infection. Adenovirus DNA has been identified by *in situ* hybridization in 1 in 10^4 to 10^6 peripheral lymphocytes of healthy individuals (123), and lymphocytes could be the source of virus in the original isolations of adenoviruses from adenoid tissue. Thus, adenovirus probably persists in lymphocytes. The virus encodes three gene products that should facilitate persistence by antagonizing antiviral responses of the host: E1A proteins and VA RNAs, which inhibit the cellular response to interferon-a and -b; and E3-coded products that protect infected cells from killing by CTLs and tumor necrosis factor (TNF). It is intriguing to note that these protective viral products are expressed from the three adenovirus genes most likely to be expressed in lymphocytes in the absence of active viral replication. The E1A promoter and the polymerase III–transcribed VA RNAs are constitutively expressed in all cells that have been tested, and the E3 promoter is unique among adenovirus control elements in that it contains several binding sites for the lymphoid-specific NFkB transcription factor, facilitating constitutive expression in lymphoid cells (438). Additionally, it appears that these protective viral genes might be further induced in response to the production of interleukin-6 (IL-6), a cytokine that is induced at the site of adenovirus infection in experimental animals (124), as a host antiviral measure. Transcription of the E2 gene is strongly activated by IL-6 through the cellular transcription factor NF–IL-6 (364); the resulting E2-coded DNA-binding protein, in turn, can activate the E1A and E3 promoters (53). Thus, the production of a cytokine by the host

as a protective response likely induces a viral countermeasure.

Viral Antagonists of Interferon-a and -b

The adenovirus E1A protein and virus-associated (VA) RNAs both afford protection from interferon-a and -b. E1A proteins inhibit the antiviral affect of interferon (7) by blocking the activation of interferon response genes (150,321). At least part of this effect results from the ability of E1A to bind to STAT1 (247) and its coactivator p300/CPB (see Activation of the Host Cell) and inhibit their activity. STAT1 is a transcription factor that mediates activation of interferon-responsive genes.

The small, abundant VA RNAs were named when their viral origin was still uncertain (322). Different adenovirus serotypes have been reported to encode one or two VA RNAs; Ad2 and Ad5 encode two species, termed VA RNA_I and VA RNA_{II}. The RNAs are each about 160 nucleotides in length, are GC rich, adopt stable secondary structures that are important for their function, and are transcribed by RNA polymerase III (112,147,427). VA RNA synthesis begins during the early phase of the infectious cycle and dramatically accelerates during the late phase. VA RNA_I accumulates to about 10^8 molecules per infected HeLa cell, roughly the abundance of ribosomes, and VA RNA_{II} reaches about 10^7 molecules per cell.

The first hint to the function of VA RNAs came from analysis of a mutant Ad5 virus in which the VA RNA_I gene was deleted (387). The virus grew poorly, and its defect was traced to inefficient protein synthesis during the late phase of infection. Additional work identified a defect in polypeptide chain initiation (323,345) resulting from phosphorylation of the eukaryotic initiation factor-2 (eIF-2) (323,344).

The eIF-2, which includes three subunits (a, b, and g), is central to one of the best-studied pathways of translational control. Early in the initiation process, eIF-2 binds to guanosine triphosphate (GTP) and the initiator transfer RNA (tRNA) to form a ternary complex, which then interacts with the 40S ribosomal subunit. Subsequent steps in the initiation process involving additional factors result in the binding of mRNA and the 60S ribosomal subunit. As the round of initiation is completed, eIF-2 leaves the ribosome, lacking the initiator tRNA and complexed with guanosine diphosphate (GDP) instead of GTP. For eIF-2–GDP to participate in another round of initiation, its GDP must be replaced with GTP in a reaction catalyzed by eIF-2B (also termed *guanosine nucleotide exchange factor*). The exchange reaction is inhibited by phosphorylation of the a subunit of eIF-2. The eIF-2a(P) forms a tight complex with eIF-2B, preventing it from cycling and catalyzing the exchange reaction. As a result, initiation is brought to a halt when about one third to one half of eIF-2 is phosphorylated, trapping all available eIF-2B. The degree of eIF-2a phosphorylation is greatly increased during the late phase of infection with the VA RNA_I–negative mutant (301), and protein synthesis in extracts of these infected cells can be restored to normal levels by addition of eIF-2 or eIF-2B (323,344). Further, the mutant phenotype is abrogated in cells that contain mutant forms of the eIF-2a subunit (77) or lack the eIF-2a kinase (301,344). Thus, the reduction in late translation results from the phosphorylation and inactivation of eIF-2.

Phosphorylation of eIF-2 is mediated by PKR. Synthesis of an inactive form of PKR is induced by interferon, and the latent enzyme is activated by double-stranded RNA. PKR is activated by autophosphorylation, which appears to require that two molecules of the enzyme interact with a molecule of double-stranded RNA (213). Activated PKR can phosphorylate the eIF-2a subunit; this leads to sequestration of eIF-2B and the cessation of translation. VA RNA_I can bind to PKR (203,269) and block its activation (208,300). The current structural model for VA RNA_I (Fig. 9A) suggests that it consists of two extended duplex domains bracketing a central domain that is composed of several stem-loop structures. The central domain includes two complementary tetranucleotides that are conserved in VA RNAs encoded by a variety of adenovirus serotypes (251,253), and mutational analysis indicates that the conserved tetranucleotide pair is essential for VA RNA_I structure and function (252).

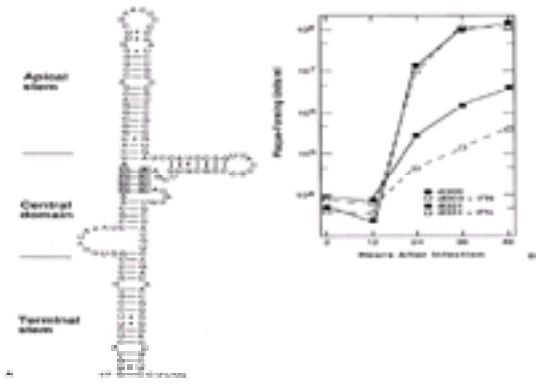

FIG. 9. Adenovirus VA RNA structure and function. **A:** Current model for the secondary structure of Ad2 VA RNA_1. The molecule is divided into three domains by convention: apical stem, central domain, and terminal stem. The two tetranucleotides in the central domain that are conserved among different adenovirus serotypes are identified (*shading*). **B:** VA RNA_1 antagonizes the antiviral effects of a-interferon. *Cell*s were infected with a virus that contained a wild-type VA RNA_1 gene (*d1309, circles*) or a mutant with a deletion blocking expression of VA RNA_1 (*d1331, squares*), and either treated (*open symbols*) or not treated (*solid symbols*) with a-interferon. The adenovirus with the wild-type VA RNA_1 gene was resistant to a-interferon, whereas the mutant virus was inhibited. (**A** modified from ref. 252, with permission; **B** from ref. 208, with permission.)

In an adenovirus-infected cell, PKR is probably activated by double-stranded RNA produced as a result of the symmetric

transcription of the viral chromosome (260,301). Activation of endogenous latent kinase is likely responsible for the inhibition of translation observed in cells infected with VA RNA $_{I}$–negative mutants (264). The level of latent PKR is induced by a factor of 5 to 10 in response to interferon. Thus, one might anticipate that VA RNA $_{I}$ antagonizes the antiviral effect of interferon by blocking activation of PKR, and this has proved to be the case (208). Whereas interferon-a inhibits the growth of VA RNA$_{I}$–negative virus, it has no effect on wild-type Ad5 (see Fig. 9B). In summary, VA RNA$_{I}$ blocks activation of latent PKR, and this function would seem critical for optimal viral growth in an infected host capable of responding to viral infection by the production of interferon.

In contrast to VA RNA$_{I}$, VA RNA$_{II}$ exhibits limited ability to block PKR activation. VA RNA $_{II}$ binds to RNA helicase A and NF90, a component of the nuclear factor of activated T cells (234). It is not yet understood how these interactions might promote viral replication.

Viral Antagonists of Cytotoxic T Lymphocytes and Tumor Necrosis Factor-a

Upon intranasal inoculation of cotton rats (*Sigmodon hispidus*) or mice with Ad5, viral gene expression is detected in the epithelial cells of the bronchi and bronchioles of the lung and nasal mucosa. The pulmonary histopathology is similar to that observed in humans (126), and disease proceeds in two stages (314). The earlier stage consists of a mild-to-moderate damage to bronchiolar epithelial cells and a diffuse cellular infiltration of peribronchiolar and alveolar regions. At this time, TNF-a, IL-1, and IL-6 appear in infected lung tissue (124). The later stage of the disease consists almost entirely of an infiltration of lymphocytes. A normal early phase ensues, but little late response is observed when athymic nude mice are infected (124), consistent with the interpretation that the late phase results from infiltration of virus-specific CTLs. Thus, the two stages of pathogenesis appear to result from an initial nonspecific host response to viral infection that includes synthesis of cytokines followed by an immunologically specific CTL response. Adenovirus E3-coded proteins, which are not needed for efficient viral growth in cultured cells, combat at least a portion of these host antiviral measures, inhibiting cytolysis of infected cells by CTLs or TNF-a.

Recognition and lysis of a virus-infected cell by CTLs requires that viral peptide antigens be displayed on the infected cell's surface in a complex with a class I MHC antigen. Ad2- or Ad5-infected cells expressing the E3-coded 19-kd glycoprotein (E3 gp19-kd) are considerably less sensitive to CTL-mediated lysis than cells infected with mutant viruses unable to express the E3 protein (8,42). E3gp 19-kd is a transmembrane protein of 142 amino acids, after removal of its amino-terminal signal sequence. It resides in the membrane of the endoplasmic reticulum, where it is held through the action of a retention signal that has been mapped to its C-terminal domain (305). The luminal domain of E3gp 19-kd binds directly to the peptide-binding domain of class I MHC antigens (42,220), and this interaction retains class I antigen in the endoplasmic reticulum through the di-lysine retention signal in the E3 protein. E3 gp19-kd also binds to TAP (28) and prevents it from transferring peptides processed in the cytosol to class I antigen in the endoplasmic reticulum. A reduced level of class I antigen on the cell surface and a block to TAP-mediated loading of class I antigen should protect against premature lysis of the infected cell by CTLs. Such protection can be inferred from experiments with cotton rats (126), but not mice (363). Pulmonary infection of cotton rats with a mutant virus, unable to express E3gp 19-kd, induced a markedly enhanced late phase inflammatory response (126). Thus, the E3 protein apparently ameliorates the late-phase response in cotton rats by protecting against lysis by CTLs.

CTLs carry the Fas ligand on their cell surface and induce apoptosis when the Fas ligand interacts with the Fas receptor (CD95) on a target cell. Products of the E3 region block Fas-mediated apoptosis. The membrane-bound E3 14.4-kd–E3 10.4-kd protein complex mediates internalization and degradation of the Fas receptor (98,355,393). Further, the E3 14.7-kd protein interacts with FLICE, a caspase acting downstream of the Fas receptor, and inhibits Fas ligand-induced apoptosis (60).

TNF-a is a cytokine that is secreted by activated macrophages and lymphocytes. It exerts cytotoxic or cytostatic effects on many tumor cells, and it can induce apoptosis and the subsequent lysis of cells infected with some viruses. Whereas uninfected cells or cells infected with wild-type adenovirus are not affected, cells infected with mutant adenoviruses lacking the E3 coding region are lysed by TNF-a (129). The CR1 domain of the E1A proteins is responsible for inducing susceptibility to TNF-a (95). This is the same E1A domain that has been reported to antagonize the activation of interferon-responsive genes, and the mapping does not precisely correlate with the binding requirements for any known E1A target. Either the E3 14.7-kd protein (129) or the E3 14.5-kd–E3 10.4-kd protein complex can prevent cytolysis by TNF-a (130). Both inhibit the activation of cytosolic phospholipase A2, which acts downstream of the TNF-a receptor (88,216,465). As noted previously, the E3 14.7-kd protein interacts with FLICE (caspase 8) (60). FLICE acts downstream of both the FAS and TNF receptors, and this interaction likely accounts for part of the mechanism by which the E3 14.7-kd protein blocks the induction of apoptosis by both receptors. The E3 14.7-kd protein also binds to a set of proteins termed FIP-1, -2, and -3 (231,232 and 233). When overexpressed, FIP-3 appears to activate a cell death pathway and to block an NFkB-mediated survival pathway (231). The interaction of the E3 14.7-kd protein with FIP-3 presumably blocks both of these pro-apoptotic activities.

In addition to its effect on the Fas receptor and the response to TNF-a, the E3 14.5-kd–E3 10.4-kd protein complex reduces the level of epidermal growth factor receptor on the surface of infected cells by inducing its internalization (44,393). It is not yet clear whether the internalization stimulates an epidermal growth factor–like response or abrogates function of the receptor.

ONCOGENESIS

All human adenoviruses that have been tested are able to transform cultured rodent cells to an oncogenic phenotype. The transformants undergo morphologic changes, and they tend to grow as dense, multilayered colonies. They can display various phenotypic hallmarks of oncogenic transformation, including growth in reduced serum, anchorage-independent growth, and growth to higher densities than normal. Only a subset of adenovirus serotypes can directly induce the formation of tumors within rats and hamsters (see Table 1). Group A adenoviruses (e.g., Ad12, Ad18) are highly oncogenic, producing tumors in most animals within 4 months; group B viruses (e.g., Ad3, Ad7) are weakly

oncogenic, inducing tumors within 4 to 18 months; at least one group D virus (Ad9) is oncogenic, efficiently inducing mammary tumors within 3 to 5 months; and group C and E viruses are not known to be tumorigenic.

Adenoviruses transform rodent cells much more efficiently than human cells, and the oncogenic adenoviruses induce tumors in rodents, whereas extensive screens have failed to correlate the presence of adenoviruses with human cancer. Initially, it seemed that the more efficient oncogenic transformation of rodent than human cells might result from the fact that rodent cells are generally less permissive for growth of human adenoviruses, and, as a result, they could more readily survive an infection and yield transformants. However, cloned E1A and E1B genes exhibit the same host cell preferences for transformation as does whole virus, arguing that differences in permissivity to viral growth are not a primary determining factor in transformation efficiency. There is a fundamental difference in the biology of rodent and human somatic cells that likely influences their response to adenovirus oncoproteins. Murine cells express telomerase and have longer telomeres than their human counterparts, which lack telomerase activity. It has recently been shown that the catalytic subunit of telomerase can cooperate with SV40 T antigen plus an oncogenic H-ras protein to transform efficiently human fibroblasts to a tumorigenic phenotype (152). T antigen plus oncogenic H-ras do not transform human cells in the absence of telomerase. This experiment suggests that the lack of telomerase expression in somatic cells is, at least in part, responsible for the block to adenovirus oncogenicity in humans. It is also possible that the immune response to adenovirus transformants (see Tumorigenesis) is fundamentally different in rodents and humans.

Transformation

Three lines of evidence initially demonstrated that the E1A and E1B genes mediate transformation. First, virus-transformed cells always contain and express these genes; second, transfection of cultured cells with cloned E1A and E1B genes leads to transformation; and, third, mutant viruses with alterations to these genes can be defective for transformation. As discussed previously, the E1A and E1B proteins manipulate cellular growth regulation. In a lytically infected human cell, E1A proteins induce quiescent cells to enter the S phase of the cell cycle, and E1B proteins prevent p53-mediated G_1 phase arrest and block the onset of apoptosis, creating an environment optimally conducive to viral replication. In the context of a rodent cell, these same events lead to oncogenic transformation.

One can construct a model for how the E1A and E1B 55-kd oncoproteins deregulate the G_0- to G_1- to S-phase cell cycle checkpoint through their interactions with pRB family members, p300 and p53. However, although E1A proteins have been shown to drive cells past the G_2- to M-phase checkpoint into mitosis, the mechanism by which this checkpoint is antagonized remains a mystery. Mutations in the E1A proteins that interfere with the binding of p300 or pRB family members can block the ability of E1A proteins to induce mitosis (182). Perhaps these cellular proteins, either in their normal complexes or as a result of their interaction with E1A proteins, influence both the G_0- to G_1- to S-phase and the G_2- to M-phase cell cycle checkpoints. Alternatively, the E1A proteins interact with additional, as yet unidentified proteins that control the G_2- to M-phase checkpoint.

Either the E4orf6 (276,286) or the E4orf3 protein (288) can substitute for E1B and cooperate with E1A to transform cells. Further, both of these proteins can enhance the tumorigenic potential of cells transformed with the E1A plus E1B oncogenes. E4orf6 inhibits p53 function and cooperates with the E1B 55-kd protein to reduce the half life of p53 (see Activation of the Host Cell). The ability to neutralize p53 probably accounts for the oncogenic activity of E4orf6. E4orf3 and E1A localize to and cause a morphologic rearrangement of POD/ND10 structures (46,94). The function of these intranuclear structures and their possible relationship to the oncogenic activity of E4orf3 are unknown.

Tumorigenesis

Rat cells transformed by the highly oncogenic Ad12 generally produce tumors in newborn syngeneic rats, whereas most cells transformed by the nononcogenic adenoviruses, such as Ad2 or Ad5, are not tumorigenic. However, some Ad2-transformed rat cell lines can induce tumors in immunosuppressed rats (118), suggesting that cells transformed by nononcogenic adenoviruses are rejected by the host's immune system. Newborn hamsters, which have not yet developed a thymus-dependent immune response, are also susceptible to tumor production by Ad2-transformed cells. Although thymectomized hamsters remain susceptible, normal animals become resistant to tumor challenge at the age of about 3 weeks when their thymic response has developed (71), suggesting that the thymus-dependent cellular immune system plays a key role in the rejection.

The thymus-dependent CTL response leads to lysis of transformed cells. As mentioned earlier, CTLs target tumor cells by recognizing foreign antigens displayed on their cell surface in the context of class I MHC antigens. In the case of Ad5 transformed cells, the E1A protein itself serves as a cell surface target (25), and several specific E1A-encoded epitopes have been identified that serve as targets of class I–restricted CTLs (202,332).

The Ad12 E1A proteins inhibit the CTL response that blocks tumor formation by cells transformed with nononcogenic adenoviruses (35). Ad12-transformed cells contain reduced quantities of class I MHC antigen on their surface (346), and, after introduction of a class I gene MHC that cannot be down-regulated by the Ad12 E1A proteins, Ad12 transformants are unable to induce tumors (383). Thus, the Ad12 E1A proteins repress expression of the class I antigen, and this prevents recognition by CTLs. The repression occurs at the level of transcription, and it appears that the activity of at least two factors that interact with the class I gene control region are altered (217,267,294).

Not all Ad12 transformants have proved resistant to CTL lysis (271), and some Ad12 transformed lines have become more tumorigenic (i.e., fewer cells can induce a tumor) when they were modified to express higher levels of class I antigen (361). Thus, although Ad12 E1A proteins reduce class I MHC levels in some transformed cells, facilitating escape from class I–restricted CTL-mediated destruction, the correlation is not reliable. This indicates that there are additional immune mechanisms that govern adenovirus tumor formation.

Many Ad2 transformed cells are markedly less efficient than Ad12 transformants in the formation of tumors in athymic

nude mice that lack class I–restricted CTLs. Nude mice possess natural killer (NK) cells, a class of immunologically nonspecific cytotoxic lymphocytes. Ad2 transformants are more susceptible to NK cell–mediated lysis than their Ad12 counterparts (70,317). Susceptibility to NK killing is governed by the E1A gene (72,73,340); addition of the Ad5 E1A gene to a highly tumorigenic sarcoma cell line induced susceptibility to lysis by NK cells, blocking its ability to form tumors (416).

Non-E1A–mediated mechanisms can also influence tumorigenesis. The E3 19-kd glycoprotein can influence class I MHC levels (see Viral Antagonists of Cytotoxic T Lymphocytes and Tumor Necrosis Factor-a). Thus, the E3 gene might also contribute to the differential CTL sensitivity of Ad12 versus Ad2 or Ad5 transformants. Although the E3 gene is often present in Ad12 transformants, it is generally not present in Ad2 or Ad5 transformed cells. Although there are exceptions, most rodent cells transformed with Ad2 or Ad5 contain only portions of the viral genome; only the E1A and E1B genes are consistently present. In a similar vein, additional E3-coded proteins, if present, might afford protection from TNF-a. The notion that additional genes play auxiliary roles in tumorigenesis is consistent with the observation that substitution of the Ad12 E1A or E1B genes into the corresponding Ad5 domain did not equip the resulting hybrid viruses to induce tumors in newborn rats or hamsters (34,340).

In contrast to group A adenoviruses such as Ad12, which induces tumors at the site of injection, Ad9, a group D virus, induces mammary tumors, irrespective of the site of injection. Subcutaneous injection of newborn Wistar-Furth rats produces mammary tumors in females but not males (11). The tumors are predominantly benign fibroadenomas, but phyllodes-like tumors and malignant sarcomas are also produced; all of the tumors are estrogen dependent (10,193). When hybrid viruses were constructed between Ad9 and a closely related group D virus that fails to induce mammary tumors, the Ad9 E4 gene was found to be required for mammary tumorigenesis (194). Remarkably, the E1A and E1B genes are dispensable for tumor induction (388). The Ad9 E4orf1 protein is responsible for Ad9 tumorigenesis. It is able to transform cultured cells efficiently to an oncogenic phenotype (195), and E4orf1 from group A and C adenoviruses can also transform cells if overexpressed (428). The 12.5-kd E4orf1 protein is localized predominantly to the cytoplasm (429), and it binds to a PDZ domain–containing protein, hD1g/SAP97 (225), a human homolog of the *Drosophila* discs large tumor suppressor protein. The carboxy-terminal domain of E4orf1 that is required for oncogenesis is also required for hD1g/SAP97 binding, suggesting that E4orf1 might act through this protein to mediate its oncogenic activity.

PERSPECTIVES

Much is known about the adenovirus growth cycle; indeed, the advances in our understanding during the 5 years since I first wrote this chapter are remarkable. An adenovirus host cell receptor has been identified, the protective (from the virus's point of view) roles of E3 proteins have been clarified, and the oncogenic potential of E4 proteins has been discovered. Yet, much remains a mystery, including the structure of the viral core both within the virion and as viral DNA is transcribed, the mechanism by which viral DNA is encapsidated, and the basis for host restrictions and tissue tropisms in infected organisms. There is no doubt that these and many other questions will be resolved in the near future.

Adenoviruses have brought much more to the table than a system of viral replication; they have also contributed to a molecular understanding of many fundamental cellular processes. For example, studies of adenoviruses have yielded important insights to the complex mechanisms by which cells express and process mRNAs and control their growth. Early adenovirus gene products have helped to identify many important cell cycle regulatory proteins, and they continue to serve as probes with which to manipulate these cellular factors and reveal their normal functions.

Adenoviruses no longer serve simply as systems for study. As discussed in Chapter 68, they are now being developed as vectors for gene therapy. Indeed, adenovirus vectors have been created that carry no viral genes, and it is becoming possible to modify the tropism of vectors by directing the virus to proteins on the cell surface other than its natural receptor. If the virus can be tamed so that it delivers and expresses therapeutic genes without attendant pathology, we will undoubtedly find ourselves “sleeping with the enemy” in the near future.

CHAPTER 68 Adenoviruses

Marshall S. Horwitz

HISTORY

During attempts to establish tissue culture lines from tonsils and adenoidal tissue surgically removed from children, Rowe and colleagues (224) recognized that a transmissible agent was causing degeneration of the epithelial-like cells. Thus, adenoviruses (Ads) were first cultured and reported as distinct viral agents in 1953. Similar viral agents were isolated from febrile military personnel with a variety of respiratory illnesses (114,124). It was soon realized that there were multiple serotypes of these new agents and that they were antigenically related by a group-specific complement fixation antigen. These viruses were first called *adenoid degeneration* (AD), *adenoid-pharyngeal conjunctival* (APC), and *acute respiratory disease* (ARD) agents. The current nomenclature of adenoviruses was subsequently adopted in 1956 (59).

Epidemiologic studies initiated by the Commission of Acute Respiratory Diseases of the U.S. Armed Forces confirmed that the adenoviruses were the cause of a large number of acute febrile respiratory syndromes among military recruits (37,50). In retrospect, acute respiratory disease syndromes caused by adenoviruses had been defined for perhaps 100 years before their association with this group of viruses (50). In addition, adenoviruses were isolated from outbreaks of epidemic keratoconjunctivitis (EKC), which had been described previously as a distinct clinical entity by German clinicians in the 1920s (118,133). As the number of adenovirus serotypes increased to the current 51 human types, additional clinical syndromes such as acute hemorrhagic cystitis, hepatitis, gastroenteritis, and myocarditis were associated with these agents (46,47,112,198,226). In 1962, it was demonstrated that Ad12 could cause tumors in rodents; this was the first description of a pathogenic human virus that could induce malignant tumors in animals (251). The oncogenic potential of the adenoviruses propelled this group of agents into the forefront of molecular biologic research, which has produced a detailed understanding of many aspects of both the lytic and transforming cycles. However, at this time, the adenoviruses have not been associated convincingly with any malignancies in humans (93). The clinical manifestations and epidemiology of this large family of human viruses are quite varied and will be discussed in this chapter.

The molecular biology of the adenoviruses has been extensively studied both during the lytic cycle in cells of human origin and during transformation in rodent cells (see Chapter 67). Molecular biology has contributed greatly to our understanding of intracellular events that could explain some of the pathologic lesions observed during infection (209,235,253). In addition, the tools of molecular biology are being increasingly applied to the diagnosis of adenovirus infections. Clinical isolates and various viral variants that occur under natural conditions have been analyzed by restriction endonuclease digestions of the genome as well as by DNA sequencing (71,104). Molecular footprints can (a) trace epidemiologic associations between clinical specimens, (b) assist in the characterization of new isolates, and (c) aid in the evaluation of variations in the structure of previously described serotypes. Polymerase chain reaction (PCR) to amplify viral DNA and nucleic acid hybridization can be rapidly applied to tissues and excretions from patients so that inactivated viral specimens that are no longer viable for growth in tissue culture can still be characterized. This has been most important for the characterization of adenoviruses in formalinized tissue fixed for histology and in the recent association of adenovirus infection with myocarditis (158,166,254). Adenovirus vectors are being used extensively for the delivery of cloned DNA into cells or into animals, including humans. There is an intensive effort by many investigators to introduce genes for therapy of various genetic diseases as well as malignancies and vascular occlusive disease using

adenovirus vectors (76,167,179,219,228,247). In parallel efforts, genes that code for epitopes that might induce immunity to various infectious diseases are being introduced with the help of adenovirus vectors (32; reviewed in 160).

INFECTIOUS AGENT

Propagation and Assay in Cell Culture

Growth of adenoviruses from patient material is best achieved in cells of human origin (11). Primary human embryonic kidney (HEK) cells are probably the best host for the replication of the entire range of human adenoviruses (153). However, HEK cells are expensive and may be contaminated with the adeno-associated virus (AAV). The A549 cell line, which was derived from a human lung carcinoma, is also a good host for most of the human adenoviruses, but some of the ocular strains may not grow well on these cells. The continuous epithelial lines, such as HEP-2, HeLa, and KB, are also highly sensitive but are difficult to maintain for the long period of time (28 days) that may be required to isolate some of the ocular adenovirus strains, such as Ad8 and Ad19 (91). However, adenovirus detection in epithelial cells has been greatly accelerated by centrifugation of viral specimens directly onto the tissue culture cells (HEP-2), using the shell vial technique. This approach has yielded positive cultures in 1 to 2 days for most of those eventually positive by conventional culture techniques (60,151). After growing for 1 to 2 days, the tissue culture cells were tested with monoclonal antibodies against the group-reactive epitope on the hexon. Human fibroblast lines are easier to maintain for long periods of time without media changes, but they are less sensitive than primary HEK cells or continuous epithelial lines.

The 293 cell line appears to be a good host for some strains of the two enteric adenoviruses, EAd40 and EAd41 (244). The sensitivity of this transformed line appears to offer the clinical laboratory a convenient host system for the growth of fastidious adenoviruses that are pathogenic in the intestinal tract (230,244). The 293 cell, which is a primary HEK transformed to a continuous line by Ad5 (88), retains the E1A and E1B regions of the adenovirus genome covalently linked to the host DNA (see Chapter 67). Infectious adenovirus cannot be produced from the endogenous sequences alone. The mechanism of facilitation of the growth of the EAd40 in 293 cells appears to be a function of the E1B-55 kd protein (169).

Primary monkey cell lines have been used to isolate human adenoviruses. However, there is a large amount of accumulated evidence that most adenoviruses grow poorly in these cells unless co-infected with the papovavirus, simian virus 40 (SV40) (10). The block in adenovirus replication is late in the viral replicative cycle after the synthesis of viral DNA, and the helper function of SV40 is supplied by the carboxyl-terminal part of the T-antigen polypeptide (10,63,283). Intramolecular hybrids between adenoviruses and SV40 have formed under conditions in which SV40 was an endogenous infection of the monkey kidney cells used for adenovirus isolation (222). Rhesus or other simian primary kidney cells are more easily maintained, require less feeding, and are less expensive to purchase. Therefore, primary monkey kidney cells are in widespread clinical use to isolate adenoviruses, even though such practices are not optimum.

Biologic Characteristics

Adenovirus cytopathogenic effect (CPE) consists of rounding and grapelike clustering of the swollen infected cells (144) (Fig. 1). Initial CPE may start at the periphery of the monolayer before generalizing. However, some of the group B adenoviruses do not cause cell enlargement or clustering. Adenoviruses increase glycolysis in continuous cell lines and thereby induce the cells to produce large quantities of acid (64). In some laboratories, the color changes of indicators caused by the lowered pH in the medium have replaced microscopic examination for CPE for some adenovirus culture work, such as viral neutralization tests. Rapid cytopathology can be induced within several hours of inoculating concentrated crude virus preparations and is not related to viral replication. The rounding and detaching of cells in such cases is caused by the penton base component of the free viral penton capsomere that is made in far greater quantities than needed for viral assembly; however, these cytopathic effects do not result in cell death. The penton base–induced cell detachment domain has been mapped to the integrin-binding RGD sequence (6).

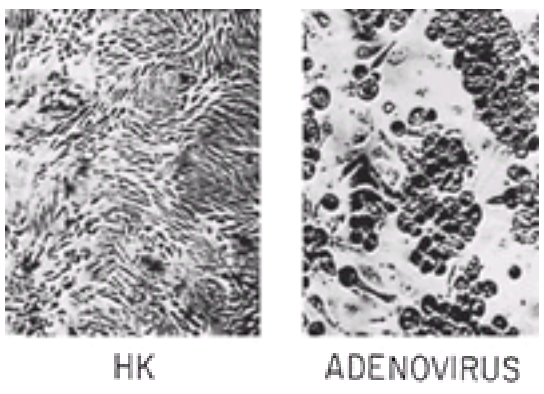

FIG. 1. Cytopathic effect induced by an adenovirus in human kidney (*HK*) tissue culture cells. Control monolayer (HK). Adenovirus-infected culture showing rounding, ballooning, and clustering of cells. (From ref. 119, with permission.)

Adenoviruses assemble in the nucleus of infected cells, and the nuclear morphologic changes can be used for diagnostic purposes. However, the viral proteins are synthesized in the cytoplasm, where some of them accumulate, and they can also be recognized by immunologic techniques. The nuclear changes after Ad1, Ad2, and Ad5 (group C) infection include overall enlargement and intranuclear inclusions that initially are Feulgen negative and eosinophilic but become Feulgen positive and basophilic as the infection progresses (27) (Fig. 2A and Fig. B). The Feulgen-positive inclusions contain adenovirions by electron microscopy (EM) (see Fig. 2C), and it is the DNA within the viruses that contributes to the

Feulgen stain. In addition, there are paracrystalline aggregates that contain viral protein without nucleic acid (180). The group B viruses also cause nuclear inclusions, and infection results in rearrangement of basophilic nuclear material (see Fig. 2).

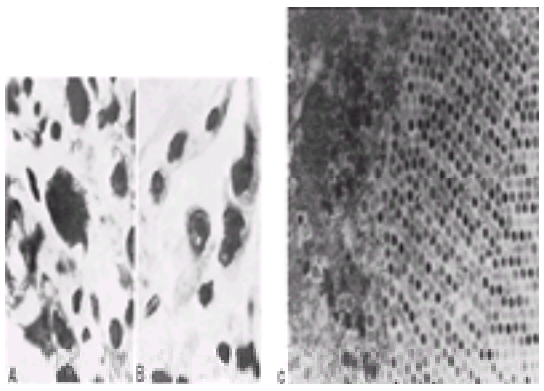

FIG. 2. Adenovirus cytopathology in human tissue. **A:** Lung tissue from a fatal case of adenovirus pneumonia showing in the center of the field a desquamated alveolar lining cell with a basophilic inclusion body filling the entire nucleus and obliterating the nuclear membrane (smudge cell). **B:** There is another desquamated cell with less-advanced cytopathology manifested by a smaller nuclear inclusion body, highlighted by a clear halo, contained within the nuclear membrane (×2800). **C:** The nuclear inclusion is full of virions, of which there may be as many as 10,000 particles per cell (EM, ×237,200). (From refs. 142 and 190, with permission.)

Although these light-microscopic cytologic changes are not absolutely pathognomonic of adenovirus infection, they are useful for the histopathologic diagnosis of biopsies, especially of lung tissue, and as an aid to tissue culture differentiation of adenoviruses from other agents. Suggestive adenovirus isolates based on the pattern of cellular degeneration must be further characterized by adenovirus-specific serologic or PCR assays for definitive identification, as described later.

Description of Key Antigens

The adenovirus proteins that provide the clinically useful antigens are the three coat proteins: hexon, penton base, and fiber. The hexon and fiber contain most of the epitopes recognized by neutralizing antibodies, but there are epitopes on penton base that are also recognized by some neutralizing antibodies (reviewed in 206a). In experimental infections in humans using replication-defective adenovirus vectors, it has been shown that the antibody responses to fiber and penton base ntigens have a synergistic effect in neutralization assays (77). The differences in neutralization of viral infectivity in tissue culture assays are the basis for the classification of distinct serotypes. The neutralization properties of polyclonal antibodies are often concordant with the inhibition of adenovirus-induced hemagglutination (HA) of selected red blood cells. However, the HA functions are the property of the fiber protein, which usually must be linked to the penton base for complete HA to occur. Because of recombination within subgroups in clinical isolates, it is not uncommon to isolate a virus that demonstrates discordant reactions in the neutralization and HA inhibition reactions. The functions of these proteins in viral entry (fiber) and in transport through the endosome membrane (penton base) and across the cytoplasm into the nucleus (hexon) are described in Chapter 67.

The cell protein receptor named CAR (coxsackie-adenovirus receptor), which is a receptor shared between these two groups of unrelated viruses and is the target of all subgroups of adenovirus fibers except for Group B, has recently been isolated (19,217). The class I major histocompatibility complex (MHC) molecule has also been proposed as a second receptor for Ad5 (119) but has not been confirmed by other groups (44,172). One of the group D adenoviruses, Ad37, appears to bind to sialic acid rather than to a protein at the cell surface (4). The penton base may be more important for the entry of some adenoviruses into hematopoietic cells (193).

There are group- and type-specific epitopes on both the hexon and fiber polypeptides. Type-specific domains have been mapped to unique sequences in loop 1 (amino acids 281 to 292) of the hexon and in loop 2 (amino acids 441 to 455) by generating neutralizing antibodies to peptides from each of these regions (248). Loops 1 and 2 had previously been shown to be on the surface of the virion by crystallography. Neutralizing antibodies to these epitopes have been found in human sera, but they do not inhibit attachment or internalization of the virus. These observations suggest that the antihexon antibody inhibits viral replication after these early steps are completed. Differences in the HA properties of rhesus and vervet erythrocytes for two important subtypes of Ad11 (Ad11p and Ad11a) have been related to nucleotide sequence differences in the shaft and knob region of the fiber. These viruses have some differences in tissue tropism in that Ad11p can be persistent in the urinary tract and Ad11a causes acute respiratory tract infections. These properties of the whole virus may be related to the changes in fiber polypeptides that are otherwise identical for 92.3% of their amino acids (173).

In addition to the type-specific neutralizing antibodies, there are group-reactive antibodies that react with domains of the hexon from all human serotypes (197). These interactions were classically measured by the complement fixation (CF) test and were useful in identifying an agent as an adenovirus. Subsequent serologic techniques, such as immunofluorescent (IF) antibody and enzyme-linked immunosorbent assay (ELISA) determinations, were also capable of detecting group reactivity shared by most of the human adenoviruses. Sequencing studies completed on adenoviruses from groups A, B, and C have confirmed that there are common sequences within the hexon protein coding domain that are extensively shared (110).

Infection of Experimental Animals

Human adenoviruses are species specific in their replication cycle, as are most adenoviruses of other mammals or avian species. There are some crosses of infectivity between closely related species, but even simian species are poor hosts for the replication of human adenoviruses. The replication of human adenoviruses in monkey cells can be achieved, but it requires co-infection with SV40 or the use of an adenovirus host range mutant (Ad5hr404, which contains a point mutation in the DNA-binding protein) for efficient replication (148). Human group C adenoviruses can replicate in the lung of cotton rats, and the pathogenesis of adenovirus pneumonia has been studied in these animals (209). Observations from this model have been reviewed in Chapter 67. An ocular model of infection with either Ad5 or Ad8 has been described in cotton rats, and the clinical manifestations, including subepithelial corneal opacities, were similar to epidemic keratoconjunctivitis (252). The animals shed virus, developed specific antibodies to the infecting virus, and even were able to spread the infection to control cotton rats. A similar ocular model was reported in New Zealand rabbits after topical or intrastromal inoculations of Ad5 (86). The virus appeared to replicate, and most of the animals developed a humoral immune response. There were findings of blepharitis, conjunctivitis, iritis, corneal edema, and subepithelial corneal infiltrates that were consistent with immune-mediated clinical disease. Other animals have demonstrated limited replication of single adenovirus serotypes but have served as neither animal reservoirs for disease nor useful models for *in vivo* studies with adenoviruses.

Adenovirus infections in a cotton rat pneumonia model, in which the E3 effects on pulmonary inflammation were studied, have been described in Chapter 67. Although human adenoviruses fail to produce virus in most other species, the virus does adsorb, penetrate, and make early proteins in a variety of cells of other animals. For example, mouse cells have been shown to support the synthesis of a variety of early adenovirus proteins, and mice have been used in pathogenesis studies, although little or no progeny virus is produced (55,85). Pulmonary pathology has been reported from the instillation of very high doses of Ad5 intranasally into mice, and the production of interleukin-1 (IL-1), IL-6, and tumor necrosis factor-a (TNF-a) has been observed in this nonreplicating pathogenesis model (85,235).

Isolated adenovirus early region 3 (E3) proteins, such as the gp19 kd, which inhibits the transport of the class I MHC to the cell surface, or the 14.7 kd, which inhibits some of the functions of TNF-a, have been studied for their potential to alter virulence of vaccinia virus in mice (94,253). The gene for Ad 14.7 kd, which was cloned into vaccinia virus together with the *TNF*-a gene (VV/TNF/14.7K), increases the virulence of the vaccinia virus carrying the TNF gene alone (VV/TNF) by reversing the antiviral effects of TNF-a. These results were obtained both in immunocompetent and in SCID mice in a pneumonia model, with death as well as inflammation as an end point (253a). The advantages of these systems are that the model includes a replicating virus, and the only permutation was the insertion of a single adenovirus gene. Other models for studying the role of single or groups of adenovirus genes in pathogenesis in mice have been developed by inserting the Ad E3 region from human Ad2 into transgenic mice (57). The Ad E3 genes placed under the control of the rat insulin promoter for targeted expression in murine pancreatic islet cells can prevent autoimmune diabetes in a virus-induced (lymphocytic choriomeningitis virus) murine model of type I diabetes or in nonobese diabetic (NOD) mice (58,261).

Human adenoviruses inoculated into a variety of rodent species cause tumors. Ad12, Ad18, and Ad31 are highly oncogenic in hamsters, and much has been learned about the mechanism of action of oncogenes from these viral models. The adenovirus genes responsible for these tumors are the *E1A* and *E1B* genes (see Chapter 67). Ad9 causes fibroadenomas and mammary sarcomas in rats, and an early region 4 gene seems to be important in this model (132). However, there is no evidence that adenoviruses are etiologically involved in human malignancies, but they are found as opportunistic infections in patients immunosuppressed by either their malignancies or chemotherapy (67).

PATHOGENESIS AND PATHOLOGY

From the interactions of adenoviruses and cells described in Chapter 67, it is possible to reconstruct some of the events that contribute to the pathologic lesions seen during the course of adenovirus infection. During the lytic cycle of many of the adenovirus serotypes, transport of host messenger RNAs (mRNAs) from the nucleus to the cytoplasm is inhibited by the action of the Ad E1B-55 kd and E4-34 kd protein complex (206,276). The inhibition of cell DNA and protein synthesis, subsequent to the interruption of the normal processing of host mRNAs, is incompatible with cell survival. The infected cell degenerates in specific ways that help the pathologist diagnose adenovirus infection on biopsy or autopsy tissue (190). The respiratory epithelial cells that are affected during adenovirus pneumonitis have enlarged nuclei containing amphophilic or basophilic inclusion bodies surrounded by thin rims of cytoplasm. Some of these cells are referred to as *smudge cells* (see Fig. 2A) and contrast with those infected cells with nuclear inclusions but intact nuclear membranes (see Fig. 2B). On occasion, these nuclear inclusions have been mistakenly identified as those of cytomegalovirus (155). However, there are no syncytia or multinucleated giant cells as found with herpesvirus infections. As in tissue culture, the epithelial cells are the primary target for adenovirus cytopathology *in vivo* (27).

One of the adenovirus structural proteins, the penton base, made in much larger excesses than needed for the assembly of the adenovirus, has been shown to bind to the a_vb_3- and a_vb_5-integrins and to cause cells to detach rapidly from the surface of monolayer tissue culture dishes (268). This effect can be demonstrated even in cells that are not directly infected with adenoviruses; it has been postulated that this protein might be involved in pathogenesis. It had initially been thought that the penton cell-rounding effect led to cell death, but it now appears that the cells are viable upon removal of the viral protein (194). Although the importance of penton in human disease has not been determined, it has been found in the blood of several fatal cases of adenovirus pneumonia (154a).

Adenovirus-induced changes at the level of single cells result in considerable organ toxicity during serious tissue invasion by adenoviruses. Necrotizing bronchitis, bronchiolitis, and interstitial pneumonia, as well as fibrin and hyaline membranes within the alveoli, characterize adenovirus pulmonary syndromes (52). Comparable lesions occur within the conjunctiva, in which exudative and mononuclear infiltrates are found. However, the lesions occur beneath the

epithelium, so that ulceration or neovascularization of the cornea usually does not occur (134,176).

Proliferative responses similar to transformation have not been recognized in acute adenovirus infections in humans. However, lymphatic tissue is often hypertrophied, and active germinal centers are found. For example, the appendices of children undergoing surgery to correct bowel obstruction found in intussusception may be associated with enlarged mesenteric lymph nodes and adenovirus isolation from stool specimens (279,280). These lymphocyte changes are often in close proximity to areas of desquamated epithelial cells in which typical viral inclusions may be found. The inclusions contain viral particles in crystalline arrays that are visualized by EM. Some of the lymphocytes are probably CD8 cytotoxic T lymphocytes (CTLs) that recognize proteolytic peptide products of viral proteins that have not been further elucidated for the human CTL response. However, in the mouse, the E1A and E1B viral polypeptide sequences have been recognized in the context of the syngeneic MHC in the plasma membrane (16,72,142,154). The potential modulation of this response by a product of the E3 region is discussed in Chapter 67.

Entry into the Host

Adenoviruses enter susceptible hosts either by the mouth, the nasopharynx, or the ocular conjunctiva. As described previously, recent experiments have defined the receptors for all the subgroups except for subgroup B as the CAR receptor (19,20,217,247a). Entry of a single group D serotype (Ad37) appears to be an exception that requires sialic acid rather than the CAR protein (4). The entry of adenoviruses into a variety of hematopoietic cells may involve the penton base rather than the fiber (193). The lower serotypes, Ad1, Ad2, Ad5, and Ad6, are ubiquitous, particularly in young children, and may be shed for months, especially in the stool, which is probably responsible for the endemic spread of these agents by the fecal-oral route to new pools of susceptible infants and children (73). An epidemic form of adenovirus keratoconjunctivitis has been spread in swimming pools (75) from contaminated water and in medical settings (135) from adenovirus-infected ophthalmologic instruments, especially tonometers (183). A third pattern of spread was unique in the military setting, occurring during the early period after induction into service. Ad4 and Ad7 caused acute respiratory distress (ARD), including pneumonia, and were the result of airborne inoculation of the respiratory tract (52,81).

Site of Primary Replication

It is clear from the original findings of adenoviruses in tonsils and adenoids that these tissues of the oropharynx were a major initial site of replication for the entering adenoviruses. The initial replication most likely occurs in the nonciliated respiratory epithelium, although some limited replication and persistence can also occur within lymphocytes (1; reviewed in 159). These conclusions are based not on careful observations of cells *in situ* but on the cells in which adenovirus replicates in tissue culture. Ciliated respiratory epithelium of the lower airway is difficult to infect with adenoviruses through the apical surfaces, which do not contain the CAR receptor; however, disruption of the integrity of cell–cell contact allows basolateral infection of such polarized epithelial cells using the CAR receptor (205,265).

Spread of Virus and Tissue Tropism in the Host

Most of the manifestations of adenovirus infection are locally in the eyes and pharynx, but contiguous extension into the lungs results in some cases. Even in the nonreplicating mouse model of human adenovirus infection, the virus can cause inflammation in the lungs, which is strong evidence for direct extension into these target organs (85). However, adenoviruses have been cultured from the blood during fatal respiratory disease caused by these agents, suggesting viremic spread in some situations (35). The successful use of oral, live, microencapsulated adenovirus vaccines by the military to prevent ARD suggests that if the respiratory tract can be physically bypassed by Ad4 and Ad7, intestinal replication of the virus causes an immunizing rather than a virulent infection (39,40). These vaccine viruses have not been intentionally attenuated by serial tissue culture passage and are believed to retain some of their initial virulence. Although most adenoviruses replicate in the intestine without causing gastroenteritis, Ad40 and Ad41 are responsible for intestinal disease. Adenovirus disease in the urinary bladder, primarily by group B adenoviruses in immunocompetent hosts, suggests that the virus probably is viremic at some stage in order to reach this organ. There is no evidence for ascending infection for these group B serotypes, which are less commonly found in the intestine and are more common in young males than in females. The route of infection of the liver, especially in immunosuppressed liver transplant recipients, is unknown, but some patients might be infected by latent adenoviruses that are present in cells such as lymphocytes in the transplant.

Immune Response

Various aspects of the immune response to this family of viruses have been described in other sections, and mechanisms that the virus uses to evade the immune response have been reviewed recently (121,163,272). Early cytokine responses (IL-1, IL-6, and TNF-a) have been described in the murine pneumonia model after nonpermissive infections with human adenoviruses (85). A biphasic mononuclear cell response in the cotton rat suggested an early appearance of monocytes and NK cells followed by specific T and B lymphocytes. The cell infiltrate was changed from a mononuclear to a polymorphonuclear leukocyte response by deletion of the adenovirus E3 anti-TNF genes (*14.7 kd, 10.4 kd/14.5 kd*). Deletion of the anti-MHC Adgp19 protein increased the intensity of the inflammatory response in the cotton rat but not in the mouse (84,235). These observations suggest that immunopathology plays a role in the host response to adenovirus infection, and this process is ameliorated by the E3 inhibitors of the host inflammatory response (83,209). However, testing the effects of the isolated adenovirus anti-TNF *14.7 kd* gene or the Ad *gp19 kd* anti-MHC gene in other animal model systems suggests that the *14.7 kd* gene can increase viral virulence in a pneumonia model and that the *gp19 kd* gene may not affect virulence in a similar model (41,94,253). Whether these adenovirus genes would affect viral persistence has not been tested. Thus, it is not clear at this point whether the cell-damaging effects of adenovirus infection or the host immune responses to the pathogen are responsible for the tissue pathology and the clinical manifestations. Despite the down-regulation of class I MHC by the Ad *gp19 kd* protein, the CTL response (in the mouse) is induced usually to a peptide from the E1A region of the virus. There is evidence that both the CD8 and CD4 responses of human cells to adenovirus infections are not serotype specific because there is cross-reactivity to targets infected by adenoviruses of different groups (70,179,234). It is important to understand these issues of pathogenesis and the immune

responses because adenoviruses are being used as vectors to deliver foreign genes into human hosts. Although most of these adenovirus vectors have been enfeebled by deletion of the E1A and E1B regions and therefore fail to grow efficiently in human cells (see Adenoviruses as Vectors for Vaccination and Gene Therapy), it is still essential to determine whether the E3 anti-MHC and anti-TNF genes should be deleted or retained in a form that would be expressed in the vectors for gene therapy.

Neutralizing and nonneutralizing antibodies are discussed in the sections, Description of Key Antigens and Viral Serology. After infection, most patients develop both group- and type-specific antibodies to the infecting adenovirus strain. Group-specific antibodies are not neutralizing of viral infectivity but are useful in measuring patient response when infection with an adenovirus is suspected but no isolate was obtained. In this case, acute and convalescent sera taken several weeks apart may demonstrate rising antibodies to a group-specific adenovirus antibody such as that measured by CF, IF, or ELISA, using a viral-infected tissue culture extract or purified hexon from a single adenovirus type. Type-specific antibodies are measured by either the neutralization test or inhibition of HA, as described in the section, Viral Serology. It is clear that patients may continue to shed adenoviruses intermittently, especially in their stools, for many months after a successful humoral immune response has occurred (73). Neutralizing antibodies may be protective against disease manifestation in the previously infected host or against reinfection with the same serotype, but they do not eliminate the carrier state.

Virulence

There is active research into the genes that can alter virulence, as discussed for the E1, E3, and E4 genes (see Chapter 67). However, it is unclear why certain serotypes characteristically cause disease in some organs and not in others. The gastroenteritis-inducing capacity of Ad40 and Ad41 is unexplained, as is the tropism of type B adenoviruses for the urinary tract or the types (Ad8, Ad19, and Ad37) that are particularly virulent in the conjunctiva. Tissue culture experiments or the existing animal models do not explain the mechanisms of such tissue tropism or organ-specific pathogenicity. Because all but the group B adenoviruses can attach to the CAR receptor, it is unlikely that this receptor can explain differences in the *in vivo* tropism of the various serotypes. Even the mechanism of attenuation of the oral vaccine strains used to prevent ARD in military personnel may depend more on physical formulation (i.e., enteric coating) of a live virus that bypasses the oropharnx and first exposes the intestinal epithelium than on mutation of virulence genes.

Persistence and Latency

Although low levels of replication-competent virus remain in tonsils, adenoids, and intestine of infected hosts, and shedding can occur for months to years (128,191,256), little is known about the mechanism of latency for adenoviruses in humans or animals. Adenovirus DNA has been detected in adult human lymphocytes, and the number of such positive samples appeared to increase with increasing age, as if latency were the end result of previous adenovirus infection (120). However, another group using PCR techniques failed to find evidence of adenovirus persistence in the lymphocytes of their study group, although they were able to isolate an Epstein-Barr–positive lymphocyte line from one patient who persistently produced adenoviruses (68,69). Carrier cultures of adenovirus-infected tissue culture cells in which the virus waxed and waned upon continued passage of the cells have been established (9). However, molecular mechanisms to maintain latency or the genes required for such a state are not known.

EPIDEMIOLOGY

Adenovirus infections occur worldwide in humans as well as in a variety of animals. With few exceptions, the human adenovirus serotypes are generally not pathogenic to animals, and animal adenoviruses are only pathogenic within the species of origin (246). However, asymptomatic infection across these species barriers has been documented by antibody determinations. Simian species occasionally have been shown to have antibodies to human Ad12 (141). Antibodies to bovine, simian, and canine adenoviruses have been detected in human sera evaluated by neutralization tests. The transmission of adenovirus infection and disease varies from sporadic to epidemic. The pattern often correlates well with the viral serotype and the age (children or adults) of the susceptible population. Because many of the adenovirus-related diseases are not clinically pathognomonic of the etiologic agent, the epidemiology of adenovirus infection is crucially dependent on the techniques used to prove the identity of the infectious agent. Therefore, the incidence and clinical spectrum of sporadic adenovirus disease were only elucidated by prospective monitoring of families, orphanages, and children's homes (260). A virus watch study was undertaken in New York and Seattle (73,74). Respiratory and fecal samples, as well as histories of disease, were collected twice a month in these latter studies. Much of the adenovirus epidemiology in civilian populations was learned from these studies, including the important information that there was a high incidence of recurrent shedding, especially of the lower serotypes, in fecal specimens. In addition, the large number of completely asymptomatic adenovirus infections was documented in such studies. Fecal-oral transmission accounts for most infections in young children. Initial spread may occur by the respiratory route, but the prolonged carriage in the intestine makes the feces a more common source during both the acute illness and intermittent recurrences of shedding (73). The epidemiologic importance of the long latency in tonsil tissue is not known. Adenoviruses probably account for 3% of the infections in civilian populations and for about 7% if only febrile illnesses are calculated (73). The corresponding figures for young children are about 5% and 10%, respectively.

Serologic surveys have furnished some estimates of the prevalence of adenovirus infections in various populations. Antibodies to Ad1, Ad2, and Ad5 are most common and are present in 40% to 60% of children (28,124,136). The incidence of antibodies to Ad3, Ad4, and Ad7 is low at the same ages. These antibody results probably explain why adults are uncommonly infected with Ad1, Ad2, and Ad5 but are more susceptible to infections with Ad3, Ad4, and Ad7. During the surveillance for the virus watch studies, it was documented that only about 75% of the adenovirus isolates were accompanied by an antibody response, as measured by the CF test (73). Some of the serologic nonresponders may be related to the insensitivity of the CF assay or the failure of some children to produce such antibodies.

The epidemic forms of adenovirus disease were studied in different ways from the sporadic endemic occurrences. The

epidemics of acute respiratory disease were well known during World War II, and this awareness preceded the isolation and the characterization of the first adenovirus by about one decade. This ARD, which occurred almost exclusively in recently assembled military recruits, was most common in winter. It did not occur in seasoned personnel in close contact with the recruits and was later identified as an Ad4 or Ad7 infection in most outbreaks (113,115,223). This disease rarely occurred in similarly congregated college students, suggesting that additional factors, such as more crowded sleeping conditions or the fatigue associated with basic training, contributed. In support of these cofactors has been the observation that ARD-causing adenoviruses did not spread to civilian personnel in contact with the military. In recruits congregated during the summer months, ARD often did not occur until the onset of colder weather in the fall. Influenza A could be distinguished because it affected both experienced and new recruits. Adenovirus-induced ARD often affected 80% of the recruits, with 20% to 40% hospitalized. The duration of infectivity was rather short; virus was not demonstrable after 4 days of illness (223). Controlled studies of routes of infectivity for the ARD-causing adenoviruses have demonstrated that aerosolized virus inhaled into the lungs of volunteers produced the disease, whereas application to the mouth, the nasal mucosa, or the intestine in enteric-coated capsules failed to produce the lower respiratory disease (39). ARD outbreaks were effectively controlled by vaccination of recruits in the first few days of military service; however, recent interruption in the supplies of adenovirus vaccine has resulted in the reappearance of the epidemic form of ARD. This is discussed further in the section on vaccines later.

The epidemiology of pharyngoconjunctival fever and keratoconjunctivitis, both of which may occur in epidemic proportions, is described later with the individual disease entities. Infection resulting in several of the adenovirus syndromes can be acquired in hospitals and can be spread as nosocomial infections. The isolation of the fastidious enteric types of adenovirus from a group of hospitalized infants on a pediatric ward demonstrates that this type may be spread within the hospital environment (277). Other adenovirus serotypes have probably been spread as nosocomial infections (12,30,260).

CLINICAL FEATURES

Adenoviruses can commonly infect and replicate at various sites of the respiratory tract as well as in the eye and gastrointestinal tract. Less frequently, adenoviruses can infect the urinary bladder and liver. On occasion, these viruses may also cause disease in other organs, such as the pancreas (196), myocardium, or central nervous system, which may be involved in meningoencephalitis complicating an adenovirus infection of the respiratory tract (146). Although there are at least 51 distinct human adenovirus serotypes, most human disease is associated with only one third of these types. Many adenovirus infections are subclinical and result in antibody formation that is probably protective against exogenous reintroduction of the same adenovirus serotype. However, the virus itself may be grown, especially from the gastrointestinal tract (73) and respiratory tract (61), for months after the initial infection and immune response. The more common illnesses associated with various adenoviruses are described in Table 1 and in the following paragraphs.

Disease	Individuals most at risk	Principal serotypes
Acute febrile pharyngitis	Infants, young children	1-3, 5-7
Pharyngoconjunctival fever	School-aged children	3, 7, 14
Acute respiratory disease	Military recruits	3, 4, 7, 14, 21
Pneumonia	Infants, young children	1-3, 7
Pneumonia	Military recruits	4, 7
Epidemic keratoconjunctivitis	Any age group	8, 11, 19, 37
Pertussis-like syndrome	Infants, young children	5
Acute hemorrhagic cystitis	Young children	11, 21
Gastroenteritis	Infants, young children	40, 41
Meningoencephalitis	Children and immunocompromised hosts	7, 12, 32
Hepatitis	Infants and children with liver transplants	1, 2, 5
Myocarditis	Children	?
Persistence:	Bone marrow transplant recipients; patients with acquired immunodeficiency or other immunosuppression syndromes	
In urinary tract		34, 35
In colon		40-49

TABLE 1. *Adenovirus infections associated with disease or persistence*

Respiratory Diseases

Endemic Adenovirus Infections of Young Children

About 5% of ARD cases in children younger than 5 years of age are due to an adenovirus (28). The usual symptoms include nasal congestion, coryza, and cough. Other patients may have an exudative tonsillitis that may be clinically indistinguishable from disease caused by the group A streptococcus (82,100). The respiratory symptoms are often accompanied by systemic manifestations, such as generalized malaise, fever, chills, myalgia, and headache. The common serotypes are Ad1, Ad2, Ad5, and Ad6 (group C or HA group III) and occasionally Ad3 (group B or HA group I), which are endemic in most populations. Sporadic cases may be indistinguishable from other viral respiratory infections, such as influenza, parainfluenza, and respiratory syncytial virus. If conjunctivitis accompanies the signs and symptoms already described, the disease is designated as *pharyngoconjunctival fever* (12). The conjunctivitis is usually follicular, unilateral or bilateral, and characteristically mild. The adenovirus serotype most commonly involved is Ad3, but Ad7 and Ad14 within the same HA group have been isolated from such patients (107,124,202). In more severe cases, pneumonia may occur. Adenoviruses are probably responsible for about 10% of the pneumonias of childhood (164). Most patients recover from these lower respiratory infections, but some epidemics of Ad7 have resulted in considerable mortality (189). Sequelae in those who recover may include bronchiectasis that can clinically manifest years after the primary infection (156,233).

Acute Respiratory Disease of Military Recruits

In many respects, ARD is similar to the description furnished earlier of the respiratory infection of children. The syndrome

is caused by Ad4, Ad7, and occasionally Ad3. ARD is a syndrome that frequently occurs under the special conditions of fatigue and crowding created soon after the induction of young military recruits (107,175,178). It is less common among healthy adults. Some cases have had a fatal outcome from the pneumonitis that may accompany and complicate the other, milder respiratory symptoms. Further aspects of this disease are discussed in the section entitled Epidemiology.

Pertussis-like Syndrome

The association of adenovirus infection with a pertussis-like syndrome has been noted, leading to some speculation that adenoviruses rather than *Bordetella pertussis* caused many of the cases of clinical whooping cough (241). Claims were made that even the lymphocytosis of pertussis might be related to the adenovirus infection (35). This point of view was given some credence by the isolation of an Ad5 from multiple organs of a patient with severe whooping cough with lymphocytosis that ended fatally (35). Later data from a controlled study of 134 children with a pertussis-like illness and 101 healthy controls reported the common association of adenoviruses with whooping cough symptoms (192). However, there was no evidence that the adenoviruses alone were responsible for the syndrome. The large number of adenovirus isolates may be due to conditions favorable for reactivation of latent viruses from tonsillar tissue during concurrent *B. pertussis* infection (195).

Infections of the Eye

An acute follicular conjunctivitis may occur as part of a respiratory-pharyngeal syndrome or as a separate entity (18,188). Both bulbar and palpebral conjunctival involvement may occur and affect both eyes. The disease is often accompanied by significant preauricular lymphadenopathy (12). Complete recovery without sequelae is the most common result of this rather mild illness. The incubation period is usually 6 to 9 days, but it was as short as 2 days in experimental infections in volunteers (14,140). Epidemiologically, these infections can occur sporadically or cause disease in large groups of contacts. Family members may be affected. When the source is a swimming pool or small lake, large numbers of children and young adults may develop symptoms. Swimming pool conjunctivitis is probably most commonly due to adenoviruses (75). Although the virus is isolated from the conjunctiva of affected individuals, it has not been isolated from water samples from putatively infected sources. The common-source water-borne outbreaks usually occur in summer and are caused by Ad3 and Ad7; however, other types, such as Ad1, Ad2, Ad4, Ad6, Ad9, Ad10, Ad11, Ad15, Ad16, Ad17, Ad20, and Ad22 (groups B, C, D, and E and HA groups I, II, and III), have been associated with this syndrome (18,188).

In contrast to the milder form of ocular disease described previously and limited to the conjunctiva, EKC is a highly contagious and more serious disease. The clinical entity was first described before the isolation of adenoviruses and occurred among German workers in the late 19th century (118,133). It was subsequently observed in shipyard workers in Hawaii and in the continental United States. “Shipyard eye” was probably transmitted in the medical facilities that cared for chemical and physical trauma to the eyes of the workers. After an 8- to 10-day incubation period, a follicular conjunctivitis with edema of the eyelids, pain, lacrimation, and photophobia began. Corneal subepithelial infiltrates often followed the initial conjunctival involvements (45). The disease is often unilateral with preauricular lymph node hypertrophy. Occasionally, other lymph nodes were involved, and constitutional symptoms occurred, especially in children. However, most often the disease was limited to the involved eye and its draining lymph nodes. Corneal opacities in some cases lasted for several years and, uncommonly, would remain for longer periods. In some patients, the involvement slowly progressed to a hemorrhagic conjunctivitis that should be distinguished from the rapidly evolving acute hemorrhagic conjunctivitis associated with enterovirus 70 (45). Ad8 was the original cause of EKC. Between 1973 and 1976, Ad19 was common (51,96,258). Ad37 was isolated in 1976 and has been the predominant cause of EKC since 1977 (147). Rarely, other types caused a similar syndrome. In addition to viral inoculation during an ophthalmologic procedure such as tonometry, EKC has occurred as a late summer and fall epidemic in certain parts of Japan, Taiwan, and Vietnam. EKC has accompanied endemic trachoma in Saudi Arabia (15). Ad8 antibody is uncommon in American schoolchildren, whereas about half the Japanese or Taiwanese children have such antibodies (245).

Acute Hemorrhagic Cystitis

Acute hemorrhagic cystitis, an illness occurring almost exclusively in boys and associated with Ad11, is characterized by gross hematuria (198). Its significance lies in the potential confusion with other, more serious diseases of the kidney (such as glomerulonephritis). This self-limited disease is usually not accompanied by fever or hypertension, and tests of renal excretory and concentrating functions have been essentially normal. Ad21, like Ad11, is a group B HA type I and can also cause hemorrhagic cystitis (185). In Japan, when acute hemorrhagic cystitis occurs in a boy between the ages of 6 and 15 years, an adenovirus isolation from urine or a rise in neutralizing antibody occurs in about 70% of patients (198). In comparable studies of hemorrhagic cystitis in the United States, only 20% of cases can be linked to an acute adenovirus infection, and for 60% of the total, the etiology remains unexplained (185).

Patients have developed Ad11 acute hemorrhagic cystitis after renal transplantation and its accompanying immunosuppression (99,149). In some patients, it appears that the infection was introduced with the transplanted kidney. Some of the causes of hematuria in immunosuppressed patients include cytotoxic drugs used to treat the underlying disease, but even in such patients, the prevalence of adenovirus isolates from the urine is increased. Various adenovirus serotypes have occasionally been isolated from urine during acute systemic adenovirus infections. Two other group B serotypes, Ad34 and Ad35, were isolated first from renal transplant recipients. Ad34 was isolated from urine, whereas type 35 was isolated from kidney and lung tissue at autopsy (109,190). Although neither was accompanied by the symptoms of hemorrhagic cystitis, the Ad35 clearly contributed to the patient's demise from pneumonia.

Meningoencephalitis

It is rare to isolate any of the adenoviruses from either the cerebrospinal fluid (CSF) or the brain. However, several reports have directly demonstrated adenoviruses in CSF (Ad3, Ad5, Ad6, Ad7, Ad7A, and Ad12). One patient with malignant lymphoma, immunosuppressed by chemotherapy, had an Ad32 isolated from brain at autopsy (33,146). There are other cases of meningoencephalitis in which viral isolation from extraneural sites or antibody titer increases have

been used to make a diagnosis, especially associated with epidemic Ad7 pneumonia in children (232). A case of sudden unilateral deafness was associated with an Ad3 infection of the nasopharynx (129).

Gastrointestinal Diseases

Diarrhea

The relationship between adenoviruses and diarrhea has had a long and complicated history but has been clarified considerably in recent years (177,269,273,277). Because many adenoviruses replicate efficiently in the intestine and are excreted in the stool, it was assumed that they would be strong candidates for causing diarrhea (54,66). However, most earlier epidemiologic studies generally found as many adenovirus isolates in the stools of controls as in those with diarrhea (211). The failure to correlate adenovirus growth from stool with clinical illness was a good example that adenoviruses should not be designated as the cause of a whole spectrum of medical illnesses just because they can be cultured from the stool of an individual with a disease. Normal children can clearly shed adenoviruses in stool and often develop antibodies to the particular type grown (73,116). These subclinical infections probably result in lifelong immunity. That young children with systemic adenovirus infections can develop diarrhea as an accompanying problem is well known but probably no more common than after any other systemic infection.

The whole issue of adenoviruses as a cause of infantile gastroenteritis was reexamined based on the observation that initially “noncultivatable” adenoviruses were seen on EM examination of stool smears of affected children (66). Serologic detection methods such as ELISA for enteric adenovirus antigens have been developed to supplement the EM observations (270). Alternate tissue culture host–cell systems, such as the HEK-293 line, have resulted in the growth of some of the “noncultivatable” viruses (47,243,270). Two different enteric adenoviruses, EAd40 and EAd41, have been associated with diarrhea (47,80,270). Epidemiologic studies to assess the importance of these agents have been completed for several population groups. A report of 14 enteric adenovirus–related cases of diarrhea in 27 hospitalized patients studied during a 12-week period suggested that these viruses may be an important cause of acute gastrointestinal disease in hospitalized young children and may be nosocomially transmitted; this report also suggested that respiratory symptoms may be a prominent part of the clinical manifestations (277). The incidence of adenovirus-related gastroenteritis differs considerably in the various studies and locations reported by many authors. In general, it is not as prevalent as rotavirus diarrhea, occurs most often in children younger than 4 years of age, and is not easily distinguished on clinical grounds from rotavirus infection (215). In Bangladesh, it was responsible for 2.8% of the cases of diarrhea in 4,409 specimens but reached 12.3% in some months as diagnosed by a monoclonal antibody specific for Ad40 and Ad41 (131). In day care centers in Houston, weekly stool specimen collections from children 6 to 24 months of age were used to demonstrate that 38% of 249 children present during 10 separate outbreaks associated with enteric adenoviruses had this agent in their stool specimens. However, 46% of these samples came from patients who were asymptomatic, demonstrating that even during epidemics of enteric adenoviruses, many infected children do not develop gastroenteritis (257). In another study of children in day care reported from the Centers for Disease Control and Prevention in Atlanta, the prevalence of all adenoviruses in stool was 8%, and EAd40 and EAd41 were 2% in both 565 patients with diarrhea and 129 controls (157). In the latter study, astroviruses were more common in children with diarrhea (4%) than in controls (1%). Thus, it is clear that the role of adenoviruses as a cause of diarrhea can vary in different clinical settings. In some population groups, 50% of the children at the age of 4 years have antibodies to the enteric adenoviruses (230).

Intussusception

Another intestinal syndrome, intussusception, has been linked in some patients to adenovirus infection (13). The telescoping bowel characteristic of intussusception may be caused by mesenteric adenitis acting as a lead point to the mechanical obstruction. Adenoviruses (group C, HA group III, Ad1, Ad2, Ad5, and Ad6) have been isolated from both stool cultures and the involved lymph nodes removed at surgery (34,207). However, there is no evidence that EAd40 and EAd41 are involved in this syndrome (22). An alternative explanation, that some hyperirritability of the small intestine might be caused by adenovirus infection and lead to the intussusception, has been proposed (280). However, many patients with intussusception have no evidence of adenovirus infection, and the disease is probably multifactorial. Adenovirus inclusions have been seen in some appendices removed at surgery (279).

Celiac Disease

Structural homology between the Ad12 E1B protein and A-gliadin, a major component of a-gliadin known to activate celiac isease, was noted. In addition, most patients with celiac disease had evidence of prior Ad12 infection, in contrast to matched controls. These observations suggest that a viral protein product of an adenovirus found in the intestine may play a role in the pathogenesis of celiac disease, perhaps by inducing cross-reacting antibodies to a-gliadin (139). In two recent studies to determine whether there was persistent Ad12 infection in the intestinal mucosa of patients with celiac disease, PCR was used. Four of 18 patients had detectable adenovirus DNA, as did 2 of 24 controls, leading the authors to conclude that Ad12 persistence is not a major element in celiac disease (162). Similar conclusions were reached by others but do not preclude that prior Ad12 infection might have been involved in the evolution of celiac disease (259).

Myocarditis

Adenovirus DNA has been detected by PCR in most myocardial biopsies primarily from children with acute myocarditis in two studies (158,166). Although there was clinical and electrocardiogram evidence of myocarditis, most of the adenovirus-positive biopsies did not show classic inflammation, in contrast to those that appeared to be associated with enterovirus infection.

Diseases Associated with Immunocompromised Patients

Although the adenoviruses are not nearly as prevalent as the various herpesviruses during immunosuppression,

adenoviruses have been isolated from immunocompromised hosts and have contributed to their morbidity and mortality. Fifteen immunocompromised patients seen between 1967 and 1978 with either an adenovirus isolate (14 patients) or typical adenovirus histology on postmortem (1 patient) have been reviewed (281). Twelve patients had pneumonia, 8 of 11 patients had hepatic abnormalities, and 9 patients died of either respiratory or hepatic failure. Only 3 patients had evidence of other concurrent infections. The adenovirus serotypes were Ad1, Ad2, Ad5, and Ad6 in children and Ad4 in the adults. These same ubiquitous serotypes were also prevalent in patients with other, less serious illnesses in normal age-matched populations. These data would imply that immunocompromised patients may be no more commonly infected with adenoviruses than normal hosts but that the outcome may be more serious and even result in fatalities. This general conclusion was reached by other investigators reporting an individual case of Ad11 pneumonia in an agammaglobulinemic patient (231), an Ad2 fatal hepatic and bronchial necrosis in a child with thymic alymphoplasia (271), and an Ad35 fatal disseminated infection in a renal transplant recipient (237).

The problem of adenovirus hepatitis in 5 of 224 pediatric hepatic transplant recipients has been demonstrated (29). The serotypes involved were common types, such as Ad1, Ad2, and Ad5. The clinical manifestations were often the direct result of infection of the transplanted liver, and viral intranuclear inclusions were readily identified. The disease was acquired *de novo* or by reactivation of latent virus from an endogenous source. Forty-nine of 484 pediatric liver transplant recipients had an adenovirus isolated from either liver, lung, or gastrointestinal tract. Twenty children had invasive adenovirus infection, which culminated in the death of 9 patients (174). Some immunocompromised patients recovered from their adenovirus infections after discontinuation of immunosuppressive drugs, but the reported cases clearly emphasize the poor outcomes of some of these acute infections. No specific antiviral agents are effective against such adenoviral diseases.

Twelve percent of patients with acquired immunodeficiency syndrome (AIDS) have been reported to have group B adenoviruses in their urine (48,122). Restriction endonuclease analyses of viral DNA of 24 urinary isolates have shown that all were related to Ad34 and Ad35. However, some of the AIDS urine isolates had the Ad7 hemagglutinin by serologic classification, suggesting recombination between the Ad35 and Ad7 group B (HA group I) agents. In addition to the HAs of Ad7 and Ad35, HAs from Ad3 and Ad11 have been found in other Ad35-like isolates from AIDS patients (122). Occasionally, Ad35 has also caused fatalities from pneumonia or hepatitis, as observed in 3 pediatric patients (152).

Adenoviruses were observed by EM in colonic tissue of 5 of 67 homosexual men infected with human immunodeficiency virus type 1 (HIV-1) and studied because of persistent diarrhea. However, it is not clear whether group D adenoviruses are associated with the chronic diarrhea that is common in these immunocompromised patients. The tissue biopsy samples had foci of mucosal necrosis, chronic inflammatory cells, and amphophilic nuclear inclusions observed by light microscopy. Thus, adenoviruses, primarily newer isolates of group D, are present in the colonic lesions of some immunocompromised patients and may cause diarrhea but do not appear to be the etiology of the large number of intestinal dysfunctions that affect AIDS patients (112,130).

After allogenic bone marrow transplantation, adenovirus isolation rates as high as 20.9% and disease in 6.5% of the patients have been reported (67). Most of these isolates were group B agents, serologically typed as Ad35 by viral neutralization assays, but were typed as Ad11, Ad34, and Ad35 by DNA analysis (67) (see Identification and Classification of Viral Isolates). More than half of these patients with adenovirus diseases succumbed to their infections. Although these rates of isolation and disease are higher than previously reported (229), the trend to more high-risk bone marrow transplantations may have contributed to the increased incidence of adenovirus infection and disease.

Latency

Adenoviruses were discovered because of their propensity for latency in adenoidal tissue (1), and there are several patterns of latent infections. The persistence or reisolation of adenovirus in normal human hosts has been documented for 24 months after initial infection (73,116). The potential role of lymphocytes (especially B cells) has been suggested in the maintenance of latency by several groups of investigators who have found low levels of adenovirus DNA persistent in peripheral blood lymphocytes (1). Confirmation of true latency in tonsillar tissue has been reported in a study demonstrating adenovirus nucleic acid sequences in this tissue but no infectious virus, even after repeated passage (195). Latent adenoviruses have been postulated to be important in the pathogenesis of chronic obstructive pulmonary disease (COPD) that occurs in cigarette smokers (168). Adenovirus DNA sequences from the E1A region were found by PCR more often in resected pulmonary nodules from patients with COPD than patients without airway obstruction. However, the detection of adenovirus DNA sequences from the E3 region was not different in the two groups studied. The viral E1A DNA was found in the epithelial cells, suggesting that it might be involved in COPD. In another study in children, persistent infection with adenoviruses was associated with asthma as well as with chronic airway obstruction (161). The significance of these observations, which were reviewed recently (159), awaits further study.

Persistent or latent adenoviruses could explain the clinical illnesses in immunocompromised hosts who might be reinfected from an endogenous source at the time of immunosuppression. However, in some renal transplant recipients, the infection appears to be exogenously acquired in the donor organ (99). Another possible outcome of infection would be the stable integration of E1A and E1B sequences of the adenovirus DNA in covalent linkage with the host chromosome. The Ad E1 region sequences have been shown to be sufficient for transformation of rodent cells by various adenovirus serotypes. In model systems in animals, it has been clearly demonstrated that some adenoviruses, especially Ad12, Ad18, and Ad31, are highly oncogenic. However, most attempts to associate adenovirus infection with the etiology of human tumors have been unsuccessful. In the adenovirus oncogenesis model, infectious virus is no longer present, but a defined segment of viral DNA is integrated into the host chromosome, from which it is actively transcribed and translated into viral polypeptides. No viral macromolecules (DNA, RNA, or proteins) suggesting an adenovirus infection have been found in most studies of the etiology of human malignancies (92,93). However, one group of investigators has found adenoviral nucleic acid in neurogenic tumors (125). These latter results await confirmation by others.

DIAGNOSIS

Differential Diagnosis

Many adenovirus infections of the respiratory tract are difficult to distinguish from other respiratory viruses and even some bacterial infections. In children younger than 3 years of age, small discrete white spots of exudate can appear on the tonsils and are consistent with adenovirus infection. They have to be distinguished from streptococcal infections and the manifestations of the Epstein-Barr virus mononucleosis syndrome or even some cases of herpes stomatitis, which in older children or young adults might start as exudate on the faucial tonsils. The most characteristic manifestation of adenovirus infection is the conjunctivitis as part of the keratoconjunctivitis syndrome, which usually begins unilaterally, causes moderate enlargement of the preauricular lymph node, and may subsequently involve the contralateral eye. The adenovirus-induced upper respiratory syndromes or pneumonias are impossible to distinguish clinically from other viral infections of these organs and must employ laboratory diagnosis for clarification of the etiologic agent. Hemorrhagic manifestations of the urinary tract can be caused by bacterial infections as well as by adenovirus infections. In patients immunosuppressed with cyclophosphamide for bone marrow transplantation, manifestations of hemorrhagic cystitis can be due to drug toxicity in the bladder soon after transplantation. However, the isolation of adenoviruses later in the course as a cause of the cystitis was reported in 13% of cases (150). Adenovirus as a cause of hemorrhagic cystitis is more common in Japan than in the United States, for reasons that have not been explained. The gastroenteritis that is manifest during Ad40 and Ad41 infection may be nosocomial and should be sought in hospital-related outbreaks in young children, when a bacterial etiology has not been identified.

Laboratory Diagnosis

Collection and Preparation of Specimens

Collection of specimens from affected sites early in the illness is necessary to optimize viral isolation and to detect adenovirus antigens or nucleic acid directly in clinical samples. The duration of excretion of adenoviruses at the time of acute infection is about 1 to 3 days from throat in adults with the common cold; 3 to 5 days from nose, throat, stool, and eye from patients with pharyngoconjunctival fever; 2 weeks from eye cultures from keratoconjunctivitis; 3 to 6 weeks from throat or stool of children with respiratory or generalized illnesses; and 2 to 12 months or longer from urine, stool, throat, or organ biopsies of immunocompromised patients (110). However, after the acute period, adenoviruses may be latent in some tissues, such as the tonsils, or may be reisolated intermittently from throat or stool cultures for periods of months to years after primary infection in some patients (73,116). Adenoviruses obtained from throat swabs, nasal washes, conjunctival swabs or scrapings, and anal swabs are generally stable agents and withstand freezing and storage at –70°C, if immediate inoculation is not possible (144). Because some of the urines may be toxic to the tissue culture lines employed, it is best to remove the input inoculum after 2 to 4 hours of incubation. This time allows the virus to be absorbed before the cultures are re-fed with fresh medium. When cultures of blood mononuclear cells are desired, heparinized blood is fractionated on Ficoll-Hypaque gradients, and the washed cells are cultured in RPMI medium with fetal calf serum (144). Portions of these cells should also be co-cultivated on such cells as HEK cells, which are susceptible to adenovirus infection.

Viral Serology

Agents growing in tissue culture and demonstrating typical adenovirus cytopathology should be further processed to identify the isolate definitively. Serologic confirmation is useful in this characterization and can be separated into two categories. The IF and CF tests, using tissue culture material as antigens and reference antibodies, measure group characteristics of the adenoviruses and are therefore usually shared by all human isolates (79,144). The hemagglutination inhibition (HAI) and serum neutralization (SN) tests measure type-specific parameters that can distinguish members of each group (144).

The adenovirus CF antigen is a property of the soluble hexon capsomere, which is made in great excess over that assembled into the virion. Although the hexon carries multiple antigenic epitopes, the alpha measured in the CF test is common to all human adenoviruses (204,246). In many laboratories, the IF or ELISA recognition of adenovirus isolates is considerably easier than CF characterization. Thus, a single reference antibody can be used for initial characterization of a clinical isolate as an adenovirus. Type-specific monoclonal antibodies that could be used in the IF test as well as in ELISA and latex agglutination procedures are currently used for differentiating EAd40 and EAd41 from other adenoviruses in the feces (105). Specific serotyping includes the use of monoclonal antibodies to type-specific epitopes on hexon or fiber.

In current practice for specific adenovirus serotyping, the HA properties of a virus isolate are determined, followed by serologic tests to inhibit HA or to neutralize the virus with type-specific antibodies. Agents preliminarily characterized as adenoviruses are tested for their ability to hemagglutinate either rhesus or rat cells (218). Further HA testing using human cells, as well as cells from various other animal species, can provide supplemental information (108,147,160). Classification of adenoviruses by HA of rat or rhesus cells is shown in Table 1 of Chapter 67. In addition to group B (HA group I), which completely hemagglutinates rhesus cells, and group D (HA group II), which does the same with rat cells, there are the group III agents, which only partially hemagglutinate rat cells. Once an adenovirus can be placed in an HA group, the various type-specific antibodies within that group are added to find the one that will inhibit the HA reaction. Preparation of the sera includes absorptions with kaolin, inactivated filtrates of *Pseudomonas* species, or heparin-MnCl2 to remove nonspecific inhibitors (144).

Various cross-reactions among serotypes commonly occur (e.g., among Ad7, Ad11, and Ad14 within subgroup I). In addition, a number of recombinants occur between adenoviruses within a subgroup (111). These recombinations appear both naturally in patients and artificially in tissue culture dually infected as described in Chapter 67. Recombination of patient-derived material complicates the typing procedure. The SN and HAI results may be discordant as a result of recombination of two adenovirus genomes between the hexon and fiber genes (Fig. 3; see Chapter 67). When the results of the SN test differ from those for the HAI test, they are reported as SN/HAI. Because the HA is a property exclusively of

the fiber, the HAI test is able to measure antigenicity from only 5% of the genome. Adenovirus neutralization is a property of both the hexon and the fiber, which together represent 15% of the genome. Because adenoviruses spread slowly from one cell to another, it takes considerable time to reach an end point in a neutralization test. To speed up the SN, many laboratories have adopted various modifications that rely on the kinetics of neutralization rather than on a stable end point. Various intersecting pools of antibody mixtures have been devised to decrease the number of individual neutralization reactions that must be used for virus identification.

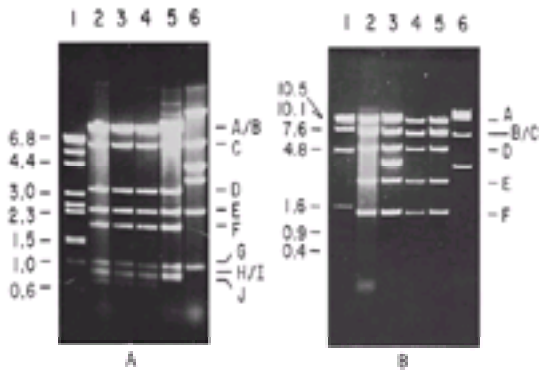

FIG. 3. Characterization of clinical adenovirus isolates by restriction endonucleases. **A:** Smal restriction endonuclease was used to digest and compare six adenovirus DNAs that were electrophoresed in 1% agarose and stained with ethidium bromide. *Lane 1:* Prototype Ad2. *Lane 2:* Prototype Ad35. *Lanes 3–6:* Clinical isolates. Lanes 3 and 4 are identical to Ad35, but lane 5 is missing one restriction cut, causing fragment J to remain fused to fragment A. Lane 6 is another clinical isolate unrelated to types 2 or 35. **B:** The same DNAs as those in **A** were digested with Hpal restriction endonuclease. Note that there is a single-band difference between lanes 3 and 2 or 4, all of which were identical following Smal digestion. (From ref. 48, with permission.)

Viral DNA

Other properties of the virus can be exploited both for identification of an isolate as an adenovirus and for subgroup typing. Characterization of the viral DNA by both hybridization and restriction endonuclease digestion patterns has been used for clinical isolates (48,147,242,262). In contrast to the limited regions of the genome analyzed by either HAI or SN tests, restriction endonucleases recognize and cut the DNA at specific sequences found throughout the genome. Viral footprints characteristic of the DNA digestion patterns for the various serotypes have been used for virus identification and classification. Modified Hirt extracts of infected cells separate the viral from the host DNA in a rather simple purification scheme before the restriction endonuclease step. Characterization of patient isolates by these techniques is shown in Figure 3 (48). For finding small differences in DNAs, multiple enzymes may be necessary. Other investigators have found it unnecessary to separate host from viral DNA and have obtained similar results (242). These procedures can be made even more sensitive by Southern blotting of the DNA restriction digests, followed by DNA–DNA hybridization (242). This procedure, which used small numbers of cells and adenovirus-specific radioactive-DNA probes, may be positive for viral DNA before any evidence of viral growth by CPE. The specific viral radioactive-DNA probes can easily detect the viral DNA restriction endonuclease bands among the contaminating host DNA. However, this procedure is tedious for routine clinical use and clearly must be reserved for special situations.

Currently, PCR assays are being used for diagnosis of adenovirus infections in various tissue specimens and body fluids. For reactivity with most human adenoviruses, PCR primers have been chosen from the hexon coding region or from the VAI and II (110,274) regions, for which there is extensive homology among serotypes. For type-specific probes, sequences from the E1B region have been used to identify the two enteric types (3). The sensitivity and specificity when compared with viral culture or the presence of hexon antigen was greater than 90% in one study (110). Such an approach would be useful late in an illness, when little viable virus was present. Modifications of these approaches are also suitable for fixed tissue specimens prepared for microscopic pathologic examination (254). However, some investigators have found that the hexon primers result in many positive PCR specimens from stool samples of normal patients, such as 50% of symptom-free children with a mean age of 21 months or 18% of normal young adults tested (3). These latter results may be detecting latent viruses from a variety of adenovirus serotypes because the PCR probes specific for the E1B gene of enteric adenoviruses were negative in the normal patients.

Direct Microscopy of Clinical Specimens

Exfoliated Cells

Rapid diagnosis by direct examination of the cytopathology of exfoliated cells has not been generally successful because IF techniques have detected only one third of the nasopharyngeal secretions from which adenoviruses subsequently grew in tissue culture (78). However, other authors have reported that the IF technique to detect adenovirus-infected cells is as sensitive as tissue culture growth (170). The IF technique has not been useful in early diagnosis of conjunctival adenovirus lesions but may be more useful in studies of exfoliated bladder cells from patients with acute hemorrhagic cystitis (17). Latex agglutination tests for detecting enteric adenovirus proteins in stool are available. They depend on specific adenovirus antibody to agglutinate latex beads in the presence of adenovirus proteins. Although evaluation of their sensitivity and specificity has indicated that they are useful in diagnosing enteric adenovirus infection, they are less sensitive than culture, they may give positive results with nonenteric adenoviruses, and a significant number of positive reactions of stool extract with the latex controls can invalidate the test (90).

Electron Microscopy

EM of clinical specimens has been used in special situations to identify viral agents rapidly and specifically. The discovery of the “noncultivatable” adenoviruses was made by EM examinations of stool extracts (66). The procedures used were developed to detect other fecal agents, such as rotavirus and Norwalk agent, that grew poorly in tissue culture (25,65,143). Because the EM morphology of the adenoviruses is unique, it was not as critical to use immune EM to differentiate the viral agents from other nonviral components of stool. On specimens from other body sites, immune EM for rapid diagnosis of respiratory infections was successful in detecting 19 of 25 throat swabs from which adenoviruses were grown (56). Although less sensitive than tissue culture growth, the EM technique was rapid. However, such approaches are not generally used to diagnose adenovirus infection of the respiratory tract.

Antibody Response to Adenovirus Infection

Patient antibody responses to infection or epidemiologic surveys have generally used CF, HAI, SN, and ELISA tests as described for serologic identification of adenovirus isolates. Because the CF antibody response is a group reactivity, single CF antigens detect responses to many adenovirus serotypes. However, adenovirus CF serologic responses may vary with the virus used as a source of the antigen, and some adenovirus infections may not be detected by this technique (225).

Although the HAI and SN antibody responses are more specific for a single infecting serotype, these tests may detect heterologous responses within a subgroup, especially when adults are being studied. Children have more specific serotype responses, perhaps related to their limited experience with the adenovirus family. Other serologic tests (e.g., Ouchterlony agar gel diffusion, radial gel diffusion, and HA enhancement) have been used by various investigators (89,197). Each has an advantage, such as economy of reagents, ease of performance, or high sensitivity for group-reactive antigens, but none has found general use in clinical laboratories.

PREVENTION AND TREATMENT

Therapy

Specific antiviral therapy for adenovirus ocular infections has been attempted. The keratoconjunctivitis has been treated during the acute inflammatory phase, and the effect of therapy on both the acute symptoms and chronic corneal sequelae was evaluated. Iododeoxyuridine and adenine arabinoside, which both inhibit the replication of the DNA-containing herpes family of viruses, were unsuccessful in the treatment of adenovirus-induced epidemic keratoconjunctivitis (53,267). Neither the acute phase nor the delayed appearance of corneal opacities has been benefited by these topical antiviral agents. Two nucleoside analogs, (S)-9-(3-hydroxy-2- phosphonylmethoxypropyl) adenine (HPMPA) and 2'-nor-cyclic guanosine monophosphate (cidofovir), have been reported to be potent, nontoxic inhibitors of adenovirus replication in human embryonic fibroblast cultures (5). Cidofovir, the cytidine analog of HPMPA, is also effective in tissue culture against Ad1, Ad5, and Ad8 (87). This drug, which is used to treat cytomegalovirus disease, has shown some efficacy in the rabbit ocular model of Ad5 infection (86). There is also a case report of a single patient with adenovirus disease complicating stem-cell transplantation treated successfully with cidofovir (216). Intravenous ribavirin has been used to treat severe local or systemic adenovirus infections in immunosuppressed patients. The reports, usually of single patients, have had mixed results (31,137,165,186). In a refractory case of adenovirus hemorrhagic cystitis after bone marrow transplantation (186), the hematuria and urinary symptomatology resolved; however, in two other similar cases, the patients succumbed to the adenoviral infection. Controlled trials must be done for both cidofovir and ribavirin for the efficacy of either drug to be determined. The use of antivirals for the adenovirus-induced respiratory syndromes, including pneumonia in immunocompetent patients, have not been reported. When these diseases occur sporadically, they are difficult to distinguish from similar illness caused by a multitude of respiratory RNA viruses. In the military, where epidemics of adenovirus pneumonia are easier to diagnose, attempts at control have focused on prevention by vaccination.

Vaccine

Effective oral enteric-coated vaccines exist to prevent disease by Ad4 and Ad7 (249,250). Although these preparations have been in use in the military, they are not licensed for administration to civilians. Adenovirus vaccines are therefore not used in susceptible children. The vaccine serotypes are packaged together in enteric capsules so that they bypass the respiratory epithelium and only replicate once they reach the intestine (40). The enteric infection is asymptomatic, and it results in good neutralizing antibody responses. Circulating antibody is a reliable standard of immunity after administration of adenovirus vaccines.

Previous attempts to immunize military recruits were beset by many problems that are illustrative of the biology of adenoviruses as well as of SV40 with which they interact (106,221,222). Early batches of adenovirus vaccines were grown in primary monkey kidney cells before the discovery of SV40. After SV40 was discovered, it was soon appreciated that this virus was also present in the adenovirus vaccine strains. In attempts to rid the adenovirus vaccine strains of SV40, the virus mixtures were passed in the presence of SV40 antibody. The elimination of replication-competent SV40 was achieved by this step, and SV40 viral (V) antigens were no longer detected in the adenovirus vaccine. However, in subsequent passage of the adenoviruses, other SV40 antigens were again detected. The then newly discovered SV40 tumor (T) antigen (an early nonstructural SV40 antigen) was demonstrated in the adenovirus-infected cells. The SV40 T antigen arose from a subgenomic piece of SV40 DNA that had been stably integrated into the adenovirus DNA and was actually needed as a helper gene for adenovirus growth in monkey kidney cells. This was the first demonstration of an adenovirus–SV40 hybrid virus. Because of the deletion of adenovirus sequences to accommodate the SV40 insertion, the hybrid virus was lacking the coding capacity for some essential adenovirus polypeptides, and it was therefore defective. The adenovirus–SV40 recombinants required the helper functions provided by the whole, intact adenovirus genomes packaged separately into other particles. Many different adenovirus–SV40 hybrid viruses have been isolated

subsequently and include nondefective recombinants (145). These latter adenovirus–SV40 hybrid viruses were discovered to have SV40 inserts and a compensatory adenovirus deletion entirely within a region of the adenovirus genome (79 to 85 map units) that is not essential for adenovirus growth in tissue culture.

While the adenovirus–SV40 recombinant viruses were being studied, it was realized that Ad12 was highly oncogenic in newborn hamsters (251). Subsequent testing of all adenoviruses known at that time revealed that Ad7 also induced tumors in rodents, but the incidence and rapidity of tumor induction were less than for Ad12. Considerable apprehension about the use of Ad7 in vaccines was subsequently allayed when more experience with isolates from humans was obtained. The failure to show an association between human tumors and infection by any adenovirus allowed the vaccine program for the military to proceed (250). Now the vaccine strains are grown in human embryonic fibroblasts and appear to be safe and effective. Initially, Ad4 was used as a vaccine strain. After successful control of this strain, Ad7 appeared and was, in turn, controlled by including it in the enteric-coated oral vaccine preparations. Further changes in strain types, anticipated to fill the gap created by successful vaccination with Ad4 and Ad7, have not materialized.

Recently with the supply of adenovirus vaccines for the military interrupted by production problems, outbreaks of ARD have recurred in military installations (7,81,103). The only manufacturer of adenovirus vaccines has stopped producing the virus. Because of limited amount of vaccine, the adenovirus immunization program was initially reduced, especially for new recruits entering the military in the summer months, when ARD was characteristically uncommon. However, several large outbreaks have occurred at Fort Jackson, South Carolina, with hospitalization rates reaching 11.6% per week and 1,000 total cases. The last outbreak was due to Ad4, which is a serotype that was successfully controlled by the standard vaccine.

Use of adenovirus vaccines has not been extended generally to young children; however, Ad4 attenuated vaccine strains were given to a small number of children during a clinical trial (184). The infection spread to household contacts and resulted in a few clinically manifest illnesses. Similar vaccine administration to adults commonly spread to sexual partners but infrequently to other adults housed together (238). This pattern of infection suggests that vaccine strains spread by contact, in contrast to the airborne or droplet routes that appear to explain many of the observations collected in studies of natural infections among military recruits. The common adenovirus types, Ad1, Ad2, and Ad5, which infect children, have not been attenuated for vaccine use (227). These strains would be expected to spread and therefore cause disease in close contacts of vaccinees. The lack of attenuation and the lingering apprehension about the oncogenic potential of the adenoviruses have interdicted their general use as routine vaccines of childhood.

Adenoviruses as Vectors for Vaccination and Gene Therapy

Adenoviruses as vectors for the delivery of foreign DNAs are being used extensively as tools of modern molecular biology. There have been many hundreds of papers published using adenovirus vectors in each of the past several years. There are at least four general goals in these approaches. The first is to deliver DNA effectively to cells in culture. Because some cells are hard to transfect but most are susceptible to adenovirus infection, the delivery of functional genes cloned into various adenovirus constructs is widely employed. The second goal is to deliver a functioning gene to a cell *in vivo* to correct a congenital absence or mutation in an essential enzyme, a critical transporter or structural protein. Adenoviruses have been used to deliver the complementary DNAs (cDNAs) for many enzymes, including ornithine transcarbamylase, blood clotting factors VIII and IX, and bilirubin UDP glucuronosyl transferase (126,127) to hepatocytes in rodents and primates. Delivery of the cystic fibrosis transporter (219) and the dystrophin cDNAs (210) using adenovirus vectors has been studied in numerous laboratories. Some of these studies have involved human subjects, but there are many obstacles to overcome before these approaches are useful in humans. The third use of adenovirus vectors is to deliver genes to control cell growth and apoptosis. For the treatment of cancer, there are numerous approaches to introduce cytotoxic and pro-apoptotic genes using adenovirus vectors or to make the virus itself selectively toxic to malignant cells (23,42,76,101). There are also considerable efforts being made to control the growth of blood vessels and their endothelial lining cells. In some uses of the latter approach, growth factors are included in adenovirus vectors to promote the growth of new vessels to replace occluded ones. In other cases, adenoviruses are being used to prevent the overgrowth of the arterial wall during the healing phase after angioplasty is performed to open blocked cardiac arteries (228,247). A fourth use of adenovirus vectors is to deliver DNA that can code for an epitope or antigen that would be useful as an immunizing agent against another infectious agent or tumor cells. Both the humoral and cell-mediated immune responses can be stimulated by these approaches. Some of the protein targets that have been inserted into adenoviruses include the hepatitis B surface or core antigens (181); HIV-1 env, gag, or p24 proteins (49); glycoproteins, such as the gB from herpes simplex virus (171) or the gP from rabies virus (208); and the respiratory syncytial virus F protein (36). This is only a short list of the many antigenic proteins that have been cloned into adenovirus vectors. In general, the protein-coding regions inserted into adenovirus vectors express much larger amounts of product than the native virus from which they were derived. In the trials to induce tumor immunity, genes for various cytokines and putative tumor antigens have been inserted into adenovirus vectors in an attempt to increase host immunity against malignant cells (2,203,240,266).

The advantages of using adenoviruses as vectors are that virus replication does not require that the recipient host cell is dividing, as for most retrovirus vectors, except for lentiviruses. Adenoviruses can be designed to enter mammalian cells and express proteins but can be otherwise defective for production of infectious progeny virus. These viruses can be grown to high titers. The disadvantages are that adenoviruses are highly immunogenic, inducing both humoral and cell-mediated immune responses (43), and do not efficiently transduce some cell types. The immune responses appear to decrease the length of time that the transgene is expressed after the initial vector administration as well as interfere with the effective readministration of the vector. Many studies have attempted to understand the components of the immune response that limit adenovirus-based expression vectors; however, the practical results for more effective gene therapy still require immunosuppression of the host to lengthen adenovirus expression. To address the difficulties of transducing some cells or to increase the specificity of adenovirus delivery to selected cell types, some investigators have changed the adenovirus fiber to increase the efficiency of attachment to specific cell types (236,268).

Adenoviruses are expressed primarily as episomal DNA because they integrate their DNA into the host chromosomes with very low efficiency. Although the absence of integration is an advantage when considering the deleterious effects

that integration could have on antioncogenes, such adenovirus vector-delivered DNAs are lost from the cells and are not conducive to long-term expression of the foreign gene. Recently, by combining the advantages of the adenovirus system with the integrative properties of the rep protein of adenoassociated virus, it has been possible to achieve integration of adenoviruses into chromosome 19 (214).

Adenovirus vectors can be prepared to be either replication competent or conditionally defective in a variety of genes required for a productive infection. From the experience with adenovirus–SV40 recombinants, it was learned that the entire adenovirus E3 region could be deleted without a major change in viral growth in tissue-cultured cells (Fig. 4; see Chapter 67). This region can be substituted with foreign DNA and the adenovirus grown in any cell line permissive for wild-type adenovirus infection. E3-substituted adenoviruses have been used primarily for the insertion of genes to produce proteins for immunization. Some of the immunogens have been described earlier. Various promoters have been used to maximize expression, but it has often been observed that strong upstream promoters, such as the adenovirus major late promoter with its tripartite leader, are the origins of the mRNAs from which the E3-inserted genes are transcribed. For antigens that do not elicit high enough titers on a single administration, booster immunizations have been possible by duplicate cloning of the desired gene into two or more distinct adenovirus serotypes (123). Because the initial immunization produces antibodies against the adenovirus surface proteins that contain neutralizing epitopes, it is usually not possible to readminister the same serotype and obtain sufficient replication for adequate reexpression of the cloned DNA insert. The second serotype, to which the host is not immune, thus serves as a booster for augmenting antibody titers to the foreign DNA contained in common between the two adenovirus serotypes.

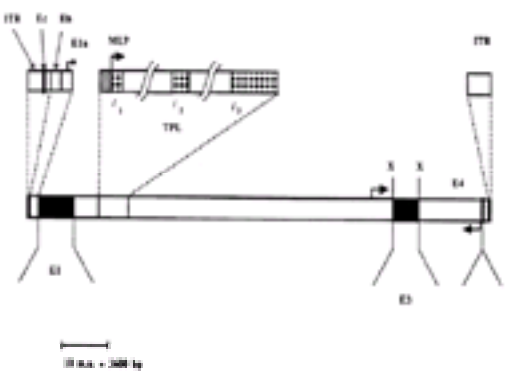

FIG. 4. Foreign genes can be inserted and expressed in the three areas (E1, E3, or near E4) as well as behind the major late promoter. The E1 or E3 genes may be deleted, whereas insertions at the right end are placed between the inverted terminal repeat (*ITR*) and region E4. The direction of transcription from the promoters is shown (*arrows*). Ec, sequence required for encapsidation of adenovirus DNA; Eh, enhancer; MLP, major late promoter; l1, l2, l3, parts of the tripartite leader (TPL) separated by introns; X, XbaI restriction exonuclease sites. (From ref. 95, with permission.)

In contrast to adenoviruses constructed for use as vectors for immunization where viral replication is desired to increase the amount of the immunizing epitopes, viruses engineered as tools for gene therapy are generally designed to be defective for replication. Most of the inserts of foreign DNA for the latter vectors replace the deleted E1A and E1B regions (see Fig. 4). The constructs are made by a variety of protocols but include plasmids into which the foreign DNA is inserted, flanked by adenovirus sequences (21,117). These sequences serve as control regions that contain the DNA packaging sequences, the left-hand origin of DNA replication at the physical end of the DNA, as well as sites for recombination with the rest of the viral DNA to reconstitute conditionally defective adenovirions. These virions grow only in cells such as the 293 cell line, which has stably expressed E1A and E1B sequences that complement the defect in the reconstituted virus. Although the viral replication cycle is aborted without producing much progeny virus, these recombinant adenoviruses are fully competent to enter human cells without the E1 region and transcribe the inserted sequences. Numerous inserts have been made using this protocol. Although the viral vectors have E1 deletions and are therefore defective for efficient growth, the E1-transactivating functions for other adenovirus promoter-enhancers can be supplied in trans by cellular genes under some special conditions (187,200). There was also low-level contamination with E1-containing viruses that were reconstituted by recombination with the endogenous E1 gene from the 293 complementing cell line used to grow the viral stocks. This problem has been solved by reconstructing new cells with a more limited E1 region that prevents the reconstitution of wild-type adenoviruses by recombination between the integrate E1 genes from the cell and the plasmids containing various other components of the adenovirus DNA (62).

The accumulated knowledge about adenovirus molecular biology during 46 years of research on these agents has been employed to make the adenovirus vectors more defective. The goal was to eliminate the leakiness of expression of other viral genes, especially those that result in immunogenic coat proteins expressed from late genes in constructs deleted of only E1 and E3 (275). Thus, the first-generation adenovirus vectors have been further altered by substituting a temperature-sensitive DNA-binding protein gene into the vector or making selective deletions of the adenovirus E4 open reading frames (ORFs) (212). The temperature-sensitive mutation made it necessary to grow the vector at lower temperatures, whereas the E4 ORF deletions required insertion of these viral genes into the complementing 293 cell line. Further vector permutations have produced “gutless” vectors, which contain only the necessary cis-acting elements, the two origins of DNA replication at each of the two physical ends of the virus, and the packaging sequences from within the first 500 base pairs of the left-hand end (182,201). The gutless vectors require a complementing helper virus, which is a temperature-sensitive adenovirus that provides all the required early and late gene products, including the structural proteins, for the assembly of progeny virus particles. Because the amounts of genomic DNA are different between the helper and gutless adenoviruses, they have different buoyant densities in the cesium chloride density gradients used to separate these two viral constructs. It was assumed that the more adenovirus genes eliminated from the vector construct, the less immunogenic and toxic it might become. These assumptions have not yet been validated sufficiently. For example, replication-incompetent adenoviruses treated with psoralen and ultraviolet light to inactivate all transcription retain the ability to induce inflammation through class I MHC and chemokine-dependent mechanisms (26,138). The

coding capacity for some of the first-generation adenovirus vectors limited the foreign gene insert to 8.3 kb before the packaging limit of 105% of the normal genome was reached. The gutless vectors could presumably contain inserts of more than 30 kb but were not efficiently assembled unless more than 75% of the original genome size was provided in the construct.

There are other ways in which adenoviruses are being used to facilitate the insertion of foreign DNAs into cells. The mechanisms of viral attachment, processing through the endosomes, and eventual delivery of DNA to the nucleus are being used to co-internalize foreign DNA external to the adenovirus particle. In a series of studies, it has been shown that DNA complexed with polylysine can be joined to adenovirus particles by several linking methods and co-internalized (38,263). The complex enters cells presumably by attachment of the fiber to its putative receptor, but there have been modifications of these techniques to include ligands-like transferrin to facilitate entry into cells with the transferrin receptor (264). Recently, it has been demonstrated that it is unnecessary to link the virus and the external DNA for efficient entry of the DNA into cells in culture (278). Although these methods have proved efficient for the insertion of foreign DNA into a variety of tissue-cultured cells, *in vivo* delivery has lagged behind.

Some of the safety and efficacy issues in the use of live adenoviruses, including vectors in humans, are worth summarizing. More than 10 million people have been immunized safely with live Ad4 and Ad7 vaccines. There are numerous phase I and II human trials in which adenovirus vectors are currently being used; most are attempts to treat various types of cancer by direct intralesional injections. In one example, there was an attempt to engineer an adenovirus, which would be selectively toxic to malignant cells. A head and neck tumor trial is using a virus called Onyx-015, which was originally described as dl-1520 and was defective in the synthesis of E1B-55 kd (24,98,101). Because the E1B-55 kd protein binds to and inactivates the function of the *p53* antioncogene, it was postulated that the Onyx-015 virus would grow and be selectively toxic to the many malignancies that are deficient in *p53* function. In normal cells with functional *p53,* the adenovirus vector would presumably not replicate. Although there are many exceptions to this paradigm of selective toxicity of Onyx-015 to *p53*-deficient cells, the virus is being studied using intralesional injection into a variety of human malignancies (97,98,102,220,239). Additional viral genes have been manipulated in attempts to make adenovirus vectors that would be selectively toxic to tumor cells. Overexpression of either the E3-11.6 kd adenovirus death protein or the E4orf4 proteins, which also induce cell death, is being exploited in attempts to selectively kill tumor cells. Other studies being done in a variety of clinical trials are using the *p53* gene inserted in adenovirus vectors in an attempt to restore the antioncogene effects of this cellular gene on malignant cells. Although preliminary evidence of efficacy has been reported at various symposia at which individual patient results were discussed, definitive results from these studies on larger numbers of patients are not yet available. In none of these studies in humans is the inserted “foreign” gene of interest deleted to establish an appropriate control virus group to study the effect of the adenovirus infection itself.

In the area of gene delivery to replace a congenitally absent gene of importance, a phase I trial of the ornithine transcarbamylase (*OTC*) gene delivered to the liver in an adenovirus vector deleted of the E1 and E4 regions has recently been completed. The experiment was done to test for the short-term expression of *OTC* because it was anticipated that the immune response would eliminate any long-term expression of the enzyme. The trial consisted of an escalation of viral dose to determine effective delivery of a functioning gene to the liver as well as to monitor toxicity. Although most patients tolerated the right intrahepatic artery injection with only minor toxicity, one subject at the highest dose had a fatal outcome 4 days after the gene therapy. Analysis of the data for gene expression in the liver both in the fatal case and in the others was disappointing in that only small amounts of gene expression could be detected in human hepatocytes. This contrasts with the exuberant amount of adenovirus gene expression in the liver of mice injected at doses that do not cause mortality (213,282). Whether the difference of expression correlates with the amount of mRNA for the adenovirus receptor, CAR, which is high in mouse liver but low in human, is not known (19,20). Although there was modest hepatocyte expression of *OTC* in nonhuman primates at viral doses that were compatible with survival, it remains a challenge to deliver adenoviruses safely to human liver in doses that would not be toxic systemically (8,199). The issue of adenovirus being a tumor virus in animals seems less of a problem because of its long safety record as a vaccine for young adults, the failure to find adenoviral DNA in human tumors, and the fact that the E1-transforming region has been removed from most adenovirus vectors. Clearly, this is an active field of research, and we can anticipate considerable progress in the near future.

PERSPECTIVES

An amazing wealth of information about cell and molecular biology has come directly from studying adenovirus replication and pathogenesis for the past half century. Some of the seminal observations in cell biology were made before the ease of cloning opened up the possibilities of studying cell processes directly without the aid of viruses. Some of these discoveries have been described in both Chapter 67 and this chapter. Future studies should lead to better use of adenoviruses as vectors for the delivery of therapeutic proteins to humans with a great variety of illnesses. Although the problems of specific and efficient delivery to selected organs and cells with a minimum of toxicity remain significant, numerous investigators are working to modify the virus in rational ways. These studies have been facilitated by recent discoveries about receptors and coreceptors for the binding and entry of adenoviruses.

Control of the immune system to foster long-term gene expression has also been a difficult task. However, much has been learned about the nature of the host immune responses to adenoviruses and those components of the immune system that limit virus expression. The large number of immunoregulatory genes that adenoviruses possess offers strong clues as to their importance both in virus replication and survival through quiescent stages, such as latency. The possibility of using the viral immunoregulatory genes out of the context of the virus to control immune and cytokine responses remains a tantalizing possibility for application in the areas of autoimmunity and transplantation. Thus, adenoviruses not only point the way to study what is important in the immune system but also provide investigators with useful new proteins to serve as reagents to understand these immunologic processes. We all hope that, with respect to therapeutics for humans, the best is yet to come from understanding the viral immunoregulatory genes and their cellular targets.

At the same time that many novel discoveries are being made using adenoviruses and their isolated genes, the supply of

live attenuated adenovirus used for many years as a vaccine in the military is being jeopardized. While we shed many old techniques and reagents in the process of acquiring new ones, it would be unfortunate to lose the protection of a very effective vaccine formulated in the days before cloning and genetic manipulations, which have become so common today.

CHAPTER 69 *Parvoviridae*: The Viruses and Their Replication

Nicholas Muzyczka and Kenneth I. Berns

The parvoviruses are among the smallest of the DNA animal viruses. The virion has a diameter of 18 to 26 nm and is composed entirely of protein and DNA. The family *Parvoviridae* (21) contains two subfamilies: the *Parvovirinae*, which infect vertebrates, and the *Densovirinae*, which infect insects. Each of the subfamilies contains three genera (Table 1). Because the host range of the *Densovirinae* lies outside the scope of this volume, the replication of these viruses is not reviewed. The interested reader is referred to several recent articles (14,29,151). The *Parvovirinae* have a wide distribution among warm-blooded animals, ranging from domestic fowl to humans (see Table 1). Dependoviruses, also known as adeno-associated viruses (AAV), are unique among animal viruses in that, except under special conditions, they require co-infection with an unrelated helper virus, either an adenovirus (Ad) or a herpesvirus, for productive infection in cell culture (11,38). In spite of this distinction, there are many similarities between AAV and the members of the *Parvovirus* and *Erythrovirus* genera in genome structure, organization, and expression. It is the intent of this chapter to compare and contrast the replication of these three genera at the molecular and biologic levels.

TABLE 1. *Parvoviridae*

THE VIRION

The parvovirus virion has a relatively simple structure composed of a mixture of VP1, VP2, and VP3, which encapsidates a linear, single-strand DNA molecule. The particle has icosahedral symmetry (277). The crystal structures of canine parvovirus (CPV), feline panleukopenia parvovirus (FPV), minute virus of mice (MVM), human parvovirus B19, and wax moth densovirus have been determined and their basic capsid organizations are similar (2,3,277, and refs. therein). The 60 protein subunits that make up the capsid have a common structure, arranged with T=1 icosahedral symmetry. The main structural motif is an eight-stranded, antiparallel b-barrel, which also has been found in most other viral capsid structures. The b-barrel motif contains only approximately one third of the amino acid composition of VP2, the major structural protein in most parvoviruses that comprises about 90% of the capsid. The remaining two thirds is present as large loops connecting the strands of the b-barrel. The loops form much of the capsid surface, onto which a number of biologic features, such as host species and tissue tropism, receptor binding, and antigenic properties have been structurally and genetically mapped. The insertions between the bD and bE strands of the b-barrel form an antiparallel b-ribbon, which together with similar insertions in four other fivefold related polypeptides form a cylinder about the fivefold icosahedral axes, with an opening to the exterior surface of the capsid in CPV, FPV, and MVM, but not in B19. VP2 is thought to be externalized for maturation cleavage to VP3 via this opening in the latter viruses. Other characteristic features of the parvoviral capsid (Fig. 1) include spikelike protrusions at the icosahedral threefold axes, a

15-Å canyon-like depression about the fivefold axes, and a dimple-like depression at the icosahedral twofold axes. Antigenic regions have been mapped to the threefold protrusions (2), and the twofold depression has been implicated in the attachment of host cell factors (3).

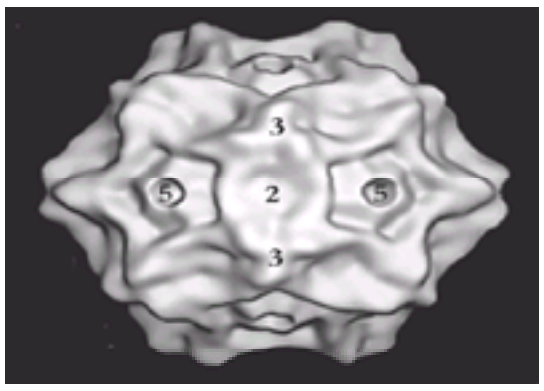

FIG. 1. *Parvovirus* structure. Cryoelectron micrograph of canine parvovirus showing some of the surface features around the two-, three-, and fivefold axes of symmetry.

The particle has a molecular weight (MW) of 5.5 to 6.2 × 10^6 daltons. Approximately 50% of the mass is protein, and the remainder is DNA. Because of the relatively high DNA-to-protein ratio, the buoyant density of the intact virion in cesium chloride (CsCl) is 1.39 to 1.42 g/cm^3 (21). The heavy buoyant density in CsCl permits the ready separation of AAV from helper Ad in co-infections. Both heavier and lighter forms of the virion occur (22,84). The latter are particles containing DNA molecules with significant deletions, and these particles can function as defective interfering (DI) particles. The exact role of the heavier-than-normal particles in infections is unknown. The encapsidated DNA molecules are indistinguishable from those of normal-density particles and so, presumably, some of the coat protein molecules are missing. Whether the missing proteins constitute a specific set is unknown. Finally, the sedimentation coefficient of the virion in neutral sucrose gradients is 110 to 122 (300).

Possibly as a consequence of its structural simplicity, the virion is extremely resistant to inactivation. It is stable between pH 3 and 9 and at 56°C for 60 min. The virus can be inactivated by formalin, b-propriolactone, hydroxylamine, and oxidizing agents (21).

The Genome

The genome is a linear, single-stranded polydeoxynucleotide chain (80,237). Several parvovirus DNAs have been completely sequenced (see Table 1) and the genome size is typically about 5 kilobases (kb). MVM DNA (the prototype autonomous parvovirus) contains 5,084 bases; AAV2 DNA (the prototype dependovirus) contains 4,679 bases (10,264). In general, autonomous parvoviruses encapsidate primarily strands of one polarity, the strand that is complementary to mRNA (i.e., the minus strand), whereas AAV encapsidates strands of both polarities with equal frequency (80,237). However, this distinction is not absolute. In the case of bovine parvovirus (BPV), only approximately 20% to 30% of the encapsidated strands are of the same polarity as mRNA, and in some hosts, LuIII (another autonomous parvovirus) encapsidates equal numbers of strands of both polarities (17).

All autonomous parvovirus genomes have palindromic sequences at both the 5' and the 3' termini of the virion (antimessenger) strand (Fig. 2). The palindromic sequence at the 3' end of the virion strand (also commonly referred to as the left end) of most murine autonomous parvovirus DNAs is approximately 115 bases long (8). In the human parvovirus B19, this sequence is more than 300 nucleotides in length (86). Because of its palindromic nature, the 3' end can fold back on itself to form a hairpin structure stabilized by hydrogen bonding between self-complementary sequences. This hairpin structure (see Fig. 2) is believed to be shaped like either a Y or a T, but its exact three-dimensional structure is not known. There is also a conserved GAA/GA mismatch bubble in the stem of the hairpin.

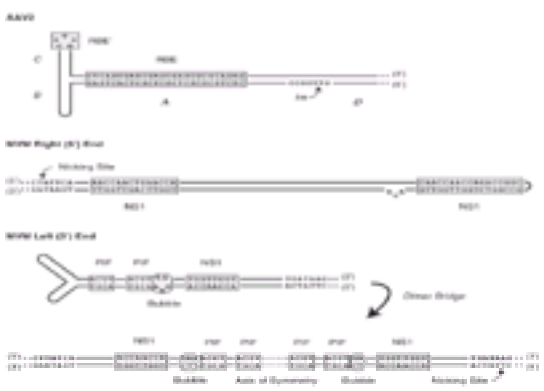

FIG. 2. Comparison of the 3' and 5' terminal palindromic structures of MVM DNA with the AAV2 terminal repeat, which is identical at both ends. Also shown is the 3' dimer bridge that is formed in a dimer replicative intermediate during MVM DNA replication. In each case, the key sequence elements are indicated that are required for AAV Rep nicking at the *trs*, or MVM NS1 nicking at the 5' (right end) hairpin or in the 3' (left end) dimer bridge. The hairpin sequences are shown in their most stable secondary structure. In the AAV hairpin, B and C by convention are the small internal palindromes flanked by the A palindrome that forms the stem of the first 125 bases. The D sequence comprises the remaining 20 bases of the TR that are inboard of the *trs*. See text for details.

The 5' end (or right end) of autonomous parvoviruses is also palindromic and can form a hairpin, but the sequence is completely unrelated to that at the 3' end of the virion strand (see Fig. 2). An exception is the 5' end of the human B19 genome, in which the two ends are identical (86). The MVM 5' palindrome is 207 bases long (10). Like the 3' terminal sequence, the 5' terminal sequence of MVM is not a perfect palindrome (see Fig. 2); again there are short, self-contained internal palindromic sequences (not shown) and an AGA bubble. The 5' terminal sequence is also not unique. Two sequences that represent an inversion of the terminal segment of the genome are found with equal frequency and are called flip and flop. The two orientations are a consequence of the fact that an inversion of the 5' sequence occurs during DNA replication (see later). Because the 5' hairpin is not perfectly symmetric, the two forms can be distinguished by restriction analysis.

In contrast to the sequence at the 5' end of the virion strand, which can exist in either of two orientations, the 3' terminal sequence is usually unique; only one orientation is found. (The relevance of this organization to the process of DNA replication is discussed later.) The exception is BPV, in which about 10% of the 3' end of the genome is, like its 5' end, inverted (255).

Unlike autonomous parvovirus DNA, the AAV genome has an inverted terminal repetition of 145 nucleotides (181). The first 125 bases form a palindromic sequence that, when folded to maximize base-pairing, forms a T-shaped structure almost identical to that formed by the 3' terminal sequence of the virion strand of autonomous parvoviruses (see Fig. 2). As with the sequence in autonomous parvovirus DNA, the palindromic terminal sequence in AAV DNA may be characterized more accurately as two internal palindromes (nucleotides 42 to 84) flanked by a more extensive palindrome (nucleotides 1 to 41 and 85 to 125). In the folded configuration, only seven of 125 bases remain unpaired. Six are required to allow the internal palindromes to fold over, and the seventh separates the two internal palindromes. Both ends of AAV exist in two orientations, flip and flop, which are essentially inversions of the terminal 125 bases. In this respect, the AAV terminal repeats (TRs) are similar to the autonomous parvovirus 5' (right end) palindromic sequence. Again, the two orientations can be detected because the two internal palindromes are not identical. In the flip orientation, the B palindrome (see Fig. 2) is closer to the end of the genome than the C palindrome, whereas in the flop orientation, the C palindrome is closer to the end. Furthermore, there is an additional heterogeneity in the extreme terminal bases. The canonical 5' terminal sequence in AAV2 DNA is 5' TTG. However, 50% of the molecules isolated from virions lack the first T, and a further 15% lack both Ts.

Because mature virion DNA is the end product of DNA replication, any model proposed must be able to account for the nucleotide sequence arrangements found in virion DNA. The terminal sequence organization has offered valuable clues to the mechanism of DNA replication. Thus, the similarities and differences between the terminal sequence arrangements of autonomous parvovirus DNA and those of AAV DNA have led to similar models of DNA replication for the two genera that differ in several key steps (see later).

There are additional similarities in the internal organization of the genomes of the vertebrate viruses (Fig. 3). All have two large open reading frames (ORFs) that do not overlap (10,228,264). One extends approximately from map position (mp) 5 to 40, whereas the second extends approximately from mp 50 to 90. As is discussed later, the ORF in the right half of the genome codes for all the caspsid proteins, and that in the left half codes for nonstructural proteins.

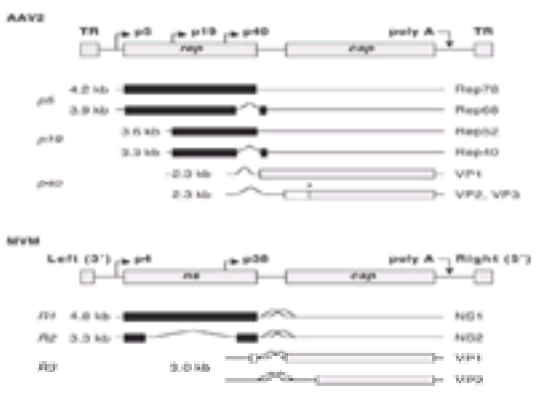

FIG. 3. Transcriptional maps of MVM, the prototype autonomous parvovirus, and AAV2, the prototype dependovirus. Terminal palindromes and ORFs are represented by *boxes.* The approximate positions of the promoters and polyadenylation sites in each genome are indicated by *arrows.* AAV has three promoters, at map positions 5, 19, and 40; MVM has two promoters, at mps 4 and 38. All AAV and MVM transcripts are co-terminal at a polyadenylation signal near the right end of the genome. Below each genome are the major mRNAs synthesized by each virus along with (on the left) their common names and their sizes in kilobases. At the right of each message is (or are) the viral protein(s) translated from each mRNA.

Coat Proteins

Both autonomous parvovirus and AAV virions contain three capsid proteins [with the exception of Aleutian disease virus (ADV), B19, and simian parvovirus, which contain only two coat proteins] (21). For different species of autonomous parvoviruses, the proteins have approximate MWs of 80,000 to 86,000 (VP1), 64,000 to 75,000 (VP2), and 60,000 to 62,000 (VP3). Those of lapine parvovirus are significantly larger: 96,000 (VP1), 85,000 (VP2), and 75,000 (VP3). Except for ADV, VP3 is the major coat protein, representing 80% to 90% of the total mass. Some virus preparations are lacking in VP3, and its abundance appears to depend on the time during infection when the virions are isolated. LuIII

preparations, for example, may contain only VP3 in detectable quantities. All AAV preparations characterized to date have three coat proteins: VP1, 87,000; VP2, 73,000; and VP3, 62,000 (143). In neither genus is there any evidence for glycosylation of any of the coat proteins; however, all parvovirus proteins appear to be phosphorylated. The N terminus is blocked in the case of the AAV VP3 protein (19,143).

In addition to the fact that all three parvovirus coat proteins appear to be coded for by overlapping in-frame DNA sequences, a further complexity has been reported. In the cases of both AAV1 and AAV2, the coat proteins VP1 and VP3 can be further subdivided by polyacrylamide gel electrophoresis into several subspecies (191). The molecular basis for the difference in mobility is unknown.

PARVOVIRUS INFECTION

Host Range

Parvoviruses replicate in the nuclei of infected cells. Of all the DNA viruses, they seem to be among the most dependent on cellular function. The autonomous parvoviruses require the cell to go through S phase to replicate (269). Unlike the polyomaviruses and Ad, the parvoviruses do not have the ability to stimulate or turn on host DNA synthesis in resting cells. The autonomous parvoviruses simply wait for S phase in the host they infect. AAV relies on a helper virus, adeno- or herpesvirus, to induce S phase or its equivalent (11,38) (Fig. 4). (The nature of the helper factors is described later.) There are also cell lines that can be made semipermissive for AAV infection, without helper co-infection, by various chemical or physical treatments, described in the section on helper functions. The autonomous parvoviruses are relatively species specific, although some hamster viruses were first isolated as apparent contaminants from human tumor cells grown in the laboratory, and MVM will grow in both mouse and human transformed cell lines (73). In the case of MVM, tissue specificity has been observed for differentiated cells (262). The prototype strain MVM(p) replicates in murine fibroblasts but not in T lymphocytes. A second strain has been discovered, MVM(i), that displays the opposite phenotype.

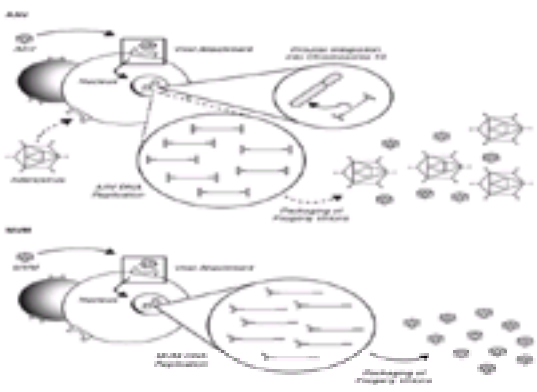

FIG. 4. Top: Replication of adeno-associated virus (AAV). Under nonpermissive conditions, AAV integrates into the q arm of human chromosome 19, where it remains silent until challenged by a helper virus (e.g., an adenovirus). This leads to rescue of the integrated virus from the chromosome and induction of the lytic cycle. Under permissive conditions (i.e., in the presence of a helper virus, such as adenovirus), AAV replicates, resulting in host cell lysis. **Bottom:** Replication of the autonomous *Parvoviridae.* After adsorption of the virus at the cell membrane of a variety of host cells, the virus enters and is transported to the nucleus. During S phase, the cellular replication machinery is recruited for viral replication, leading to virus production and cell lysis.

Genetic analysis of parvoviruses has been greatly facilitated by the discovery that clones of complete parvovirus genomes in bacterial plasmids are infectious when transfected into mammalian cells. This fact, together with the complete sequence of several prototype strains, notably MVM and AAV2, has made it possible to construct and propagate any mutant in a bacterial plasmid vector, and then to transfect the intact plasmid clone into cell culture. If the cells are permissive or (in the case of AAV) infected by helper virus, the parvoviral genes are expressed, the inserted genome is rescued from the plasmid and replicated, and infectious virions are produced. In this way, it has been possible to correlate specific phenotypes with specific mutations at fixed points along the genome, and thus it has been possible to develop meaningful genetic maps (125,244). The infectivity of parvovirus plasmids has also been the key to their development as mammalian transduction vectors (126).

Tissue Specificity, Viral Entry, and Cryptic Infection

Although dividing cells are required for the replication of autonomous parvoviruses, not all dividing cells are susceptible to, or permissive for, viral infection. In the case of MVM, susceptible cells have large numbers of surface receptors (10^5 or more). The nature of these receptors has not been defined; however, the receptors appear to contain sialic acid, as pretreatment of cells with neuraminidase prevents viral attachment (73). The surface receptors are missing from B lymphocytes. Additionally, MVM(p) is restricted in T lymphocytes at the level of gene expression even though the virus can enter the cell; in contrast, the related variant MVM(i) is permissive in T cells (262). The host range restriction is caused by several mutations in the capsid (13). In other cells, transcription can occur but DNA replication is inhibited. The loss of permissiveness seen at the level of cell culture is reflected in the general resistance of older animals to infection in spite of the presence of rapidly dividing tissues.

The narrow host range of B19 virus (primarily erythrocyte precursors) is partly the result of the distribution of its receptor. The human B19 virus receptor is globoside, the blood group P antigen, which is found on only a few cell types (35). Some of the narrow host-range specificity can also be attributed to tissue-specific gene expression (162). Both

nonstructural (NS) and capsid genes have been implicated in the porcine parvovirus host range (281). In the case of MVM, NS2 has been specifically implicated in tissue specificity (198).

Parvoviruses frequently cause semipermissive (sometimes called restrictive) infections, which can imply a low level of viral multiplication in the intact host (73). At the level of cell culture, this seems best illustrated by the establishment of carrier cultures in which viral multiplication also occurs at a low level. The situation is the result of a low fraction of cells that are permissive, and it is plastic in that viral variants frequently arise that can infect the majority of cells in the culture (236). The reciprocal situation has also been observed, in which resistant cells arise from clones of susceptible cells. The frequency of semipermissive infection raises the question of whether the autonomous parvoviruses can cause latent infections by integration of the viral genome into cellular DNA as a provirus, as is seen with AAV. To date, no evidence for integration of autonomous parvoviral DNA during viral replication can be detected, nor has integration been observed during abortive infections.

Several receptors used by AAV2 for viral entry have been identified. These include heparin sulfate proteoglycan (267), the fibroblast growth factor receptor 1 (222), and the integrin $a_v b_5$ (266). Uptake of AAV by susceptible cells occurs rapidly (half-life, 10 min) through a standard receptor-mediated endocytosis from clathrin-coated pits (16). When the virus escapes from endosomes is not clear, but within 30 minutes the virus accumulates perinuclearly and within 2 hours virus particles are detected within the nucleus. It is still not clear whether uncoating occurs in the nucleus or at the nuclear pore.

DEPENDOVIRUSES

Overview

One of the outstanding features of AAV replication in cell culture has been the requirement for co-infection of the cell by an unrelated helper virus (see Fig. 4). Either an Ad or a herpesvirus can supply complete helper functions for fully permissive AAV infection (11,38). In the absence of helper virus, AAV can establish a latent infection in cell culture that involves integration of the viral genome into a unique site on human chromosome 19 (48,155,248). Superinfection of cell lines carrying a provirus with Ad or herpes will rescue the integrated genome and initiate a fully productive infection (48,169,190). In light of this, it has been assumed that AAV uses latency in chromosome 19 as a strategy to survive in the absence of a helper.

The situation during natural infections is not as clear. *In vivo* (i.e., in human infections), AAV has typically been found as a contaminant of Ad isolates (24). It is generally assumed, therefore, that natural AAV infections occur via the respiratory or gastrointestinal route as is the case for Ad. However, as yet, it is not clear what tissue or organ is a preferred site of latency in humans. Efforts by several groups to demonstrate latency in human lung samples have failed to detect AAV. AAV has been recovered from a small percentage (1% to 5%) of hematopoietic cells and from the genital tract of female patients suspected of herpes infections (106,117). One report (273) suggested that AAV was present in some first-trimester abortion material, but this has not been confirmed (106). However, AAV has been found at a surprisingly high frequency (20%) in muscle biopsies (Xiao, personal communication, 2000). Recently, Dutheil et al. (97) demonstrated that the chromosome 19 integration site that is preferred by AAV is linked to the slow skeletal muscle–specific gene troponin T1 (TNNT1), and the cardiac troponin I gene (TNNI3). Several proviral cell lines established *in vitro* were shown to contain rearrangements of the TNNT1 gene due to integration. Additionally, Samulski and his colleagues (Samulski, personal communication, 2000) have demonstrated that recombinant AAV preferentially transduces slow skeletal muscle fibers in rodent models. Together, these observations have led to the hypothesis that the natural site of AAV latency in humans might be skeletal muscle. Skeletal muscle is known to be resistant to Ad and herpes infection when these viruses are administered intravascularly, thus muscle could be a reservoir that is protected from rescue by AAV helper viruses. Because muscle fibers are multinucleated, integration of AAV and the possible disruption of the TNNT1 locus would produce minimal effects on the host. However, as yet, no one has demonstrated that AAV is integrated into the chromosome 19 target in human samples.

As discussed later, the role of the Ad helper functions seems in part to be the induction of the appropriate cellular milieu required for AAV DNA replication. The notion that AAV replication is possible once the appropriate cellular genes have been induced suggests that the appropriate cellular milieu could be established in the absence of helper virus. Indeed, several groups have reported that pretreatment of transformed or tumor cell lines with a variety of genotoxic agents can render the cells semipermissive for AAV replication in the absence of helper virus co-infection (307, and refs. therein). Agents that have been successfully used include ultraviolet (UV) irradiation, cycloheximide, hydroxyurea, aphidicolin, topoisomerase inhibitors, and several chemical carcinogens. Recently, Hermonat and colleagues (personal communication, 2000) have demonstrated that keratinocyte cultures can support AAV replication, albeit poorly, in the absence of a helper virus. In this system, basal cells are nonpermissive for replication but become semipermissive as the cells differentiate. The value of these semipermissive systems is that they may help identify cellular functions that are normally induced by the helper virus.

Helper Functions

Adenoviruses, herpes simplex virus (HSV) types I and II, cytomegalovirus, and pseudorabies virus all serve as complete helpers for AAV replication (11,38,197). The AAV host range is identical to the normal host range for the helper virus. Genetic analysis of helper functions has been most extensive for Ad. Many of the identified Ad early functions serve as helper functions for AAV replication, but no Ad late functions have been found to be necessary. Four Ad proteins have been shown to be required for complete helper function: the early region IA (EIA) transactivator protein, the EIB 55-kd protein, the E4 34-kd protein, and the E2A DNA-binding protein. Additionally, synthesis of the Ad virus-associated (VA) RNAs is required. Ad EIA function is required for the other Ad early regions to be transcribed (197). Similarly, an EIA function is required for AAV transcripts to be detected by Northern blotting (140,170,232). Two EIA proteins with overlapping sequences of 289 and 243 amino acids, respectively, have been identified. The former can both activate and inhibit gene expression in trans, whereas the latter primarily inhibits gene expression. The 289-amino-acid EIA protein is

responsible for transactivation of AAV gene expression (46). EIA, in concert with other Ad early genes, also induces a variety of changes in cellular gene expression. The most important may be that EIA induces cells to enter S phase and to synthesize cellular DNA replication proteins that are likely to be needed for AAV DNA replication (197).

E4 was originally identified as encoding a helper function specifically required for AAV DNA replication. The E4 product involved is a 34-kd protein that is the product of the E4 ORF 6 gene and it can form a complex with the 55-kd EIB protein during a productive Ad infection (135). Both the 55-kd and the 34-kd proteins have been shown to regulate the expression of AAV genes, possibly at the level of transport of mRNA to the cytoplasm (246). In a general sense, EIB has also been identified as being required for AAV DNA replication to occur, but it does not seem to have a consistent effect on AAV transcript accumulation (140, 170, 232, 246). More recently, studies of transduction mediated by recombinant AAVs (rAAVs) that carry marker genes have suggested that the E4 ORF 6 protein enhances the conversion of single-stranded input viral genomes to a duplex form by promoting second-strand synthesis (101, 102). Grifman et al. (115) have shown that the ORF 6 gene product promotes degradation of cyclin A and inhibits the kinase activity of cdc2. The net effect of these changes would be to stop the cell cycle in late S or G2. Because cellular DNA replication enzymes are induced during this phase of the cell cycle, this could in part explain the effect of ORF 6 on AAV DNA replication.

E2A encodes a 72-kd single-strand DNA binding protein (DBP) that is required for Ad DNA synthesis but that does not appear to be required for AAV DNA replication (39), although particle formation is greatly inhibited by certain E2A gene mutations (141). DBP stimulates transcription from AAV promoters (39, 45) and may be involved in mRNA transport and stability. In spite of the absence of genetic evidence that Ad DBP is required for AAV DNA replication, recent *in vitro* studies of AAV DNA replication using cell-free extracts suggest that Ad DBP is preferentially used for AAV DNA replication in place of the human single-strand DBP, replication protein A (RPA) (290). In contrast, the E2B region, which produces the Ad terminal protein, and the Ad DNA polymerase, both of which are directly involved in the process of Ad DNA replication, is not required for AAV replication. Finally, Ad VAI RNA has been reported to facilitate the initiation of AAV protein synthesis (139) by preventing the interferon-induced host-cell shutoff of translation.

Two detailed studies on the HSV-1 genes required for productive AAV infection have been reported. Unfortunately, the conclusions were somewhat different. The first study (193) identified the following HSV proteins as providing helper functions for AAV: ICP4 transactivator, DNA polymerase, ICP8 single-strand DBP, the origin-binding protein, and two of the three subunits of the helicase–primase complex (UL5, UL8). The second study (294) identified ICP8 and all three components of the helicase–primase complex as helper functions. It should be noted that the latter study used a heterologous promoter; normally, ICP4 function is required for expression of HSV replication genes. The former study found that maximal AAV replication required all the genes identified but that only ICP4 was essential for AAV replication per se. It is not clear why with Ad, most of the viral DNA replication genes are not required, but with herpes, most of the helper functions are replication enzymes.

Genetic Map

The AAV genetic map (see Fig. 3) has been derived primarily from studies of AAV2 (125, 190, 247, 252, 274) but is highly conserved among all of the AAV serotypes. There is a large ORF (cap) on the right side of the genome (mp 50 to 90), which encodes the three coat proteins of the virus. Frameshift and deletion mutants within this region do not block DNA replication, but the accumulation of progeny single strands is inhibited, presumably because this requires encapsidation (126, 274). Mutations in the N-terminal region of the cap ORF, which affect VP1 exclusively, package DNA but produce virus particles that have lower infectivity. There is also a large ORF in the left half of the genome (mp 5 to 40), which has been called the rep region because any frameshift mutation or significant deletion within the region blocks DNA replication (126, 274). At least four proteins have been detected (Rep78, Rep68, Rep52, and Rep40), which correspond to the four mRNAs that have been mapped to this region (see Fig. 3) (192). It is possible to selectively eliminate Rep78 and 68 (from the p5 transcripts), and this type of mutation completely blocks all AAV-directed transcript accumulation that can be detected by Northern analysis, and it completely eliminates DNA replication (126, 168).

The larger Rep proteins play a critical regulatory role in every phase of the AAV life cycle. Under nonpermissive conditions (no helper virus) Rep68/78 negatively regulates AAV gene expression and DNA replication and is required for site-specific integration in the host cell genome to establish a latent infection (148, 164, 253, 275). In the presence of helper, Rep68/78 is a transactivator of AAV gene expression (168) and is essential for DNA replication and rescue of the viral genome from the integrated state (125). Mutants that are defective for the synthesis of the two smaller Rep proteins (Rep52 and 40 from the p19 promoter) have been made by changing the initiator AUG for these proteins to GGG (47). The resulting mutant is able to replicate DNA, but no mature single-stranded DNA is encapsidated. The phenotype is thus similar to a coat protein mutant. Other smaller ORFs exist near the middle of the genome, but the production of proteins corresponding to these regions is less clear.

Mutations in either the rep or cap ORFs can be complemented in trans. In contrast, the inverted TRs of 145 bases are required in cis for both DNA replication and transcription (18, 252). In addition to these functions, the TR is required for encapsidation (190), integration of the genome during the establishment of a latent infection (309), and rescue of the genome from the integrated state (247). All of these functions are detailed later.

Transcription

In a productive infection, six polyadenylated, capped RNAs are detectable by Northern blotting (see Fig. 3) (171). In decreasing size, the mRNAs have apparent lengths of 4.2 kb, 3.9 kb, 3.6 kb, 3.3 kb, 2.6 kb, and 2.3 kb. These are synthesized from three conventional RNA polymerase II promoters at mp 5, 19, and 40 (114, 182). All of the RNAs are 3' co-terminal and are polyadenylated downstream from an AATAAA signal at mp 96 (264). The two largest transcripts (4.2 and 3.9 kb) are synthesized from the promoter at mp 5 (p5), the next two (3.6 and 3.3 kb) are from the promoter at mp 19 (p19), and the two smallest RNAs (2.6 and 2.3 kb) are from the promoter at mp 40 (p40). There is an intron at mp 42 to 46, and there are both spliced and unspliced mRNAs produced from all three promoters, hence the three pairs of

transcripts. The smallest RNA (2.3 kb) is the major species and is produced from the p40 promoter. It is used to translate all three capsid proteins. The 2.3-kb species actually consists of two alternatively spliced mRNAs (196). The major spliced species directs the synthesis of the major capsid protein, VP3, from a conventional AUG codon, and the minor capsid protein, VP2, from an upstream in-frame ACG codon. The minor spliced 2.3-kb message includes an upstream AUG codon that allows the translation of the entire cap ORF to produce the minor capsid protein VP1. No clear role has been established for the unspliced 2.6-kb message. The p5 and p19 promoters generate two mRNA species each (spliced and unspliced), which code for the four AAV nonstructural proteins, Rep78 and 68 from p5, and Rep52 and 40 from p19 (182,192). In the case of the p5 and p19 RNAs, the unspliced species is the major one, but the reverse is true of the p40 RNAs. During the course of infection, the unspliced p5 transcript, and the Rep78 protein coded by it, appear first (192). This is followed shortly by the synthesis of the p19 and p40 transcripts and the proteins they encode. Additionally, the spliced p5 and p19 RNA species accumulate later in infection than the unspliced species. This is apparently the result of a change in splicing that is caused by either Ad infection or Rep78 expression (276).

Several groups have mapped the regulatory signals that control AAV transcription (Fig. 5). Chang et al. (46) mapped two regulatory sequences in the p5 promoter. The first corresponded to a sequence in the Ad major late promoter activated by EIA (Ad MLP). The second was a sequence that binds the cellular transcription factor YYI. Two YYI sites were found, one upstream of the TATA box and one overlapping the p5 message start site. McCarty et al. (188) subsequently mapped a Rep binding element (RBE) between the TATA box and the downstream YYI site. There are four additional RBEs, two in each of the two TRs. Together, these elements seem to be responsible for controlling AAV p5 transcription (164,212). Regulatory sequences upstream of the p19 and p40 promoters have also been identified (see Fig. 5). In the p19 promoter, the proximal TATA box, two Sp1 sites, and a novel sequence that binds an as yet unidentified cellular factor, cellular AAV activating protein (cAAP), were found to be sufficient by mutation analysis for p19 transcription (214). In the p40 promoter, an Sp1 site and the TATA box were essential, and ATF and AP1 sites also may play a role (213). The regulation of AAV transcription is complex. This is apparently because following infection, the virus can choose one of two paths for persistence: It can either establish a latent infection or proceed through a productive viral infection. The switch for these two paths appears to be controlled primarily by the Ad EIA gene and the AAV *rep* gene, as discussed later.

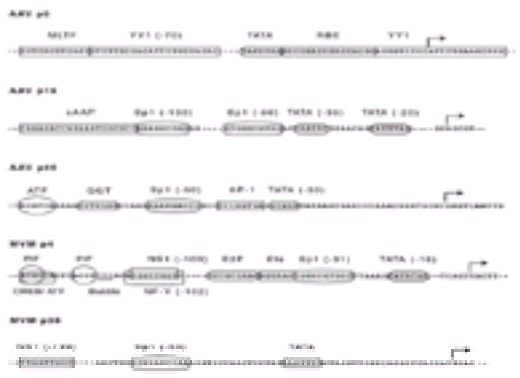

FIG. 5. Approximate position of promoter elements within the AAV2 and MVM promoters. *Arrow* indicates the start of the major mRNA from each promoter. See text for details.

In the absence of helper virus, only a small amount of Rep78 is synthesized from the p5 promoter. This is sufficient to bind to the p5 RBE and completely repress further p5 transcription (164,212). Mutation of the p5 RBE can lead to higher p5 expression and a virus that is partially permissive for DNA replication in some cell lines (288). Repression is tight, so that generally it is not possible to detect p5 transcripts or Rep protein. However, it is possible to detect *rep* gene function biologically because Rep inhibits expression from a number of heterologous promoters (122,128,134,167). Although the domain of Rep78/68 that binds to the RBE has been mapped to the region of Rep78 that is not present in Rep52 and 40 (210), the p19 Rep proteins are also capable of repressing the p5 promoter (163). Furthermore, although there is no strong RBE within the p19 promoter, Rep52 is capable of repressing p19 transcription (134,163). This suggests that binding to the RBE at p5 is not the sole mechanism by which Rep proteins can repress transcription. Indeed, studies of the papilloma virus transcription control region and the human immunodeficiency virus (HIV) long terminal repeat (LTR) suggest that Rep can repress transcription from these heterologous promoters, which have no RBE, by interacting with a variety of transcription factors (134). Although there is active repression of p5 and p19 promoter activity by the Rep proteins, repression of p40 has been difficult to demonstrate. Yet there is little accumulation of p40 transcripts or capsid protein in the absence of Ad infection (169,186).

In the presence of Ad co-infection, a cascade of transcriptional regulation seems to rapidly induce the synthesis of all AAV genes. First, the Ad EIA transactivator protein induces transcription from the p5 promoter and synthesis of Rep78/68. The mechanism of EIA transactivation of p5 is not clear, but it may involve interaction with YYI, which can function as a transactivator or a repressor (254). Additionally, Rep may interact with the TATA binding protein (TBP) or Rep may be displaced from the p5 RBE by YY1, thereby derepressing the p5 promoter (127,164). Rep78/68 in turn now behaves like a transactivator protein rather than a repressor and induces transcription from the p5 and p19 promoters (168,212,293). To accomplish this, Rep apparently needs to be bound to the RBE that is present either in the TR or at the p5 promoter, as the absence of both elements reduces transactivation of p19 and p40. Curiously, mutations in the p5 RBE continue to derepress p5 transcription (212), suggesting that Rep bound to the p5 RBE continues to repress p5 even while it transactivates p19 and p40. The absence of the RBE within the TR, however, leads to lower p5 activity, suggesting that Rep bound to the TR transactivates the p5 promoter as well as the p19 and p40 promoters (18,212). Finally, transactivation of the p19 and p40 promoters and repression of p5 appears to be coordinately regulated by the p5 RBE and Rep protein (186,212,213 and 214). Deletion of the p5 RBE element (and the TR) simultaneously increases p5 transcription and decreases p19 and p40 transcription. The elements in p5, p19, and p40 required for this coordination have been partially mapped (see Fig. 5). p19 Transcription requires the p5 or TR RBE, as well as the –50

p19 Sp1 site and the cAAP site upstream of p19 (214). Transactivation of p40 requires the same elements required for p19 transactivation and the proximal –50 Sp1 site upstream of the p40 start (213). How this is accomplished is not clear, but Rep has been shown to bind to Sp1 (214), TBP (127), and PC4 (292), a general transactivation protein for pol II transcription. Presumably, some or all of these Rep interactions are involved.

Several other regulatory circuits have been uncovered: (a) Rep52/40, which represses p5 in the absence of Ad, derepresses p5 in the presence of Ad, possibly by interacting with the larger Rep proteins (212). (b) Overexpression of Rep78/68 reduces the level of capsid protein by a posttranscriptional mechanism, possibly by reducing translation of the capsid message (276). (c) At least one cis-active negative regulatory sequence has been mapped to a region between mp 28 and 37 (168). Deletion of the sequence leads to higher levels of the upstream transcripts, and insertion of the sequence downstream of the p40 promoter reduces p40 transcript levels. Whether this cis-active negative regulatory sequence inhibits transcript elongation or adversely affects transcript stability is not known.

The net effect of these positive and negative feedback loops appears to be the maintenance of a constant ratio of Rep78/68, Rep52/40, and the three capsid proteins during productive infection. Why it is critical to maintain this ratio so tightly is not entirely clear. One possibility is that overexpression of capsid proteins might prematurely deplete the pool of replicative intermediates required to sustain a productive infection. On the other hand, overexpression of the Rep proteins might increase the replicative pool of DNA at the expense of packaging.

DNA Replication

AAV DNA replication occurs via a single-strand displacement mechanism (Fig. 6) (120,265). No evidence has been found for RNA primers or for the equivalent of Okazaki fragments (the presence of which would be indicative of lagging strand synthesis). Because all known DNA polymerases have a requirement for a primer with an available 3' OH, in addition to a template, linear DNA genomes have had to evolve specialized terminal sequences to allow them to maintain the 5' terminal sequences intact when the primer structure is resolved during replication. The basic model for parvovirus DNA replication (often called the rolling hairpin model) was first described by Straus et al. (265) and Tattersall and Ward (272). As noted earlier, the two ends of AAV are identical in sequence and palindromic. The palindromic inverted TR at the 3' end of either strand can form a hairpin to serve as a primer to initiate synthesis of the complementary strand (181). This produces a linear duplex molecule in which the original 3' end is covalently closed in the hairpin configuration, also called a monomer turnaround form (see Fig. 6, mT). The hairpin is nicked at a site near the end of the terminal palindrome (nucleotide 124 of the AAV sequence), and this produces a new 3'-hydroxyl primer that allows repair synthesis of the hairpin. This process is called terminal resolution (or strand transfer) and the site-specific and strand-specific nicking site is called the terminal resolution site (trs). The net result of terminal resolution is the first complete duplex molecule in which both ends are extended, the monomer extended form (see Fig. 6, mE). Either end can then denature and reanneal to form a double hairpinned structure, or rabbit ears (a process sometimes called reinitiation), and the newly hairpinned 3' end initiates leading-strand displacement synthesis to generate a single-stranded genome (which is packaged) and a duplex genome covalently closed at one end. The process of terminal resolution and reinitiation is then repeated (see Fig. 6, gray box). Each time the cycle is completed, a new single-stranded progeny strand (see Fig. 6, ss) is generated, and the strand transfer process that occurs during terminal resolution inverts the TR. If a molecule covalently closed at one end is not resolved before completion of strand displacement from the other end, then a dimer molecule can be formed in which two genomes are present in an inverted orientation (head to head or tail to tail) with a single TR at their junction (see Fig. 6, dimer turnaround or dT).

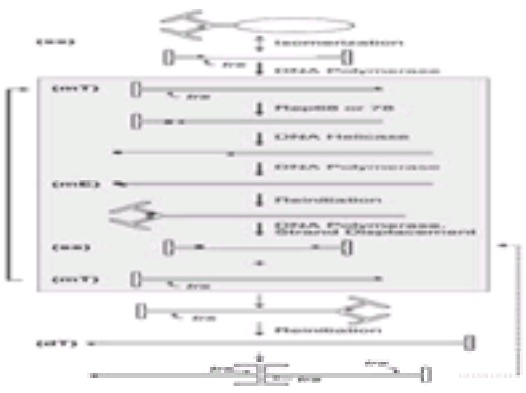

FIG. 6. Model for AAV DNA replication. *Gray box* highlights the reactions essential for generating single-stranded progeny DNA. mT, monomer turnaround RF; dt, dimer turnaround RF; ss, single-stranded viral DNA; mE, monomer extended RF. See text for details.

A large amount of evidence now supports this mechanism. All of the predicted replicative intermediates have been found *in vivo* (201,265) and can also be generated with *in vitro* replication systems (201). These include monomers and dimers, with both ends extended or with one end covalently closed (201,265). Two orientations of the TR (flip and flop) are seen in replicative intermediates and in packaged DNA as predicted (180,244). Biochemical analysis of the Rep protein carried out by several groups *in vitro* also supports this mechanism. This has shown that Rep78/68 protein carries out the site-specific nicking reaction necessary for terminal resolution and has a DNA-DNA (and DNA-RNA) helicase activity and an ATPase activity, that is essential for nicking and probably for strand displacement (138,260,302).

The outstanding feature of the TR is the T- or Y-shaped structure that is formed when the terminal 125 bases are folded on themselves to optimize base-pairing (181). This structure is quite stable and appears to exist predominantly as B form DNA. Recent thermal melting and UV spectra analysis suggests a DH_{cal} of 614 kcal mol^{-1} (226). Thus, the T-shaped structure is likely to need the active intervention of a DNA helicase to unwind during terminal resolution and to re-form

during the reinitiation step following resolution. Another issue is that the nicking site (*trs*) is present in both the hairpinned and linear extended forms of the TR, as well as in the linear junction between two genomes within a dimer molecule. Thus, some method for discriminating between these three forms must exist that allows nicking preferentially on the hairpinned substrate and the dimer, rather than on the linear extended TR, in which nicking appears to be minimal (50,188).

Mutational analyses of both the Rep coding sequence and the TR, as well as the development of a number of *in vitro* biochemical assays, have led to a good preliminary understanding of the terminal resolution reaction (see Fig. 2). The TR contains at least three specific sequences that direct the Rep-mediated *trs* endonuclease reaction. A 20- to 22-bp linear sequence, the RBE (also called RRS or RBS), within the stem of the T structure is sufficient to bind a Rep78 or 68 complex that consists of two to six Rep molecules (50,188,241,259,295). Most of the RBE sequence consists of a tandem $(GAGC)_4$ repeat. As few as two GAGC repeats are sufficient to bind Rep, and considerable heterogeneity in the RBE is tolerated (51,188,303). One of the functions of the RBE is apparently to assemble the Rep complex in a particular orientation that is subsequently required for *trs* endonuclease activity. Substrates that contain inversions of the RBE, for example, will bind Rep but are poorly nicked (32). The enzyme also makes contact with a GTTTC motif that is present in the small internal palindrome that is furthest away from the *trs*. This sequence motif, called the RBE' (or RRS'), is present in both the flip and the flop orientations in the same position with respect to the *trs* (see Fig. 2) (32,241). Contacts with this motif as well as with several other bases within the small internal palindromes apparently account for the difference in binding affinity between the hairpinned and linear forms of the TR, which has been estimated to be as much as 100-fold (189,259), and the fact that the linear form of the TR is nicked with a lower efficiency than the hairpin (32,50,188,259,304). DNase protection and chemical interference assays suggest that the enzyme complex bound to the RBE in the absence of ATP does not actually make contact with the *trs* site (137,241).

Once bound to the TR, Rep carries out two sequential reactions. First, the DNA helicase activity of Rep unwinds the stem of the TR in a reaction that requires ATP hydrolysis and generates a single-stranded *trs* site (31,83,259); this explains why the *trs* endonuclease reaction is ATP dependent (138). A highly conserved inverted repeat sequence that flanks the nick site is probably used to form a cruciform structure, which brings the *trs* closer to the Rep complex that is still bound to the RBE (31,32). Evidence that Rep does not let go of the RBE prior to nicking comes from mutants in which the spacing between the RBE and the *trs* is increased; insertion of even three bases significantly reduces nicking activity (32). In the second step of the reaction, the endonuclease active site carries out a transesterification reaction, in which the tyrosine at amino acid position 156 of Rep is covalently joined to the 5' phosphate end of the nick at the *trs* (83,138,257). This reaction is ATP independent. Y156 is part of a rolling circle replication (RCR) protein motif that is common to all parvovirus NS proteins and is similar to motifs found in many enzymes of bacterial and eukaryotic origin that nick the origin of plasmids that undergo rolling circle DNA replication (136).

The *trs* is also a specific sequence recognized by Rep. It consists of a seven-base sequence (3'CCGGT/TG5') that is recognized only on the correct strand (31). Nicking occurs between the two Ts (138), and mutation of any of the seven bases on the nicked strand reduces nicking (31). Changes in the sequence of the complementary strand, however, have no effect on nicking. Thus, the AAV origin for DNA replication is a tripartite sequence that consists of the RBE, the RBE', and the *trs*.

Several groups have clearly demonstrated that the transesterification reaction does not require ATP. The best evidence is that Rep will nick a variety of substrates in an ATP-independent reaction, provided that the RBE is duplex but the *trs* is single stranded (259). Generally, these substrates lose some specificity in the nicking site. However, recently Brister and Muzyczka (31) have constructed what appears to be the actual intermediate for nicking by deleting the *trs* sequences on the complementary strand, thus artificially extruding the *trs* into a stem-loop structure that contains the *trs* in a single-stranded loop. This substrate is cleaved in an ATP-independent fashion only at the correct nicking site; moreover, the substrate is nicked more efficiently than the conventional hairpin. Most recently, Rep also has been shown to nick a completely single-stranded substrate that contains only one strand of the RBE and the *trs* (257).

Additional evidence for the two-step *trs* endonuclease reaction comes from mutagenic analysis of the Rep coding sequence. Rep contains two domains that can be functionally separated. The C-terminal end that is present in Rep52 and 40 contains the Rep-associated DNA helicase activity (256). Rep52, like Rep78 and 68, has full DNA helicase activity when tested on primed single-stranded DNA substrates and behaves like a conventional 3' to 5' DNA helicase (256,316). In contrast, C-terminal truncations of Rep78, which retain the N-terminal sequences that are not present in Rep52, have no helicase or ATPase activity, but they are capable of binding to the RBE and they nick substrates that contain a single-stranded *trs*—that is, substrates in which the DNA helicase activity is not necessary to generate a single-stranded *trs* (83). Thus, the N-terminus of Rep78/68 contains most of the amino acid residues that are required for specific binding to the RBE and nicking the *trs*.

Unlike conventional RCR proteins, there does not appear to be an unlinking step for the Rep tyrosine phosphate bond with DNA. The Rep protein continues to be joined to the 5' end of the nick through subsequent steps of DNA replication, and it apparently remains attached during packaging of the progeny strand (96,161,219,300). Mature, highly purified virus particles, however, do not appear to have significant quantities of Rep protein (161,317); thus, some mechanism exists for hydrolyzing the tyrosine phosphate linkage that has not yet been discovered.

Once the terminal hairpin is nicked, it is believed that the Rep helicase unwinds the hairpin and a cellular DNA polymerase copies the TR to form an extended terminal sequence. Evidence for this comes primarily from *in vitro* reactions in which Rep is the only helicase available (138). The possibility that a cellular helicase or a viral-encoded helicase (in the case of herpesvirus) participates in the reaction has not been excluded. Rep helicase is then most likely responsible for unwinding and refolding the duplex end to form the double-hairpin TR that is needed for further DNA synthesis. Evidence for this comes from *in vitro* assays in which cell-free extracts are used (289). By themselves, the extracts replicate linear AAV templates poorly. When purified Rep is added, these extracts become competent for AAV DNA replication. This suggests that Rep78/68 can induce the formation of the double-hairpin substrate required to initiate strand displacement synthesis. That Rep is capable of initiating the double-hairpin intermediate is also supported by characterization of its DNA helicase activity using defined substrates. Simple linear oligonucleotides appear to be poor

substrates for Rep helicase, but oligonucleotides that contain an RBE can be unwound efficiently (316). Thus, the extended duplex TR, which contains two RBEs, is an efficient substrate for Rep helicase activity.

Both uninfected and Ad infected cell-free extracts have been used to replicate AAV DNA *in vitro* in a Rep and AAV ori-dependent manner. Typically, these extracts are supplemented with Rep78 or 68 purified from baculovirus, vaccinia, or bacterial clones, and study of these *in vitro* systems has provided additional information about AAV DNA replication. In general, Ad-infected extracts are significantly more active for *in vitro* AAV DNA synthesis (131,202,289). The block in DNA synthesis when uninfected extracts are used is not in the terminal resolution reaction but rather in the elongation reaction during strand displacement synthesis (202,289). Ward et al. (290) have presented evidence that the Ad-encoded DBP increases the processivity of AAV replication *in vivo*, allowing more efficient strand elongation. In spite of the fact that deletions of DBP are apparently viable for AAV DNA replication *in vivo* (39), DBP is preferentially used in place of the host single-strand binding complex, RPA, in the *in vitro* reaction. However, adding Ad DBP to uninfected extracts does not raise the level of DNA replication to the same level seen with an Ad-infected extract, suggesting that there are additional factors in an Ad-infected extract that are needed.

Ni et al. (201) have also examined AAV DNA replication in uninfected extracts. This group found conditions for stressing cells that apparently produced cell extracts that were permissive in the absence of Ad infection. Such conditions might be a model for the semipermissive *in vivo* AAV replication that has been demonstrated by several groups. As expected, Ni et al. (201) found that AAV DNA replication did not depend on DNA polymerase alpha–primase but was dependent on the presence of RPA, proliferating cell nuclear antigen (PCNA), and replication factor C (RFC). PCNA is a processivity factor that is essential for DNA polymerase delta and epsilon, both of which are believed to be involved in replication of cellular DNA. Epsilon was originally identified as a DNA repair enzyme. Both polymerases are essentially leading-strand DNA synthesis enzymes, and either would be appropriate for AAV DNA replication. RFC is a 3' primer recognition enzyme that assembles PCNA at a 3' hydroxyl. Reconstitution of the *in vitro* reaction with one or both purified polymerases, however, did not restore AAV DNA replication, suggesting again that there is an additional unidentified cellular factor necessary for AAV DNA replication.

At least two other cellular factors have been implicated in AAV DNA replication. The first is high mobility group protein 1 (HMG1), a protein that binds cruciform DNA (65). This protein has been shown to bind AAV hairpins and Rep. HMG1 stimulates Rep nicking of the TR, Rep ATPase activity and Rep repression of the p5 promoter. It is, therefore, likely to be directly involved in DNA replication. The second factor is a protein that binds specifically to one strand of the D sequence within the AAV TR (see Fig. 2), hence the name single-stranded D binding protein (ssD-BP) (183,223). This protein exists in two phosphorylation states. When bound by the phosphorylated form, the input single-stranded AAV genome is unable to synthesize the second strand to form the first replicative intermediate. The protein, which appears to be the 52-kd FK506 binding protein, FKBP52, binds to the 10 bases of D sequences (see Fig. 2) proximal to the *trs* and prevents DNA replication. When the nonphosphorylated form of the protein binds, second-strand synthesis proceeds normally. Phosphorylation of the protein appears to be controlled by the epidermal growth factor receptor protein (EGF-R) tyrosine kinase and correlates well with the ability of cells to be transduced by recombinant AAV vectors in the absence of helper virus. This is because the input vector single-stranded DNA must synthesize the second strand to produce a substrate for RNA polymerase II transcription. The role of this protein in productive infections (i.e., when helper virus is present) has not been reported.

Three types of substrates have been used for *in vitro* DNA replication. The first is a linear AAV duplex molecule, which is covalently cross-linked at both ends by the hairpinned form of the TR, a substrate called NE (no end) DNA. In this assay, Rep 68/78 protein is required, as is an extract from cells infected by Ad (202). The major product is linear duplex AAV DNA containing one newly synthesized strand and extended ends. Extracts of uninfected HeLa cells do not support replication, even if supplemented with Rep68. A second assay has been described (49,131,132,291) in which the substrate is either linear duplex AAV DNA or the same DNA contained in a bacterial plasmid vector. Again, Rep68/78 is required and an extract from uninfected HeLa cells does support replication. When the template is the plasmid construct, replication leads to rescue of the AAV insert from pBR322 and, in some instances, pBR322 gets replicated in addition to AAV. Whether the vector sequences are preferentially replicated as opposed to the AAV sequences appears to depend on the presence of Ad DBP.

An important observation is that rescue of the AAV insert from bacterial plasmids *in vitro* can be separated from the initiation of DNA replication in terms of template sequence requirement. Deletion of the terminal 55 bases from both TRs in the plasmid construct prevents rescue of the AAV insert but allows the entire construct to be replicated. The implications of this are that ori function does not require the entire TR and that a hairpin per se is not required for DNA replication (131). The minimal requirements for this reaction are an RBE and a *trs*. Replication in this case appears to be similar to the *in vitro* replication seen with plasmids that contain a copy of the chromosome 19 integration sequence (280). These plasmids have been shown to undergo a rolling circle type of replication in the presence of Rep and cell-free extracts, and a nick at the *trs*-like site within chromosome 19 apparently initiates replication. In both cases, nicking by Rep appears to occur because of the presence of an RBE and a nearby *trs* without an RBE' or significant secondary structure. *In vitro* assays using such substrates have demonstrated that Rep can both bind and nick substrates that do not have an RBE' or the cross-arms of the AAV hairpin (50,188). This reaction proceeds 20- to 100-fold less efficiently than nicking of the complete hairpin and may be an important aspect of the mechanism for AAV integration or rescue from human chromosome 19. There is evidence as well that rescue of AAV does not require Rep or DNA replication. One group identified a cellular enzyme, endo R, that recognizes potential triple-stranded DNA in the TR and excises AAV from recombinant plasmids (113). Another group has shown that a plasmid containing a single TR with two D sequences, analogous to an internal TR junction from a dimer replicative form (RF) molecule (see Fig. 6), can be converted rapidly to linear molecules when transfected into cells in the absence of Rep expression (306).

Single-stranded AAV DNA can form circles that are hydrogen bonded through the 20-bp D sequence (see Fig. 6). This type of structure is believed to be responsible for the ability of AAV TR deletions to be repaired to the wild-type sequence (247). As described earlier, the cloned duplex form of the genome is infectious when transfected into Ad-infected cells. Clones with deletions of up to 113 bases at one end are still infectious, and the resulting progeny contain genomes with wild-type termini at both ends (247). The repair process is thought to involve (a) base-pairing between the remaining

complementary bases (32 base pairs in this case) and (b) use of the shorter 3'-terminal strand as a primer for repair synthesis, using the intact 5' TR strand as the template. Mutants with deletions that extend beyond the bounds of the TR cannot be rescued. Thus, not only does the TR help to resolve the problem inherent to linear genomes of maintaining the integrity of the 5'-terminal sequences during the process of DNA replication, but it also confers the ability to repair terminal deletions of the type described earlier.

Deletion of an 11-base symmetrical sequence (at nucleotides 50 to 60) from both TRs, thus effectively removing one of the cross-arms of the T, abolishes the ability of a cloned genome to be rescued and replicated (247). Substitution of an alternative 8- or 12-base symmetrical sequence restores viability to the cloned genome (172). No differences can be detected in either the rate or the extent of DNA replication that occurs after viral infection under permissive conditions. Substitution of an asymmetric 12-base sequence does not significantly restore viability (28). This observation has been interpreted to mean that, at least in the region of the cross-arms, the conformation of the TR, when folded on itself, takes precedence over the actual sequence in terms of rescue and replication of the genome from the cloned state in a plasmid. However, it is now known that the sequence deleted in these constructs was the RBE' motif that makes specific contacts with Rep. The RBE' has a specific three-dimensional location with respect to the RBE and *trs* in the hairpinned TR and this, in addition to the sequence of the RBE', may play a role in TR recognition by Rep. Thus far, it has been difficult to separate the role of the hairpin secondary structure from the RBE' sequence for Rep binding, helicase, and nicking activity. Recent experiments in which the RBE' sequence has been mutated without changing the overall structure of the TR suggest that the RBE' contacts are important primarily for initiating DNA helicase activity on the hairpin and are essentially dispensable for the transesterification reaction (32).

The viability of the symmetrical substitutions offers the possibility of testing whether or not the ability of the TRs to perfectly base-pair and form a single-stranded circle is a requirement for normal AAV DNA replication. Constructs in which a viable TR substitution is inserted in one end and not the other are found to be capable of being packaged. Under some conditions, the chimeras were able to undergo many rounds of replication and encapsidation without the occurrence of gene conversion (27). Similarly, packaged genomes derived from wild-type AAV are equally divided between those whose TRs at both ends are in the same orientation (flip or flop) and those with TRs in the opposite orientation (180). Thus, although the termini definitely can interact during the process of replication, TR interaction or gene conversion does not appear to be essential for replication.

As with many DNA viruses, AAV DNA replication generates defective genomes. These structures contain internal deletions flanked by TRs. In some cases, the defective genomes contained inverted duplications of sequences from either end of the genome (84,121).

Protein Synthesis

Four nonstructural proteins, Rep78, 68, 52, and 40, have been identified immunologically and purified from bacterial or eukaryotic expression vectors. They have been named according to their apparent MWs on sodium dodecyl sulfate (SDS) acrylamide gels, but their actual MWs are 72, 62, 46, and 34 kd, respectively. The amounts of the individual proteins correspond reasonably well to the relative accumulations of the individual transcripts. The two larger species are predominantly nuclear proteins, whereas the smaller ones, Rep52 and 40, are also found in the cytoplasm (192).

Various functions ascribed to the Rep proteins have been mapped along the primary structure. As noted earlier, Rep52 (amino acids 225 to 621 of the rep ORF) retains full helicase activity (256). The region unique to Rep78/68 plus a few amino acids shared with Rep52/40 (amino acids 3 to 251) are sufficient for nicking a single-stranded *trs* substrate (83), and a slightly smaller N-terminal region is sufficient for RBE binding (210). Efficient TR binding, however, requires sequences within the C-terminal region as well (187). A number of specific amino acids involved in TR binding have been mapped (82,110,187,279). The N-terminal region contains several motifs common to RCR proteins (amino acids 9 to 14, 89 to 94, and 146 to 156) (136) that are believed to be involved in nicking activity, and mutations in these motifs are defective in both *trs* endonuclease activity and integration at chromosome 19 (279). This includes the tyrosine residue at amino acid 156 that makes a covalent linkage with the *trs* site (83,257). C-terminal deletions (amino acids 490 to 621) appear to retain most Rep functions *in vivo* and *in vitro* (134,154). This includes the region of Rep52 and 78 that is spliced out in Rep40 and 68 (amino acids 529 to 621). However, repression of the p5 promoter and a heterologous promoter, the HPV18 upstream regulatory region, was most pronounced with Rep78, followed by Rep68 and Rep52. Rep40 repression was undetectable (134). Transactivation of the p40 promoter appears to be exclusively caused by either Rep78 or 68, with Rep68 having a more pronounced effect (293). A zinc-binding domain in the C-terminal region that is spliced out in Rep68 and 40 has been mutated; the mutant Rep78 protein no longer binds Zn *in vitro*, but the mutation does not change the ability of Rep78 to inhibit transcription from AAV or heterologous promoters *in vivo* (134). Rep is phosphorylated primarily on threonine residues, but these have not been mapped (62). As yet there is no clear evidence that Rep phosphorylation has an effect on any of its biochemical activities. A canonical ATP binding site is located at amino acids 334 to 349. Mutations in this region are defective for ATPase and helicase activity, DNA replication, and transactivation and repression of the p5 promoter *in vivo*; however, they retain some ability to repress the p19 and heterologous promoters. Curiously, virtually all mutants that are defective for helicase or DNA replication activity are also defective for transactivation; this has led to the suggestion that the helicase activity may be involved in transactivation (187). Mutants in other putative helicase motifs conserved among parvovirus nonstructural proteins eliminated helicase activity (187,284). A divalent cation binding site, apparently the one used for DNA helicase activity, has been mapped at amino acid 421 (110). Another divalent cation binding site in the N-terminus that is used for nuclease activity (presumably one of the conserved RCR motifs discussed earlier) remains to be definitively mapped. A nuclear localization region has been mapped to amino acids 483 to 519 (313). Rep 68/78 inhibits oncogenesis induced by a variety of carcinogens; mutants involving amino acids 25 to 56, 73 to 74, 164 to 165, and 257 to 346 had a significantly reduced capacity to inhibit EIA + *ras* transformation (312). Rep interacts with a variety of cellular proteins, but most of the interaction domains have not been completely mapped. Most of the N-terminal region (amino acids 1 to 174) is dispensable for interaction with PC4 (a transcription activator), as well as for inhibition of herpes virus replication (154,292). Rep–Rep interaction domains have been mapped to several specific regions (82,83,96,258), and Rep–capsid protein interaction has been mapped to amino acids 322 to 482 (96).

As mentioned earlier, all of the coat proteins, VP1 to VP3, are translated from two alternatively spliced p40 mRNAs (196). The most abundant of these messages is used to translate VP2 from a nonconventional ACG codon, and VP3 from a downstream AUG. VP1 is translated from the low-abundance spliced p40 message. All three proteins share the same ORF. Amino acid numbers below begin with amino acid 1 of VP1; VP2 begins at amino acid 138, and VP3 at 203. Why the first AUG in the predominant mRNA should be so far downstream is uncertain. However, evidence has been presented that *rep* activity can inhibit gene expression from the p40 promoter at the level of protein translation when a vector with a reporter gene under control of the p40 promoter is co-transfected with a plasmid containing *rep* into Ad-infected cells (275). Thus, it is possible that the long leader sequence in the major p40 spliced RNA from which VP2 and VP3 are translated serves to protect against this type of inhibition.

Expression of the structural proteins in insect cells leads to spontaneous particle self-assembly. VP2 was specifically required for self-assembly; either VP1 or VP3 could be omitted, but all three were required for infectivity (239). VP3, however, lacks a nuclear localization signal (NLS) (299); if a heterologous NLS is fused to VP3, it also becomes capable of self-assembly into empty particles (133). At least one NLS has been mapped to the N-terminus of VP2, amino acids 167 to 172 (133), but there appear to be redundant NLS sequences (305). As mentioned earlier, AAV2 uses heparin sulfate proteoglycans as a primary cell surface receptor (267). The heparin sulfate binding region of the AAV2 capsid protein has been mapped to two clusters, amino acids 509 to 522 and 561 to 591 (305). Several substitution and insertion mutants have been characterized in a preliminary way (305, and refs. therein). In general, insertions into putative loop regions are on the surface of the capsid and at least partially viable. The N-terminus of VP2 and a portion of the N-terminus of VP1 are also on the capsid surface. The N-terminus of VP3 and the C-terminus are internal to the capsid and essential for capsid structural integrity. One mutant (R432A) makes only empty capsids. Nonviable mutants tend to map to alpha-helix or beta-sheet regions, which are known to be necessary for capsid integrity.

Latent Infection

In the absence of a helper virus co-infection, the AAV genome is often integrated into cellular DNA to establish a latent infection that can be activated by a subsequent helper virus infection. AAV latent infection was discovered by Hoggan et al. (130) in the course of a federal project to screen primary cell lots intended for vaccine production. Although there was no immunologic evidence for AAV, upon challenge by Ad infection, 20% of the lots of African green monkey kidney cells and 1% to 2% of the lots of human embryonic kidney cells tested produced AAV. Thus, AAV latent infection *in vivo* appeared to be common. Although most human transmission of AAV appears to be horizontal, evidence for vertical germline transmission of avian AAV has been reported in chickens (23). Human cells in culture can be latently infected simply by infecting with a high multiplicity of AAV (multiplicity of infection of 10 to 1,000) in the absence of helper virus (126,169). The frequency of positive clones (estimated either by isolation of single-cell colonies or by selection with recombinant vectors carrying a *rep* gene and a selectable marker) suggests that up to 10% of the infected cells become latently infected (126,169). These figures exceed those seen with other DNA animal viruses and approach the efficiency of lambda bacteriophage lysogeny and rescue.

Characterization of AAV DNA in latently infected clones shows that the viral genome is in most cases integrated into cellular DNA (48,169). The junction with cellular sequences is usually within the TR, but the site of integration within the viral TR is not unique. Recombination junctions occur throughout the TR sequences and the p5 promoter region (155,309), and portions of the TR are deleted. The viral DNA in most latently infected cell lines is integrated as a tandem (head-to-tail) array of several genome equivalents (48,169,190). Inverted (tail-to-tail or head-to-head) arrays have also been seen but occur at a much lower frequency (155). The presence of TR deletions raises the question of how the AAV provirus is rescued. Presumably this occurs by excision of an internal tandemly repeated genome that is intact. Indeed, the junctions between tandem repeats appear to be intact, consist of a single TR flanked by two D sequences, and correlate with rescue (94,190,306).

It is not known whether deletions of the TR occur during integration or during subsequent passage of the cells. In one clone of latently infected cells that was followed for over 100 passages, the restriction patterns obtained, using enzymes that cut in the unique sequences, were unchanged, but significant changes were noted using a restriction enzyme that cuts exclusively in the TR (48). This raises the possibility that the TR is an unstable sequence. This notion was supported by the observation that after 100 passages, free copies of the AAV genome were present, even though all of the detectable sequences had been integrated into high-MW DNA in earlier passages.

Initially, it was concluded that integration was random with respect to cellular sequences because restriction analysis found that junction fragments of viral and cellular DNA differed in size in every independently derived clone carrying a provirus. It is now clear that integration occurs at a specific site on human chromosome 19q13.3-qter (157,158,248). Integration is by nonhomologous recombination, although there are four to five base homologies at the site of recombination, and integration is often associated with rearrangements and inversions of both viral DNA and cellular sequences (156,309). Although integration is site specific, it is not specific at the individual nucleotide level but occurs within a region of several hundred nucleotides (156,248,309). Additionally, only about 70% of the integration events appear to occur on chromosome 19.

The preintegration site has been isolated as an 8-kb fragment, of which the first 4 kb have been sequenced (156). The sequenced region, called AAVS1, contains all of the known sites of recombination. The average base composition is 82% GC in the first 900 bases, which are near the recombination sites. Toward the 3' end of the AAVS1 sequence, there is a tandem repeat of 10 copies of a 35-mer minisatellite, which occurs at 60 places in the human genome, all of which are on 19q. There are also a large number of direct repeats in which there is an 11/12 base match. The first 900 bases fulfill the criteria for a CpG island, which could serve as a promoter for expression of the ORF found in the middle of the sequenced region. As noted earlier, Dutheil et al. (97) have recently identified two of the coding regions within this region. A gene proximal to the integration site codes for the slow skeletal muscle troponin T gene, TNNT1, previously mapped to 19q13.4. This gene is located approximately 15 kb to the telomere side of AAVS1, and integration into AAVS1

has been shown to cause rearrangements of TNNT1 in some proviral clones.

The most interesting feature of the preintegration site is that it contains an RBE and an abbreviated version of the *trs*. The sequences within the AAVS1 site necessary for site-specific recombination have been identified by the use of an extrachromosomal Epstein-Barr virus shuttle vector carrying the preintegration sequence. When human cells carrying the shuttle vector are infected with wild-type AAV virions, the viral genome preferentially integrates into the chromosome 19 target site. The critical region has been mapped to a 500-base fragment, which contains the RBE and a *trs*-like element (111). It was possible to dissociate the RBE from the sequences at which recombination occur in the latently infected cell lines. Thus, it appears as though the critical factor is a recognition site, and the actual recombination takes place several hundred bases distal to the recognition site. Additionally, any higher-order chromatin structure specific to chromosome 19q does not appear to be essential for site-specific integration. Site-specific mutagenesis has been used to further define the critical elements. Mutation of either the RBE or the putative *trs* site dramatically reduces site-specific integration (176), and these two elements appear to be the only essential elements required for integration.

Several groups have shown that Rep expression is essential for site-specific integration. Recombinant AAV (rAAV) vectors carrying a selectable marker flanked by two TRs, but deleted for the *rep* gene, do not integrate into chromosome 19 (148), whereas those that contain the *rep* gene integrate site specifically. Plasmids carrying an rAAV genome, when co-transfected with a Rep-expressing plasmid (or Rep protein) into human cells, will excise the rAAV genome and integrate it into chromosome 19 (253). The same occurs when human cells are infected with herpes, Ad, or baculovirus vectors carrying an rAAV genome, provided Rep is expressed (225, and references therein). Most recently, site-specific integration has been demonstrated in nonhuman cells. Mice do not have the AAVS1 preintegration sequence. However, when cells from transgenic mice carrying the AAVS1 locus are infected with rep^+ AAV, integration occurs in the transgenic S1 locus (233).

Biochemical evidence also supports a role for Rep in site-specific integration. Weitzman et al. (295) have demonstrated that Rep68 can bind to a plasmid containing a fragment of the preintegration site and can also serve as a bridge between the AAV TR and the chromosome 19 RBE. Thus, *in vitro*, Rep can bring the chromosome 19 target site and the AAV genome together through Rep-Rep contacts. As noted earlier, Urcelay et al. (280) have shown that plasmids containing the AAVS1 site can be nicked by Rep, which in turn initiates DNA replication. Recently, Smith and Kotin (257) have shown that Rep can both nick a *trs* and ligate the nicked DNA to another sequence in a second transesterification reaction *in vitro*. Dyall et al. (99) have also provided evidence for nicking and joining *in vitro*.

Integration in the absence of Rep generates proviral structures in cell culture that are essentially the same as those seen in the presence of Rep, with the exception that the site of integration is not chromosome 19 (93,190,240,309). (This includes the formation of head-to-tail repeats, deletions within the TR, rearrangements of cellular DNA, and microhomologies at junctions between cellular and viral DNA.) The efficiency of Rep-minus integration is variable and seems to depend on the cell line under study, but it can be as high as 80% (190). This suggests that cellular enzymes are largely responsible for recombination, and Rep is essential only for site specificity. The only AAV related sequence that is necessary for integration seems to be the TR, which is recognized by the cellular machinery as a recombination or amplification signal (309).

No clear consensus model has emerged thus far for integration. The key elements to explain are the tandem (head-to-tail) repeats, the high rescue frequency implying that at least one intact copy is always integrated, the role of Rep, the ability of Rep to rearrange the host target site even in the absence of an input AAV genome, and the lack of site specificity at the sequence level for either viral or host DNA. The existence of head-to-tail repeats prompted some to suggest that the integration intermediate is a circular AAV genome that undergoes RCR (169,190). Both AAV and chromosome 19 could be nicked at their respective *trs*s, exposing a TR end for illegitimate recombination to a random cellular sequence in the S1 site. This would explain the frequent occurrence of tandem repeats with intact internal TRs. Giraud et al. (112) have suggested that copy-choice replication mechanisms during RCR could account for the rearrangements and inversions that have been found in some proviruses. Dyall et al. (98) have suggested a deletion substitution method of recombination.

The need for *trs* nicking on the input genome apparently has been eliminated by Young and Samulski (314), who demonstrated that site-specific integration occurs even when plasmids carrying AAV with mutant *trs*s are transfected into human cells. The mutant *trs* is defective for Rep-mediated nicking or DNA replication, but it integrates into chromosome 19 at about the same frequency as wild-type DNA.

Evidence for the formation of circular intermediates comes from recent studies of rAAV transduction in cell culture and muscle tissue (94). These experiments are done in the absence of Rep expression but, as noted earlier, this produces similar proviral structures in cell culture. Persistent transduction appeared to correlate with the formation of circular rAAV intermediates, which could be recovered by subsequent transfection into bacteria. Previous studies had shown that the expression of the Ad E4 ORF 6 gene product or a variety of genotoxic agents would increase transduction or reduce the time required for expression of a transgene in cell culture and *in vivo* (101,102). This was interpreted to mean that a variety of agents could promote second-strand synthesis, which was required for transcription. More recent experiments suggest that either linear duplex or circular duplex intermediates are formed, depending on the type of stimulus—for example, UV light versus ORF 6 gene expression (249). The significance of this is not clear.

Perhaps the most surprising development in rAAV integration has been the realization that recombinant AAV genomes persist *in vivo* for extended periods of time (up to a year) as episomes. These are converted slowly from linear or circular monomer genomes to high-MW concatemers, and this may or may not be accompanied by integration (1,105,148,184,282). In addition, it is now clear that two different rAAV genomes will recombine to form circular or linear concatemers. Several groups have shown that this occurs frequently and can be used to reconstruct split genes that are infected into cells in two different vectors (95,268,308).

AAV as a Vector

AAV has received a significant amount of interest as a potential vector for gene therapy (41,126,245). There are a number of characteristics that contribute to the potential utility of the virus for this purpose. Recombinant AAV vectors can efficiently transduce a variety of nondividing, terminally differentiated tissues *in vivo*. These include cells of the eye, central nervous system, muscle, liver, and lung. Significantly, the vector genome persists for extended periods (up to 2 years in muscle, brain, and eye of rodents) with no apparent decrease in expression. In part, this is because essentially no pathogenicity or inflammatory response is generated by *in vivo* injections of vector. The cytotoxic T-lymphocyte (CTL) response also appears to be lower than that seen with most other viral vectors (20,52,129). This may be due in part to the absence of genes (other than the transgene) in the vector, or to the observation that AAV does not efficiently infect antigen-presenting cells (145). Long-lived expression is due also to the fact that foreign promoters appear to behave as expected in the context of an AAV vector. Tissue-specific and inducible promoters are expressed only in the appropriate cell types or in the presence of inducer and do not appear to be shut off by mechanisms that affect other types of vectors. Although the AAV TR is itself a TATA-less promoter (104), its basal level of expression is low and detectable only in some cell types. Expression from an rAAV vector typically takes 3 to 6 weeks to reach a maximum level (149,261). The slow onset is generally believed to result from the slow synthesis of the second strand (101,102).

Ex vivo gene therapy has also been investigated, particularly in hematopoietic cells. One group has successfully transplanted ablated mice with transduced hematopoietic stem cells and achieved long-term expression in recipients. However, it is clear that the efficiency of transduction is variable, and that it depends on several factors that have so far been poorly defined but may include the genotype of the donor cells (218), the phosphorylation state of ssD-BP (221), the ability of virus to traffic to the nucleus, or the presence of the appropriate cell surface receptors (222,266,267).

Permanent transduction in cell culture was first shown by Hermonat and Muzyczka (126). The vectors used in these studies deleted the capsid gene and substituted foreign DNA. This type of vector retains the *rep* gene and can integrate with high frequency into chromosome 19. The second type of vector, which simply puts an AAV TR on both ends of the foreign DNA (190), has received the most attention because it contains more room for the transgene, about 4.5 kb. This type of vector was the first to be used *in vivo* (103), and it is currently being used in two human trials for the treatment of cystic fibrosis and factor IX deficiency. Preliminary results from both trials have been encouraging (147,283).

The rAAV vector system has suffered from several disadvantages, some of which have now been addressed or eliminated. The small packaging size has been a problem for some transgene–promoter combinations. Two groups have recently showed that this problem can be overcome by the use of split genes that are cloned into two separate vectors (95,268,308). These are expressed *in vivo* from head-to-tail concatemers of the vector with the use of appropriate splice signals. Another problem has been the lack of effective methods for purification of rAAV virus, and this also has been addressed. There are now several new methods for virus production and purification that produce virus with low particle-to-infectivity ratios and low wild-type AAV and helper contamination (59,116,317). Scalable production methods have also been developed (59,63,108). Several problems remain, however. The slow onset of transgene expression eliminates rAAV as a vector for acute clinical applications. It is still not clear from biodistribution experiments whether rAAV permanently transduces germline cells *in vivo*. Finally, because rAAV integrates into some primary cells, the potential long-term risk from insertional mutagenesis needs to be assessed.

Inhibition of Helper Virus Replication and Heterologous Gene Expression

In addition to AAV gene expression and replication being affected by Ad or herpes co-infection, the course of Ad infection is also significantly affected by AAV co-infection (40,42,43). There is also evidence that Rep can directly or indirectly interfere with replication of other viral genomes, specifically SV40, papilloma, and herpes, as well as with replication of cellular DNA (123,154,166,310,311). In the case of Ad, the net effect is enhanced AAV gene expression and replication, with greatly reduced Ad gene expression and replication. These effects depend on the ratio of the multiplicities of infection of the two viruses and the temporal order of addition. AAV is effectively autoinhibitory because, if the ratio of AAV to Ad becomes too great, the inhibition of Ad gene expression is sufficient that it no longer provides the helper functions needed for AAV replication. By the same token, if AAV infection is delayed until Ad DNA synthesis has begun, AAV replication occurs but that of Ad is not inhibited. The inhibition appears to require *rep* gene expression because DI particles of AAV, which have very large internal deletions but intact TRs, cannot inhibit Ad replication (84). Whether the inhibition of Ad includes direct effects on DNA replication or simply a lack of early regulatory proteins is not known. This type of inhibition is not usually seen with herpesvirus co-infections (15), probably because the herpesvirus infection is so rapid, but it is seen when the *rep* gene is overexpressed (154).

Initially, infection by AAV in the absence of helper virus was not noted to affect the cell phenotype. More detailed studies of latently infected cells have indicated several phenotypic changes. These include decreased plating efficiency, evidence of cell cycle arrest, and increased sensitivity to a variety of genotoxic agents [e.g., UV, chemical carcinogens (286,287)]. Latent infection can also inhibit DNA amplification after exposure to genotoxic agents (298). AAV infection of the human leukemic cell line HL60 and immortalized keratinocyte lines led to reduced cell growth and reduced levels of detectable differentiation-associated antigens, plus altered expression of c- *myc*, c-*myb*, and c-*fos* (153). In the case of c-*myc* and c-*fos*, this appears to result from Rep repression of the cellular promoters (124). This may also account for the observation of Yang et al. (311), who have shown that the *rep* gene is cytostatic. Cells carrying an inducible *rep* gene were arrested for growth when the *rep* gene was induced and returned to normal growth in the absence of inducer. Even low constitutive levels of *rep* expression increased cell doubling time.

AAV has also been reported to inhibit permanent cellular transformation by selectable markers under the control of the SV40 early promoter, the HSV type 11 thymidine kinase promoter, and the inducible murine metallothionein promoter. The level of inhibition was greater than 95% and depended on an intact *rep* gene. Under the conditions employed, the cells were not killed by *rep* gene expression, nor was the ability of plasmid DNA to integrate into cellular DNA decreased. Thus, it appeared as though the inhibition was caused by repression of gene expression. This notion was supported by

the observation that in co-transfections, the AAV *rep* gene was able to inhibit chloramphenical acetyl transferase (CAT) expression under control of the SV40 early promoter. These types of inhibitory effects have been observed in both murine and human cells (167,276), but the extent of inhibition was very dependent on the specific cells used.

Inhibition of Adenovirus, Herpesvirus, and Papillomavirus Oncogenicity

Oncogenic serotypes of Ad induce tumors in newborn Syrian hamsters. Co-infection of AAV with oncogenic Ad reduces the frequency of tumors and lengthens the induction time of those that do occur (152,185). AAV co-infection also inhibits the ability of Ad to transform cells. Ad-transformed hamster cells are also oncogenic in the newborn, and this oncogenicity was reduced by infection of the cells with AAV, although the growth rate in culture was unaltered (209). The primary effect appeared to be on the level of E1B expression in the transformed cells. de la Maza and Carter (85) reported that DI particles of AAV and DI genomes could inhibit Ad induction of tumors in hamsters. Because some of the preparations of defective particles contained only the termini of the AAV genome, it was suggested that the termini may be sufficient for inhibiting Ad oncogenicity. AAV has also been reported to inhibit the oncogenicity of HSV-II-transformed cells after infection (81). Not only was the incidence of tumor induction decreased after cells were injected into hamsters, but the induction period was lengthened. Possibly the most interesting result was that even in those animals that did develop tumors there was no evidence of metastasis. AAV has also been shown to inhibit transformation by bovine papilloma virus and human papilloma virus 16 (HPV16), and this inhibition is attributable to Rep (123,285). Rep-mediated inhibition appears to involve binding of Rep to an HPV16 promoter and direct interaction between Rep and the HPV E7 oncoprotein (128). Similarly, Rep inhibits cell transformation by the combined action of the E1A and human *ras* oncogenes (150).

The reports of AAV inhibition of oncogenicity have raised the question of whether AAV might inhibit oncogenicity in humans. More than 90% of adults are seropositive for AAV, suggesting that many carry AAV as a latent infection. According to the model hypothesized, latent virus might be activated by oncogenic virus infection and, once activated, inhibit oncogenesis. Several retrospective epidemiologic studies have been done, studying patients suffering from cervical carcinoma. Interestingly, in each study the patients were markedly deficient in antibodies to AAV compared to a group of matched controls (263, and references therein). These results raise the unusual possibility that a viral infection might, for once, be beneficial to the host.

AUTONOMOUS PARVOVIRUSES

Genetic Map

Like that of AAV, the autonomous parvovirus genome contains two large ORFs (see Fig. 3). The first covers much of the left half of the genome (approximately mps 6 to 42) and encodes two NS proteins, NS1 and NS2, from alternately spliced mRNAs that are initiated at mp 4 (see Fig. 3). Mutations within NS1 block viral replication and gene expression (229,230). Only NS1 is absolutely required for DNA replication. NS2-specific mutants are defective for capsid synthesis, gene expression, and DNA replication in murine cells but show variable phenotypes in human cells (36,68,174,198,199). The second large ORF occupies much of the right half of the genome (mp 45 to 90) and encodes the coat proteins (228,255). Up to three coat proteins have been detected in the virion. In the case of MVM, the smallest capsid protein, VP3, is generated in the intact capsid by proteolytic cleavage of VP2 (271). The amino acid sequences of VP1 and VP2 are identical except for additional amino acids at the N terminus of VP1, and they are synthesized from two alternatively spliced messages initiated at mp 38 (see Fig. 3). The VP1 message contains a second (smaller) ORF at the 5' end of the major right-hand ORF (165,194). Mutants altered in either the NS or coat protein ORFs can be complemented in trans. However, the palindromic sequences at both termini are required in cis for DNA replication and packaging.

Transcription

For most autonomous parvoviruses, three major size classes of polyadenylated transcripts have been identified (see Fig. 3). Two of these (R1 and R2) are initiated downstream of a promoter (TATA box) at mp 4 and extend to a point near the right end of the genome near mps 95 to 96, where a polyadenylation signal (AATAAA) is located. Both of these transcripts have an intron removed between mps 44 and 46, and one has a large intron removed between mps 10 and 39 (144,194,217). These two transcripts are translated to yield NS proteins NS1 and NS2, respectively (72,228). The other major size class (R3) is initiated downstream from a promoter at mp 38 and alternatively spliced between mps 44 and 46 to produce the coat proteins VP1 and VP2 (165,194). The region between mps 44 and 46 is unusual in that two pairs of donor and acceptor splice sites occur in a very small region. In all, three of the four possible splicing combinations that could occur in this region are observed in each of the three major mRNA size classes, R1, R2, and R3 (see Fig. 3), to produce a total of nine mRNA species that are made at detectable steady-state levels (144,194). Unspliced mRNA species are also a major portion of nuclear RNA found in infected cells. In the case of MVM, excision of the large intron and the ratio of the R1 and R2 messages depend on sequences within the small intron (mps 44 to 46). The role of the small intron in this process has been hypothesized to involve initial entry of the spliceasome (315). Improvement of the polypyrimidine tract of the large intron relieves the requirement for the small intron and makes prior excision of the small intron unnecessary for large intron excision. As an added factor, any mutations that insert stop codons in either exon will block splicing (200).

Significant variations of this general scheme occur. All transcripts of the autonomous human parvovirus B19 have been reported to initiate from the promoter at mp 6 (25,90,211). Potential internal polyadenylation signals (AATAAA) exist near the middle of several parvovirus genomes, and these sequences are used for polyadenylation in the case of ADV and B19 virus (6,211). An additional NS protein, NS3, has been identified in ADV, which is coded by an alternatively spliced left-side ORF transcript (58).

Both MVM NS1 and H1 NS1 (a closely related parovirus) are necessary for transactivation of their respective p38 promoters (92,230). In the absence of functional NS1, p38 mRNA is difficult to detect by most RNA detection methods. The transactivation domain in NS1 has been mapped to the C-terminal 129 amino acid residues (173). Three sequences

are essential for transactivation. The first is the tar element (transactivation response element, sensitive to NS1) or an alternative NS1 binding site–containing sequence (178,179,231). NS1 binds to the tar region in an ATP-dependent manner (53). However, because there are many NS1 binding sequences upstream of the p38 promoter (more than 100), mutations of the NS1 binding site within the tar region have not always shown a decrease in p38 transcription, presumably because of redundant NS1 binding sequences. Two other sequences are essential for transactivation, an SP1 site and the TATA box (5,179) (see Fig. 5). NS1 can bind to Sp1, and the general transcription proteins TBP and TFIIA in the absence of DNA (159,179), and, presumably, these interactions are involved in transactivation. However, the mechanism of transactivation is not yet clear.

Activation of p4 transcription by NS1 has been seen in LuIII, B19, and MVM (91,119), and it depends in part on sequences within the upstream terminal palindrome, presumably because they contain NS1 binding sites (see Fig. 5). Transactivation of p4 by NS1 essentially creates a positive feedback loop for p4 transcription, thereby creating a switch that commits the virus to lytic infection.

Several other elements necessary for p4 transcription have also been mapped in MVM (4,87,88,107,118,215). A TATA box and an Sp1 site at –29 and –45 bases relative to the p4 mRNA start (see Fig. 5) are essential for promoter activity (4). Additionally, because MVM requires cellular proteins that are expressed in S phase for productive infection, some mechanism must exist for sensing when S phase begins, because unregulated expression of NS1 is cytotoxic (235). This is apparently supplied by an E2F site (see Fig. 5) at –60 relative to the message start (87,88). Mutation of this site abolishes NS1 induction in S phase and produces a replication-negative phenotype that can be rescued only if NS1 is supplied in trans. The E2F transcription factor consists of a heterodimeric factor composed of E2F and DP family members. Their transcriptional activity is controlled during the cell cycle by binding to members of the pocket protein family (pRb, p130, and p107). Free E2F heterodimers are active for transactivation and are released at the G1–S transition as a result of phosphorylation of the pocket proteins by cell-cycle-regulated cyclin-dependent kinases. A second transcription factor family also is involved in sensing and responding to the cell cycle. Two cyclic AMP response elements (see Fig. 5, CREs), which are present within the left palindrome (at –130 and –160), and which bind the ATF/CREB family of transcription factors, activate the p4 promoter in growing and serum-starved cells but repress the p4 promoter in contact-inhibited cells (87,215). Promoter silencing in contact-inhibited cells is apparently mediated by the cyclin-dependent kinase inhibitor (CKI) p27, as overexpression of p27 reduces p4 transcription in growing cells. Thus, control of NS1 expression by the E2F and CREB families of transcription factors effectively couples MVM p4 transcription (and DNA replication) to the cell cycle.

Two other transcription factors participate in p4 control, NF-Y and Ets (see Fig. 5). NF-Y binds to an atypical site, CCAAC, which is present in the left TR (–100 upstream of p4) as well as at the internal dimer junction of MVM. Its mutation reduces p4 transcription approximately twofold (118). The Ets transcription factor binding site is located at approximately–50, just upstream of the Sp1 site, and it also increases p4 transcription (about threefold) (107). The Ets site appears to cooperate with the nearby Sp1 site in activating p4. Interestingly, both the Ets site and the CRE sites increase transcription from the p4 promoter in a *ras*-transformed cell (107,215). The increased NS1 levels in *ras*-transformed cells may account in part for the well established sensitivity of some tumor cells to MVM killing (235).

Negative regulation of p38 has also been observed (109,160), which can be caused by a cellular repressor. Evidence for regulation by RNA processing and protein stability has also been found (251). Another form of regulation that apparently occurs involves attenuation of transcription of the p4 promoter via an RNA polymerase pause site (*att*) between nucleotides 259 and 383. The *att* site contains a sequence that can form a cruciform in the DNA template (216, and refs. therein). Temporal regulation of gene expression has been reported for MVM (61), which is consistent with transactivation of the p38 transcript by the NS1 protein.

Regulation of gene expression is also a major factor in tissue specificity. The parvovirus HI NS2 gene regulates gene expression in a manner dependent on cell type; it does so by virtue of sequences in the 3' untranslated region (175). As noted earlier, a different type of host-range mutant is observed for MVM. Wild-type MVM(p) productively infects murine fibroblasts but not T lymphocytes. A mutant MVM(i) has the reverse phenotype. Both strains are replicated for one round after transfection. The genetic difference is in the middle of the capsid gene and represents several amino changes on the surface of the virion. However, simple binding to the cells is not affected. Thus, the physiologic lesion is somewhere between entry and uncoating (13).

DNA Replication

Like AAV, autonomous parvovirus DNA replication takes place in the nucleus. The location of replication, combined with the fact that the cell is required to go through S phase for replication to occur (227,269,301), suggests a very close relationship between viral and cellular DNA replication. Sequence analysis of the termini of virion and replicative forms of MVM DNA suggests a modified rolling hairpin model for autonomous parvovirus DNA replication (7,272). However, there are some important differences between the model for autonomous parvoviruses and the mechanism described for AAV. Like AAV, the autonomous parvovirus genome has palindromic ends. Unlike AAV, the two ends are not identical in size or primary sequence (9,228). Furthermore, unlike in AAV, only one of the two strands (the minus or noncoding strand) is packaged in most rodent autonomous parvoviruses. This places significant constraints on the model of autonomous parvovirus DNA replication (Fig. 7) as compared with the AAV model described earlier (see Fig. 6). The following is currently the consensus model for rodent autonomous parvovirus DNA replication, and it is drawn primarily from work done with MVM. However, there are still some significant steps that are not clearly supported with experimental evidence, so the model should be considered one example of how MVM might replicate its DNA to generate the species of replicative intermediates and packaged viral DNA that are seen in cell culture.

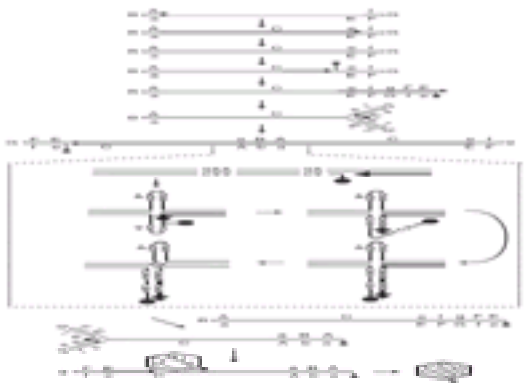

FIG. 7. Model for MVM DNA replication. See text for details. ABa, 3' terminal palindrome of virion strand; FGf, 5' terminal palindrome of virion strand; e, 18- to 26-nucleotide sequence present in replicative intermediates but not in DNA of nuclease-treated virions; V, virion strand; V^{par}, parental virion strand; V^{prog}, progeny virion strand; C, complementary strand; *heavy arrows*, new DNA synthesis; *solid circle*, site of nicks and NS1 covalent attachment in right end and dimer bridge. (The model was developed from the discussion in ref. 78, with permission.)

It is assumed that the 3' terminus (by convention the left end) of the virion strand folds back on itself to serve as the primer to initiate DNA synthesis of the complementary strand (see Fig. 7). When DNA synthesis reaches the hairpinned 5' end, it is believed that a ligation occurs to produce a linear molecule in which both ends are covalently joined—that is, there are no free 5' or 3' ends. Such molecules have been found *in vivo* (69). (They can be thought of as single-stranded dimer circles that have collapsed via base pairing to duplex linear molecules.) The 5' end (by convention the right end) is then nicked at a site that is inboard of the original 5' end of the parental molecule by NS1, which forms a covalent linkage with the 5' end of the nick. This generates a 3' OH that is used to repair the right end to a duplex extended form (see Fig. 7, steps 4 and 5). In the process, the right end undergoes a strand-transfer event, which inverts its sequence and results in the two orientations seen at the right end, flip and flop. Subsequently, the newly repaired extended right end forms a double hairpinned intermediate in which the 3' strand at the right end of the genome serves as a primer for further DNA synthesis (see Fig. 7, steps 6 and 7). Synthesis proceeds through the left end to form a duplex dimer molecule in which the left end (the original 3' end) is now in the form of a linear junction between two copies of the MVM genome that are inverted with respect to each other. The viral right ends, which flank the dimer, can continue to undergo terminal resolution and strand transfer, generating flip and flop orientations. The junction in the middle of the dimer is often called the left-left junction, the dimer bridge, or the 3' junction. Unlike the right end that exists in two orientations (flip and flop), the left end is found in only one orientation, called flip. Thus, a mechanism exists to maintain only one orientation of the left end and to generate only one strand of the viral genome for packaging. This is accomplished by asymmetric nicking at the internal left-left junction in a process called junction resolution (see Fig. 7, steps 8 to 12), which generates 3' termini in only one orientation (7,78). Thus, one of the key replicative species in MVM DNA replication appears to be an obligatory dimer intermediate containing a left end–left end junction. The products of bridge resolution have been shown *in vitro* (71) to be a monomer intermediate that is covalently joined at the left end and a monomer intermediate in which both ends are extended (see Fig. 7, step 13). The latter can undergo DNA replication from the right end (the 5' end) of MVM to generate the minus strand of the virus with the correct orientation at its 3' end (and either orientation at its 5' end) for packaging into mature virions. (This process could be repeated multiple times.) The former intermediate can also undergo DNA replication from its right end to regenerate a dimer intermediate with a left end–left end bridge.

The details of this model have not been completely settled but several lines of evidence support the keys steps outlined. Concatemers of dimer and tetramer length, as well as molecules covalently closed at both ends, have been detected in parvovirus-infected cells (69,270) as predicted by the model. Additionally, the expected bias toward left-left bridges has been seen *in vivo* (278). Biochemical characterization of NS1 also supports the model. In addition to having endonuclease activity, NS1, like the AAV Rep protein, is a DNA helicase and an ATPase (57,297). Whenever NS1 nicks, it forms a covalent linkage with the 5' end of the cut (12,74). Linkage is through a tyrosine residue at amino acid 210 of NS1 (204), which is part of the RCR motif (136). NS1 cuts the 5' (right end) at a position some 18 bases upstream of the sequence that is found in viral DNA (7), and it remains attached to the DNA during packaging. Mature MVM virus particles initially contain NS1 still attached to the DNA on the outside of the viral capsid (75). The protein is subsequently removed along with some of the 5'-end DNA, by nucleases in the culture medium or during cell entry. Recovery of the 18 bases missing from the right end presumably occurs when NS1 nicks the initial RF form (12,69), which is made *in vivo* and is covalently closed at both ends.

In vitro DNA replication studies using viral single-stranded DNA (or duplex RF) and cell-free crude extracts supplemented with purified NS1, have also confirmed key elements of the model (12,296). First, there is an apparent preference for formation of the linear duplex covalently closed at both ends from viral DNA, which is apparently the first RF intermediate made (12). Second, the left end is relatively insensitive to NS1 resolution when it is in the hairpin configuration (12); NS1 cuts the left end only when it is in the linear dimer bridge form. This is important because it accounts for why only one orientation of the left end (flip) is seen. Third, NS1 helicase activity is apparently responsible for unwinding and refolding the linear extended right end into the double hairpin that is used for initiation of DNA replication at several steps in the model (296). Unwinding is ATP dependent and NS1 mutants that have mutations in the canonical ATP binding site are inactive for the refolding reaction. Additionally, the TR isomerization occurs more efficiently at the right extended TR than at the left end in the extended configuration (12). This means that initiation of strand-displacement DNA synthesis is initiated preferentially at right ends. Coupled with the absence of left-end hairpin resolution, this would explain the preferential formation of dimer molecules with left-end bridges and the predominant synthesis of only minus strands.

Resolution of left-left and right-right end junctions also has been demonstrated *in vitro* and *in vivo* using plasmids that contain these junctions. In both cases nicking requires MVM NS1 protein and NS1 becomes covalently attached to the 5' end of the nick (70,71,76,77,177). Resolution of the left-left dimer bridge *in vitro* and *in vivo* is asymmetric as predicted, producing predominantly extended forms from one arm of the bridge and predominantly hairpinned (also called

turn-around) forms from the other arm (71,76). Precisely how one of the products winds up having a covalently closed end is still not clear. The model illustrated in Figure 7 is just one possible mechanism. Cleavage of the right-right junctions, on the other hand, produces predominantly extended structures in both the flip and flop orientations with covalently associated copies of NS1 (70,76). NS1 also cuts the right end hairpin conformation, which results primarily in extended forms both *in vivo* and *in vitro* (12), again as predicted by the model.

An implication of the model for MVM DNA replication is that NS1 must be able to cut two dissimilar sequences in the right-end hairpin and the left-left dimer bridge. This has been confirmed *in vitro* and the sequences required for nicking at the right and left ends have been identified. The left end in the hairpin configuration contains a bubble in the stem (see Fig. 2), in which the inboard arm contains a GAA sequence and the outboard arm contains a GA doublet directly opposite the GAA. When these are replicated to form the dimer bridge, one arm of the duplex bridge contains the doublet GA/TC (usually called the TC arm) and the other contains the triplet. NS1 nicks only the arm with the doublet TC sequence *in vitro* when the substrate is a plasmid containing the MVM dimer bridge and the reaction is supplemented with a crude cell-free extract (see Fig. 2) (77). Purified NS1 binds the sequence $(ACCA)_{2\text{-}3}$ (66), which is present on both sides of the center of symmetry of the 3' (left end) dimer bridge, but neither the GAA nor the TC side is cut (204), suggesting that a cellular protein is needed to activate NS1 nicking. Christensen et al. (54,55 and 56) have recently purified the cellular factor and called it parvovirus initiation factor (PIF). In the presence of purified PIF, NS1 cleaves the GA/TC side of the dimer bridge. Although the position of the nick has been mapped (77), it is not yet clear whether a specific sequence at the site of the nick is recognized as in the case of AAV.

PIF is a heterodimer composed of related 96- and 79-kd polypeptides (56); it binds coordinately to two ACGT motifs (see Fig. 2) that overlap the ATF site just upstream of the NS1 binding site (55). The PIF subunits (p96 and p79) have recently been cloned (56), and PIF has been identified as a member of a family of transcription factors that contain the KDWK amino acid motif. Its role in transcription of MVM is not clear, but it appears to be another example of how a virus can recruit a cellular transcription factor to promote the synthesis of DNA. Together, PIF and NS1 protect virtually all of the minimal origin sequence (50 bp) required for NS1 nicking of the dimer bridge, and they meet at the position of the TC dinucleotide (55). The actual sequence of the TC dinucleotide is not essential but the spacing is, because insertion of any third nucleotide (as on the GAA side of the bridge) abolishes nicking and subsequent DNA synthesis (77). In the case of MVM, the NS1 binding site (ACCA) occurs many times in the MVM genome. Thus, some mechanism must confine NS1 nicking to the right hairpin and the left-end dimer bridge, and prevent nicking within the 3' hairpin or at other locations within the MVM genome. PIF (and the spacing between the PIF site and the NS1 site) apparently serves this function by stimulating nicking on only one side, the TC side, of the 3' bridge. Presumably, the same mechanism inhibits nicking of the same 3' origin sequence when it is in the hairpin configuration.

Cotmore et al. (67,79) have identified the sequences and cellular protein required for nicking at the right (5') end of MVM (see Fig. 2). In this case, NS1 must nick and resolve a covalently closed hairpinned species to continue DNA synthesis. The cellular cofactor required to activate NS1 in an *in vitro* reaction is either HMG1 or HMG2 (HMG1/2) (79). In the absence of either protein, NS1 does not nick the hairpin. HMG1/2 preferentially binds bent DNA, cruciform DNA, or four-way junctions (i.e., Holliday intermediates). Three sequence elements are essential for nicking the 5' hairpin (see Fig. 2): (a) an NS1 binding site at the very end of the hairpinned 5' end, just beyond the AGA bubble, (b) an NS1 binding site near the nick site, approximately 110 bp upstream of the first NS1 site, and (c) a specific sequence at the nick site just inboard of the second NS1 site (67). In the presence of HMG protein, the NS1 sites appear to form a higher-order nucleoprotein complex, in which the intervening sequence is distorted in a way that suggests the formation of a double helical loop. Thus, NS1 carries out a similar reaction at the left-left dimer junction and the hairpinned right end, two distinct sequences, by interacting with two different cellular proteins.

Although the two NS1 sites and the nicking site appear to be the essential sequences required for endonuclease activity in the right hairpin, Costello et al. (64) showed that *in vivo* the presence of the unpaired AGA triplet within the left hairpin was important for efficient DNA replication. Absence of the bubble significantly reduced replication of the mutant MVM genome, but replacement of the bubble with a different sequence restored DNA replication, suggesting that the sequence of the bubble was not important but the actual presence of unpaired bases was. Additionally, in both 3' dimer bridge nicking and 5' hairpin nicking, ATP is required for the reaction to proceed. This may simply reflect the fact that NS1 binding requires ATP, unlike AAV Rep. Alternatively, it may mean that the DNA helicase activity of MVM must modify the DNA substrate prior to nicking. The nature of the modification, however, is not clear. In the 5' hairpin, a potential cruciform structure could form that would include the NS1 site at the tip of the hairpin. Mutation analysis of this cruciform structure, as well as the companion NS1 site that is present just inboard of the right end hairpin (not shown in Fig. 2), indicated that neither was essential for nicking the 5' hairpin (67).

In addition to the sequences within the 5' palindrome, two other sequences at the right end of the genome but inboard of the palindrome have been shown to have an effect on DNA replication. One of these is a 65-bp repeat between nucleotides (nts) 4,760 and 4,850 of MVM, each of which contains multiple copies of a CC(C/A) repeat (243). Deletion of this sequence reduces DNA replication in some cell lines by as much as 100-fold, and a similar sequence has been mapped in H1. The second sequence is located between nts 4,489 and 4,695 (37). This region has been referred to as an internal replication sequence (IRS). Mutation of this region has identified two sequence blocks that reduce DNA replication about fivefold, and several cellular proteins that bind specifically to this region of the genome have been detected. It is not clear what role these internal sequences play in DNA replication, but some groups have suggested that they may act as internal origins that initiate DNA replication via a cellular primase (37, and refs. therein). Initiation of DNA replication close to the 5' end has been postulated to be a possible alternative mechanism for unwinding and refolding the right-end palindromic sequence, a step that is normally energetically unfavorable (37).

Christensen et al. (54) have identified some of the other cellular factors that are required *in vitro* for replication when a 3' dimer bridge origin is used. In addition to PIF, DNA synthesis required PCNA, RPA (the cellular single-strand DBP), and a partially purified fraction that contains DNA polymerases. PCNA is an accessory protein for DNA polymerases d and e, suggesting that one of these two polymerases is involved in MVM DNA replication. *In vitro* studies using purified DNA polymerases or polymerase inhibitors have not definitively identified the cellular DNA polymerase used *in vivo*, but they do show that the viral single-stranded DNA can be converted into a double-stranded RF *in vitro* using a variety of DNA

polymerases (73).

Any model of DNA replication must be able to account for the particular features found in mature virion DNA, as well as for intracellular structures (73). In particular, the model in Figure 7 is somewhat more complex than that illustrated earlier for AAV, because the rodent parvoviruses, which have been studied in most detail, have terminal sequence arrangements in which the 5' terminal sequence of the virion is inverted during replication but the 3' terminal sequence is not. Additionally, the rodent viruses tend to package only one of the two strands. There are some exceptions to these features among the other autonomous parvoviruses, and presumably this means that alternative mechanisms for parvovirus DNA replication will be uncovered. BPV DNA, for example, shows evidence that both terminal sequences are inverted during replication, although the majority of the virion strands have the 3'-terminal sequence in the same orientation (255). An additional complexity of replication is the generation of variant genomes similar to those seen with AAV (73). The first represents internal deletions of varying extents, and the second is a duplex hairpin molecule representing segments from either the left or the right end of the molecule. Virions containing the incomplete genomes can function as DI particles.

Protein Synthesis

Synthesis of the NS proteins appears to occur first, because the NS protein transcripts appear earlier in the course of infection than the transcripts for the structural proteins, and because one or both of the NS proteins regulate gene expression (91,175,231). Both NS1 and NS2 are phosphorylated subsequent to translation (73). NS1 binds poorly to its recognition site, but binding can be detected in the presence of ATP (53). Binding, ATPase, and DNA helicase activity are modulated by phosphorylation of NS1 (89,203,205). Phosphorylation is on serine and threonine residues by the lambda isoform of protein kinase C and possibly other PKC family members. Dephosphorylated protein has lower nickase and helicase activity but enhanced binding activity, and it retains its ability to regulate transcription. Thus, the phosphorylation state of the NS1 protein seems to determine whether it will be used for transcriptional control or DNA replication. The ATPase binding site and several helicase motifs have been mapped with specific mutations (142), as has a metal coordination site (204). NS1 self-associates prior to nuclear localization (206), and at least one interaction domain has been mapped between amino acids 261 and 280 (220). MVM NS2 is required for efficient virus growth in a host-range-dependent manner. Although not required in hamster, transformed rat, monkey, or human cell lines, it is essential for growth in mouse cell lines and in the whole animal (36,44,198,199). An earlier report suggested that NS2 is required for efficient translation of MVM mRNA (199), but subsequent studies suggested that it was more likely to be involved in particle assembly (68). NS2 also has been shown to interact with 14-3-3 proteins and CRM1 (26,33,207).

The capsid proteins are thought to be acetylated at the N termini (143). VP2 has also been reported to be phosphorylated (250). Synthesis of coat proteins is marked by two unusual phenomena. The first is that the major coat protein, VP2, is proteolytically cleaved to produce VP3 during entry into the cell, and it can be cleaved *in vitro*, but only in the context of full virions (271). The ratio of VP2 to VP3 depends on the time course of the infection. The second is that, as in the case of the AAV capsid proteins VP2 and VP3, the initiator AUG for MVM VP1 is several hundred bases (the whole of the NS2 second exon) downstream from the cap site. The AUG codon for VP2 is another several hundred nucleotides farther downstream. The reason for this is not clear. When expressed in insect cells, the coat proteins can self-assemble to form particles (34,60,146). In the case of B19, the unique region of VP1 (the N terminus) appears to project from the surface of the particle (238).

Oncolysis

Autonomous parvoviruses are normally species restricted. However, transformation of nonpermissive cells, including human cells, with a variety of viral and cellular oncogenes or chemical carcinogens can render the cells permissive for productive infection by rodent parvoviruses such as MVM (reviewed in refs. 234 and 235). In cell culture experiments, infection of transformed cells with MVM or H1 leads to lytic death of the culture; in animal experiments, infection of tumor cells inhibits tumor formation or progression and leads to improved animal survival. A variety of experiments have led to the conclusion that the cytotoxic effect of MVM (or H1) on tumor cells is the result of expression of NS1. Notably, Mousset et al. (195) isolated a Fisher rat fibroblast cell line (FR3T3) that expressed NS1 under the control of an inducible mouse mammary tumor virus (MMTV) promoter. When NS1 was induced in this cell line, no cell death was seen. However, when the same cell was transformed with c-Ha-*ras* or the polyoma oncogenes, the cells died within a few days after induction of NS1. Many but not all oncogenes produced similar NS-induced cytotoxicity. For example, in one study (242), FR3T3 cells transformed with SV40, v-*myc*, and v-*src* were susceptible to MVM killing, but cells transformed by BPV1 were not. If the BPV-transformed cells were supertransformed with Ha-*ras*, they became susceptible to the MVM cytotoxic effect. Although NS1 expression appears to be sufficient for tumor cell killing, NS2 expression had a synergistic effect in some cell types (30).

NS1 expression in nontransformed and transformed cells leads to cell accumulation in the G2 phase of the cell cycle, suggesting that at least part of the cytotoxic phenotype has to do with alteration of the cell cycle (208), but the essential trigger for tumor cell killing is not yet clear. In this respect, Rayet et al. (224) have recently shown that H1 infection of human U937 tumor cells downregulates c-*myc* and activates the CPP322 ICE-like protease (believed to be involved in apoptosis). This is similar to what happens when these cells undergo killing due to tumor necrosis factor (TNF)-a, and it suggests that the TNF pathway may be one of the signaling pathways involved in tumor cell cytotoxicity. It is worth noting that the oncosuppressive effect of parvovirus infection is potentially of clinical value. For example, Faisst et al. (100) have demonstrated that mice with severe combined immunodeficiency disease (SCID), injected with human tumor cells and then infected with H1, showed a dose-dependent regression of the tumors.

SUMMARY AND CONCLUSION

In terms of physical structure, genetic map, autoregulation, and close dependence on the state of the intracellular milieu, the autonomous parvoviruses are closely related to the dependoviruses. There are significant stretches of homology at the amino acid sequence level in both structural and NS proteins of viruses of both genera, and the details of the

biochemical reactions involved in DNA synthesis illustrate how the same RCR reaction can be modified to produce quite different overall outcomes. This produces a continuous spectrum of properties among the viruses of both genera—for example, LuIII and BPV encapsidate both strands, the 3' terminal palindrome of the BPV shows evidence of inversion during replication, and B19 contains TRs. However, there remain several major differences at the biologic level. It seems certain that latent infection plays a major role in the replication cycle of AAV, whereas this is not the case with the autonomous parvoviruses. They do frequently cause cryptic infections, and perhaps these are the biologic equivalent of the AAV latent infection. Another major difference, of course, is that all of the autonomous viruses are serious pathogens in their normal hosts, whereas AAV has yet to be associated with disease. The key difference between the genera seems to be that autonomous viruses simply wait for the cell to enter S phase, relying entirely on their ability to infect dividing cells or tumor cells. In contrast, AAV relies on a helper virus, which can induce S phase in a variety of terminally differentiated, nondividing cells, to expand its host range; but this comes at a price—the helper virus is not always available.

CHAPTER 70 Parvoviruses

Marshall E. Bloom and Neal S. Young

As a subject of study, parvoviruses appeal to diverse groups. Parvoviruses interest veterinarians because they are responsible for many serious diseases in animals. Some parvovirus infections, like feline panleukopenia and Aleutian mink disease, are models of human illness. Microbiologists have been concerned with parvoviruses as contaminants of cell culture; later, molecular biologists studied them intensively because their simple genomes make them attractive for the dissection of gene expression and regulation. B19, the first pathogenic human parvovirus, has entered the medical curriculum as an agent of human disease, and the adeno-associated viruses (AAVs) have become attractive vehicles for therapeutic gene delivery.

This chapter primarily describes pathogenesis and medical aspects of parvovirus B19. AAV is briefly described because of its potential in gene therapy. The viruses described in this chapter are members of the subfamily *Parvovirinae* of the family *Parvoviridae* (25,26). B19 and the related simian parvoviruses are placed in the genus *Erythrovirus,* whereas all other presently characterized autonomous parvoviruses are in the *Parvovirus* genus (type species, minute virus of mice [MVM]). The defective AAVs are classified in the *Dependovirus* genus. The chapter begins with an abbreviated survey of the autonomous animal parvoviruses because these agents and the diseases that they cause are common and provide insight into B19 infections. Chapter 69 should be consulted for the molecular biology of the *Parvoviridae.* A number of excellent review articles and monographs have dealt with parvoviruses, and these sources are cited liberally throughout the chapter.

HISTORY OF PARVOVIRUSES

In the first part of the 20th century, there were numerous epidemics of enteritis, panleukopenia, and congenital cerebellar ataxia in feline populations (195,196). In 1947, a similar syndrome of enteritis suddenly appeared in ranch mink, and by 1952, it was concluded that the same hardy viral agent caused disease in both species (234). In 1959, a small hemagglutinating stable virus was inadvertently recovered from rat tumor lysates and named *rat virus* (RV) (109). At about the same time, another virus with similar characteristics, denoted *H-1,* was shown to cause a complex syndrome of craniofacial anomalies in newborn hamsters (218). By the mid-1960s, investigators had determined that feline panleukopenia virus (FPV), mink enteritis virus, H-1, and RV were all members of the same family of small, nonenveloped viruses with single-stranded DNA genomes. Defective parvoviruses were first recognized as common contaminants of adenovirus stocks in the mid-1960s and named AAV (15,25,99) because replication required co-infection with an adenovirus (27,28 and 29). The generic designation, parvovirus (*parvus* means small) was proposed in 1965 (25,127) and formally accepted in 1970 (14).

Subsequently, parvoviruses have been associated with a broad array of diseases in animals (25,75,196). In addition, persistent and inapparent infections of animals and cell cultures were also described, indicating that parvovirus infection was not inextricably linked to overt disease (196). In the late 1970s, a new syndrome of viral enteritis and myocarditis in puppies and dogs swept rapidly across the world. The virus was named *canine parvovirus* (CPV) and was closely related to FPV and mink enteritis virus (221,222). The rapid spread of CPV was enhanced by the remarkable physical stability of parvoviruses (25,177). In 1980, another parvovirus was shown to be the cause of a chronic immune complex disease in mink known as *Aleutian disease* (37,38). Finally, in the early 1980s, a human parvovirus, B19, was found to cause several disease states, including fifth disease, polyarthropathy, transient aplastic anemia, and erythroblastosis fetalis.

In 1984, a parvovirus, RA-1, was isolated from mice neonatally infected with samples from rheumatoid arthritis patients (198,208). The mice developed a syndrome of spinal and skeletal deformities. No additional work has been reported on RA-1, and the genomic sequence, true provenance, and nature of this agent remain unclear. In addition, a newly described human DNA virus with a single-stranded genome (TTV) appears to *not* be a parvovirus (159,197). This makes B19 the only parvovirus known to cause clinical disease in humans.

GENERAL FEATURES OF AUTONOMOUS PARVOVIRUS INFECTIONS

Several principles provide a basis for understanding the pathogenesis of parvoviral infections and diseases

(25,75,195,196). First, the autonomous parvoviruses have a near-absolute requirement for rapidly dividing cell populations in S phase of the cell cycle (25,75,161). This principle does not generally apply to AAV infections because the co-infecting helper viruses circumvent the dependence for replication upon the cell cycle (27,28). Second, identifying targets for virus infection can often explain the precise pathogenesis (170). For example, targeting of the developing cerebellum by FPV leads to congenital ataxia (195). Third, short segments of viral genes, usually in the capsid coding sequences, govern the host range or pathogenicity of parvoviruses (17,36,58,75,220,221). In addition, parvovirus infections are often persistent and in some cases asymptomatic (100,195). In this section, several parvovirus systems are used as abbreviated examples of these principles. This is not a comprehensive recitation, and many viruses are not mentioned but are dealt with elsewhere (25,75,100,162,170,195,196,222).

The preference for rapidly dividing cell populations as targets for viral replication suggests that fetal and newborn animals would be highly susceptible after transplacental infection. Several parvoviruses are responsible for fetal wastage, including porcine parvovirus (PPV) (101,132,162,196) (Fig. 1**A**), bovine parvovirus (196,209), H-1 parvovirus (196), goose parvovirus (45,196), parvovirus B19 (57) (see Fig. 1**B**), and ADV (41).

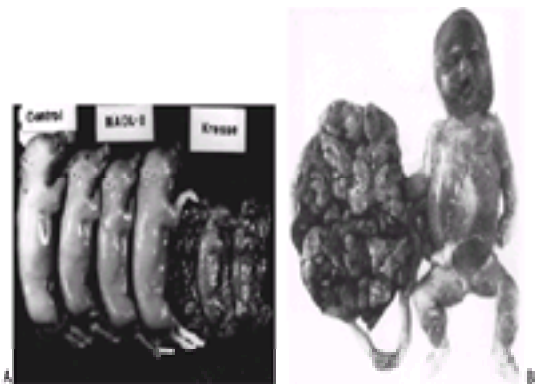

FIG. 1. A: Fetal loss in pigs. Animals were inoculated *in utero* with two strains of porcine parvovirus, including the virulent Kresse strain; shown here are dead and mummified 23-day fetuses. (Photograph courtesy of Tom Molitor.) **B:** Human hydropic fetus and placenta after intrauterine parvovirus B19 infection. (From ref. 57, with permission.).

Some infections in late gestation or the immediate newborn period are not fatal but lead to severe sequelae. Rodent parvoviruses and FPV induce a congenital cerebellar ataxia by lytically targeting cells in the differentiating cerebellum (195,218). The destruction of the developing cerebellum may be mediated by virus-induced apoptosis (157). Another example is the development of craniofacial and dental deformities in hamsters infected either *in utero* or in the early postnatal period by rodent parvoviruses (195,196,218). This syndrome results because the cell populations susceptible to virus replication are found in developing osteogenic tissue (185). A fatal perinatal myocarditis results from CPV infection *in utero* or in very young puppies (170). In contrast, a strain of MVM infects renal vascular endothelial cells and lymphocytes in baby mice (100). Finally, newborn mink infected with ADV develop a severe, often fatal, respiratory distress syndrome subsequent to permissive infection of the type 2 alveolar pneumocytes, which proliferate in the newborn period (6,37). It is apparent that the disease patterns are diverse; however, because the organs and cell types mentioned divide rapidly only in developing animals, the same viruses do not usually target the same tissues in adult animals.

Parvoviral diseases in older animals fall into two categories: those due to direct effects of acute virus infection on replicating target tissues, and those due to the subsequent immune response. In the acute category (reviewed in 25,37,75,170,195, and 196) are (a) enteritis induced in a number of species, but probably best known in CPV-infected dogs; (b) panleukopenia in cats (FPV), swine (PPV), and bovines; (c) hepatitis in hamsters and geese, and (d) erythrocyte aplasia in humans (B19). The pathogenesis of these diseases directly reflects the target organ in which virus replicates and is often different from that induced by the same virus during early development.

Although a detailed description of the immunologic features of parvovirus infections is beyond the scope of this chapter, several points are relevant to discussion of B19. Vaccination is very effective against the CPV-FPV family (170); however, other parvoviruses, including ADV, can persist in the face of robust immune responses (37,100,196). Several disorders result from the host response to infection (37,63,195,196,216). The most dramatic of these is probably the chronic immune complex disorder caused by persistent infection by ADV, which is worsened by vaccination (1,37). Another example is the ability of certain PPV isolates to induce immunologically mediated vesicular skin lesions in late-gestation swine fetuses (24,61,117). In addition, the immune response is responsible for fifth disease and the polyarthropathy caused by B19 infection (235).

Studies from a number of autonomous parvovirus systems, including MVM, CPV-FPV, PPV, and ADV, indicate significant differences in host range and pathogenicity among closely related strains or isolates (17,36,58,75,100,158,162,195,216,220,221 and 222). Because the structures for several parvoviruses have been solved (3,5,58,130,223), it has been possible to map the sequences controlling these aspects of viral biology to specific regions on the viral capsids (Fig. 2). The viral sequences governing pathogenicity map primarily to the capsid proteins, and structural studies model the determinants onto the surface of the capsid near the threefold axis of symmetry (3,5,36,58,130). The same general region of the capsid is also involved in mediating the pronounced differences in host range among members of the CPV-FPV family and MVM (3,58,222). Although the capsid genes appear to be the major viral determinants of host range and pathogenicity, nonstructural gene products also play a role in some systems (54,147,226).

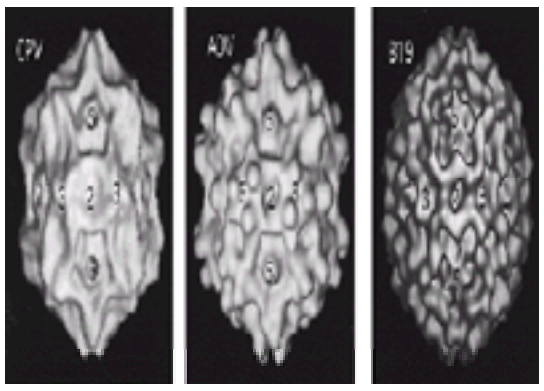

FIG. 2. Comparison of three autonomous parvoviruses: reconstructed images of Aleutian mink disease parvovirus (*ADV,* 22 Å), canine parvovirus (*CPV,* 22 Å), and parvovirus B19 (*B19,* 26 Å). These three viruses produce very different diseases in their hosts. Although the threefold (*3*), fivefold (*5*) and twofold (*2*) axes of symmetry are readily apparent, differences in the surface topography are evident. Surface regions related to host range, pathogenicity, antigenicity, and receptor binding are located near the threefold axes. (Adapted from refs. 5,130, and 223, with permission.).

Viral persistence is another facet of many autonomous parvoviruses infections both in cell cultures and in animal hosts. The mechanisms involved remain undefined (25,100,188,196) but may involve restricted infection (37). The defective AAVs persist by integrating into the cellular genome (28), but there is no evidence that autonomous parvoviruses use this strategy for persistence.

The animal models described in this section should be kept in mind when reading about B19. Many features of B19 infections have definite parallels in the animal models.

PARVOVIRUS B19

History

In the mid-1970s, Yvonne Cossart, a virologist working in London, was investigating assays for hepatitis B virus (73). When material from false-positive reactions was examined in the electron microscope, parvovirus-like particles were seen (Fig. 3). The name B19 derives from the blood bank code of a viremic donor.

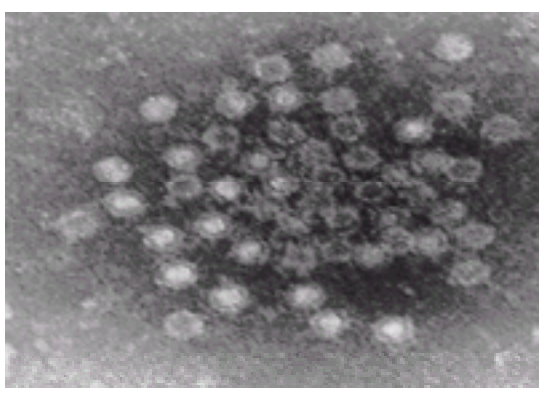

FIG. 3. Electron micrograph of Aleutian mink disease parvovirus (*ADV*) capsids immune-complexed with antiviral antibody. The antibody molecules can be observed bridging and aggregating the 25-nm virions. Images like this provided Yvonne Cossart the initial clues to the presence of B19 parvovirus particles in sera.

The infection was initially thought to be asymptomatic (73), and 30% of normal adults (70,194) were found to have antibody, suggesting common exposure in childhood. However, a 1981 survey of sera archived at University Hospital in London identified antigenemia or seroconversion in children with sickle cell anemia suffering from transient aplastic crisis (TAC) (171,194), suggesting an etiologic role for B19 in an acute disease of presumed infectious origin. Two years later, parvovirus B19 infection was implicated in an outbreak of fifth disease in London (11), linking the virus to a common childhood exanthem. In 1984, parvovirus B19 was found in a hydropic infant (13), and the known propensity of parvoviruses to cause fetal wastage led to the association of B19 infection with hydrops fetalis (57,95). The spectrum of B19-associated diseases was expanded when persistent infection with parvovirus B19 was diagnosed in an anemic, immunosuppressed patient (122). These findings clearly implicated B19 as the cause of a number of important human medical problems.

The amount of virus present in acute-phase sera allowed characterization of the virus as a proper member of the *Parvoviridae* family (64,212). In the mid-1980s, the genome was cloned and sequenced (73,192), and virus was cultivated *in vitro* in human bone marrow cells (166). Human erythroid progenitors remain the most convenient productive culture system, and the molecular biology and infectious cycle have been described in these cells. Expression of parvovirus B19 capsid proteins using recombinant technology has been useful for development of clinical assays for specific antibody (103) and as a human vaccine reagent (18,134).

In the early 1990s, an outbreak of severe anemia in cynomolgus monkeys was found to be due to infection with a simian

parvovirus (154). This was the first description of a B19-like virus in nonhumans and led to the present animal model.

Infectious Agent

As noted earlier and in Chapter 69, the autonomously replicating parvovirus B19 is classified in the *Erythrovirus* genus, of which it is the type species (26). The genus name connotes the tightly restricted host range for cells of the erythroid series. Parvovirus B19 shares genetic features with both autonomous and defective parvoviruses. The closest relatives to parvovirus B19 are parvoviruses of cynomolgus monkeys (44,154,156), rhesus monkeys (52), and pig-tailed macaques (52). All of these are about 60% to 80% homologous to B19, and the simian parvovirus has a cellular host range and biology similar to B19 (44,156). A new parvovirus was recently isolated from the sera of healthy Manchurian chipmunks (240). The chipmunk agent is about 50% homologous to parvovirus B19. This may be the first nonprimate erythrovirus to be described, but firm ranking must await confirmation of its genomic organization, biology, and host range.

Despite the characterization of many isolates of B19, little variation in B19 has been identified. The two prototype B19 isolates, Au and Wi, differ by only 41 bases (51). The sequence divergence is generally less than 1%, with even less variation in regions corresponding to epitopes (80). In a Japanese study, viruses were isolated at two different times separated by 5 years (224). The sequence of the predominant genome differed slightly at the two times, but there was no evidence of geographically restricted distribution of viral genotypes (224). Although various isolates can be divided into groups based on restriction enzyme digestion, there is no obvious correlation with disease patterns. However, observations from other parvovirus systems indicate that host range and pathogenicity can be governed by minor sequence variation (17,36,220); hence, this issue presently remains open.

Cell Culture Systems

Parvovirus B19 has a pronounced tropism for human erythroid cells *in vitro.* Cultures of human bone marrow (167,206), peripheral blood (186), fetal liver (238), and a few leukemic cell lines (144,193) have been used to reproduce the effects of the virus on natural target cells and to determine functional correlates of virus structure (Fig. 4). Permissive viral replication occurs at high levels only in erythroid progenitor cells (166), and replicative form DNA can be detected in the bone marrow of infected patients (118,121,122). Erythroid colony formation by the late erythroid progenitor cell (erythroid colony forming unit, and the more primitive erythroid burst-forming unit) is strongly inhibited by infection, and susceptibility of marrow cells increases with erythroid differentiation (214). B19 can also replicate in cynomolgus monkey bone marrow cells (86). In all culture systems, productive virus propagation is dependent on the presence of erythropoietin (193), suggesting that cell susceptibility is related to the sustained effects of erythropoietin on erythroid differentiation. The immunophenotype of infected cells is typical of the normoblast or pronormoblast (140,141). Myelopoiesis, formation by the granulocyte-macrophage colony forming unit, is unaffected even by high concentrations of virus *in vitro* (142,206).

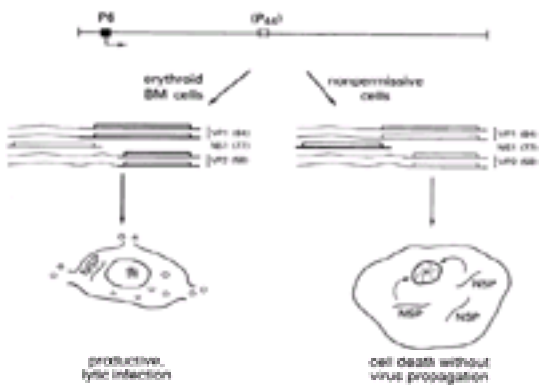

FIG. 4. Schema showing two routes to cell death after parvovirus B19 infection. Permissive cells allow full-length transcription of both the nonstructural and the capsid gene RNAs. Capsid RNAs are the predominant RNA species in erythroid cells. Nonpermissive cells have a functional RNA-processing block in the middle of the genome that results in relative overexpression of nonstructural protein RNA and cell death without viral propagation.

Interestingly, a “block” to replication in nonpermissive cells is a consequence of aberrant transcription (116,126) (see Fig. 4), leading to the messenger RNA (mRNA) for NS1 being the most abundant species (126). This is in contrast to permissive infections, in which the capsid protein mRNA predominates (165). Limited expression of NS1 in the absence of detectable DNA replication can suppress megakaryocytopoiesis and inhibit hematopoietic colony formation by both simian and human parvoviruses (85,86,205). Predominant expression of NS1 could explain virus-induced inhibition of megakaryocytic progenitor proliferation *in vitro* and reduction of platelets and white blood cell numbers in patients, even in the absence of productive viral infection.

The cytotoxicity induced by B19 is the result of expression of NS1 (165) and may reflect NS1-induced apoptosis (125,139) (see Fig. 4). Cotransfection of the *NS1* gene and a selectable gene into certain nonpermissive cells abrogates colony formation by these cells (164), whereas expression of the capsid protein genes alone has no effect on cell proliferation (105). It remains to be determined whether B19 cytotoxicity results solely from *NS1* expression.

Pathogenesis and Pathology

Human Infection

Experimental parvovirus B19 infection is an acute, biphasic illness and is similar to natural infection (10,174) (Fig. 5).

After intranasal inoculation of volunteers, virus can first be detected in serum at days 5 and 6, and levels peak at days 8 and 9. Viremia is accompanied by nonspecific, influenza-like symptoms, including fever, malaise, and myalgia. Red-cell aplasia coincides with viremia, leading to a drop in hemoglobin, reticulocytopenia, and modest lymphopenia and neutropenia. Patients with transient aplastic crisis develop symptoms early in the course of infection, when 10^{8} to 10^{14} genome copies per milliliter of virus DNA may circulate (12,65). Appearance of specific immunoglobulin M (IgM) and IgG antibodies 10 to 14 days after inoculation is accompanied by classic fifth disease symptoms; in volunteers, both a generalized erythematous eruption and joint inflammation occur. The clinical manifestations of fifth disease are coincident with the development circulating immune complex formation (10,87), and patients therefore present to medical attention after the peak of viremia. Administration of commercial immunoglobulin preparations to patients with persistent B19 infection produces classic fifth disease symptoms (118,122) strongly suggesting that immune complex formation and deposition play a prominent role in fifth disease.

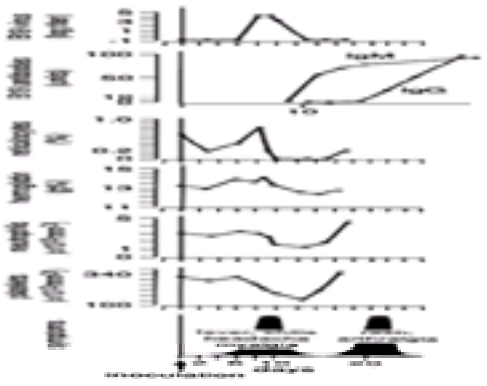

FIG. 5. Course of human parvovirus infection in normal volunteers. (Adapted from ref. 10, with permission.).

In infected volunteers, B19 is found in the nasopharynx, and the major route of transmission is probably through the upper airway (10). There is little evidence of virus excretion in feces or urine (10), but fomites may also be common source of infection, owing to the hardiness of parvoviruses (177). Infection can also be acquired from contaminated blood products (51,143).

Because parvovirus B19 has an extreme tropism for erythroid progenitor cells *in vitro,* by extrapolation, the major site of viral replication in patients has been assumed to be the adult marrow and the fetal liver, the site of erythropoiesis during development. As expected with the intense viremia, B19 DNA may be detected in any tissue perfused by blood, but replication in adults has been documented only in marrow cells (118,121,122).

Consistent pathologic changes have been confined to hematopoietic tissues: giant pronormoblasts in bone marrow aspirates (84,120,122) and fetal liver tissue sections (7,57), accompanied by depletion of later erythroid precursor cells. Erythroid precursor cells infected with parvovirus B19 are readily identified as giant pronormoblasts (84,120,122) by characteristic light microscopic (167) (Fig. 6) and electron microscopic (243) (Fig. 7) morphologic changes. The presence of these abnormal cells in the bone marrow of patients with transient aplastic crisis has been recognized since 1948 (163), and the morphology can be reproduced in culture (167). Less frequently, dysplastic changes in myeloid and megakaryocytic cells are observed.

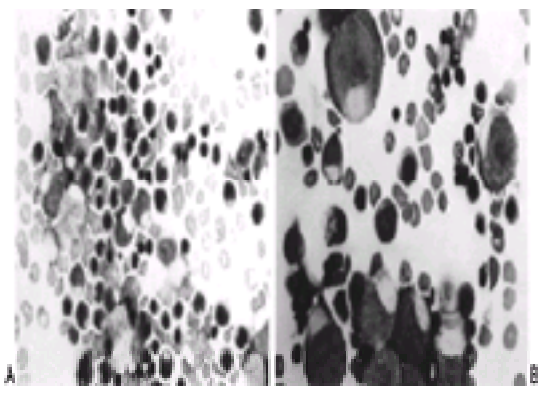

FIG. 6. Cytopathic giant pronormoblasts in normal bone marrow cultured for 48 hours after inoculation with parvovirus B19.

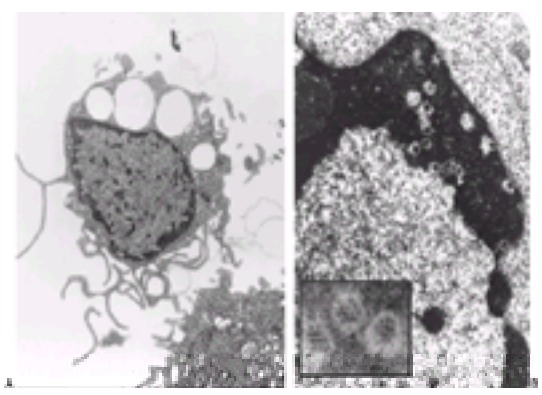

FIG. 7. Ultrastructure of parvovirus-infected human erythroid progenitor cells. **A:** Cell showing pseudopod formation, vacuolization, and margination of nuclear chromatin. **B:** On higher power, crystalline arrays of viral particles (*inset*) are present in lacunae with the marginated chromatin.

That B19 is likely transmitted through the nasopharynx (10,174), together with the fact the virus can be transmitted vertically from mother to fetus, suggests that nonerythroid cells may also be targets for B19 replication. For example, fetal cardiac myocytes can be infected (151,173), and B19 DNA and antigen have been demonstrated in skin biopsies (153,187). Some of these cell types may bear the parvovirus B19 receptor (42). Other nonerythroid cells might also be infected by means of uncharacterized receptors. In addition, virus contained in immune complexes might be able to infect Fc receptor–bearing immune cells (macrophages) through an antibody-dependent enhancement of infection (79,106). This mechanism would allow B19 to infect cells involved in regulating immune reactions (37,106). B19 gene products can induce the cytokine interleukin-6 in some cells (136,213), and cytokines might play a role in the immunopathogenesis of some B19 syndromes (fifth disease, polyarthropathy) (37).

Animal Models

A simian parvovirus (erythrovirus) was identified in a cynomolgus monkey colony (154). Severe chronic anemia and persistent simian parvovirus infection were occurring in monkeys immunosuppressed by an active concurrent infection with the type D simian retrovirus (52,120,152). This clinical picture was similar to persistent B19 infection in humans. About 50% of animals in the colony had serologic evidence of prior infection (52); similar viruses have also been identified in rhesus monkeys and pig-tailed macaques (52). Studies of natural and experimental infections of healthy cynomolgus monkeys indicate that simian parvovirus causes an acute disease remarkably similar to that seen in humans (47,155). The clinical symptoms range from inapparent to very mild; however, the obvious arthropathy seen in humans has not been noted (155,156). Monkeys would seem an ideal model to study B19 infections, however, lack of susceptible cell lines and expenses associated with primate work limit their usefulness. The recent detection of an erythrovirus-like parvovirus in Manchurian chipmunks (156) may provide an alternative model.

Cellular Receptor

A cellular receptor for parvovirus B19 has been identified as globoside or erythrocyte P antigen (42,46,72). Globoside is glycosphingolipid tetrahexoseceramide; high-affinity binding of virus (Ka = 10^{10}/M) is specific for the carbohydrate moiety and not the lipid portion. The importance of this receptor is confirmed because individuals who genetically lack P antigen (p phenotype) are not susceptible to parvovirus B19 infection (46). In tissue culture, either excess soluble globoside or anti-P monoclonal antibody can protect erythroid progenitors from infection. The binding of globoside to empty capsids of B19 has been resolved to 26 Å by cryoelectron microscopy (60). The receptor molecules dock into depressions on the threefold axes of the capsids, adjacent to sequences identified as neutralizing epitopes (see Fig. 2).

Globoside is expressed on mature erythrocytes and erythroid precursors. Other cells contain this protein, but it is uncertain whether the globoside is displayed on the cell surface or can function as a B19 receptor (72). The existence of coreceptors or multiple receptors on different cell types, as suggested for AAV (135,175,210,211), might partly explain a presumed respiratory route for infection and the induction of B19-associated disease in nonhematopoietic organ systems.

Immune Response and Key Antigens

Both virus-specific IgM and IgG antibodies to the B19 capsid are made after experimental (10) and natural (182) parvovirus B19 infection (see Fig. 5). IgM antibody appears at about 10 to 12 days (10) and can be found in serum for several months (9). IgG appears about 2 weeks after inoculation (10) and probably persists for life (10). IgA antibodies can also be detected and presumably play a role in protection against infection by the natural nasopharyngeal route (81). Transient aplastic crisis resulting from B19 infection is a singular event in the life of a sickle cell patient, further implying durable, lifelong immunity (190). The important role of antibody can also be deduced by the efficacy of commercial immunoglobulin to cure or control chronic infection in immunodeficient patients (84,118,120,152).

In immunocompetent people, the early antibody response is to the major capsid protein VP2, but as the response matures, reactivity to the minor capsid protein VP1 dominates (119,128). By analogy with the three-dimensional structure of canine parvovirus, some of the B19-neutralizing epitopes defined by murine monoclonal antibodies reside on the surface of the virion (see Fig. 2) (4,58,223,241), but the relationship between neutralizing activity and antibody titer is not simple (40). Some linear neutralizing epitopes are present on the VP1-unique region and are on the outside of the capsid (179). Human monoclonal antibodies against both the VP1-unique region and VP2 have potent neutralizing activity (89), confirming that humans recognize neutralizing epitopes on both VP1 and VP2.

Patients with persistent B19 infection uniformly lack strong reactions to capsid antigens on immunoblot analysis of antiviral antibodies and typically contain only anti-VP2 antibody (119). Congenitally immunodeficient patients may show normal reactivity on enzyme-linked immunosorbent assay (ELISA) testing for IgG and IgM parvovirus-specific antibodies (119). These results suggest that the antibody against linear epitopes detected by immunoblotting is functionally important for effective viral clearance (40), but it must be recognized that these results come from a limited number of studies.

The role of antibody against the major nonstructural protein NS1 has recently been examined (39,227,229,230), but the presence of antibody to this viral protein has not been convincingly linked to a particular syndrome. A human monoclonal antibody against NS1 has been derived but had very weak neutralizing activity (89).

Antibody may play a dual role in B19 infections. On the one hand, antibody can clear virus from the system in both acute and persistent infections. On the other hand, antiviral antibody may be important in producing the immune complex–mediated manifestations of B19 infections.

Because most patients with persistent B19 infection have T-cell as well as B-cell immune deficits, it is probable that a cellular component to the normal response must exist. Few studies have examined cellular immunity to B19 infection (119,228).

Clinical Syndromes

Fifth Disease and Polyarthropathy

Most B19 infections are unrecognized. In investigations of B19 outbreaks, 25% of infected patients report no symptoms, and up to 50% recall no rash (62,235), the most obvious clinical sign.

Acute infection with parvovirus B19 causes the common childhood exanthem, fifth disease (erythema infectiosum) (11,53,62). Children with fifth disease usually are not very ill. The rash is a characteristic “slapped-cheeks” facial erythema and a lacy, reticular evanescent maculopapular eruption over the trunk and extremities (Fig. 8 and Fig. 9). Fifth disease occurs after the viremic phase of infection and results from the host immune response to infection. Because the virus is readily transmitted, an epidemic may be recognized in the community. In a single patient, however, fifth disease is often confused with other childhood exanthems.

FIG. 8. “Slapped-cheek” rash in a child with typical erythema infectiosum or fifth disease. (Photograph courtesy of Mary Anderson.).

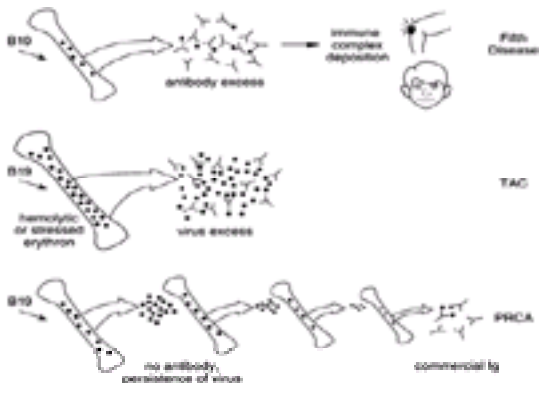

FIG. 9. Pathogenesis of diseases resulting from parvovirus B19 infection in children and adults. (TAC, transient aplastic crisis; PRCA, pure red-cell aplasia.).

Adults with acute B19 infection, especially women, more commonly suffer a symmetric polyarthropathy than a rash (235) (see Fig. 9). The patient's symptoms, including the distribution of joints affected, the presence of frank inflammation, and even a positive rheumatoid factor test, can mimic acute rheumatoid arthritis (148,233). This syndrome also follows the viremic phase of the infection and is most likely a consequence of the host immune response. Parvovirus-induced arthropathy can persist for weeks, months, or years. In one arthritis clinic, 12% of new patients had evidence of recent parvovirus infection (233).

Any association of B19 with chronic joint diseases, particularly rheumatoid arthritis, remains controversial. Despite numerous studies, a convincing link has yet to be demonstrated (55,68,133,148,150,181,203,213). In addition, B19 DNA is also found in normal synovia (55,202).

Transient Aplastic Crisis and Hematologic Disorders

In patients with underlying hemolytic disorders, acute B19 infection causes transient aplastic crisis (TAC) (see Fig. 9), an abrupt cessation of red blood cell production, characterized by reticulocytopenia, absent erythroid precursors in the marrow, massive viremia (12,65), and a precipitous worsening of anemia (reviewed in 49 and 242). TAC was the first

clinical illness associated with B19 infection (171). Temporary depression of erythropoiesis is likely a constant feature of acute B19 infection in all patients (10,49), although it is generally of no significance in the absence of underlying hemolysis or erythroid compartment stress. TAC results only when a shortened red-cell life span is coupled with failed erythropoiesis. Examples of predisposing conditions are sickle cell anemia, hereditary spherocytosis, enzymopathies, thalassemias, and acquired hemolytic anemias (reviewed in 53 and 242). Conditions of erythroid stress, such as hemorrhage and iron deficiency or bone marrow transplantation, have also been associated with TAC.

Ultimately, the condition is self-limiting. Nevertheless, the patient may be acutely ill with the symptoms of severe anemia (49,189). Community outbreaks can occur (191), and B19 infection should be a leading diagnosis in any patient with acute cessation of erythropoiesis. Resolution of the crisis, first manifested by reticulocytosis, begins about 7 to 10 days after onset, concomitant with the appearance of antiviral antibody and viral clearance.

B19 infection has also been less convincingly implicated in other hematologic disturbances (51,53). Fifteen cases of virus-associated hemophagocytic syndrome in adults and children have been firmly linked to B19 infection (50).

Fetal Infection and Hydrops Fetalis

The demonstration in 1984 (13) that B19 could be a cause of nonimmune hydrops fetalis led to significant public concern. *In utero* infection may be persistent and characterized by severe anemia, high-output cardiac failure, and often death (8,236) (Fig. 10; see Fig. 1**B**). Erythroblasts in the fetal liver exhibit clear signs of B19 infection, including cytopathology, viral DNA, and antigen (7,57,74). In addition, fetal myocarditis occurs (57,137,151,173) and may contribute to the pathogenesis. The risk for a fatal outcome is greatest during the first two trimesters.

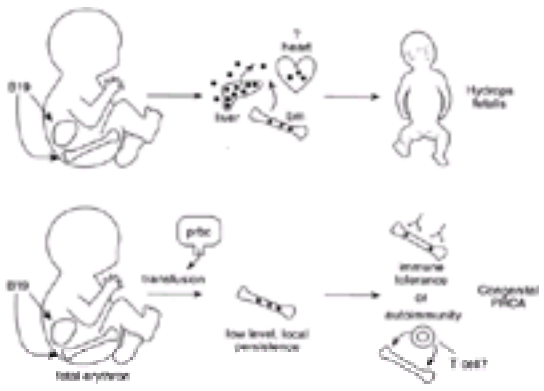

FIG. 10. Pathogenesis of diseases resulting from fetal infection with parvovirus B19. The fetal erythron consists of the liver and bone marrow. Packed red blood cells (*prbc*) are used for intrauterine transfusion. The severe anemia of congenital pure red cell aplasia (*PRCA*) can be a consequence of nonfatal fetal infection with B19.

Fetal infection need not be fatal but may persist after birth as pure red-cell aplasia (PRCA) (23,43,51,83,237). The data suggest a severe chronic anemia accompanied by persistent viral DNA in the bone marrow but not in the blood (43,51) (Table 1; see Fig. 10). Intravenous immunoglobulin did not ameliorate the anemia (43). Analysis of the effectiveness of intrauterine immunoglobulin treatment is complicated because fetal B19 infections may often have no adverse outcomes (8,83).

Syndrome	Clinical features	Host characteristic
Fifth disease	Cutaneous eruption, arthralgia/arthritis	Children
		Adults
Transient aplastic crisis	Severe acute anemia	Hemolysis
Pure red-cell aplasia	Chronic anemia	Immunodeficiency
Hydrops fetalis	Fetal anemia, heart failure	Mid-trimester fetus
Congenital red-cell aplasia	Aregenerative chronic anemia	Treated hydrops fetalis

TABLE 1. *Parvovirus B19 diseases*

Exposure of the fetal immune system to virus might result in tolerance to viral antigens and the absence of an antibody response despite persistent virus production. However, there is no direct evidence demonstrating this phenomenon.

Pregnant women are commonly exposed to B19 through other children in a variety of settings (225). About 30% of maternal infections are vertically transmitted to the fetus, and fetal death is thought to occur in 2% to 10% of maternal infections (93,176,225). The demonstration of IgM antibody to B19 in the cord blood of healthy infants suggests that fetal infection may sometimes have no adverse consequences (8,83). Systematic studies have failed to provide evidence of congenital abnormalities after fetal B19 infection (51,108).

Persistent Infection

Many patients with persistent parvovirus B19 infection suffer from the hematologic disease PRCA (see Fig. 9). Persistent infection has been associated with a wide variety of congenital and acquired immune disorders, including congenital immunodeficiency (120,152), acquired immunodeficiency syndrome (2,84), leukemia in remission (51,118), and organ transplantation (51). Clinically, the anemia is severe, and the patients become dependent on transfusions. The marrow contains the characteristic giant pronormoblasts, and there may be associated neutropenia (122). Persistently infected patients fail to mount a neutralizing antibody response to the virus and do not exhibit the immune complex–mediated symptoms of fifth disease. The diagnosis is established by detection of parvovirus B19 genome in serum, blood, or bone marrow cells by dot-blot hybridization or PCR (2,51,65,66,77). Administration of immunoglobulin can be beneficial and ameliorative, if not frankly curative, in cases of PRCA; however, evidence of its utility in clearing persistent infection in other settings is less well established (84,118,120,152).

Other Disease Associations

Infection with parvovirus B19 has also been implicated in a variety of other diseases, although the causal links are weak in many instances. A limited number of cases of myocarditis have been reported concomitant with B19 infection, an association worthy of additional study because P antigen is present on myocardial cells (72,137,151,173). B19 has also been suggested as a cause of hepatitis or fulminant liver failure associated with aplastic anemia (48,123,149,200). This is a provocative finding, too, because P antigen and globosides are present in fetal liver cells (42,72).

B19 infection has also been associated with vasculitic syndromes (53,82), including polyarteritis nodosa, Henoch-Schönlein purpura, vasculitis, and Kawasaki disease. The presence of P antigen on endothelial cells (42) and the ability of B19 to cause immune complex deposition (153) may explain involvement of the virus in this type of syndrome, but additional studies are needed to determine the significance of parvovirus in these disorders. The causal role of B19 is also uncertain in case reports linking infection to meningitis and neurologic diseases (16,51,53,152,160,232). The relevance of these associations is complicated by the fact that the serum and tissues of some immunocompetent patients can contain detectable B19 DNA for extended periods of time.

Epidemiology

Prevalence and Incidence

Human infection with parvovirus B19 is common. IgG antibody against B19 persists for life (9,10) and is the most convenient marker for past exposure. By the age of 15 years, about 50% of children have detectable IgG antibody to the virus (51). Infection continues to occur throughout life, and in excess of 90% of elderly people have antibody (67). The annual seroconversion rate for women of childbearing age is estimated at 1.5% (110). Similar patterns of prevalence are generally noted in different countries (51).

The high antibody prevalence is not matched by a correspondingly high frequency of viremia. Only about 1 in 20,000 to 40,000 units of blood contains high titers of B19 in epidemic seasons (69). One study using polymerase chain reaction (PCR) as a detection test found B19 DNA in 1 of 3,000 units of pooled samples from blood donors (131). Another study using PCR found B19 DNA in 11 of 9,568 (0.1%) blood donor units, of which 3 contained no measurable B19 IgG (102).

Origin and Spread of Epidemics

An infectious basis for TAC and fifth disease was suspected long before the discovery of parvovirus B19 based on epidemiology. Both fifth disease and TAC are seasonal, with peak occurrence in late winter, spring, and summer (51). Epidemics of both syndromes occur concurrently (62,182), and both appear to cycle in 3- to 4-year periods (190).

Attack rates are high during outbreaks. Between 10% and 60% of susceptible schoolchildren develop fifth disease in school outbreaks (62,110,209); and for adult school and daycare personnel, parvovirus infections occurred in 20% to 30% of susceptible individuals (51,90). Sibling-to-sibling transfer is probably a major path of transmission (110). Nosocomial transmission probably also occurs and is different to distinguish from community acquired infections (22). Patients with acute or persistent infection should be considered infectious, and appropriate precautions should be employed to limit transmission.

Although the prevalence of viremia is low, infection can be transmitted by blood and blood products (143). Because of the resistance of parvoviruses to heat and solvents (177), a fraction of virus can withstand the inactivation treatments usually employed for blood products (51,143). In addition, viral particles escape filtration because of their small size, and as a consequence, the virus in a single positive unit of blood can be readily spread throughout the pooled preparations.

Diagnosis

Diagnostic laboratory assays are useful to distinguish the rash of fifth disease from other viral exanthems, to determine the presence of protective antibodies or recent exposure in pregnancy, to distinguish parvovirus infection from other causes of erythropoietic failure, and to establish the diagnosis of persistent infection in an anemic patient.

IgM directed against parvovirus B19 can be detected 10 to 12 days after infection (10,182) and is a convenient marker for recent or ongoing infection. The most sensitive methods use the capture technique in radioimmunoassay or ELISA formats (51,70). Testing for IgG is useful for seroprevalence studies but is not helpful in diagnosing acute infection because it simply indicates past exposure to virus. Determination of IgG avidity may also prove useful in gauging recent

exposure (91,201).

No method is suitable for routine virus isolation; hence, detection usually relies on probing for the presence of the viral genome. During acute uncomplicated infections in immunocompetent patients, B19 DNA is only detectable for 2 to 4 days by dot-blot hybridization (see Fig. 5) (2,12,65,76). The sensitivity of B19 DNA detection has been greatly increased by the use of PCR (56,66,81,111). However, confusing results can be a problem in diagnosing acute disease because of the ease of contamination, long-term persistence of low levels of virus in uncomplicated infections, and false-positive results. Because of these issues, DNA hybridization is more certain than PCR, and the results are easier to interpret (2). DNA can also be detected by *in situ* hybridization of tissues (141), but this is not a useful routine screening test.

In the event of B19 infection or seroconversion during pregnancy, hydrops can be detected by ultrasound and fetal infection determined by PCR (219). Treatment of hydropic infants with intrauterine transfusions has been reported, although this procedure is fraught with risks (83,172,219).

Prevention and Control

Treatment

Antiviral therapy in the form of commercial immunoglobulin preparations is effective in PRCA associated with persistent infection, although not all persistent infections are terminated with this treatment. Immunoglobulins are administered by daily intravenous infusion at a dose of 0.4 g/kg for 5 to 10 days (84,119,120). Relapses may occur in patients with human immunodeficiency virus as a result of the high virus burden, but such patients can respond to a second course (84). Serial measurement of serum virus levels may be helpful in predicting relapse. The recent development of human monoclonal antibodies that neutralize B19 infection *in vitro* (89) may presage therapy without the numerous risks associated with human blood products.

Vaccines

Prospects for a parvovirus B19 vaccine are good. A vaccine derived from self-assembled capsids expressed in recombinant baculoviruses induces a robust neutralizing antibody response in experimental animals, particularly when used with adjuvant (18,40,104). Phase 1 trials of one B19 vaccine commenced in 1995; however, the target population for such a vaccine remains to be determined (71).

Perspectives

B19 is the only parvovirus with demonstrated pathogenicity for humans. The virus is remarkable for its extremely narrow tropism, and productive infection has only been demonstrated in human erythroid progenitor cells. Viral tropism for productive infection appears to be regulated by expression of its cellular receptor, erythrocyte P antigen or globoside, and an intracellular block in transcription in nonpermissive cells. The virus is cytotoxic to host cells through action of the nonstructural protein. Because the nonstructural protein is expressed in nonpermissive cells, abortive infection in these cells might nevertheless result in cell death.

The pattern of disease that follows B19 infection reflects the balance among virus, target cell, and the immune response (see Fig. 5, Fig. 9, and Fig. 10). Bone marrow depression occurs early, during viremia. Normally, virus replication is terminated by a neutralizing antibody response. The immune response produces the clinical manifestations of fifth disease, in children a rash illness and in adults a rheumatic syndrome; these symptoms are coincident with antibody formation and are probably immune complex mediated. In both persistent infection in children and adults and *in utero* infection, failure to mount a neutralizing antibody response allows B19 to persist and cause a chronic anemia. However, it must be recognized that the role of cellular immune responses is poorly understood in B19 infection. Cellular responses to B19 may play a role in viral clearance and may explain why some patients treated with immunoglobulin fail to be cured. Congenital infection is characterized by low-level infection of marrow, and the chronic anemia may be the result of indirect, perhaps immune-mediated, host responses.

Persistent infection is treatable with immunoglobulin preparations that contain neutralizing antibody. Recombinant molecular technology will allow development of a vaccine (see Table 1). The safety and effectiveness of a B19 vaccine will have to be evaluated in coming years before widespread application is contemplated.

An unresolved issue is the implication of B19 in a number of conditions that do not directly involve the erythroid system. A firm causal role for involvement in rheumatoid arthritis, hepatitis, and other disorders has not yet been demonstrated, but further study is warranted. A possible pathogenetic mechanism of these diseases might be mediated by expression of nonstructural proteins in nonpermissive cells, leading either to direct cytopathology or induction of inappropriate cytokine responses. Alternatively, minor sequence differences between different viral isolates might predispose to induction of specific syndromes. As noted under “General Features of Autonomous Parvovirus Infections,” this is the case for many animal parvovirus systems.

The development of better *in vitro* and *in vivo* models would facilitate studies of erythrovirus infections. In addition, a permanent cell line permissive for high-level productive replication would make it practical to prepare viruses chimeric between isolates and look for virally encoded pathogenicity determinants. A readily available, small animal model would enable investigators to compare chimeric viruses and also to study pathogenesis under tightly controlled conditions.

ADENO-ASSOCIATED VIRUSES

The adeno-associated viruses (AAVs) are helper-dependent parvoviruses and are assigned to the *Dependovirus* genus of the subfamily *Parvovirinae* of the family *Parvoviridae* (26). As implied by the genus name, these ubiquitous viruses are

defective and originally were thought to replicate only in the presence of a helper adenovirus. It is now recognized that various herpes viruses (27,88,183), human papillomavirus (231), and vaccinia virus (183) can also supply helper functions for AAV. AAV can establish long-term latent infections in the absence of helper virus and be rescued by addition of helper virus. In addition, under certain genotoxic conditions, AAV can be induced to replicate to a limited extent without helper virus.

A brief discussion of AAV infections in a general virology textbook is warranted because the AAV are attractive and promising vector systems for gene therapy (28,94,112). To understand some of the potential problems in the development of these therapies, an understanding of AAV infections is helpful.

History

The AAV were initially observed in the mid-1960s as 20-nm particles, contaminating preparations of adenoviruses (15,99), and it was rapidly determined that the particles were defective viruses and not adenovirus breakdown products. Studies soon revealed that antibodies to several distinct serotypes of AAV (98) were common in human populations and that the viruses could be isolated from a variety of clinical specimens (20,33). It is now appreciated that AAV are extremely widespread in the animal kingdom and may occur in every species that has an adenovirus (reviewed in 29 and 177).

Because of their small genome size and relatively simple genomic organization, AAVs were the subject of numerous studies on DNA replication, DNA structure, gene expression, and gene regulation (27,28,207). Earlier work had suggested that AAV could initiate a latent infection in cell lines and be rescued hundreds of passages later by adding helper virus (113). When these observations were restudied with modern molecular biology, it was discovered that AAV persisted by integrating into chromosomal DNA in a nonrandom fashion (113,114 and 115). These findings, coupled with the apparent lack of pathogenicity, directly led to investigations of AAV as possible gene therapy vectors (28,112,146). Successful application of AAV vectors in gene therapy studies (78,94,107,199,215) has led to a renaissance in this interesting virus system.

Infectious Agent

Cell Culture Systems

AAV can be grown productively in a variety of continuous and primary cell lines, including HeLa cells, KB cells, African green monkey kidney cells and human embryo fibroblasts, provided a helper adenovirus or herpes virus is co-infected (21,28,33,135,145). Limited replication of AAV in the absence of helper virus can occur in some cells pretreated with a variety of genotoxic stresses (heat shock, ultraviolet irradiation, gamma-irradiation, carcinogens) (28,183,239). AAV can be rescued from latently infected cells by adenovirus superinfection (28,88,113,115).

Biologic Characteristics

There are six serotypes of primate AAV (denoted AAV1 to AAV6) currently described (20,88,99), with AAV2 being the type species (26). These can be discriminated by a variety of capsid-based antibody assays, including complement fixation, immunofluorescence, and neutralization (88,99). All AAVs exhibit the stability characteristic of parvoviruses (177).

All serotypes except AAV5 were initially found as contaminants of adenovirus stocks. AAV5 was isolated from a condylomatous genital lesion (20), and the natural helper for AAV5 may be a herpesvirus (88). AAV4 appears to be a monkey parvovirus (34,59,178). DNA sequence information is available for AAV2, AAV3, AAV4, AAV5, and AAV6 (19,59,145,180,207). A detailed description of the relatedness at both the DNA and protein level is beyond the scope of this chapter, but suffice it to say that AAV5 is the most distantly related to other members of the AAV (19). The divergent capsid residues have been modeled on the virion surface near the region involved with receptor binding, tropism, and neutralizing epitopes for other parvoviruses (5,19,58,180) (see Fig. 2).

Pathogenesis

Human Infections

Of necessity, AAV infections must initially occur in the presence of an adenovirus or herpesvirus infection. Based on viral isolation studies, the most likely routes of infection would appear to be respiratory, fecal-oral, and direct conjunctival inoculation (31,33,184). Although not conclusively demonstrated, sexual transmission has also been suggested (88,96,231). A discussion of latent AAV infections is not included in this chapter.

Animal Models

AAV infections are easy to study in a variety of convenient animal systems. In early studies, rhesus monkeys were used to examine possible teratogenicity of AAV1 (30), and mice were used to study virus distribution in various tissues after transplacental infection (124). The recent interest in AAV as a gene therapy vehicle has led to a large number of animal studies, including mice (199), rats (78,107,168), rabbits (94), and dogs (97,199).

Receptors

The AAVs have extremely broad cellular tropisms and can infect across species barriers (21,146,175,211). However, the efficiency of infection can vary among cell lines, and not all cells that bind AAV can be productively infected (59,135,146,175,211). Infection with these small, nonenveloped icosahedral viruses may involve participation of more

than one cell surface molecule. Molecules suggested as receptors or coreceptors are heparan sulfate proteoglycan (135,211), human fibroblast growth factor receptor 1 (175), and a_vb_5 integrin (210).

These results, along with others implying that different serotypes of AAV use different receptors (59), have direct implications for gene therapy studies. To direct gene expression to specific target cell populations, it will be crucial to ensure that the transducing virus can infect the desired cell type. Efficient transduction may require matching surface macromolecules on desired target cells with type-specific transducing virions (175,210). It may be necessary to develop hybrid capsid structures that bind to ligands on the target cell membranes.

Epidemiology

Virus Isolation and Molecular Epidemiology Studies

Infectious isolates of AAV2, AAV3, and AAV5 have been obtained from humans in the presence of numerous adenovirus serotypes (20,31,33). As might be expected, given the defective nature of AAV, all subjects were experiencing concomitant adenovirus infections. AAV3 was isolated during an outbreak of adenovirus type 3 conjunctivitis among children and adults (184). Virus was found in conjunctival, throat, and fecal specimens. As noted previously, a single isolation of AAV5 has been made from a male with a flat condylomatous genital lesion (20).

Evidence of AAV infection has also been sought using molecular epidemiology tools. AAV DNA, primarily AAV2, has been detected in peripheral blood cells, cervical biopsy samples, and tissues from spontaneous abortions (92,96,138,217,231). The significance of these identifications is unclear.

Seroepidemiology

Serum antibodies to AAV1, AAV2, AAV3, and AAV5 are extremely common (32,34,35,88,129,169,178,204). Average titers peak by the age of 10 years, at which time more than 60% of the population have neutralizing antibody to AAV1, AAV2, or AAV3, and more than 50% retain antibody into adulthood. The age pattern of seroconversion to AAV parallels acquisition of antibodies against adenoviruses. The seroepidemiology of AAV5 may be significantly different (88). The peak average titers occurred between 15 and 20 years of age, and about 50% of adults in the former West Germany tested positive (88).

In contrast, antibody to AAV4 is detected much less frequently (34), with peak incidence of about 10% between 2 and 5 years of age. The exception seems to be military recruits who have received respiratory vaccines prepared in monkey cells (178).

Despite the high seroprevalence to AAV, no study has conclusively linked AAV infection to any human disease. In addition, no evidence associating AAV with congenital infections or malformations has been found (30). Several surveys have found a lower incidence of anti-AAV antibodies in cancer patients (88,96,129).

Studies in cell cultures and in animal systems indicate that the presence of neutralizing antibody to a particular serotype of AAV reduces the efficiency of gene transduction (94,180). Efforts to deliver genes using AAV2 may have to circumvent the high prevalence of antibody to that serotype. It is the high prevalence of antibody to AAV that has stimulated investigators to develop gene therapy vectors from a variety of serotypes.

Perspectives

The AAVs were studied initially as useful tools for unraveling viral and cellular molecular biology. Once the ability of AAV to integrate into the cellular genome was appreciated, interest expanded to new groups of investigators.

The AAV have high potential as agents of gene delivery. Their imminent application as vectors in animals and humans will likely sustain and enhance interest in AAV. Their utility may ultimately be restricted because only relatively short sequences can be encapsidated in the small virions.

Additional problems will likely arise from the high prevalence of neutralizing antibody. This issue may be circumvented by developing vectors from a variety of AAV serotypes or by preparing vectors with hybrid capsids. Elucidation of the capsid structure will aid in addressing these problems.

Targeting of genes to specific cell types will require comprehensive analysis of virus–receptor interactions. It may be necessary to engineer the capsid surface to promote binding to receptors molecules on specific cell types.

CHAPTER 71 The Family *Herpesviridae*: A Brief Introduction

Bernard Roizman and Philip E. Pellett

Who made the world I cannot tell;
'Tis made, and here I am in hell.

My hand, though now my knuckles bleed,
I never soiled with such a deed.

A. E. Housman, No. XIX in *More Poems*

DEFINITION

Inclusion in the Family *Herpesviridae*

Membership in the family *Herpesviridae* is based on the architecture of the virion (Fig. 1). A typical herpesvirion consists of a core containing a linear double-stranded DNA, an icosadeltahedral capsid approximately 100 to 110 nm in diameter containing 162 capsomeres with a hole running down the long axis, an amorphous-appearing, sometimes asymmetric material that surrounds the capsid and is designated the tegument, and an envelope containing viral glycoprotein spikes on its surface. A hotly debated issue is whether inclusion in the family should also be based on DNA sequence conservation. Thus viruses have been isolated from poikilothermic animals that retain conserved herpesvirus structural features, but their DNAs appear to have little if any similarity to the herpesviruses of homoiothermic animals. All of these viruses are presently included in the family.

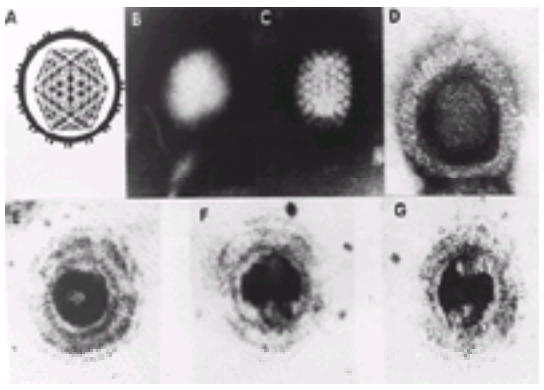

FIG. 1. The morphology of herpesviruses as visualized by transmission electron microscopy. **A:** Schematic representation of the herpesvirion seen through a cross section of the envelope with spikes projecting from its surface. The sides of the icosadeltahedron forming the capsid show a twofold symmetry. The irregular inner perimeter of the envelope is meant to represent the occasional asymmetric arrangement of the tegument. **B:** An intact, negatively stained HSV-1 virion. The intact envelope is not permeable to negative stain. The diameter of the virion is approximately 120 nm. **C:** An HSV-1 capsid exposed to negative stain and showing twofold symmetry matching the diagrammatic representation of the capsid in A. **D:** HSV-1 capsid containing DNA permeated with uranyl acetate. The electron micrograph shows the presence of threadlike structures 4 to 5 nm wide on the surface of the core. **E, F, G:** Electron micrographs of thin sections of HSV-1 virions showing the core cut at different angles. The preparation was stained with uranyl acetate and counterstained with lead citrate. The DNA core preferentially takes up the stain and appears as a toroid with an outer diameter of 70 nm and an inner diameter of 18 nm. The toroid appears to be suspended by a fibrous cylindrical structure. The micrographs show the toroid seen looking down the hole **(E)**, in cross section **(F)**, and from the side **(G)**. (The electron micrographs shown in panels **D** to **G** are from ref. 22, with permission.)

Distribution in Nature

Herpesviruses are highly disseminated in nature and most animal species have yielded at least one herpesvirus and frequently several diverse herpesviruses upon examination. Inasmuch as few herpesviruses naturally infect more than one species, the number of herpesviruses in nature is likely to exceed the approximately 130 herpesviruses identified to date. Thus far, nine herpesviruses have been isolated from humans [herpes simplex virus 1 (HSV-1), herpes simplex virus 2 (HSV-2), human cytomegalovirus (HCMV), varicella-zoster virus (VZV) and Epstein-Barr virus (EBV), and *Human herpesviruses 6A*, *6B*, *7*, and *8* (HHV-6A, HHV-6B, HHV-7, and HHV-8)]. The known herpesviruses are listed in Table 1.

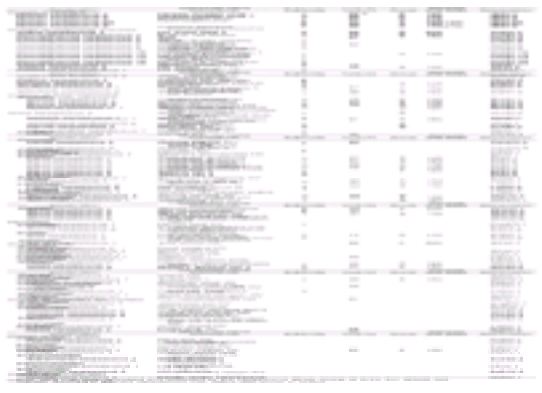

TABLE 1. *Viruses of the family* herpesviridae[a]

Biologic Properties

The known herpesviruses appear to share four significant biologic properties:

1. All herpesviruses specify a large array of enzymes involved in nucleic acid metabolism (e.g., thymidine kinase, thymidylate synthetase, dUTPase, ribonucleotide reductase), DNA synthesis (e.g., DNA polymerase, helicase, primase), and processing of proteins (e.g., protein kinases), although the exact array of enzymes may vary from one herpesvirus to another.
2. The synthesis of viral DNAs and capsid assembly occurs in the nucleus. Capsids are enveloped as they transit through the nuclear membrane. A contentious issue is the fate of the herpesvirion as it transits the cytoplasm, whether it undergoes internal maturation/single envelopment or whether it undergoes successive de-envelopment and envelopment (reviewed in ref. 18).
3. Production of infectious progeny virus is invariably accompanied by the destruction of the infected cell.
4. The herpesviruses examined to date are able to remain latent in their natural hosts. In cells harboring latent virus, viral genomes take the form of closed circular molecules, and only a small subset of viral genes are expressed. Latent genomes retain the capacity to replicate and cause disease upon reactivation. The precise molecular mechanisms that lead to reactivation from the latent state are not fully understood and may differ from one virus to another. Latency differs from chronic infection in that infectious progeny are not present. Conversely, the capacity to reactivate differentiates latency from abortive infection.

Herpesviruses also differ with respect to their biologic properties. Some have a wide host-cell range, multiply efficiently, and rapidly destroy the cells they infect (e.g., HSV-1, HSV-2). Others have a narrow host cell range (EBV, HHV-6) or have a long replicative cycle (HCMV). Although all herpesviruses remain latent in a specific set of cells, the exact cell in which they remain latent varies from one virus to another. For example, whereas latent HSV has been detected only in neurons of dorsal root ganglia, latent EBV has been found primarily in B lymphocytes. Herpesviruses differ substantially with respect to the clinical manifestations of diseases they cause.

NOMENCLATURE AND CLASSIFICATION

Nomenclature

A formal binomial nomenclature is not currently applied. The International Committee on the Taxonomy of Viruses (ICTV)-endorsed nomenclature consists of designation of herpesviruses by serial Arabic number and the family (most cases) or subfamily (for primates and some animals) of the natural host of the virus (e.g., *Human herpesvirus 7*, *Cercopithecine herpesvirus 1*; see Table 1). The species number is not intended to imply anything about the relationship between a virus and other herpesviruses that infect the same host species (e.g., HHV-7 and HHV-8 are members of different subfamilies) or between similarly numbered viruses that infect different host species (e.g., EHV-2 and BHV-2 are members of different subfamilies). A recent nomenclature change that applies to all viruses is italicization, plus capitalization of the first letter of the first word of the names of ICTV-recognized virus species (61); this system will be used in this chapter.

Classification

The members of the family *Herpesviridae* were initially classified by the Herpesvirus Study Group of the ICTV into three subfamilies (i.e., the *Alphaherpesvirinae*, the *Betaherpesvirinae*, and the *Gammaherpesvirinae*) on the basis of biologic properties and before DNA sequences of the individual members of the family were known (50,51). The same study group classified a small number of herpesviruses into genera based on DNA sequence homology, similarities in genome

sequence arrangement, and relatedness of important viral proteins demonstrable by immunologic methods. Whereas a few genes [e.g., homologs of glycoprotein B of HSV-1 (46,64), or of glycoprotein H (23)] are conserved among members of different subfamilies, nucleic acid and protein sequence similarities are particularly useful for the classification of viruses that are closely related (genera).

Alphaherpesvirinae

The members of the subfamily *Alphaherpesvirinae* were classified on the basis of a variable host range, relatively short reproductive cycle, rapid spread in culture, efficient destruction of infected cells, and capacity to establish latent infections primarily but not exclusively in sensory ganglia. This subfamily contains the genera *Simplexvirus* (HSV-1), *Varicellovirus* (VZV), *Marek's disease-like virus*, and *Infectious laryngotracheitis-like virus.*

Betaherpesvirinae

A nonexclusive characteristic of the members of the subfamily *Betaherpesvirinae* is a restricted host range. The reproductive cycle is long and the infection progresses slowly in culture. Infected cells frequently become enlarged (cytomegalia) and carrier cultures are readily established. The virus can be maintained in latent form in secretory glands, lymphoreticular cells, kidneys, and other tissues. This subfamily contains the genera *Cytomegalovirus* (HCMV), *Muromegalovirus* (murine cytomegalovirus), and *Roseolovirus* (HHV-7).

Gammaherpesvirinae

The experimental host range of the members of the subfamily *Gammaherpesvirinae* is limited to the family or order to which the natural host belongs. *In vitro*, all members replicate in lymphoblastoid cells, and some also cause lytic infections in some types of epithelioid and fibroblastic cells. Viruses in this group are usually specific for either T or B lymphocytes. Latent virus is frequently demonstrated in lymphoid tissue. This subfamily contains two genera: *Lymphocryptovirus* (EBV), and *Rhadinovirus* (AtHV-2 and SaHV-2).

Since this classification system was adopted, nucleotide sequence analyses (detailed later) support and have expanded the platform on which the system rests. The issues that the new data pose are dealt with at the end of this chapter.

ARCHITECTURE

Structural Components

The Core

The core of the mature virion contains the viral DNA in the form of a torus (21,22,44). In some herpesvirions, the torus appears to be suspended by a proteinaceous spindle consisting of fibrils embedded in the underside of the capsid and passing through the hole of the torus. The precise arrangement of the DNA in the torus not known.

The Capsid

The structural features of the capsid (i.e., its 100-nm diameter and 162 capsomeres) are characteristic of all herpesviruses. The pentameric capsomeres at the vertices have not been well characterized. The hexameric capsomeres are 9.5 × 12.5 nm in longitudinal section; a channel 4 nm in diameter runs from the surface along their long axis (65).

The Tegument

The tegument, a term introduced by Roizman and Furlong (54) to describe the structures between the capsid and the envelope, has no distinctive features in thin sections, but it may appear to be fibrous on negative staining (42,43,65). Structural polarity across the tegument has been visualized by immunoelectron microscopy (59), indicating that it is an ordered structure. The tegument is sometimes distributed asymmetrically, and its thickness may vary depending on the location of the virion within the infected cell; when the amount is variable, there is more of it in virions accumulating in cytoplasmic vacuoles than in those accumulating in the perinuclear space (21). The available evidence suggests the amount of tegument is more likely to be determined by the virus than by the host (36).

The Envelope

Electron microscopic studies on thin sections have shown that the outer covering of the virus, the envelope, has a typical trilaminar appearance (19). It appears to be derived from patches of altered cellular membranes (1,21,43). The presence of lipids was demonstrated by analyses of virions (3) and by the sensitivity of the virions to lipid solvents and detergents (57). The herpesvirus envelope contains numerous protrusions of glycoprotein that are more numerous and shorter than those appearing on the surface of many other enveloped viruses (65). The number and relative amounts of viral glycoproteins vary; HSV specifies at least 11 glycoproteins (see Chapter 72); the copy number of individual glycoproteins can exceed 1,000 per virion.

The Virion

Herpesvirions have been reported to vary in size from 120 to nearly 300 nm (reviewed in ref. 54). The variation is in part due to variability in the thickness of tegument. Another major source of variability is the state of the envelope. Intact envelopes are impermeable and generally retain the quasi-spherical shape of the virion during preparation for electron microscopy (see Fig. 1). Damaged envelopes are permeable to negative stains; permeated virions have a

sunny-side-up-egg appearance with a diameter much larger than that of intact virions.

The precise number of polypeptide species contained in the virions is not known and may vary from one virus to another. Estimates generally range from 35 to 45 polypeptides.

Herpesvirus DNAs

Size, Conformation, and Base Composition

Herpesvirus DNAs extracted from virions and characterized to date are linear and double stranded, but they circularize immediately upon release from capsids into the nuclei of infected cells.

Variable features of herpesvirus DNAs include their length and base composition. The length of herpesvirus DNAs varies from approximately 120 to 250 kbp (see Table 1). The variability in genome lengths of different herpesviruses is distinct from the polymorphism in the size of DNAs of individual viruses. Variation in the size of the genome of any one herpesvirus appears to be minimal, but not insignificant. Thus, herpesvirus genomes contain terminal and internal reiterated sequences that can vary in copy number, leading to variations in genome length of more than 10 kbp. Spontaneous deletions also occur; they have been noted in HSV and EBV strains passaged outside the human host (e.g., EBV strain P3HR1, HSV-1 strain HFEM). Recently, a highly passaged strain of HCMV was found to lack a segment encoding at least 19 genes present in wild-type isolates (10).

The base composition of herpesvirus DNAs varies from 31% to 75% total G+C content (see Table 1). Furthermore, herpesvirus DNAs vary with respect to the extent of homogeneity of G+C content across the length of the genome. The extent of inhomogeneity in the base composition varies from minimal (e.g., HSV) to very extensive. For example, the DNAs of SaHV-2 and AtHV-2 (6) consist of reiterated sequences of high G+C content at the genomic termini and unique segments of low G+C content.

Sequence Arrangements in Herpesvirus DNAs

An interesting feature of herpesvirus DNAs is their sequence arrangement. The sequence arrangement shown in Figure 2 emphasizes the presence and location of reiterations of terminal sequences greater than 100 bp. According to this scheme, the herpesviruses can be divided into six groups designated by the letters A to F. In the genomes of viruses comprising group A and exemplified by channel catfish herpesvirus, a large sequence from one terminus is directly repeated at the other terminus. In the group B genomes exemplified by herpesvirus saimiri, the terminal sequence is directly repeated numerous times at both termini, and furthermore, the number of reiterations at the termini may vary. In the group C genomes exemplified by EBV, the number of direct terminal reiterations is smaller, but there may be other, directly repeated and unrelated sequences greater than 100 bp that subdivide the unique (or quasi-unique) sequences of the genome into several well-delineated stretches. In group D genomes exemplified by VZV, the sequence from one terminus is repeated in an inverted orientation internally. In these genomes, the domain consisting of the stretch of unique sequences flanked by inverted repeats (small, or S, component) can invert relative to the remaining sequences (large, or L, component), so that the DNA extracted from virions or infected cells consists of two equimolar populations differing solely in the orientation of the S component relative to the L component. In group E viral genomes exemplified by those of HSV and HCMV, sequences from both termini are repeated in an inverted orientation and juxtaposed internally, dividing the genomes into two components each of which consists of unique sequences flanked by inverted repeats. In this instance, both components can invert relative to each other, and DNA extracted from virions or infected cells consists of four equimolar populations differing in the relative orientation of the two components. The genomes comprising group F are exemplified by tupaia herpesvirus; the terminal sequences are not identical and are not repeated either directly or in an inverted orientation. Although the potential of inverted repeat sequences to cause inversions and gene expansion is well appreciated, their role and the advantage they confer to viral replication are not understood.

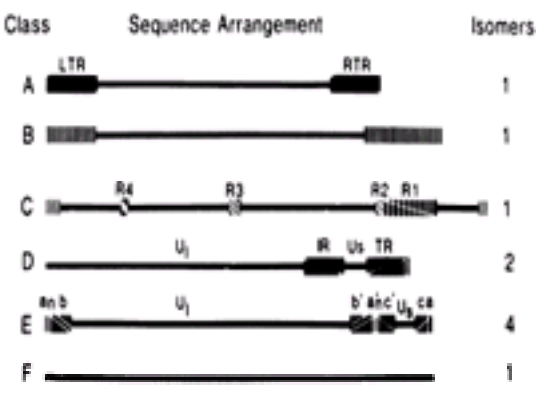

FIG. 2. A schematic diagram of the sequence arrangements in the six classes of genomes of the viruses comprising the family *Herpesviridae*. The genomes A, B, C, D, E, and F are exemplified by the channel catfish herpesvirus, herpesvirus saimiri, Epstein-Barr virus, varicella-zoster virus, herpes simplex viruses, and tupaia herpesvirus, respectively. In the schematic diagram, the *horizontal lines* represent unique or quasi-unique regions. The reiterated domains are shown as *rectangles* and are designated as left and right terminal repeats (LTR and RTR) for group A, repeats R1 to R4 for internal repeats of group C, and internal and terminal (IR and TR) repeats of group D. The termini of group E (e.g., HSV) consist of two elements. One terminus contains *n* copies of sequence *a* next to a larger sequence designated as *b*. The other terminus has one directly repeated *a* sequence next to a sequence designated *c*. The terminal *ab* and *ca* sequences are inserted in an inverted orientation (denoted by *primes*) separating the unique sequences into a long (U_L) and short (U_S) domains. Terminal reiterations in the genomes of group F have not been described. In group B, the terminal sequences are reiterated numerous times at both termini. The number of reiterations at each terminus may vary. The components of the genomes in classes D and E invert. In class D, the short component inverts relative to the long. Although (rarely) the long component may also invert, most of the DNA forms two populations differing in the orientation of the short

component. In the class E genomes, both the short and long components can invert and viral DNA consists of four equimolar isomers.

All herpesvirus genomes examined to date contain at their termini signals for packaging the DNA into capsids (16).

Genetic Architecture

Herpesvirus Genes

Most herpesvirus genes contain a promoter/regulatory sequence spanning 50 to 200 bp upstream of a TATA box, a transcription initiation site 20 to 25 bp downstream of the TATA box, a 5' nontranslated leader sequence of 30 to 300 bp, a single major open reading frame (ORF) with a translation initiation codon that meets the host requirements for efficient initiation, 10 to 30 bp of 3' nontranslated sequence, and a canonical polyadenylation signal with standard flanking sequences. Exceptions exist and are important. Genes without a TATA box [e.g., HSV-1 $g_1$34.5 gene (12)] and initiation from a second in-frame methionine (34) have been reported. In the case of HSV late genes, the promoter-regulatory sequences may be located 3' to the TATA box (35).

Gene overlaps are common. Thus, except for head-to-head gene arrangements, the promoter-regulatory sequences of 3' genes are located within the coding domain of the 5' gene. In several instances, a second transcriptional unit is embedded in the coding sequence to yield a truncated polypeptide initiated at an internal methionine and colinear with the carboxyl-terminal domain of the larger protein [e.g., HSV U_L26 and U_L26.5 (33)]. The resulting proteins thus share a domain of identical amino acid sequence yet can differ markedly in their function. Finally, ORFs can be expressed that are situated entirely antisense to each other [e.g., HSV-1 $g_1$34.5 and ORFs P and O (32)]. A common feature of herpesvirus genomes is clusters of 3' co-terminal transcripts, each designed to express a different ORF. Within these clusters, coding domains seldom overlap by more than a few codons of the same or opposite strand. Although most genes are transcribed by RNA polymerase II, at least a small set of transcripts (EBERs) made in cells infected with EBV are synthesized by RNA polymerase III (27). Most herpesvirus genes are not spliced; that is, their primary transcription product is the mature mRNA sequence, minus polyadenylation. Nonetheless, every herpesvirus encodes at least a handful of spliced genes. One strategy is to use splicing to enable differential regulation of a gene at different parts of the virus life cycle. In some cases, this means that the same ORF is accessed from different promoters. Herpesviruses also encode noncoding RNAs (e.g., the Ori_S RNA and latency-associated transcripts of HSV and the EBERs of EBV).

Herpesviruses encode between 70 (the smallest genome) and 200 (the largest genome) genes. These estimates are rooted in studies of viral mutants, transcriptional mapping, analysis of the translation products of particular transcripts, and computational analyses of protein coding potential. Current estimates probably understate the number of gene products. Noncoding RNA have not been included in this count, and proteins can be encoded by very small ORFs that have not yet been identified as functional. Alternative splicing, translational frameshifting, and antisense ORFs, and tissue-specific transcription are only now beginning to be fully appreciated. Elucidation of the true genetic complexity encoded in herpesvirus genomes remains one of the major objectives of herpesvirus research.

Gene Functions

Two characteristics clearly define the functions of herpesvirus gene products. First, they frequently have multiple disparate functions that may or may not be related. For example, HSV infected cell protein no. 0 (ICP-0) acts as a promiscuous transactivator, but at a molecular level it localizes sequentially first in the nucleus and later in the cytoplasm, and it interacts with several host proteins located in both compartments (20,31). Even some of the smaller proteins (e.g., HSV-1 U_S11 and $g_1$34.5) have been ascribed more than one function. The decision as to which function is performed by a particular protein may be determined by the nature of posttranslational modifications, to which many herpesvirus proteins are subjected. Full assessment of the multifunctional nature of viral proteins and their dependence on interactions with other viral proteins requires that they be studied in the context of infection with wild-type or mutant viruses.

The second characteristic is related to the role of viral-encoded proteins in viral replication. For HSV, more than 50% of the ORFs are dispensable for growth in cells in culture. For the most part, however, these genes are not dispensable for viral replication or for reactivation from the latent state in experimental animal systems. On the other hand, in assays involving establishment of latency, no virus gene has been found to be indispensable. The herpesvirus genes (other than those involved in entry, DNA replication, packaging of viral genomes, and envelopment) function in creating a suitable environment for viral replication, blocking host defenses to infection, and, where proven, establishment of the latent state. Assessment of the full set of functions of viral proteins in human hosts is hampered by the fact that no experimental system can fully mimic the biology of the natural host.

Genes involved in viral replication encode proteins required for entry into the cell, regulation of viral gene expression, nucleotide metabolism, synthesis of viral DNA and structural proteins, and virion assembly. Regulatory genes are specifically adapted to the requirements of the cell type inhabited by the virus *in vivo.* Some subsets of herpesviruses (e.g., the alphaherpesviruses) share clear homologs of regulatory genes such as a4, a0, and a27. Other groups of herpesviruses have important regulatory genes that have little obvious sequence similarity, although they may occupy similar genomic locations and even share splicing patterns (e.g., the immediate-early genes of the betaherpesviruses).

Every herpesvirus studied to date establishes latent infection in a specific population of cells. The mechanisms differ from one virus to the next. There appears to be no general strategy or shared genetic component for establishment, maintenance, or termination of the latent state, even though latency is the cornerstone of herpesvirus biology. Whereas

members of some genera of herpesviruses encode several proteins that are expressed during maintenance of the latent state (e.g., EBV), others (e.g., HSV) have no absolutely required expression of the viral genome during this phase of latency.

The cellular and organismal host ranges of herpesviruses differ enormously, from very wide (e.g., HSV) to very narrow (e.g., EBV, HHV-6B). The host range is determined only in part by the availability of receptors. Little is known about the cell-specific factors that enable herpesviruses to replicate in specific hosts or cell types.

Herpesviruses are able to alter the cellular environment to suit their needs. These alterations include shutting off or stimulating host cell macromolecular synthesis, inducing or inhibiting host cell DNA replication, or immortalizing the host cell. Parenthetically, although many herpesviruses encode genes that can transform cells in experimental systems outside the context of viral infection, in only a few cases, such as the immortalization of B cells by EBV in the process of establishing its latent repository, is transformation or immortalization an integral part of the *in vivo* life cycle.

The environment in which herpesviruses replicate is decidedly unfriendly to the virus. An armamentarium of viral functions is encoded by herpesviruses to fend off both cellular and organismal reactions to the presence and expression of viral genes (reviewed in ref. 63). At the cellular level, the virus blocks the induction of programmed cell death and the activation of the interferon pathway (e.g., by activation of protein kinase R, which leads to shutoff of protein synthesis). At the organismal level, the response is highly varied and depends in part on the cells in which the virus replicates. Here the responses range from blocking the presentation of antigenic peptides on the surfaces of antigenic cells, to molecular mimicry, in which herpesvirus-encoded proteins perform some, but not all, functions of immunomodulators. A common consequence is a delay in the elimination of the infected cell—long enough to enable the virus to replicate, colonize the host, and become available for transmission to another nonimmune individual. The range of genes evolved to this end varies from one genus to another, with limited conservation among members of subfamilies. The diversity of approaches is a remarkable testimony both to the depth and complexity of host defenses and to the adaptive prowess of the virus. That the virus wins in the infected cell but normally allows the host to survive attests to an evolutionary necessity, since viruses that kill their host ultimately disappear.

Regulation of Gene Expression

Herpesvirus genes belong to any one of several regulatory classes; the more they are studied, the more complex appears to be the system that regulates their expression. Standing apart are genes expressed during latency, and even here, as in the case of EBV, there are multiple stages of latency that differ with respect to the genes that are expressed. In cells productively infected with HSV, viral genes form at least four groups that differ with respect to the order of gene expression and the mechanisms that drive it. These are the a (immediate-early) genes, which require no prior viral protein synthesis for their expression; the b (early) genes, whose expression is totally independent of viral DNA synthesis; g_1 (partial-late) genes, whose expression is augmented by the onset of viral DNA synthesis; and g_2 (true-late) genes, whose expression is totally dependent on viral DNA synthesis. The immediate-early, early, and late nomenclature is rooted in early phage studies; it has the virtue of instant recognition but does not fully describe the events taking place in the infected cell. Both systems are used widely and interchangeably. Herpesvirus gene expression during productive infection represents a classic regulatory cascade, the basic features of which are conserved across the family.

Gene Relatedness and Arrangement

Complete genomic sequences have been determined for approximately 20 herpesviruses; smaller segments have been sequenced for many others. From this information, several fundamental principles of herpesvirus genetic architecture have been deduced.

Herpesvirus gene sequences are related to each other in ways that reflect the longstanding, biology-based classification of herpesvirues into subfamilies and their respective genera, as described later. These relationships are substantial and easy to detect with any of the widely available tools for sequence analysis. Thus the nucleotide sequence of a 200-bp polymerase-chain-reaction product amplified from the viral DNA polymerase gene by the use of degenerate consensus primers is sufficient to establish the identity of a herpesvirus and place it into the appropriate subfamily. Higher resolution and more robust classification can be obtained by expanding the size of the comparison sequence and by analyzing more than one gene. Comparisons of the available herpesvirus glycoprotein B (gB) sequences are shown in Figure 3 and Figure 4. The gB tree shown in Figure 3 provides a good representation of the current state of the taxonomy of the alpha-, beta-, and gammaherpesviruses down to the genus level.

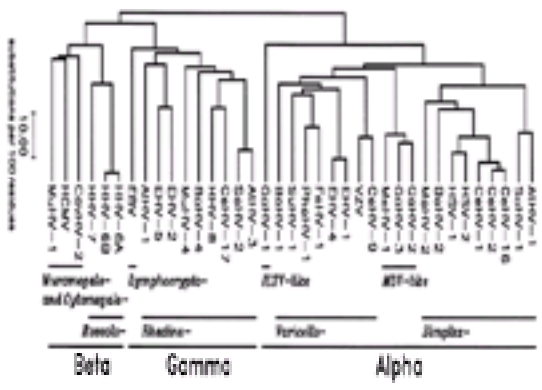

FIG. 3. Relationships among herpesvirus gB sequences. This phylogram was constructed from aligned sequences by the UPGMA method. Virus abbreviations are as listed in Table 1. (Figure courtesy of Yuan-Xiang Meng, Centers for Disease Control and Prevention.)

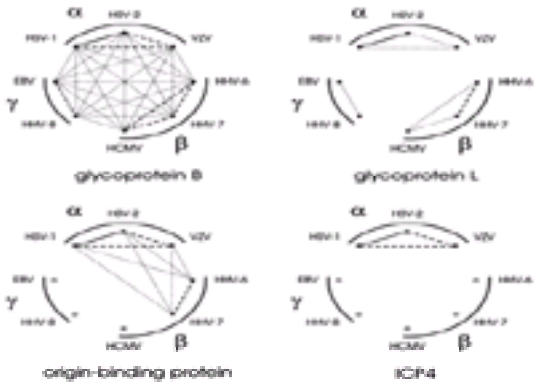

FIG. 4. Clustering of conserved genes among the human herpesviruses. Viruses encoding the indicated protein are shown by *filled dots*; *empty dots* indicate viruses that do not encode the protein. Degrees of similarity are indicated by the *lines* connecting the viruses; *solid*, *dashed*, and *dotted lines* represent >70%, 40% to 70%, and <40% identity, respectively. Glycoprotein B is highly conserved and is represented in all of the viruses; glycoprotein L is conserved within subfamilies; the origin-binding protein is conserved among the alphaherpesviruses and a subset of betaherpesviruses; ICP4 is found only in the alphaherpesviruses. The HHV-6A and HHV-6B counterparts of these proteins are highly related to each other and have similar distances to the other viruses, and they are represented here as a single entity.

Approximately 26 genes, referred to as the herpesvirus core genes, are conserved across the alpha-, beta-, and gammaherpesviruses (Table 2). Each of these genes belongs to one of seven core gene blocks, which encode 2 to 12 genes. Within each gene block, gene order and polarity are conserved. Across the family, the core gene blocks are found in various permutations of order and orientation. In general, block arrangement, and thus gene order, is conserved at the subfamily level. The arrangements of the conserved gene blocks in the genera containing human herpesviruses are summarized in Figure 5.

Gene regulation
HSV-1 ICP27 homolog
Nucleotide metabolism
Ribonucleotide reductase, large subunit
Uracil DNA glycosylase
dUTPase
DNA replication
Alkaline exonuclease
Helicase/primase (3 subunits)
DNA polymerase
ssDNA binding
Virion
Maturation
Transport?
Terminase/packaging
DNA packaging
Scaffold protease
Capsid
Major capsid protein
Minor capsid protein
Capsid (2)
Tegument
Large tegument protein
Envelope
Glycoprotein B
Glycoprotein H
Glycoprotein M
Four genes of unknown function

TABLE 2. *Genes conserved among the alpha-, beta-, and gammaherpesviruses*

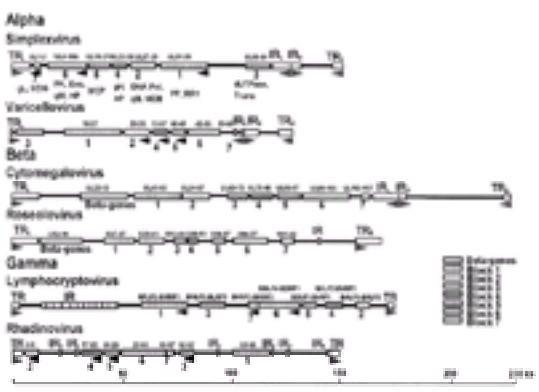

FIG. 5. Conserved gene blocks of the *Alpha*-, *Beta*-, and *Gammaherpesvirinae* (adapted from refs. 7,11,24,39, and 45, with permission). Each genus is represented by a member in its prototype genomic arrangement. Gene nomenclatures are from the following references: *Simplexvirus* (38), *Varicellovirus* (14), *Cytomegalovirus* (11), *Roseolovirus* (17,24,29), *Lymphocryptovirus* (4), and *Rhadinovirus* (55). The seven conserved herpesvirus sequence blocks (block 1 through block 7), plus an additional sequence block (beta-genes) found only in betaherpesviruses, are diagramed. ORFs bounding the conserved sequence blocks are indicated. Gene blocks inverted relative to the betaherpesviruses are indicated by the *black arrowheads.* Structures of genomic termini are indicated. TRL, IRL, IRS, and TRS denote inverted repeats flanking the L or S component, respectively. *Hatched arrowheads* indicate directionality of terminal repeats. Gene product abbreviations: gL, glycoprotein L; UDG, uracil-DNA glycosylase; PK, phosphotransferase; Exo, alkaline exonuclease; gM, glycoprotein M; HP, helicase/primase complex; MCP, major capsid protein; gH, glycoprotein H; AP, protease; DNA Pol, DNA polymerase; gB, glycoprotein B; PP, polymerase-associated processivity factor; RR1, ribonucleotide reductase large subunit; and Trans, herpesvirus transactivator. (Figure provided courtesy of Geraldina Dominguez, Centers for Disease Control and Prevention.)

Some genes are conserved at the subfamily level. Thus alphaherpesviruses encode related latency-associated genes, glycoprotein D, a tegument-associated protein that induces transcription from a-genes, and a transcriptional regulatory protein related to HSV a4 (see Fig. 4). Betaherpesviruses encode a block of 14 genes that have no counterparts elsewhere in the family, sets of diversified genes that are related to HCMV U_S22, and highly divergent immediate-early genes that nonetheless have shared evolutionary history. Gammaherpesviruses encode more homologs of cell genes than do other herpesviruses, plus proteins needed to maintain latent genomes in dividing cells.

An interesting variation on the linkage of gene sets to subfamilies is offered by the origin-binding protein (OBP) and its binding site. OBP binds to its cognate sites in origins of lytic replication and serves to nucleate the DNA replication machinery and play a role in initiating DNA replication. Only alphaherpesviruses and members of the *Roseolovirus* genus of the betaherpesviruses encode OBP homologs and OBP sites (28) (see Fig. 4). Other betaherpesviruses and the gammaherpesviruses do not encode OBP homologs or sites; they initiate DNA replication by another mechanism.

Gene content (the presence or absence of homologous genes) has been used to deduce phylogenetic relationships among the herpesviruses that are consistent with phylogenies based on gene sequences (40). In addition, comparisons of the presence or absence of members of gene families from virus to virus enable the construction of reciprocal trees that reveal the groups of genes encoded in each of the possible combinations of subfamilies (Fig. 6). This amplifies some of the relationships shown in Figure 4 and illustrates both the depth of shared evolutionary history and the breadth of divergence among these viruses.

FIG. 6. Reciprocal tree showing clustering of groups of related genes (each group being a cluster of orthologous groups, or COG) based on the phylogenetic profile of each group, as identified from a collection of 13 complete herpesvirus genome sequences (40). The tree was constructed by identifying 104 COGs among the genes encoded by the 13 viruses and then tabulating for each virus the presence or absence of a member for each of the COGs. Clusters among the phylogenetic profiles were identified by the UPGMA method and the results plotted as shown. COGs common among, or specific to, various combinations of the herpesvirus subfamilies are evident. As also shown in Figure 4, the COG for some highly conserved genes (e.g., glycoprotein B) included members from all of the viruses except for channel catfish virus (IHV), and some functionally related proteins are split among more than one COG because their sequences are very different [e.g., glycoprotein L (see Fig. 4)], and other genes are represented in only a small subset of the viruses [e.g., ICP4 (see Fig. 4)]. (From ref. 40, with permission.)

Herpesviruses generally encode at least one gene of obvious host origin; HHV-8 has acquired 12 (55). Examples include thymidylate synthase and bcl-2. These genes appear to have been acquired by retrotransposition events from cDNAs, given that they are most often encoded on the viral genome as continuous ORFs that do not require splicing. Some of these genes appear to have been acquired independently by different herpesvirus lineages (again, bcl-2 and thymidylate synthetase). Host-acquired genes tend to be located toward the viral genomic termini and between core gene blocks. In some cases, the host-acquired genes retain a function similar to its cellular counterpart; expression from the viral genome allows the desired product to be produced when needed by the virus. In other cases, the host-acquired gene has been modified to alter its function—for example, the HHV-8 homolog of the cellular D-type cyclin does not respond to signals that inhibit the cellular version, rendering the viral version constitutively active and capable of transforming cells (2).

HERPESVIRUS EVOLUTION

The origins of herpesviruses are the subject of interesting but largely unverifiable speculations. The presence of cellular homologs in many viruses indicates that herpesviruses acquired many of their genes from cellular genomes. The similarity between mechanisms and pathways of replication of herpesviruses and those of DNA phages cannot be explained totally on the basis of convergent evolution, and it places the ancestry of herpesviruses at the early stages of the evolution of parasitism. The similarities in the structure of herpesviruses suggest that they have arisen from a common ancestor. The ancestral virus evolved into at least two highly diverged lineages, one represented by the alpha-, beta-, and gammaherpesvirus subfamilies that infect birds and mammals, the other represented by the herpesviruses of poikilothermic animals. Although there is very little obvious genetic similarity between the latter herpesviruses and the rest of the family, their capsid structures are well conserved (5). Because the capsid sizes of all herpesviruses are nearly identical, it could be predicted that the capsid evolved to contain the largest herpesvirus genomes, which are conserved today only among some members of the betaherpesviruses.

The ancestral herpesvirus of birds and mammals must have encoded at least some of the core genes that are shared by the contemporary progeny. The three major lineages of these viruses emerged prior to the mammalian radiation (37).

According to one analysis, the alphaherpesviruses emerged prior to the beta- or gammaherpesviruses (37); a different method suggested that HHV-6 is closest to being a progenitor herpesvirus and that the alphaherpesviruses emerged relatively recently (30). The evolutionary distances between closely related herpesviruses that infect different species [e.g., the rhadinoviruses HHV-8 (in humans) and HVS (in squirrel monkeys)] suggest that viral speciation occurred at approximately the same time as did host speciation (37, 41). Thus herpesviruses have an intimate shared evolutionary history with their hosts.

In the past decades, a large number of rational but unprovable mechanisms have been used to explain the divergence of herpesviruses. These include (a) acquisition of and subsequent evolution of chunks of cellular DNA, (b) transposition of viral or cellular DNA or RNA, (c) gene duplication and evolutionary divergence, (d) shifts in base and dinucleotide composition in response to viral DNA polymerase mutation rates or concentrations of intracellular nucleotide precursors and pools, and (e) standard mutagenic processes (8, 13, 15, 25, 37, 50, 58).

An important point is that herpesviruses are well adapted to their hosts. In the natural immunocompetent host, fatal infections are rare; from the point of view of viral survival, fatal infections are counterproductive as they do not lead to transmission of virus. This is not always the case when herpesviruses infect a heterologous host, such as the frequently fatal outcomes of infection of cattle with pseudorabies virus, of humans with simian B virus, or infection of African or Asian elephants with herpesviruses from the other species (49). Thus, in addition to adaptation to specific cellular niches, many of the auxiliary genes must also function in striking the optimal balance between virus growth in the host and a combination of avoidance and stimulation of host responses, so that the virus can persist in populations of organisms over an evolutionary time scale.

TRENDS AND ISSUES IN HERPESVIRUS NOMENCLATURE AND CLASSIFICATION

Naming of Genes and Their Products

The ICTV has established a framework for naming herpesviruses but not viral genes or their products. This has led to several problems: The nomenclature applied to viral genes and their products is a hodgepodge, difficult to follow, and potentially misleading. Historical precedents, self-interests, and common usage maintain nomenclatures whose time has long past. The complexity of the problems facing us may be summarized with a few examples:

The HSV-1 virion transactivator was first identified as a component of the virion and designated by its migration in denaturing gels relative to that of other virion proteins [VP16 (56)]. Subsequently, it was designated by its migration in denaturing gels relative to other infected cell proteins [ICP25 (26)]. Still later, it was designated by its apparent molecular weight in denaturing polyacrylamide gels [vmw65 (9)], by its best-known function [a-trans-inducing factor or a-TIF (47)], or by the position of the gene encoding it [U_L48 (38)]. Another example is the major regulatory protein of HSV-1, which was designated initially as ICP4 and subsequently as vmw175 and a4.

HSV is the most extensively studied herpesvirus, but it is not the only one beset by problems in the nomenclature of its genes and proteins. For example, with the exceptions of the proteins expressed during latent infection, EBV genes and their products are named after the DNA fragment in which the gene maps. This nomenclature precludes all but the most dedicated from visualizing the position of the gene.

The least precise current designations are based on apparent molecular weight. For example, ICP4 (vmw175), is expressed in several forms that differ in electrophoretic mobility in denaturing polyacrylamide gels. In addition, the apparent molecular weights relative to standards may vary depending on the composition of the gel. Furthermore, although the HSV-2 homolog has a higher apparent molecular weight, it is sometimes designated by the apparent molecular weight of its HSV-1 counterpart.

The naming of homologous genes based on their HSV-1 counterparts enables a relational database but leads to a loss of information and may be misleading. For example, glycoprotein B is encoded as U_L28 in HSV, U39 in HHV-6B, U_L55 in HCMV, orf8 in HHV-8, and so on. A designation such as gB(HHV-6B) addresses sequence homology but not map position. A real hazard rests in the assumption that the functions of gB are fully conserved from virus to virus. Many herpesvirus proteins perform multiple functions; proteins sharing a conserved block of amino acids may diverge in the functions encoded in other domains. To join in nomenclature by finite commonalities or splinter by fine distinctions is a dilemma that must be solved on middle ground; future nomenclatures may have to allow for the multifunctionality of viral proteins. Ideally, protein names would convey key information useful to the field, such as major function, kinetic class, and genome map location.

Speciation

The definition of viral species accepted by the ICTV is “A virus species is a polythetic class of viruses that constitutes a replicating lineage and occupies a particular ecologic niche” (60). Consistent with this, herpesvirus are defined as distinct species if “(a) their genomes differ in a readily assayable and distinctive manner across the entire genome (e.g., restriction endonuclease cleavage site patterns obtained with many enzymes) and not merely at a specific site (e.g., small number of genes or small number of restriction endonuclease sites) and (b) if the virus can be shown to have distinct epidemiologic and biologic characteristics” (53). Several circumstances have arisen over the past few years that at first glance seemed to challenge these definitions, but, as illustrated below, the definitions allow resolution of the issues.

The EBV variants EBV-1 and EBV-2 differ markedly in several nuclear antigen (EBNA) gene sequences (Chapter 74). The differences lead to differences in some biologic properties, including transforming potential. However, (a) the variants do not occupy distinct ecologic niches, (b) the differences map to a small number of genes, and (c) intermediates carrying one variant allele at one locus and the other variant allele at another locus have been detected. Thus the EBV variants must be recognized as allelic variants of the same species. At least two alleles of the HHV-8 K15 gene, which

maps at the right end of the unique segment of the genome, have been identified (48). As for the EBV variants, recombinants have been detected between viruses encoding the different K15 alleles, thus this represents another example of intraspecies allelic variation. It is possible that the EBV and HHV-8 allelic variants represent early steps in speciation. The process of adaptation to a specialized niche might ultimately result in lineages characterized by additional mutations elsewhere in their genomes, a unique epidemiology, and ultimately reduced biologic fitness of recombinants between different lineages.

HHV-6A and HHV-6B are independent lineages that may represent relatively recent products of this process. Although they are closely related, (a) these viruses differ in a readily differentiable manner across their entire genomes, (b) they differ significantly in their epidemiology and association with disease, and (c) if recombinants occur, they do not appear to persist in nature. Thus by all criteria, they represent distinct species.

Species Nomenclature

The current host name–serial number nomenclature system was devised in an attempt to rectify problems associated with earlier systems in which viruses were named based on their disease associations, discoverer, geographic source, or whatever inspired the discoverer. Some viruses ended up with multiple names and some names were applied to multiple viruses. Of the various vernacular names in use, the most objectionable were disease associations, because viruses either rarely cause a specific disease, or they cause multiple and quite different clinical entities, or the disease for which the virus is named is caused by multiple agents. The system adapted in 1973 (51) was designed to create an orderly system in which each virus would be named unambiguously and independently of classification or properties (which at that time were largely unknown). Like all nomenclatures and classifications, it was meant to be provisional, meaning that it could in time be supplanted by a relational scheme. It was designed to bring herpesviruses into a cohesive order, but unlike a binomial nomenclature, it was not meant to supplant vernacular names grandfathered by time and usage.

The challenges to the current nomenclature system are twofold. First, there is no formal connection between nomenclature and classification. The naming of HHV-6A and HHV-6B reflects, among other things, an attempt to introduce a degree of classification into a system designed to preclude such attempts. An immediate effect is to compromise the status of these viruses as independent species.

The second challenge is based on the absence of any connection in the formal system between nomenclature and disease association, and the understandable desire to make such associations. An example is the designation of HHV-8 as Kaposi's sarcoma–associated herpesvirus on the basis of its association with Kaposi's sarcoma; others include VZV and the malignant catarrhal fever viruses. Although in these cases the disease association was already or ultimately proven, that questions remain after more than 30 years over the etiologic role of EBV in Burkitt's lymphoma (an association made at the time of EBV discovery), as well as the possibility of making an incorrect or incomplete linkage between name and disease, should inspire caution as designations are chosen for the yet-to-be discovered herpesviruses.

Fortunately, as noted, names and classifications are forever provisional.

CHAPTER 72 Herpes Simplex Viruses and Their Replication

Bernard Roizman and David M. Knipe

> Dans l'ignorance ou nous vivons du processus exact de l'herpes, nous voyons chaque generation medicale creer une theorie adaptee aux idees, aux decovertes du moment.
>
> Castel DU, Herpes P *Pratique dermatologique,* vol. II. Paris: Masson, 1901:814, 815.

Herpes simplex viruses (HSVs) were the first of the human herpesviruses to be discovered and are among the most intensively investigated of all viruses. Their attractions are their biologic properties, particularly their abilities to cause a variety of infections, to remain latent in their host for life, and to be reactivated to cause lesions at or near the site of initial infection. They serve as models and tools for the study of translocation of proteins, synaptic connections in the nervous system, membrane structure, gene regulation, gene therapy, and a myriad of other biologic problems, both general to viruses and specific to HSV. For years, their size and complexity served as formidable obstacles to intensive research. More than 40 years passed from the time of their isolation (341) until Schneweiss (542) demonstrated that there were in fact two serotypes of HSV, HSV-1 and HSV-2, whose formal designations under International Committee on Taxonomy of Viruses (ICTV) rules are now human herpesviruses 1 and 2 (508). Not until 1961 were practical plaque assays published (513), and only much later were the genome sizes and the extent of homology between these two viruses reported. This chapter recounts well established facts, but its main emphasis is on burning issues, the problems whose time has come.

To the preface to the third edition of this book, which we affirm but do not repeat here, we add an additional comment. The field has grown enormously since the dawn of studies on the molecular biology of HSV more than 40 years ago. Studies on HSV are entering, at last, a most exciting period for two reasons. First, the words *structure* and *function* are beginning to have an operational meaning. Second, HSV gene products have become powerful probes for the study of cellular metabolic pathways. Host factors crucial to virus multiplication and, potentially, to latency are being identified. The armamentarium for a major assault on the mysteries underlying the biology of these viruses is in place and reflects the contributions of many laboratories over many, many years.

At the same time, the field and the literature have grown enormously. The task before us was far greater for not having followed Ludwig Wittgenstein's dictum that “Whereof one cannot speak, thereof one must be silent,” but chapters of citations bereft of commentary are dull. The decision to avoid assembling an annotated bibliography was in large part dictated by the space available to us.

VIRION STRUCTURE

The HSV virion (Fig. 1) consists of 4 elements: (a) an electron-opaque core, (b) an icosadeltahedral capsid surrounding the core, (c) an amorphous tegument surrounding the capsid, and (d) an outer envelope exhibiting spikes on its surface (509). The core contains the double-stranded DNA (dsDNA) genome wrapped as a toroid (171) or spool (702) and

possibly in a liquid crystalline state (42). The tegument is largely unstructured, except for some icosahedral structure around the pentons (702). The capsid is composed of 162 capsomers (676) arranged in a T=16 icosahedral symmetry. Finally, the envelope consists of a lipid bilayer with about 12 different viral glycoproteins embedded in it.

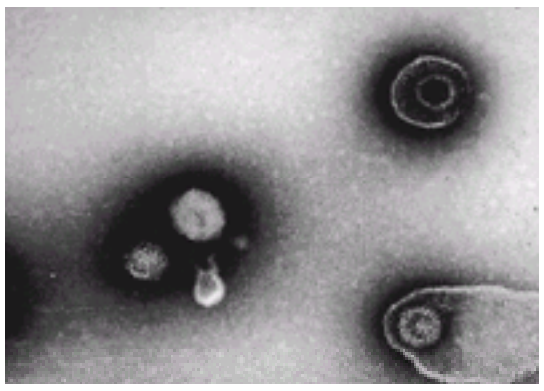

FIG. 1. Electron micrograph of negatively stained HSV virion particles. The *lower left* shows a capsid released from the envelope, revealing the icosahedral structure of the capsid shell. At the *lower right* is shown a virion with a distended envelope. The *upper right* shows a more intact particle, in which stain has penetrated to the core of the particle revealing the multiple layers of the virion, including the envelope as the outer layer, then the dark tegument layer, the capsid shell, and the dark core.

The dry masses of herpes simplex virions, full nucleocapsids, empty nucleocapsids, and cores were calculated from permeability of virions to electrons to be $13.33 \pm 2.56 \times 10^{-16}$ g, $7.55 \pm 1.11 \times 10^{-16}$ g, $5.22 \pm 1.10 \times 10^{-16}$ g, and $2.07 \pm 0.95 \times 10^{-16}$ g, respectively. The average mass ratios of the virion, full capsid, and core to DNA are 8.1, 4.6, and 1.25, respectively. The experimentally derived ratio of virus mass to DNA is 10.73 ± 0.96, from which it has been calculated that the virion contains 19.4×10^{-16} g of protein (216). A similar value was derived from counts of virions in purified virus preparations (R. W. Honess and B. Roizman, unpublished data), although the error in these determinations was higher. This ratio was used in the calculation of the polypeptide content of HSV virions by Heine and colleagues (216).

Virion Polypeptides

Early studies on purified HSV-1 virions suggested that they contain more than 30 distinct proteins, which were designated as virion polypeptides (VP) and given serial numbers (216,589). All of the virion proteins were made after infection, and no host proteins could be detected in purified virion preparations. Of the about 30 known and another 10 suspected virion proteins (Table 1), at least 11 are on the surface of the virion (accessible to antibody), and at least 10 are glycosylated. The glycoproteins are gB (VP7 and VP8.5), gC (VP8), gD (VP17 and VP18) and gE (VP12.3 and VP12.6), gG, gH, gI, gK, gL, and gM. The presence of gJ (U_S5) and gN ($U_L49.5$) in virions has not been demonstrated. Virion envelopes also contain at least two (U_L20 and U_S9) and possibly more (U_L24, U_L43, and U_L34) nonglycosylated intrinsic membrane proteins. Stannard and associates (599) reported that spikes projecting from envelopes are, as was expected, the viral glycoproteins, and that the latter were nonrandomly distributed.

TABLE 1. *HSV genes and their functions*

Gibson and Roizman (188,189) described three kinds of capsids: those that lack DNA and were never enveloped (type A), those that contain DNA and were never enveloped (type B), and those that contain DNA and were obtained by deenveloping intact virions (type C). In the current nomenclature, the term *A capsid* refers to capsids without an internal toroidal structure; those with internal scaffolding proteins but without DNA are designated as *B capsids*; and those with DNA have been designated as the C capsids. The A capsids are a defective byproduct (558) rather than precursors of the B capsids. A short-lived assembly intermediate termed the *procapsid* has recently been described (636).

The empty (A) capsids consist of four proteins: VP5 (U_L19), VP19C (U_L38), VP23 (U_L38), and a smaller Mr 12,000 protein described subsequently (95) and often referred to as VP26 (U_L35) (110,439). VP5 was estimated to be present in ratios of 850 to 1,000 per virion, that is, about six per hexameric capsomere (216,509,647), but Schrag and co-investigators (543) suggested that VP5 is a component of both pentameric and hexameric capsomeres. VP19C and VP5 appear to be linked by disulfide bonds (706) and are present in about similar ratios per virion (216). Braun and associates (45) showed

that VP19C, identified as the infected cell protein (ICP) 32, bound to DNA and may be involved in anchoring the viral DNA in the capsid. The HSV-2 counterpart has also been mapped (694). VP26 is located at the hexon tips. B-type capsids differ from the A type in that they contain three proteins: VP21, VP22a, and VP24. VP22a corresponds to ICP35e-f, the product of the open reading frame (ORF) U_L26.5 cleaved at the carboxyl terminus by the protease resident in VP24 (333,334). VP21 corresponds to ICP35b (amino acids 248 to 610) of the protease Pra, the nascent U_L26 gene product. VP24 corresponds to the N-terminal domain (codons 1 through 247) of Pra designated as Prn, the smallest form of the protease encoded by the ORF U_L26. Pra is cleaved by the autologous protease between ala247 and ser248 and between ala610 and ser611 (126,331). The ICP35 family of proteins described by Braun and colleagues (45) plays a vital role in capsid assembly and encapsidation of viral DNA (178,462,493,558). Gibson and Roizman (189) suggested that VP21 is an internal capsid protein. Newcomb and Brown (404,405) demonstrated that VP19C and VP23 are on the surface of the capsid and form triplex structures that link the hexon capsomers and that VP22a is in the interior of the capsid and forms a ringlike structure that is quantitatively removed by 2.0 molar (M) guanidine hydrochloride.

Type C capsids were reported to contain a smaller protein—VP22—but not VP22a, and it has been suggested that the proteins are related (189). Sherman and Bachenheimer (558) and Rixon and colleagues (493) suggested that the VP22 found in the C-type capsids may not be related to VP22a. Depending on the procedure for stripping the envelope, the C-type capsids may contain variable amounts of tegument proteins. C capsids retain VP24 (the protease).

Cryoelectron microscopy has provided moderately high-resolution models of the HSV nucleocapsid and virion (42,543,702). These studies have shown that the HSV nucleocapsid is composed of three layers: the outer layer arranged in a T=16 symmetry, an intermediate layer organized in a T=4 lattice, and an inner layer consisting of genomic DNA (543). The same study concluded that the outer and intermediate layers are organized so that channels along their icosahedral twofold axes coincide, forming a direct pathway and potential channel between the DNA layer and the exterior of the virion (543). Another study of intact virions has shown that the channel is plugged, possibly with tegument proteins (702). These authors suggested that the VP1-3 tegument proteins regulate the transport of DNA through the channel.

In the interval between 1965 and 1974, a large number of articles dealt with the structure and morphogenesis of herpesvirus capsids; a list of citations and review of that literature was published by Roizman and Furlong (509). On the basis of the electron microscopic appearance of the capsid and the core, as many as eight distinct capsid forms were identified (509). Although the various forms probably reflect different stages of capsid assembly, the reagents necessary to relate the various forms to specific proteins are only now becoming available. The use of specific antibody reagents, viral assembly mutants, cryoelectron microscopy, and methods for *in vitro* as well as *in vivo* assembly hold out the prospect of relating specific proteins, protein assemblies, and capsid forms in a comprehensive view of capsid morphogenesis.

The space between the undersurface of the envelope and the surface of the capsid was designated as the tegument (509); thus, it contains the rest of the virion proteins (see Table 1). The most notable of the proteins associated with the space between the underside of the envelope and the capsid are the a-trans-inducing factor (aTIF; ICP25; VP16), VP11-12 (U_L46), VP13-14 (U_L47), the virion host shutoff (vhs) protein (U_L41); the product of the U_S11 gene; and a very large protein (VP1-2) associated with a complex that binds to the terminal *a* sequence of the viral genome (22,79,483,521,522). Extensive discussion of the various types of capsids and virions can be found elsewhere (227,509,604).

Several publications have reported on the production of “light particles” that are devoid of DNA. These particles consist of enveloped tegument-like structures (371,492,616). They appear to contain, in addition, other nonstructural proteins previously associated with virions (e.g., ICP4) (690). Little is known of their synthesis beyond the facts that they do not appear to be uniform in size and that the capsid is not an essential trigger for envelopment or egress.

Viral DNA

Like other herpesvirus DNAs, the bulk of packaged HSV DNA is linear and double stranded (24,272,444). In the virion, HSV DNA is packaged in the form of a toroid (171) or a spool (702). The ends of the genome are probably held together or are in close proximity inasmuch as a small fraction of the packaged DNA appears to be circular and the bulk of the linear DNA circularizes rapidly in the absence of protein synthesis after it enters the nuclei of infected cells (445). DNA extracted from virions contains ribonucleotides, nicks, and gaps (26,169,677).

Based on physical characterization studies, the HSV genome was originally estimated to be about 150 kilobase pairs (kbp), with a G+C content of 68% for HSV-1 and 69% HSV-2 (24,272). Complete sequencing of the HSV-1 strain 17 genome described the genome as 152,260 base pairs (bp) (accession number X14112) (363); minor updates altered this sequence to 152,261 bp (132). Complete sequencing of the HSV-2 strain HG52 genome defined it as 154,746 bp (accession number 286099) (132). However, these numbers include only single copies of the *a* sequence at the ends of the L component and do not take into account the variation in the size of the *a* sequences (200 to 500 bp each) or the variable number of direct repeats present throughout the genome but especially in the inverted repeats flanking the L and S components.

The HSV genome can be viewed as consisting of two covalently linked components, designated as L (long) and S (short) (Fig. 2). Each component consists of unique sequences bracketed by inverted repeats (650). The repeats of the L component are designated *ab* and *b'a',* whereas those of the S component are *a'c'* and *ca* (see Fig. 2). The number of *a* sequence repeats at the L-S junction and at the L terminus is variable; thus, the HSV genome can then be represented as follows:

$$\mathbf{a_L a_n b\text{-}U_L\text{-}b'a'_m c'\text{-}U_S\text{-}ca_S}$$

where a_L and a_S are terminal sequences with unique properties (described later), and a a_n and a_m are terminal *a* sequences directly repeated 0 or more times (n) or present in one to many copies (m) (335,503,505,650,655). The structure of the *a* sequence is highly conserved, but it consists of a variable number of repeat elements. In the HSV-1 (F) strain, the *a* sequence consists of a 20-bp direct repeat (DR1), a 65-bp unique sequence (U_b), a 12-bp direct repeat (DR2) present in 19 to 23 copies per *a* sequence, a 37-bp direct repeat (DR4) present in 2 to 3 copies, a 58-bp unique sequence (U_c), and a final copy of DR1 (388,389). The size of the *a* sequence varies from strain to strain, reflecting in part the number of copies of DR2 and DR4. The structure of the HSV-1 (F) *a* sequence can be represented as follows:

$$\mathbf{DR1—U_b—DR2_n—DR4_m—U_c—DR1}$$

with the adjacent *a* sequences sharing the intervening DR1. Linear virion DNA contains asymmetric terminal *a* sequence ends. The terminal *a* sequence of the L component (a_L) contains a truncated DR1 with 18 bp and one 3' nucleotide extension, whereas the terminal *a* sequence of the S component (a_S) ends with a DR1 containing only 1 bp and one 3'-overhanging nucleotide (390). The two truncated DR1 sequences form one complete DR1 upon circularization.

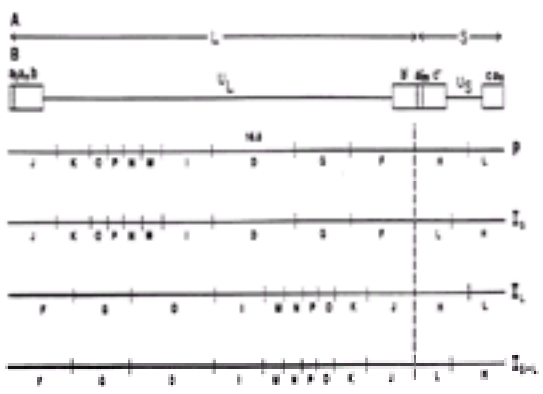

FIG. 2. Schematic representation of the arrangement of DNA sequences in the HSV genome. **A:** The domains of the L and S components are denoted by the *arrows.* The second line shows the unique sequences (*thin lines*) flanked by the inverted repeats (*boxes*). The letters above the second line designate the terminal *a* sequence of the L component (a_L), a variable (*n*) number of additional *a* sequences, the *b* sequence, the unique sequence of the L component (U_L), the repetitions of the *b* sequence and of a variable (*m*) number of sequences (a_m), the inverted *c* sequence, the unique sequence of the S component (U_S), and finally the terminal *a* sequence (a_S) of the S component. **B:** The HindIII restriction endonuclease map of HSV-1 (F) strain for the P, I_S, I_L, and I_{SL} isomers of the DNA. Note that, because HindIII does not cleave within the inverted repeat sequences, there are four terminal fragments and four fragments spanning the internal inverted repeats in concentrations of 0.5 and 0.25 M, respectively, relative to the concentration of the viral DNA.

The L and S components of HSV are found inverted relative to one another, to yield four linear isomers. Populations of unit-length DNA from wild-type virus-infected cells consist of equimolar concentrations of the four predicted isomers (see Fig. 2) (120,211). The isomers have been designated as P (prototype), I_L (inversion of the L component), I_S (inversion of the S component), and I_{SL} (inversion of both S and L components) (211,395,396). The first evidence for the existence of repetition of terminal sequences in inverted orientation was based on electron microscopic studies of denatured HSV-1 DNA allowed to self-anneal (554). Electron microscopic analyses of denatured molecules allowed to self-anneal and of partial denaturation profiles of HSV DNA revealed that the terminal repeats are also repeated internally and that the repeats flanking the L component differ from those of the S component in size and sequence arrangement (650). The demonstration that restriction endonucleases that cleave outside the inverted repeats yield four terminal fragments, each present in half of the molecules (also called half molar or 0.5M fragments), and 4 L-S component junction fragments that are each present in one fourth of the molecules (also called *quarter molar* or 0.25M fragments) (211) (see Fig. 2), as well as analyses of the partial denaturation profiles of Wadsworth and coauthors (650), supported the conclusion that the L and S components can invert relative to each other.

The internal inverted repeat sequences are not essential for growth of the virus in cell culture; thus, mutants from which portions of unique sequences and most of the internal inverted repeats have been deleted have been obtained in all four arrangements of HSV DNA (253,446). The genomes of these mutants do not invert and are frozen in one arrangement of the L and S components, but all retain their viability in cell culture.

Other Constituents

Polyamines

The search for polyamines in the virion evolved from the observations that HSV capsid assembly requires addition of arginine to the medium (352,620) and that the capsid does not contain highly basic proteins, which would neutralize the negative charges on viral DNA to allow proper folding within the capsid. Highly purified virions contain the polyamines spermidine and spermine in a nearly constant ratio of 1.6 ± 0.2:1, or about 70,000 molecules of spermidine and 40,000 molecules of spermine per virion (187,190). The polyamines appear to be tightly bound and cannot be exchanged with exogenously added, labeled polyamines. Disruption of the envelope with nonionic detergents and urea removed the spermidine but not the spermine. The spermine contained in the virion is sufficient to neutralize about 40% of the DNA phosphate (190). Parenthetically, proteins have been noted in association with the toroidal structure (171) in the capsid,

and a capsid protein has been reported to bind DNA (45).

The compartmentalization of spermine and spermidine may reflect the distribution of polyamines in the infected cell. It is of interest to note that after infection, the conversion of ornithine to putrescine appears to be blocked, but the synthesis of spermine and spermidine does not appear to be affected (190).

Lipids

It has been assumed that HSV acquires the envelope lipids from its host. The hypothesis that the lipid composition of the viral envelope is determined by the host was supported by the observation that the buoyant density of the virus was host cell dependent on serial passage of HSV-1 alternately in HEp-2 and chick embryo cells (588). More recent studies (642) suggest that the virion lipids are similar to those of cytoplasmic membranes and different from those of nuclear membranes of uninfected cells. This conclusion assumes that the lipid content of nuclear membranes remains unchanged during infection notwithstanding the change in the overall surface area of nuclear membranes and lack of *de novo* synthesis of cellular proteins in infected cells.

Herpes Simplex Virus Polymorphism

Intertypic Variation

Although the genetic maps of HSV-1 and HSV-2 are largely colinear, they differ in the locations of restriction endonuclease cleavage sites in their genomic DNAs and in the apparent sizes of their proteins. Thus, analyses of HSV-1 × HSV-2 recombinants took advantage of the intertypic differences in the sizes of the proteins and the locations of restriction endonuclease cleavage sites to determine the initial locations of viral genes on the linear map of HSV genomes (354,395,396,463). Comparison of the complete DNA sequences of an HSV-1 genome and an HSV-2 genome confirmed the colinearity of the genetic maps (132).

Intratypic Variation

The first evidence of intratypic polymorphism emerged from studies of virion structural proteins and indicated that nonglycosylated proteins vary sufficiently in electrophoretic mobility to be used as strain markers (436). Although specimens from epidemiologically related individuals appeared to yield similar electrophoretic profiles, the usefulness of virion proteins as markers for molecular epidemiologic studies was limited by the effort required to purify virions for such analyses.

At the DNA level, differences between HSV-1 strains appear to result from (a) base substitutions, which may add or eliminate a restriction endonuclease cleavage site, and on occasion change an amino acid; and (b) variability in the number of repeated sequences present in a number of regions of the genome (e.g., g $_1$*34.5,* U_{s11}) (82,494). The restriction endonuclease cleavage patterns of a given strain are relatively stable, whereas the number of repeats is not (53,210,507,632). Thus, no changes in restriction endonuclease patterns were noted in isolates from the same individual over an interval of 13 years or in genomes of an HSV-1 strain passaged serially numerous times in cell culture. However, restriction endonuclease site polymorphism was readily noted in isolates from epidemiologically unrelated individuals (202,520). On the basis of these properties, restriction endonuclease site polymorphism was used in several epidemiologic studies of HSV transmission in the human population (53,507,520), and blind restriction endonuclease analysis of virus isolates has been used to trace the spread of infection from patients to hospital personnel (51), from patient to patient (328), and from hospital personnel to patient (3,52). Sakaoka and associates (529) reported on clustering of divergent sites along geographically and racially distinct areas. Although these authors concluded that the evolution of HSV-1 may be host dependent, it seems more likely that random mutations were conserved and dispersed in different populations.

GENOME STRUCTURE AND ORGANIZATION

Viral Genes: Pattern of Organization and Expression

Distribution and Organization of Transcriptional Units

The HSV DNA encodes by current count about 90 unique transcriptional units (see Table 1). The HSV-1 sequence and gene map can be found at website http://www.stdgene.lanl.gov/. At least 84 of these transcriptional units encode proteins. As described in more detail later, these genes are classified into at least three general kinetic classes: a, or immediate early; b, or early; and g, or late. The key elements of genome organization are as follows:

1. With three known exceptions, each viral transcript encodes a single protein. In the first exception, a single transcript serves as the template for both ORF P and ORF 0 proteins. Protein synthesis is initiated from a single methionine but diverges between the 1st and 35th codons to yield different polypeptides (480). Second, the U_L*26* gene encodes a polypeptide that cleaves itself to form two proteins. The amino-terminal product functions as a protease. The carboxyl-terminal product, ICP35a,b, is a component of the capsid scaffolding. The third exception is the messenger RNA (mRNA) that encodes the U_L3 protein. This RNA, 2.9 kb in size, contains the ORFs of U_L1, U_L2, and U_L3, but U_L1 and U_L2 proteins are encoded by distinct mRNAs (569). The mechanism of expression of U_L3 protein is unknown.
2. Many clusters of transcriptional units are 3' co-terminal. In addition, these clusters may be arranged either head-to-head, head-to-tail, or tail-to-tail. The precise transcription initiation sites are not known for all transcriptional units. In many instances, but especially late in infection, transcription termination sites are ignored, with the consequence that run-on transcripts of giant size are present along with the properly terminated transcripts. Some of the 3' co-terminal mRNAs initiate within the body of an expressed ORF and encode only the carboxyl-terminal

portion of the protein encoded by the ORF. For example, the mRNA encoding $U_S1.5$ initiates within the ORF expressing ICP22, and the amino acid sequence of $U_S1.5$ is identical to that of the carboxyl-terminal domain of ICP22. The same situation exists for U_L26 and $U_L26.5$.

3. Some of the expressed ORFs are antisense to each other. These include *ICP34.5* and *ORF P*, *U_L43* and *$U_L43.5$*, and *gB* and *$U_L27.5$*. The existence of additional antisense ORFs cannot be excluded.
4. Few of the transcripts accumulating in infected cells arise as a consequence of splicing of RNA. In only two cases, those encoding ICP0 and U_L15, are the introns within coding domains. The intron of U_L15 is transcribed antisense to U_L15 and encodes two ORFs, U_L16 and U_L17 (363). The intron of ICP0 mRNA is stable and transported into the cytoplasm but appears to play no role in productive infection because substitution of the wild-type *ICP0* gene with an intronless *ICP0* gene has no effect on its known functions (147). In all other cases (genes encoding ICP22, ICP47, and gC), the introns are in the 5'-noncoding domains. In one instance, that of the gene encoding ICP34.5, an intron is present in the coding domain of HSV-2 but not that of HSV-1 (362,482).
5. Several transcripts appear not to encode expressed ORFs. Those best known are the latency-associated transcripts (LATs) described in the section dealing with latency and the *Ori_S* mRNA that is expressed late in infection and is 3' co-terminal with the mRNA encoding ICP4. The functions of these RNAs in productive infection are not known.

Functional Organization of Herpes Simplex Virus Genomes

a genes map near the termini of the L and S components (9,258,259,347,396,400,463,661,662). The a*0* and a*4* genes map within the inverted repeats of the L and S components, respectively, and are therefore each present in two copies per wild-type genome. However, a single copy of each is sufficient inasmuch as mutants lacking the internal inverted repeats are viable but are attenuated for growth in animals (446).

With few exceptions, b and g genes are scattered in the unique sequences of both the L and S components. The exceptions are the g_1*34.5* and *ORF P* genes located in the reiterated sequences flanking the L component between the terminal *a* sequence and the a*0* gene (2,84,307). At present, only two functional gene clusters are strikingly apparent, but their significance is uncertain: The b genes specifying the DNA polymerase and the ICP8 single-stranded DNA (ssDNA)-binding protein flank the L component origin of DNA synthesis (*Ori*L) (98,226,478), and the g genes specifying membrane glycoproteins D, E, G, I, and J map next to each other within the unique sequences of the S component (2,165,311,490,510,526,584,662).

Application of Genetic Techniques to the Identification of Gene Product Function: Genes Essential and Nonessential for Growth in Cell Cultures

Key to the identification of viral functions and mapping of viral genes encoding these functions are temperature sensitive (ts) and null mutants. Earlier studies identified about 30 complementation groups (668)—an extraordinary accomplishment in itself given the difficulties inherent in the selection and testing of the numerous mutants produced by many laboratories. The ts mutants have been enormously helpful in mapping genes. Nevertheless, this approach to identification and mapping of viral functions suffers from several problems: (a) the phenotypes of viruses containing mutations in nonessential genes cannot be readily differentiated from that of the wild type parent; (b) conditional lethal (e.g., ts) mutants produced by general mutagenesis of the viral genome may contain a large number of silent nonlethal mutations in both essential and nonessential genes; (c) the phenotypes of mutations introduced into domains shared by more than one gene cannot be readily attributed to the malfunction of a specific gene product; and (d) although the usefulness of ts mutants is in part dependent on their efficiency of plating at permissive and nonpermissive temperatures, tight mutants with high permissive-to-nonpermissive ratios may well contain more than one point mutation. Although the presence of multiple mutations in a single gene should not affect the mapping or identification of the gene function, it does present a problem in mapping the functional domains of the gene.

An alternative to the random or fragment-specific substitution of bases in DNA is localized mutagenesis of the viral genome. Much of the HSV genetic work thus far has used a co-transfection procedure involving the introduction of infectious viral DNA with a viral DNA fragment that contains a marker or mutation to be introduced into the viral genome by a double crossover event (279,526,611). This has been used for marker rescue mapping of viral ts mutants, introduction of markers into a viral genome (marker transfer) (279,526), and introduction of mutations into a viral genome (86,98).

A protocol for site-specific insertion and deletion of viral genes was reported by Post and Roizman (454). It was based on selection of recombinants generated by double recombination through homologous flanking sequences between an intact viral DNA molecule and a DNA fragment containing an insertion or deletion and a selectable marker. The selectable marker used in these studies was the viral thymidine kinase (*tk*) gene because (a) it can be deleted from the HSV genome without affecting the growth of virus in cell culture, (b) a plasmid-borne *tk* gene can be altered so that it cannot recombine by double crossover to repair the deletion in the genomic *tk* gene; (c) viruses carrying a functional *tk* gene can be selected against by plating viral progeny in the presence of nucleoside analogs phosphorylated by the viral thymidine kinase (TK) (e.g., Ara T), and (d) viruses expressing the TK gene can be selected for by plating the virus on TK-negative cells in medium containing methotrexate or aminopterin, which blocks the conversion of thymidine monophosphate (TMP) from deoxyuridine monophosphate (dUMP) by thymidylate synthetase and precludes the *de novo* pathway of TMP synthesis. This procedure permits the selection of viable mutants with deletions or insertions in genes that appear to be nonessential for growth in cells in culture.

A second popular approach for mutagenesis of a specific gene is to replace the gene with *Escherichia coli lacZ* coding sequences so that the b-galactosidase enzyme is expressed by the recombinant virus. The recombinant virus can be identified by the formation of blue plaques in the presence of chromogenic substrates such as X-GAL (194). If the recombinant virus can be isolated and propagated on normal cells, such as Vero cells, the mutated gene is considered to be nonessential. If the viral gene is essential for growth in that cell line, stable complementing cell lines have often been

used to propagate these null mutant viruses (122). In this protocol, the gene to be mutated is transfected into and stably maintained in a cell line that serves as the complementing cell line. The complementing cell line is then transfected with intact viral DNA and the mutated DNA fragment. The progeny of transfection are screened for mutants that form blue plaques or multiply only in the complementing cells (122,326,424).

In recent years, several other techniques have come into vogue that promise to simplify greatly the construction of mutants. The first involves the use of overlapping cosmids that contain viral DNA sequences that encompass the entire genome. After transfection into cells, viral gene expression from the overlapping cosmids enables recombination at the overlapping ends to reconstitute the intact genome (104). The second technique is based on the use of bacterial artificial chromosomes to propagate the viral genome in bacterial cells. Mutations can be introduced into the HSV sequences, and introduction of the recombinant bacterial artificial chromosome into mammalian cells yields infectious virus (235). Both techniques enable construction of multiple mutants. The genomes cloned as bacterial accessory chromosomes are amenable to random insertional mutagenesis by transposons. Finally, an adjunct to all methods designed to inactivate viral genes is the use of baculoviruses carrying the target gene under a viral promoter. Such genes are expressed only in infected cells and enable selection of mutants lacking essential genes (691).

The genes known to be dispensable for viral replication in cells in culture are listed in Table 1. Of importance, most of the dispensable genes are required for replication in experimental animal systems, and in no instance has a virus lacking a dispensable gene been isolated from human lesions (although viruses that fail to react with a specific monoclonal antibody are readily isolated).

Genes dispensable for viral replication in cells in culture fall into several groups whose products are involved in entry of HSV into cells, regulation of gene expression, posttranslational modification of proteins, exocytosis, inhibition of host response to infection, and spread of virus from cell to cell.

In a special category are deletion mutants, whose ability to multiply in cells is species dependent. One example of such mutants is the a22^{-} virus, which grows well in Vero and HEp-2 cell lines but not in human fibroblast strains or in rodent cell lines (547). In the nonpermissive cells, the virus fails to express g2 genes efficiently. Another example of a cell-specific gene is g $_1$*34.5*, which enables HSV to multiply in human cells but is dispensable in Vero, baby hamster kidney cells, and so forth. In the absence of the gene, there is total shutoff of protein synthesis before significant amounts of virus are synthesized (78,80,81).

It could be predicted that viral genes that specify products whose functions are identical and interchangeable with those of cellular genes would be dispensable, at least in cells that express these functions. In this category are the *tk* gene and the genes specifying ribonucleotide reductase. The observation that some virion proteins are dispensable for infection and replication of virus at least in cell culture presented was puzzling for many years. Although we cannot exclude the possibility that cells express proteins with similar functions that complement the deletion mutants, a more likely scenario is that cells in culture express many more genes than cells *in situ* in animal organs. The exceptions to date are polarized epithelial cells and neuroblastoma cells, in which the gene products are sorted differently or which differ from other cells in culture with respect to the nature of the genes that are expressed. HSV may carry a set of genes that enables the virus to enter (e.g., the dispensable glycoproteins), multiply (e.g., g $_1$*34.5*) or egress (e.g., U_L*20*) from a wide variety of human cells. Because these genes are not required for replication in all cells, there exists the formal possibility that functional analogs of the viral gene are encoded and may be expressed by cells. The obvious examples are the *tk,* ribonucleotide reductase, and so forth. The less obvious homologs are the cellular protein kinases that substitute for some of the viral enzymes and the homolog of U_L20, which enables virus to egress from a variety of cell lines other than Vero cells. The complexity involved in defining the function of the numerous genes whose products are dispensable for viral replication in at least some cells in culture is offset by the fact that these genes are excellent probes of cellular functions that, at least in some instances, complement the missing viral function.

VIRAL REPLICATION

Overview of Replication

It is convenient to begin this section on viral replication with a bird's eye view of the major events of HSV replication (Fig. 3).

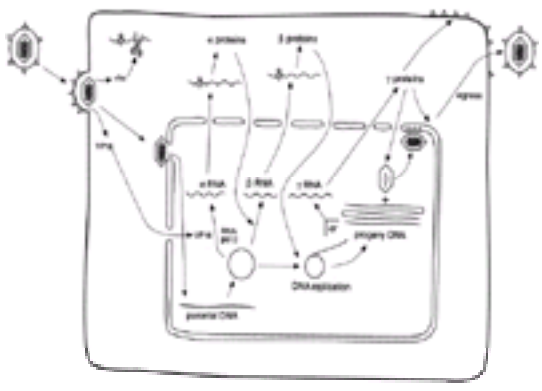

FIG. 3. Diagram of the replication cycle of HSV. At the *upper left,* the virion binds to the cell plasma membrane, and the virion envelope fuses with the plasma membrane, releasing the capsid and tegument proteins into the cytoplasm. The vhs protein acts to cause degradation of mRNAs. The capsid is transported to the nuclear pore, where the viral DNA is released into the nucleus. The viral DNA circularizes and is transcribed by host RNA polymerase II to give first the IE or a mRNAs. IE gene transcription is stimulated by the VP16 tegument protein. Five of the six IE proteins act to regulate viral gene expression in the nucleus. They transactivate E or b gene transcription. The E proteins are involved in replicating the viral DNA molecule. Viral DNA synthesis stimulates L or g gene expression. The L proteins are involved in

assembling the capsid in the nucleus and modifying the membranes for virion formation. The filled capsid buds through the inner membrane to form an enveloped virion, and the virion exits from the cell by mechanisms described in the section on Virion Assembly and Egress.

To initiate infection, the virus must attach to cell surface receptors. Fusion of the envelope with the plasma membrane rapidly follows the initial attachment. The deenveloped tegument–capsid structure is then transported to the nuclear pores, where DNA is released into the nucleus.

Transcription of the viral genome, replication of viral DNA, and assembly of new capsids take place in the nucleus. Viral DNA is transcribed throughout productive infection by host RNA polymerase II, but with the participation of viral factors at all stages of infection. The synthesis of viral gene products is tightly regulated: Viral gene expression is coordinately regulated and sequentially ordered in a cascade fashion. The gene products studied to date form at least five groups as a result of both transcriptional and posttranscriptional regulation.

Several of the gene products are enzymes and DNA-binding proteins involved in viral DNA replication. The bulk of viral DNA is synthesized by a rolling-circle mechanism, yielding concatemers, which are cleaved into monomers during the process of nucleocapsid assembly.

Assembly occurs in several stages. After packaging of DNA into preassembled capsids, the virus matures and acquires infectivity by budding through the inner lamella of the nuclear membrane. The transit of virions from the space between the inner and outer nuclear membranes to the subcellular space is less well defined. It has been suggested that the virion envelope is processed by transit through Golgi stacks or by being deenveloped and then reenveloped at the trans-Golgi network. In fully permissive tissue culture cells, the entire process takes about 18 to 20 hours.

Virus Attachment and Entry

Entry of HSV into cells is effected in three stages (Fig. 4). The first involves the attachment of the virion to the surface of the cell. The second step involves the interaction of gD with one of several cellular receptors. In the last step, the viral envelope and the plasma membrane fuse to release the capsid–tegument structure into the cytoplasm. Most of the information on this process is based on studies of nonpolarized cells in which the membrane proteins interacting with envelope proteins are most likely randomly distributed. Attachment and entry of viruses into polarized cells—most epithelial cells in the human body—may differ in detail.

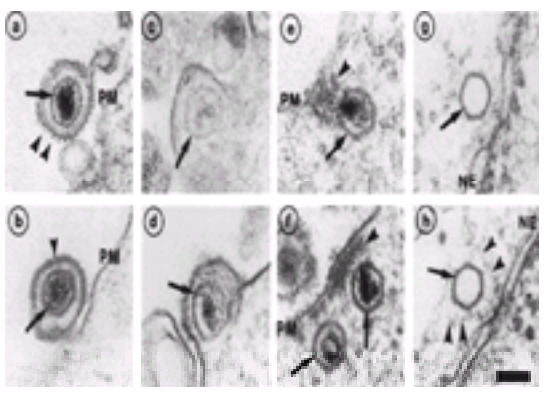

FIG. 4. Entry and uncoating of HSV-1. Shown are ultrathin Epon sections of Vero cells infected with HSV-1 at an MOI of 500 in the presence of cycloheximide (*CH*). After 2 hours of virus binding at 4°C, the cells were either fixed immediately (***a*** and ***b***), or warmed up for 30 (***c*** to ***f***) or 60 (***g*** and ***h***) minutes. Binding (***a*** and ***b***). The main morphologic features of the intact virus bound to the plasma membrane (*PM*) are the viral envelope (***b,*** *arrowhead*) with the viral spikes (***a,*** *arrowhead*), the viral capsid (*arrow*), and the electron-dense viral DNA genome within the capsid. Fusion (***c*** and ***d***). Upon warming up, the viral envelope fuses with the plasma membrane, and the capsid (*arrow*) and the tegument proteins are released into the cytosol. Release of the capsid (***e*** and ***f***). Preparations, which display a prominent contrast of the tegument, show that the tegument (*arrowheads*) stays behind at the PM. Binding to the nuclear pore (***g*** and ***h***). At later time points, the capsids (*arrows*) have arrived at the nuclear envelope (*NE*), where they are exclusively located in close apposition to the nuclear pore complexes. Occasionally, fibers emanating from the pores (*arrowheads*) are visible, to which the capsids appear to bind. Almost all of the capsids at the nuclear pores appear empty and have lost the electron-dense DNA core. Bar, 100 nm. (From ref. 578, with permission).

The initial attachment to nonpolarized cells involves the interaction of the viral envelope gC, and, to a lesser extent gB, with the glycosaminoglycan moieties of cell surface heparan sulfate (560,686). Although gC confers the greatest efficiency for attachment in these systems, it is not essential for either entry or viral replication (216).

Attachment to heparan sulfate enhances infection but is not an absolute requirement for HSV infection of cells because cells devoid of heparan sulfate but expressing other glycosaminoglycans (e.g., chondroitin sulfate) can be infected. Cells devoid of both of these types of glycosaminoglycans can also be infected, although at a reduced efficiency (19). The second, sequential step, designated here as binding to a coreceptor, involves the interaction of gD with one of several cellular molecules that belong to three structurally unrelated molecular families. As is often the case, they have been given different designations based on their cellular function or their function in viral infection.

The first of these coreceptors is a member of the tumor necrosis factor (TNF) receptor family originally called *herpes virus entry mediator* (HVEM) (392) but renamed HveA after other receptors were discovered (659). HveA is present primarily in lymphoid cells, and thus it is unlikely to function as the major mediator of HSV entry into human cells. It serves as a receptor for entry of some selected HSV-1 strains, HSV-2, but not for the related alphaherpesvirus, pseudorabies (PRV) virus (392,670).

The second family of coreceptors belongs to the immunoglobulin superfamily and is related to the poliovirus receptors (183). The first identified members of this family were named HveB (659) and HveC (183) and herpesvirus immunoglobulin-like receptor (HIgR) (92). This family includes several isoforms present in both human and nonhuman cells that are encoded by mRNAs generated by alternative mRNA splicing. More recently, these cellular proteins have been shown to act as intercellular adhesion molecules and to be localized at adhesion junctions where their C-terminal domains bind to L-afadin, a PDZ-binding protein that anchors these molecules to cytoskeleton and adherens junctions. On the basis of their cellular function, they have been named *nectins* (617); therefore, the designations that appear now in the literature are nectin-1a (HveC, Prr1), nectin-1b (HIgR), nectin-2a (HveB, Prr2), and nectin-2d (91,340,586). Nectin-1a and nectin-1b, two splice variants with a common ectodomain, are broadly expressed in cells of epithelial, fibroblastic, neural, and hematopoietic origin; in keratinocytes; and in human tissues that are targets of HSV infection, including skin, brain, and spinal ganglia (92,183). They mediate entry of all HSV-1 strains tested, HSV-2, PRV, and bovine herpes virus 1 (183). They also mediate cell-to-cell spread of HSV (91). Nectin-2a (HveB) and nectin-2d, also splice variant isoforms, mediate the entry of HSV-2, PRV, and certain viable mutants of HSV-1, but not of wild-type HSV-1 (340,659). The distribution of this general class (immunoglobulin superfamily) of receptors in human tissues reflects the susceptibility of cells to infection and is likely to account for both entry and spread of virus from cell to cell.

Homologs of human nectins have been found in a wide variety of species. The murine homolog of human nectin-1 also mediates entry of HSV-1 and HSV-2 into murine cells (382). This raises the possibility that the ability to use the animal homologs of the nectin-type proteins can account for the broad host range of HSV in cell cultures and animals of different species. Interestingly, this receptor activity was reported to function independently of gD binding (382).

The third family has to date only one member: 3-*O*-sulfated heparan sulfate (563). The 3-*O*-sulfated heparan sulfates are broadly distributed on human cells and tissues and mediate efficient HSV-1 but not HSV-2 entry (563). Whether they can mediate entry into human cells remains to be determined. It is interesting that either protein molecules or specific sites on heparan sulfate can serve as receptors for HSV entry.

The last step in entry is the fusion of the viral envelope with the plasma membrane of the host cell. There is overwhelming acceptance of the hypothesis that productive infection results from the entry of virus mediated by fusion of the envelope and plasma membranes (394). Key evidence is the demonstration that gI and gE—the viral Fc receptors—can be detected on the surface of cells immediately after penetration of the virus (430). Conversely, a body of evidence suggests that entry by endocytosis does not result in productive infection. Thus, cells expressing gD internalize virus by endocytosis, but viral replication does not ensue (58,703).

Current evidence indicates that virus–cell fusion requires the participation of gD (326), gB (536), and the gH-gL heterodimer (164). The exact role of these proteins in the fusion process is unknown, but one could speculate that the binding of gD to the cellular receptors leads to a rearrangement of viral proteins on the virion surface, a conformational change in their structure, or both, so that gB, gH/gL, or both can promote fusion. An additional observation underlying the hypotheses is that cells are infected with wild-type virus aggregate (*syn*$^+$ phenotype), whereas certain viral mutants cause the cells to fuse (called either *syn*$^-$ or *syn* phenotype). *Syn*$^-$ mutations map in the genes encoding gB, gH, and gK and in the U_L24 membrane protein (526). The data suggest that these proteins may form a complex and that mutations in any one of the syn proteins cause a rearrangement or a conformational change in the complex, resulting in cell fusion (526). For detailed reviews on this topic, see references 57 and 585.

Studies on viral entry into polarized cells have progressed to a much lesser extent. Current data are based on studies of viral entry into a few polarized cell lines in culture and on corneal cells *in vivo.* These data indicate that attachment to the apical surface is gC dependent, whereas entry through the basolateral surface is gC independent (548), and that gG, a viral glycoprotein with no other known function, plays a key role in the postattachment entry on the apical surface but is not essential for basolateral entry (633).

The transition from attached to penetrated virus, as measured by the loss of susceptibility to neutralization, inactivation by acidic pH, or proteases, is very rapid and occurs within minutes (121,236).

Transport to the Cell Nucleus

After fusion of the envelope to the plasma membrane, some tegument proteins remain in the cytoplasm (e.g., vhs, U_S11) whereas others are either transported to the nucleus (VP16) or may remain associated with the capsid (e.g., VP1-2), as discussed later in the text. The capsid with associated tegument structures is then transported through the microtubular network to the nuclear pore. The extent of our knowledge of virus transport is limited but can be described as follows:

HSV capsids have been observed bound to microtubules in neurons (343,344,433). In cultured cells, antibodies specific for capsid proteins co-localize with microtubules after viral entry (578). Microtubule depolymerizing agents such as colchicine and nocodazole block the transport of nucleocapsids to the cell nucleus, and antibody labeling of dynein, the microtubule-dependent motor, showed that it was attached to HSV capsids (578). These authors proposed that incoming capsids bind to microtubules and use dynein to propel them to the cell nucleus. The precise mechanism of loading capsid–tegument structures onto the cytoplasmic dynein motors is unknown, but two observations are relevant. First, shortly after infection, the microtubules at the junction with the plasma membrane become disrupted (657), suggesting the possibility that the loading of the capsid–tegument structures may affect the interaction of microtubules or associated proteins with cognate structures in the plasma membrane. More extensive rearrangements of the microtubular network

take place late in infection. Second, recent studies have shown that the U_L34 protein binds the amino-terminal domain of the intermediate chain 1a of cytoplasmic neuronal dynein and that, in the presence of nocodazole, which causes the depolymerization of dynein, U_L34 protein is not transported to the nucleus (692). Finally, because the normal dynein motor terminus is at the microtubule-organizing center, it is not clear how the nucleocapsids ultimately come in apposition with the nuclear pore complex.

After intracytoplasmic transport, the nucleocapsids accumulate at the nuclear envelope and associate with the nuclear pore complexes (21,578) (see Fig. 4). At the pore, the nucleocapsid releases its DNA into the nucleus, leaving an empty capsid at the cytoplasmic side of the complex. Little is known about the mechanisms of HSV DNA release and transport through the nuclear pore into the nucleus. The HSV-1 ts mutant *ts*B7 is completely blocked for viral gene expression at the nonpermissive temperature (NPT) (278) because it is defective for the release of DNA from capsids at the NPT (21). The ts mutation in *ts*B7 maps in the *VP1/2* gene (21), suggesting that this large tegument protein plays a role in DNA release at the nuclear pores. These results also suggest that the VP1/2 tegument protein is transported to the nuclear pore with the capsid; nevertheless, it is still conceivable that the defective protein is unable to be released in the cytoplasm and thus is kept artifactually with the nucleocapsid during transport through the cytoplasm and blocks uncoating at the nuclear pore. Recent *in vitro* results have shown that binding of the capsid to the nuclear pores is blocked by wheat germ agglutinin, antinuclear pore complex antibodies, or antibodies against importin b (422). Thus, the available data suggest that the interaction of capsid–tegument structures with the nuclear pore proteins causes a structural change in the former, with the consequence that viral DNA is extruded from the capsids into the nucleus; however, the molecular details remain to be defined. The presence of intact, empty capsids for at least 2 hours after exposure of cells to the virus suggests that the extrusion of the DNA does not coincide with complete dissociation of the capsid.

Some of the functions of viral tegument proteins and of genes expressed after infection suggest that the environment inside the host cell is decidedly hostile to the incoming virus. The tegument proteins are introduced into the cell concurrently with the capsid, and some play a key role in creating an environment that allows efficient viral replication. Although the functions of many tegument proteins remain elusive, it seems clear that their distribution varies early in infection. For example, two of these proteins, VP16 and U_L41, are described in detail in later sections, but they promote a gene transcription in the nucleus and shutoff of host protein synthesis in the cytoplasm, respectively. These two virion proteins play a clear role in preparing the host cell for efficient viral replication.

Table 1 lists a large number of viral proteins reported to be components of the viral tegument. With the two exceptions listed previously, the functions of the tegument proteins are not readily discernible, largely because many are either dispensable for viral replication or their function as tegument proteins is different from that expressed in the course of productive infection after *de novo* synthesis. For example, U_S11, genetically engineered to be expressed early in infection, blocks the shutoff of protein synthesis induced by activated protein kinase R (PKR) (66). Virions carry about 2,000 copies of U_S11 protein; after infection, these are associated with polyribosomes and 60S ribosomal subunits and do not block the shutoff of protein synthesis caused by activated PKR in cells infected with $g_134.5$-negative mutants. Similarly, ICP22 and other a proteins are posttranslationally modified by both the U_L13 and U_S3 viral protein kinases. However, there is no evidence that ICP22 is modified by the viral kinases introduced into the infected cell as tegument proteins (421,471,472). Thus, the functions of many of the tegument proteins remain to be identified. Nevertheless, the process of entry and release of tegument proteins can be harmful to the cell because cells arrested at the stage of release of tegument proteins can undergo apoptosis (176,700).

The Fate of Viral DNA upon Entry into the Nucleus

The bulk of the incoming viral DNA circularizes rapidly after infection and in the absence of viral protein synthesis (179,445), suggesting that under these conditions, circularization of the genome is promoted by cellular proteins or viral proteins brought into the infected cell in the virion. It has been suggested that the viral DNA ends are held together in the virion and are rapidly ligated by cellular enzymes (445). Because viral DNA is nicked and contains ribonucleotides (see Genome Structure and Organization), repair, circularization, and conversion to the appropriate conformation must then take place. These events may explain the involvement of the RCC1 (regulator of chromosome condensation) gene product in early events in viral infection reported by Umene and Nishimoto (638), but this remains to be verified. It has also been suggested that circularization may result from recombination between direct repeats in the terminal *a* sequences (37), consistent with the hypothesis that fluctuation in the number of *a* sequences could be the consequence of recombination between free ends (390). Such recombination events undoubtedly take place because the number of such repeats varies within the DNA populations arising from a single plaque. It is likely, however, that such recombination events also occur during viral DNA synthesis and packaging.

Leinbach and Summers (317) reported that HSV DNA remains in a nonnucleosomal form during the course of productive infection of cells.

Overview of Productive Infection Gene Expression

During productive infection, more than 80 HSV proteins are expressed in a highly regulated cascade fashion (Fig. 5) in a number of coordinately expressed groups of gene products (230), and several viral proteins play a role in regulation of viral gene expression. Transcription of viral DNA takes place in the nucleus, and as would be expected, all viral proteins are synthesized in the cytoplasm. The host RNA polymerase II is responsible for transcription of all viral genes on the viral DNA during infection (8,102), although viral gene products may modify its activity and structure. Very soon after infection, about 2 to 4 hours postinfection (hpi) at a multiplicity of infection (MOI) of 10 to 20 or in the absence of other *de novo* synthesized viral proteins, the viral a or immediate-early (IE) genes are expressed. These consist of six proteins designated as ICP0, ICP4, ICP22, ICP27, ICP47, and $U_S1.5$. Although transcription of a genes requires no prior viral protein synthesis, an HSV protein brought in with the virion tegument, VP16 (also called aTIF and Vmw65), stimulates the transcription of the a genes, as described later. Five of the six a gene products, including ICP4, ICP0, ICP27, ICP22, and

U_S1.5, stimulate E gene expression in at least some types of cells. As described later, HSV infection inhibits host transcription, RNA splicing and transport, and protein synthesis to facilitate the transition from cellular to viral gene expression.

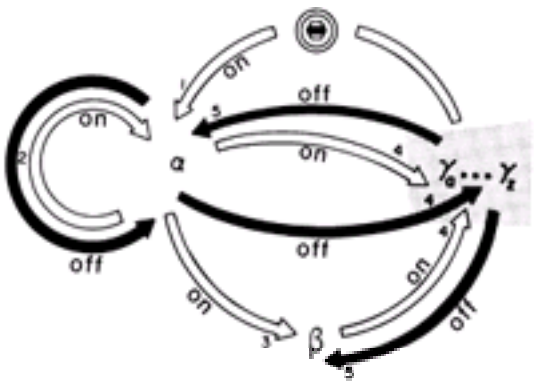

FIG. 5. Schematic representation of the regulation of HSV gene expression. *Open* and *filled arrows* represent events in the reproductive cycle that turn gene expression "on" and "off," respectively. 1. Turning on of a gene transcription by a-TIF, a g protein packaged in the virion. 2. Autoregulation of a gene expression. 3. Turning on of b gene transcription. 4. Turning on of g gene transcription by a and b gene products through transactivation of g genes, release of g genes from repression, and replication of viral DNA. Note that g genes differ with respect to the stringency of the requirement for DNA synthesis. The heterogeneity is shown as a continuum in which inhibitors of viral DNA synthesis are shown to have minimal effect on g_a gene expression but totally preclude the expression of g_z genes. 5. Turning off of a and b gene expression by the products of g genes late in infection.

Expression of the next set of HSV genes, the b or early genes, requires at least the presence of functional ICP4 but not the onset of viral DNA synthesis. Between about 4 to 8 hpi, the b proteins are expressed at peak rates. Among these are proteins involved in replication of the viral DNA and nucleotide metabolism. These viral proteins promote viral DNA replication, and expression of g, or late, genes is then stimulated. Two general groups of b proteins have been identified, although rigid criteria for classification into the two groups have not been defined. The b1 genes are expressed within a short time after or almost concurrently with the onset of synthesis of a proteins and are exemplified by *U_L29* encoding ICP8, the single-stranded protein, and *U_L39* encoding ICP6, the large subunit of ribonucleotide reductase. The b_2 genes are expressed with more delay after a protein expression and are exemplified by *U_L23* encoding thymidine kinase. Some of the b genes require ICP27 for their expression, and this may correlate with the later kinetics characteristic of b_2 genes.

The g, or late, genes are expressed at peak times after viral DNA synthesis has commenced, and their expression is enhanced by viral DNA synthesis. They have been lumped for convenience into two groups, one called g_1, early-late, or leaky-late, and one called g_2, late, or true-late, although in reality, they form a continuum differing in their timing and dependence on viral DNA synthesis for expression (98,101,259,565,651). The typical g_1 gene (e.g., the genes encoding ICP5, gB, gD, and ICP34.5) is expressed relatively early in infection and is stimulated a few fold by viral DNA synthesis. The relatively abundant major capsid protein ICP5 is made both early and late in infection. In contrast, typical g_2 genes (e.g., *U_L44*, the gene encoding gC, *U_L41, U_L36, U_L38*, and *U_S11*) are expressed late in infection and are not expressed in the presence of effective concentrations of inhibitors of viral DNA synthesis.

Based on our limited knowledge of the structure of the promoter and regulatory regions of HSV genes at this time, there appear to be differences in the general organization of the promoter and regulatory sequences of typical genes in each class (Fig. 6). In general, the a gene promoters contain numerous binding sites for cellular transcription factors (see Fig. 6, *ICP4* gene) upstream of a TATA box. The b gene promoters thus far studied contain binding sites for two or three cellular transcription factors upstream of the transcriptional start site (see Fig. 6, *TK* gene). The g_1 gene promoters contain only one or two upstream binding sites (see Fig. 6, *ICP5* gene), whereas the g_2 promoters consist of a TATA box, an initiator element, and a downstream activator element, each of which may vary considerably from cellular homologs (see Fig. 6, *gC* or *U_L44* gene). The level of transcription of viral genes increases in general for the later kinetic classes of genes (699), likely because large amounts of late proteins are needed for virion assembly. This increased level of transcription is apparently due to increased template number and virus-induced modification of the transcription apparatus that is operating on the viral DNA molecule.

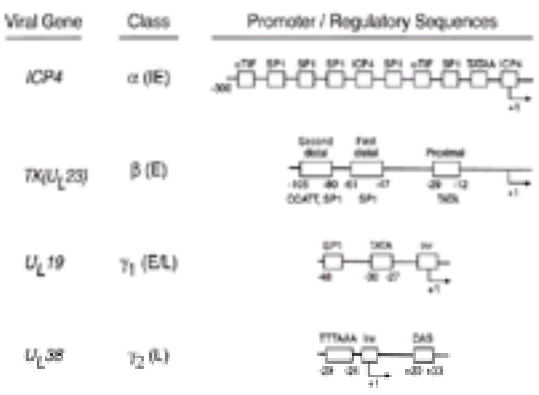

FIG. 6. Diagram of the structure of prototypic HSV gene promoters. The promoter and regulatory sequences of prototypic

genes of a, b, g_1, and g_2 kinetic classes are diagrammed.

We would like to emphasize that although there are prototype genes that allow the definition of four post-a classes of genes, there is likely to be a continuum of genes from b_2 to g_1 genes, in terms of their kinetics and requirements for viral gene expression. First, b and g gene expression in the context of the viral genome requires the participation of five of the six a proteins: ICP0 (528), ICP4 (279,456), ICP27 (527), ICP22 (454,547), and US1.5 (421). Only a few viral genes have been completely characterized with regard to their requirement for these a proteins; thus, we do not know how the requirement for these genes correlates with the kinetic classes already defined. Second, the differences between b and g_1 genes are difficult to quantify and are not perfectly delineated. In principle, the expression of b genes is not augmented by the onset of DNA synthesis, whereas the expression of g_1 genes is reduced in the presence of inhibitors of DNA synthesis. However, expression of some of the b genes is inhibited slightly by inhibitors of viral DNA synthesis (639), whereas some g_1 genes are expressed early and are affected only minimally by inhibitors of DNA synthesis (e.g., *gB*) (478). Nevertheless, it is useful to consider b and g gene expression separately while discussing events in the course of productive infection.

The *ORF O* and *ORF P* genes present a special case. These genes are repressed by ICP4 and therefore are not expressed during productive infection or in the presence of functional ICP4. These genes have been designated as pre-a genes in recognition of the special requirements for their expression (307).

Expression of a Genes

Upon entry into the cell nucleus, the HSV genome, presumably in a circular form, localizes to intranuclear sites near the cellular ND10 structures where transcription of a genes is thought to take place (358). The a gene promoters contain numerous binding sites for cellular transcriptional factors. The major characteristic that differentiates a genes from other viral genes is the presence of the consensus sequence 5'-GyATGnTAATGArATTCyTTGnGGG-3' in one to several copies within several hundred base pairs upstream of the cap site (173,346,347 and 348). This sequence binds Oct-1 but acts as a response element to a complex of the viral protein VP16, host cell factor (HCF) or C1, cellular Oct-1, and other transcriptional factors to promote the expression of the a genes (185,292,293,295,418,459,634).

VP16

VP16 was first described as a virion protein number 16 (VP16) by Spear and Roizman (589) and as ICP25 during the enumeration of proteins accumulating in cells after infection (230). The first evidence that HSV encodes a function that transactivates a genes after infection was reported by Post and co-investigators (453). Subsequently, this virion factor, named a gene transactivating factor (a-TIF) was shown to be a component of the tegument capable of inducing genes carrying the cognate promoter response element, even in the absence of the release of viral DNA into the nucleus (22). VP16 was identified as the virion protein responsible for the transactivation of a genes by Campbell and colleagues (61), and the gene was sequenced by Pellett and associates (432). Upon release from the tegument, VP16 binds to a cellular protein called host cell factor (HCF) or C1 (265,297,603,688). It has been reported that HCF carries VP16 into the nucleus (302), where the VP16–HCF complex binds to Oct-1 bound to viral DNA, forming the activator complex.

The functional organization of VP16 involves several domains of the protein: Residues 378 to 389 are required for interaction with the POU domain of Oct-1 (197,198,297,603), residues 173 to 241 are required for binding of the complex to DNA (603), and the acidic carboxyl-terminal residues 411 to 490 are required for transactivation (634). The C-terminal region likely activates transcription by interaction with host transcription factors, possibly the TFII-B (327) and TFII-D general transcription factors (612). Little is known about the portions of VP16 needed for assembly into virions other than the observation that the amino-terminal 389 residues are sufficient for interaction with the vhs protein, another tegument component (570).

As illustrated in the case of the gene encoding ICP4 (see Fig. 6), a promoters also contain binding sites for other cellular transcriptional activators (e.g., Sp1) in addition to Oct-1. The precise mix of cellular and viral response elements varies between different a gene promoter and regulatory sequences, and their relative contribution to the abundance and duration of transcription has been investigated in only a few instances. In rapidly dividing cells, VP16 increases the accumulation of transcripts by about fourfold and is not a critical factor in viral gene expression (592). Presumably, Oct-1, Sp1, and other cellular transactivating factors account for the basal level of a gene expression. The requirement for VP16 may be different in resting cells or differentiated cells in which these transcriptional factors are unavailable or tightly regulated.

Shutoff of a Gene Expression

The mechanism of the shutoff of a gene transcription is not entirely clear, but three mechanisms are thought to play a role:

1. ICP4 represses its own gene by binding to its cognate DNA binding site located across the transcription initiation site (see Fig. 6). The original consensus sequence of the binding site reported by Faber and Wilcox (154) was ATCGTCNNNNYCGRC, but binding sites vary considerably with respect to degeneracy and affinity for ICP4. The strongest binding sites are those located across the transcription initiation sites of the *ICP4* and the *ORF P* and *ORF O* genes (154,296,399). The effectiveness of the binding site in repressing transcription in the context of the viral genome varies depending on the distance from the transcriptional initiation site. The further downstream it is, the less the repression. Also, displacement by half of a helical turn is more effective in minimizing repression than that by a full helical turn (320). In addition, whereas mutagenesis of the ICP4-binding site across the transcription

initiation site resulted in a 10-fold increase in accumulation of transcripts, the added mutagenesis of the upstream and more distant binding site had barely a twofold effect on transcript accumulation (320). It is less clear whether ICP4 represses the expression of the other a genes. ICP4 binds upstream of the *ICP0* gene transcriptional initiation site (294), and ICP4 represses the *ICP0* promoter in transfected cells (181). Nevertheless, the specific effect of ICP4 on *ICP0* gene expression in infected cells has not been defined by construction of a mutant virus with the binding site in the *ICP0* gene mutated. Consensus ICP4-binding sites are not evident in or near the promoters of the other a genes.

2. During productive infection, b gene products down-regulate a gene expression (230). One b protein identified as a candidate is ICP8, the ssDNA-binding protein encoded by the b_1 gene U_L29. ICP8 decreases the expression of all genes from the parental viral DNA molecules (191, 192), in particular transcription of the gene encoding ICP4 (193). The mechanism of this effect of ICP8 is not known, but it may involve the sequestration of viral DNA molecules in replication complexes, changes in the conformation of viral DNA, or displacement of DNA to sites of DNA synthesis away from those required for transcription.
3. In cells infected with *vhs* mutants, the transition from a to b and subsequently to g protein synthesis lags behind that observed in wild-type virus-infected cells. One function of *vhs* is to synchronize sequential viral gene expression. Underlying this process is the expectation that the a transcripts would overwhelm and outcompete the b mRNAs with respect to translation initiation.

Activation of b Gene Expression

The b_1 and b_2 groups of polypeptides reach peak rates of synthesis about 5 to 7 hours after infection (230). The b_1 proteins, exemplified by polypeptides ICP6 (the large component of the viral ribonucleotide reductase (239) and ICP8 (the major DNA binding protein (98), appear very early after infection and in the past have been mistaken for a proteins (90). They are differentiated from the latter by their requirement for functional ICP4 protein for their synthesis (230, 231). The b_2 polypeptides include the viral TK and DNA polymerase. The appearance of b gene products signals the onset of viral DNA synthesis, and most viral genes involved in viral nucleic acid metabolism appear to be in the b group. The b genes are heterogeneous with respect to time of peak synthesis, although those defined as b_2 are generally made later in infection.

Unlike a genes, b or g genes do not share common promoter elements that instantly predict the timing, duration, or abundance of gene expression. Rather, the overall impression is that they appear to be made up of a diversity of elements, and both the organization and the context in which these elements are placed determine the expression of the gene.

ICP4

ICP4 is required for all post-a gene expression (90, 130, 279, 456, 660), and the effect of ICP4 is exerted at the transcriptional level, as demonstrated by nuclear runoff assays (193). Despite the extensive studies of ICP4 through transfection studies, viral genetic studies, and biochemical studies, the mechanism by which ICP4 transactivates post-a genes remains elusive; however, three lines of investigation are noteworthy.

The first centers on the DNA-binding activity of ICP4. As noted earlier in the text, ICP4 binds to both consensus and nonconsensus sites as measured by gel shift assays (294, 384, 385). Binding of ICP4 to specific DNA sites seems unlikely to explain its transactivation activity because the strongest affinity of ICP4 is for sites known to repress rather than activate transcription (e.g., at the transcription initiation sites of the *ICP4* or *ORF P* genes), and destruction of the sole sequence-specific binding site of ICP4 upstream of the transcription initiation site of the *ICP4* gene attenuated repression in the context of the viral genome (320). With regard to the role of DNA-binding in the transactivation function of ICP4, early mutational analysis studies showed that the sequence-specific binding activity of ICP4 correlated extensively with its ability to activate b gene expression in infected cells (556). In addition, insertion of ICP4 binding sites was reported to render reporter genes responsive to ICP4, albeit in transfected cells (622). However, at least one viral mutant has been obtained in which the DNA-binding activity of ICP4 was greatly reduced but the ability to activate b genes in infected cells was nearly unchanged (555). Furthermore, most post-a genes do not have recognizable consensus binding sites for ICP4, and mutation of consensus sites has not affected the level of expression of the surrounding genes in the viral genome (572). Thus, the bulk of the data from studies of infected cells have failed to correlate ICP4 DNA binding with transactivation of b genes.

As noted earlier, gel shift studies have shown that ICP4 binds to several nonconsensus b and g gene sequences (241, 384, 385, 427, 428). It was postulated that, by binding to DNA sequences near promoters, ICP4 might stabilize the binding of cellular transcription factors to the b gene promoters (427, 428).

The second line of studies has centered on the interaction of ICP4 with transcriptional factors. ICP4 has been shown to form complexes *in vitro* with TATA-binding protein, TFII-B, and TAF250 (63, 573), and most current models for ICP4 transactivation involve interactions with cellular transcription factors to stimulate transcription. Again, given the ability of ICP4 to both activate and repress gene expression, it is not clear whether the binding of cellular transcriptional factors represents the transactivation or repressive function of ICP4.

The mechanism of activation of b genes has also been approached in studies attempting to map the cis-acting sequences needed for activation by virus infection or ICP4. The most extensively studied b gene promoter is that of the U_L23 or *tk* gene. Extensive mutagenic analysis of the promoter showed that the sequences needed for basal level transcription (369) or activated transcription (94) were the same (see Fig. 6): (1) a proximal signal from nt –12 to –29 containing a TATA box and (2) two distal signals from nt –47 to –61 and –80 to –105 containing an SP1 transcription factor–binding site, an SP1 site, and a CCAAT transcription factor (CTF) site, respectively. These studies also supported the hypothesis that ICP4 transactivates b gene promoters through interactions with cellular basal transcription factors.

Considerable work has been devoted to defining the functional organization of the ICP4 molecule. Residues 143 to 210 and 800 to 1298 are required for transactivation (431,556); residues 263 to 487 are required for DNA-binding (556,683); residues 723 to 732 are required for nuclear localization (123,398); residues 309 to 489, including the DNA-binding domain, are required for dimerization (557,682); and residues 171 to 251, including the serine-rich domain from residues 175 to 198, are required for phosphorylation (123,687).

ICP4 is modified extensively by phosphorylation, poly(ADP-ribosyl)ation *in vitro* (461) and *in vivo* (27), and nucleotidylylation (30). The latter modification, carried out by casein kinase II (386), is signaled by the sequence RPRA/S-R shared with the nucleotidylylated proteins ICP0, ICP22, ICP27, and the products of the U_L21, U_L31, U_L47, and U_L49 genes (28). The available evidence suggests that nucleotidylylation of some a proteins requires the presence of proteins made later in infection (27).

Posttranslational processing of ICP4 is associated with translocation into the nucleus. ICP4 forms numerous spots in two-dimensional gels (1) and at least three bands named ICP4a, b, and c in one-dimensional SDS-PAGE gels (437). The slower one-dimensional electrophoretic forms are due to posttranslational modifications. They appear at about the time when ICP4 associates with the nucleus (158), and they do not form with ts mutant ICP4 molecules that are unable to localize into the nucleus (279,456). ICP4 is probably phosphorylated at multiple sites, as suggested by the complex pattern of phosphopeptides generated from it (687). The serine-rich region from residues 142 to 210 contains many potential sites for phosphorylation, and this region has been shown to be phosphorylated. The serine-rich region or its phosphorylation is essential for efficient phosphorylation of the rest of the molecule (687).

Residues 515 to 520 of ICP4, gly-tyr-gly-ala-ala-gly, match an adenosine triphosphate (ATP)-binding motif, gly-X-gly-X-X-gly, characteristic of the catalytic domain of certain protein kinases (687). ICP4 has a tightly associated protein kinase activity (687), but it is not known if this activity is intrinsic to ICP4.

There is considerable indirect evidence that the various isoforms of ICP4 may have different properties and functions. The isoforms of ICP4 differ in their affinities for different DNA-binding sites (385). A later study reported that dephosphorylated forms of ICP4 bound to a promoters, whereas phosphorylated forms bound to b and g promoters (429). The transition from one isoform to another may well be dependent on the function of other a proteins inasmuch as ICP27 causes a shift of ICP4 to a faster migrating form (485,613) and stimulates the transactivation of g genes by ICP4. Some of the ICP4 isoforms cycle phosphate on and off (675), an activity that may be related to the protein kinase activity tightly associated with the protein (687).

In summary, ICP4 performs the functions of a transcriptional activator but, except for its repressive functions, does not behave like a classic transcriptional regulator. The many isoforms accumulating in the infected cells suggest that its different functions may be dependent on the posttranscriptional modification and the context of the cognate DNA-binding site. A perhaps simplistic view summarizing the current models of ICP4 action is that it represses transcription by binding to consensus sequences near sites of transcriptional initiation but activates transcription by binding to transcription factors and perhaps nonspecifically to DNA.

ICP27

ICP27 is an essential (360,527), multifunctional a protein that is required for expression of several classes of post-a genes (360,489,527,639), viral inhibition of RNA splicing (206,208), and inhibition of transcription of many host genes (593). ICP27 localizes into the nucleus independently of other viral proteins and, at early times, has been reported to be distributed diffusely in the nucleus or with small nuclear ribonucleoprotein particles (snRNPs) (441,534) and in replication compartments at later times of infection (114).

Functional domains mapped on the 512-residue ICP27 molecule include an amino-terminal acidic region essential for viral replication from residues 12 to 63 (487), an N-terminal nuclear localization signal from residues 110 to 137 (375), an N-terminal leucine-rich nuclear export signal from residues 7 to 15 (532), a methylated internal RGG box required for RNA-binding (378), a C-terminal transactivator region from residues 262 to 512 and a transrepressor region from 434 to 512 (533), and a zinc finger motif from 483 to 508 (646).

Early studies on viral gene expression concluded that ICP27 is required only for viral DNA replication and late gene expression (485,527), but recent results have shown that ICP27 is also needed for efficient expression of certain b genes (365,530,639), in particular the less abundant viral DNA replication proteins (639). Thus, ICP27 is required indirectly for viral DNA replication to promote the expression of viral gene products that are essential for viral DNA synthesis. These studies have shown that ICP27 increases the mRNA levels for these b genes, but it has not been determined whether this effect is transcriptional or posttranscriptional. Further discussion of the mechanisms by which ICP27 stimulates g gene expression and inhibits RNA splicing and host transcription is presented in the sections that follow.

ICP0

ICP0 is not essential for viral replication but promotes viral infection and viral gene expression, especially at low multiplicities of infection (MOI) (528,610). At low MOIs, cells infected with ICP0 deletion mutants yield about 10- to 100-fold less virus than cells infected with wild-type virus. ICP0 null mutant viruses are able to enter cells and express a proteins but are defective for progression through the productive cycle. Therefore, the particle-to-plaque-forming unit (PFU) ratios of ICP0 null mutant virus stocks are significantly higher than those of wild-type virus stocks (610). The phenotype of ICP0 null mutants is MOI dependent because at MOIs of 5 and higher, ICP0 null mutants give viral yields similar to those of wild-type virus.

The early literature on ICP0 clearly established that it is a nonspecific (sometimes called promiscuous) transactivator because in transfected cells, it induces the expression of HSV a, b, and g promoters (148,182,419,476) as well as

heterologous promoters (401). ICP0 null mutants are defective for expression of a, b, and g mRNAs (74), a defect manifest at the level of RNA synthesis (260). Because ICP0 does not bind DNA directly (153), it appears to be affecting transcription indirectly. Functional analysis of mutant proteins has defined an N-terminal C3HC4 zinc-binding domain or RING finger motif (146). ICP0 is phosphorylated by both viral (U_L13) and cellular kinases in infected cells (420) and is nucleotidylylated (29).

The mechanisms by which ICP0 stimulates viral gene transcription in infected cells have not been defined, but a number of interactions of ICP0 with cellular proteins and organelles have been observed, and these may ultimately lead to an understanding of the mechanism of action of ICP0.

1. Early in infection, ICP0 localizes in the nucleus. Beginning 3 hours after infection, ICP0 is translocated to the cytoplasm (primary human embryonic lung fibroblasts). The translocation is nearly complete by 7 to 9 hours, depending on multiplicity of infection. Translocation is blocked by inhibitors of DNA synthesis, suggesting that the translocation required g_2 proteins (644).
2. During the nuclear phase, ICP0 localizes at or near nuclear structures known as *nuclear domain 10* (ND10) structures and causes the loss of the ND10 component PML and the disorganization of the ND10 structures (151,356,357). The function of these cellular structures is not known, but several viral DNA genomes are believed to target to these structures early in infection (243,244). A key component of ND10 is PML, named after promyelocytic leukemia, in which an aberrant form consisting of PML fused to rectinoic acid receptor-a accumulates. Certain forms of PML are lost after HSV infection. A simple model for this viral effect on the host cell is that the ND10 structures are part of a host cell repression system that the virus evades by causing disruption of the structure.
3. ICP0 interacts with components of the protein degradation machinery (150,152). ICP0 binds to a ubiquitin-specific protease named HAUSP and increases its localization to ND10 sites (152). ICP0 and HSV infection causes a loss of PML isoforms that are known to be conjugated to SUMO-1 or PIC1 (150). Thus, it has been hypothesized that ICP0 binds to HAUSP and stimulates the cleavage of SUMO-1 from PML and possibly other proteins, allowing their ubiquitination and subsequent degradation (150). ICP0 is also required for the loss of the regulatory subunit of the cellular DNA-dependent protein kinase (313), which may be a result of this same activity.
4. In dividing cells, ICP0 associates with kinetochores and causes the degradation of centomeric protein C (CENP-C) (149). This protein plays a key role in the assembly of the kinetochore, and non–virus-induced degradation of this protein results in delayed transit ion of metaphase to anaphase. The zinc finger is required to bind to the kinetochore, but the actual structure to which it binds is unknown; thus, the mutation that abolishes the degradation overlaps the site required for binding of the ubiquitin-specific protease and may be a manifestation of the interaction of ICP0 with the latter protein.
5. ICP0 also binds several other proteins. These include cyclin D3, BMAL-1, elongation factor-1d (eF-1d), and a protein currently known as p60. In cells infected with wild-type virus, the levels of cyclin D3 and D1 decrease with time after infection (136,269,581). However, the rate of decay in cyclin D3 levels in cells infected with wild-type virus is slower than in cells infected with ICP0-negative mutant or a mutant whose ICP0 (D199A) does not bind cyclin D3. In addition, in cells infected with wild-type viruses, cdk4, the partner of D cyclins, is activated because p21, the cdk4 inhibitor, is degraded; whereas in cells infected with the D199A mutant, cdk4 is not activated, and p21 levels remain unchanged. The D199A mutant showed reduced capacity to replicate in stationary contact-inhibited cells and reduced neurotoxicity in mice infected by a peripheral route (643). The D199A co-localizes with PML and causes the disaggregation of ND10, but unlike the wild-type virus, it is not transported out of the nucleus into the cytoplasm. Neither wild-type nor the D199A mutant activates cdk2. Analyses of the interaction of cyclin D3 with ICP0 led to two significant observations. First, cyclin D3 co-localizes with wild-type ICP0 but not with the D199A mutant during the nuclear phase of ICP0. Second, overexpression of cyclin D3 accelerates the transport of ICP0 to the cytoplasm (644). The picture that emerges is that by stabilizing cyclin D3, ICP0 also stabilizes the cyclin-dependent kinase cdk4 and cyclin D1, another partner of cdk4. The function of cdk4–cyclin D complexes is not known. By analogy with the apparent function of activated cdc2, the activated function of cdk4–cyclin D complexes may lead to more rapid activation of viral DNA synthesis, synthesis of late proteins, and translocation of ICP0 into the cytoplasm. The apparent preoccupation of HSV with D cyclins is underscored by the observation that members of other herpesvirus subfamilies either induce a D-type cyclin (568) or encode a cyclin D homolog (70,261,324,411).
6. ICP0 has been shown to interact with eF-1d (267). The interaction of ICP0 with eF-1d, an elongation factor responsible for adenosine diphosphate (ADP)-ATP exchange, appears to be significant inasmuch as a truncated ICP0 polypeptide containing the binding site interfered with *in vitro* synthesis of a reporter protein. The significance that HSV places on eF-1d is underscored by the observations that U_L13 phosphorylates eF-1d and that this protein is also phosphorylated in cells infected with representative betaherpesviruses and gammaherpesviruses. The protein p60 binds ICP0 and ICP22 and is discussed in conjunction with the latter protein. ICP0 appears to have other functions, which are dealt with in the section on cell death.
7. ICP0 has also been postulated to have an effect similar to that of a histone deacetylase inhibitor (224), potentially resulting in increased acetylation of histones and increased gene expression from DNA condensed in nucleosomes. It seems more likely that alterations of histone acetylation would affect transfected genes or viral reactivation as compared with HSV productive infection because the former forms of DNA are wrapped in nucleosomes whereas HSV DNA during productive infection is not.

In summary, ICP0 is emerging as a multifunctional protein directed primarily toward modification of cellular functions to promote viral gene expression and viral productive infection. Precisely how the sum total of all of these modifications account for the function of ICP0 remains to be ascertained.

ICP22 and $U_S1.5$

As noted previously, the $U_S1.5$ transcription unit resides within the coding sequence of the gene encoding ICP22, and the amino acid sequence of the corresponding protein is identical to the carboxyl-terminal two thirds of the amino acid

sequence of ICP22 (64). Like ICP22, U_S1.5 is expressed as an a protein.

Viral mutants that fail to express the carboxyl-terminal half of ICP22 (454) have been studied extensively and exhibit several phenotypes, such as (a) restricted growth in primary human fibroblasts, rabbit, mouse, and rat cells (549); (b) attenuated virulence by intracerebral inoculation in mouse; (c) reduced expression of some (e.g., U_S11, U_L38, U_L41) but not all g_2 (e.g., gC) proteins; (d) abolished posttranslational modification of the C-terminal domain of the large subunit of RNA polymerase II, which takes place in some but not all cell lines (338); (e) reduced stability of ICP0 mRNA (64); and (f) increased stability of several cell cycle proteins (e.g. cyclins A and B) (4). The same phenotype is exhibited by a mutant defective for the U_L13 protein kinase (471,472). ICP22 also interacts with p60, a protein that also binds ICP0, and with p78, a cell cycle protein of unknown function (50).

ICP22 and U_S1.5 are phosphorylated by the U_L13 and U_S3 viral protein kinases, and ICP22 is nucleotidylylated by casein kinase II. Sequential deletions have established a relatively detailed functional map of ICP22 (421) and made apparent three significant features of its structure and organization. First, a mutant lacking the sequences unique to ICP22 (i.e., not shared with U_S1.5) behaved like the wild-type parent with respect to expression of g_2 genes but was avirulent on intracerebral inoculation of mice. Second, two sets of sequences are required for the phosphorylation of ICP22 by U_L13 and U_S3. One is within the carboxyl-terminal domain shared with U_S1.5; whereas the other highly homologous sequence is within the amino-terminal portion of ICP22 that is not shared with U_S1.5. Alteration of either sequence abolishes the phosphorylation of ICP22. Mutagenesis of the amino-terminal domain enables wild-type expression of g_2 proteins, but alteration of the carboxyl-terminal sequence caused a reduction in the expression of the selected g_2 proteins, similar to that seen in cells infected with deletion mutants in ICP22 (452). These studies indicate that U_L13 and ICP22 and U_S1.5 proteins act independently and either jointly or sequentially to regulate several aspects of HSV gene expression.

Synthesis and Processing of Viral Proteins

Viral proteins appear to be made on both free and bound polyribosomes. Many HSV proteins are posttranslationally modified, and these modifications include cleavage, phosphorylation, sulfation, *N*-linked and *O*-linked glycosylation, myristoylation, ADP-ribosylation, and nucleotidylylation (514). With the exception of some glycoproteins, the extent to which processing is a requirement of virus growth rather than the consequence of an encounter between cellular or viral enzymes and molecules resembling natural substrates remains uncertain. Much of this processing is by cellular enzymes and pathways (reviewed in 514), but some enzymes are virus encoded. The HSV-encoded protease is discussed later in the section on capsid assembly.

Herpes Simplex Virus Protein Kinases

HSV specifies at least three protein kinases, the large subunit of the ribonucleotide reductase (RR1), U_L13, and U_S3.

RR1

A protein kinase activity was first reported to be associated with the large subunit of the ribonucleotide reductase (ICP6) of HSV-2 but not of HSV-1 (87). Later studies showed autophosphorylation activity with the HSV-1 RR1 protein as well (99). Whereas the ribonucleotide reductase activity is associated with the conserved carboxyl-terminal domain, the protein kinase activity maps near the amino terminus (7,99). The large subunit of ribonucleotide reductase is therefore a multifunctional protein. The substrate of this protein kinase activity is not known.

U_S3

McGeoch and Davison (364) predicted that U_S3 encodes a protein kinase on the basis of its sequence, a prediction borne out by biochemical (166) and genetic studies (470). A major substrate of this enzyme is an intrinsic membrane protein exposed on the surface of infected cells and encoded by *U_L34*. The U_L34 protein contains the amino acid motif recognized by the U_S3 protein kinase; thus, substitution of the serine or threonine residues within this motif with alanine resulted in a loss of phosphorylation, but the virus grew poorly and revertants were readily detected. It is noteworthy that four prominent phosphoproteins unrelated to the U_L34 protein appear in lysates of baby hamster kidney cells infected with the U_L3-negative mutant or with mutants in the amino acid motif recognized in U_L34 by the U_S3 kinase. The anti-U_L34 serum copreciptates the four phosphoproteins along with the U_L34 protein. It would appear that the four phosphoproteins compensate in some fashion for the absence of phosphorylation by U_S3 kinase. U_S3 also phosphorylates the U_L3 protein and ICP22 (353,421,452). The major targets of U_S3, however, may well be host proteins, as discussed in the section on apoptosis.

U_L13

Smith and Smith (577) and Chee and coauthors (73) reported that the sequence of the *U_L13* ORF contains the signature amino acid motif common to other protein kinases and is shared among alphaherpesviruses, betaherpesviruses, and gammaherpesviruses. Cunningham and colleagues (105) reported on the properties of a new kinase very similar to the protein kinase activity demonstrated in tegument–capsid structures described by Lemaster and Roizman (319) and ascribed the new kinase to the product of the *U_L13* gene. Studies of U_L13- and U_L13-U_S3-negative mutants led to the conclusion that the U_L13 protein kinase affects the phosphorylation and processing of the gene products of ICP22 and U_S1.5, ICP0, and U_L47 and affects the accumulation of the a0, U_L26 and U_L26.5 (protease and its substrate), U_L38 encoding the VP19C capsid protein, U_L41, and U_S11 gene products (471,472).

Although the U_L13 protein kinase is associated with structural proteins, the enzyme brought into the infected cell by the

virion does not phosphorylate the newly synthesized ICP22. The phenotype of the U_L13-negative virus is similar to that described for the a22-negative mutant by Sears and coauthors (6,471,547). As noted earlier in the text, U_L13 protein kinase phosphorylates EF-1d. This function appears to be highly conserved among herpesvirus subfamilies.

A large number of other proteins (e.g., ICP4, gE; see Table 1 for a more detailed list) are phosphorylated in the course of the reproductive cycle. The kinases responsible for the phosphorylation and the role of phosphorylation in the functions of these gene products have not been elucidated.

Adenosine Diphosphate Ribosylation

Preston and Notarianni (461) reported that ICP4 and VP23 are poly(ADP-ribosyl)ated in isolated nuclei, a significant finding that nevertheless left unanswered the question of whether this reaction actually takes place in the infected cell. Blaho and coworkers (27) reported that antibody specific for poly(ADP-ribose) reacts with ICP4 extracted from cells late in infection, in effect answering the question in the affirmative. However, the poly(ADP-ribose) added to ICP4 was digested by poly(ADP-ribose) glycohydrolase, but only after denaturation of the protein. In contrast, poly(ADP-ribose) added to ICP4 in isolated nuclei was readily removed from the native protein by the glycohydrolase. The results indicate that ICP4 is poly(ADP-ribosyl)ated and suggest that, in the isolated nuclei, the poly(ADP-ribose) is added either by elongation of existing chains or to novel sites.

Nucleotidylylation of Viral Proteins

An initial report by Blaho and Roizman (30) showed that ICP4 is both guanylated and adenylated. The label transferred by a ^{32}P-ATP or a ^{32}P-guanosine triphosphate (GTP) is associated with the slowly migrating forms of the protein. Conclusive evidence for the nucleotidylylation emerged from transfer of a ^{3}H-labeled purine ring from ATP to ICP4. Subsequent studies revealed that ICP0, ICP22, ICP27, and the proteins encoded by *U_L21*, *U_L31*, *U_L47*, and *U_L49* are also nucleotidylylated and that all these proteins share the sequence R/PRAPS/R (27,28). Nucleotidylylation is carried out by casein kinase II. U_L21 is dispensable for growth in cultured cells (15), U_L31 cofractionates with the nuclear matrix (71) and appears to be an important component of the nuclear membrane of the infected cell (Baines, personal communication), and U_L47 may interact with VP16 (368). U_L49 is a virion protein (VP22/3?) that is labeled in cells with [^{32}P]orthophosphate and also is (ADP-ribosyl)ated.

Modification of Membrane-associated Proteins

Of the 11 predicted glycoproteins, at least 10 have been studied in sufficient detail to demonstrate the presence of oligosaccharide chains. The 11th, gJ, remains elusive, although recent studies indicating that gJ plays a role in blocking apoptosis are likely to lead to more extensive studies of this protein (254,700). In addition, it has been reported recently that the products of the U_L47 gene, VP13-14, contain *O*-linked polysaccharide chains and are phosphorylated (383).

At least one protein, the product of the *U_L11* gene, has been shown to be myristoylated (349). Deletion mutants in the *U_L11* gene show an impairment in egress from infected cells (17).

Viral DNA Replication

Once the b proteins are expressed, several of these proteins localize into the nucleus and assemble onto the parental viral DNA molecules in punctate structures called *prereplicative sites* located near ND10 structures (243,639) (Fig. 7A), where viral DNA synthesis initiates on the circular molecule, probably to give theta replicative forms. As viral DNA synthesis progresses, the progeny DNA molecules and replication complexes accumulate in the nucleus in globular structures called *replication compartments* (475) (see Fig. 7B). Viral DNA synthesis proceeds within these areas of the nucleus. At some point, presumably relatively early after its initiation, viral DNA synthesis switches from a theta replication mechanism to a rolling-circle mechanism, the latter producing concatemeric molecules. Thus, most of the viral progeny DNA molecules that accumulate in the infected cell nucleus are “head-to-tail” concatemers containing the four sequence isomers described previously (245).

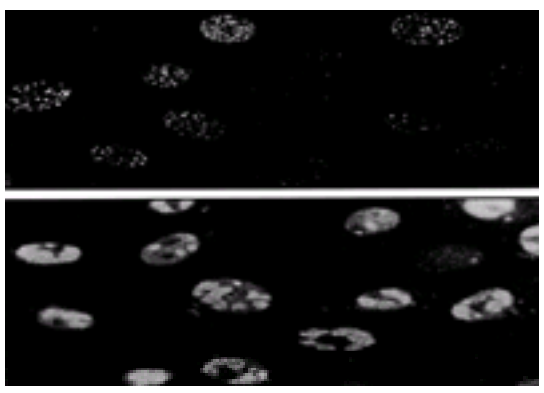

FIG. 7. Prereplicative sites and replication compartments. Immunofluorescence micrographs showing the localization of the ICP8 to prereplicative sites (**A**) when viral DNA synthesis is inhibited and to replication compartments, and (**B**) when viral DNA replication is proceeding. (Micrographs courtesy of E. McNamee.)

Seven viral proteins are required for viral DNA replication. Phenotypic analysis of viral ts mutants first identified two

virus-encoded gene products required for viral DNA synthesis, the viral DNA polymerase (469) and the ICP8 ssDNA-binding protein (98), and transfection studies showed that seven viral genes are sufficient to replicate a viral origin sequence co-transfected into cells (69,681). The gene products of the other five genes were identified through biochemical purification and genetic studies. The seven gene products are the viral DNA polymerase (U_L30) and its accessory protein or processivity factor (U_L42), an origin-binding protein (U_L9), the ICP8 ssDNA-binding protein (SSB; U_L29), and the helicase–primase or primeosome complex of three proteins, U_L5, U_L8, and U_L52. Host cell factors are presumably also involved in viral DNA synthesis, but these have not been identified, in large part because HSV DNA replication involving origin-dependent initiation and synthesis has not been achieved *in vitro.* Nevertheless, host enzymes, including the DNA polymerase a-primase, DNA ligase, and topoisomerase II, are probably also required.

The origins of viral DNA synthesis were identified through mapping of sequences found in defective viral genomes (168,336) and sequences needed for plasmid DNA amplification in transfection studies (390,648,669). The origins include *oriS,* a sequence located in the *c* sequences bounding the S component and therefore present in two copies in the viral genome, and *oriL,* a sequence located between the divergent transcription units of the genes for two viral DNA replication proteins, ICP8 and DNA polymerase.

Both *oriS* and *oriL* are palindromic structures, *oriL* being a 144-bp palindrome (281,337,477,669) and *oriS* being a shorter palindrome of 45bp (116,390,607,608) that center around AT-rich regions of 18 and 20 bp, respectively. Inverted repeats that contain binding sites for the U_L9 protein, called Box I, are located on either side of the AT-rich region of *oriL.* The *oriS* contains a Box I sequence to the 5' side of the AT-rich region and a similar sequence with a 10-fold lower binding affinity for U_L9, called Box II, located 3' to the AT-rich region. In *oriL,* the Box I sequences are flanked by another homologous sequence, called Box III, which has greatly reduced affinity for U_L9. The *oriS* contains one copy of Box III flanking the 5' Box I. The *oriL* is notoriously unstable when cloned into plasmids; hence, little genetic analysis has been performed on this sequence. Box I is required for *oriS* function, and mutations in Box II greatly reduce DNA replication. Although Box III shows weak binding to U_L9 *in vitro,* mutations in Box III reduce replication by about fivefold in transfection assays.

The reasons for three potential origins of replication in the viral genome are not apparent at this time. Neither origin is specifically required for viral replication. A mutant virus with a deletion in *oriL* is viable and showed normal burst size and latent infection (450). In addition, mutant viruses with both *oriS* sequences deleted showed at most a fourfold reduction in viral yields and only slightly delayed viral DNA synthesis (240). It has been suggested that one of these origins may represent vestigial origins from the L and S components of the viral genome (514) and that one of these origins, *oriL,* may function in reactivation from latent infection (207).

Viral DNA Replication Proteins

The properties and functions of the seven essential HSV DNA replication proteins are summarized here but reviewed in detail elsewhere (37).

Origin-binding Protein, U_L9, OBP

The U_L9 origin-binding protein forms a homodimer and binds specifically to the sequence CGTTCGCACTT (139,140,283,284). U_L9 also has ATP-binding and DNA helicase motifs that are essential for viral replication. Binding of U_L9 to origin sequences induces a bend in the DNA and formation of a single-stranded stem-loop structure. The addition of the HSV ssDNA-binding protein, ICP8 (see later), allows U_L9 to unwind Box I of *oriS* if an 18-nucleotide single strand tail is present 3' to Box I. Thus, ICP8 may provide a ssDNA region in the AT-rich region, from which U_L9 can separate the strands. As an origin-binding protein, U_L9 would play a role in origin-dependent synthesis originating from the circular molecules, but once synthesis has converted to a rolling-circle mode, U_L9 would presumably not be needed as an origin-binding protein.

Single-Stranded DNA-Binding Protein, ICP8, U_L29.

ICP8 is an abundant protein in HSV-infected cells and was first identified as the major DNA-binding protein in HSV-infected cells (23). ICP8 binds preferentially to ssDNA (310,525), and this ssDNA-binding (SSB) function is essential for viral DNA replication. ICP8 also exhibits a helix-destabilizing activity but can also catalyze the renaturation of complementary single strands (134). Probably as a consequence of the latter two activities, ICP8 can promote strand transfer (43), and this may contribute to the high frequency of homologous recombination observed in infected cells. In addition to its SSB function, ICP8 interacts with several other viral DNA replication proteins, as evidenced by its physical interaction and stimulation of U_L9 helicase activity (36,38,162), stimulation of the $U_L5/8/52$ helicase activity (155,201,619), functional interaction with DNA polymerase (77,218), and coimmunoprecipitation with U_L9, U_L8, and pol proteins (639). Consistent with these numerous interactions, ICP8 is required for localization of other viral proteins and cellular proteins to prereplicative sites in infected cell nuclei (54,112,329,342). As a result of its size and numerous protein interactions, ICP8 is likely to play a scaffold role in assembly of HSV DNA replication complexes (112). ICP8 also exerts a repressive effect on IE and E gene expression under certain conditions (191,192 and 193), possibly as a consequence of promoting the formation of DNA replication complexes on viral DNA.

DNA Helicase–Primase Complex

This complex, which contains the protein products of the *U_L5, U_L8*, and *U_L52* genes, was first identified as a helicase activity from infected cells (103). The complex unwinds short oligonucleotides annealed to single-stranded M13 DNA in the 5' to 3' direction. U_L5 has ATP-binding and DNA helicase motifs, and these are essential for DNA replication (704). U_L52 has a proposed divalent metal-binding motif that is conserved in DNA polymerases and primases, and this motif is

required for DNA replication. A complex of U_L5 and U_L52 has DNA-dependent ATPase, helicase, and primase activities; hence, this constitutes the core enzyme. U_L8 promotes the nuclear localization of this complex and, in concert with ICP8, stimulates optimal activities of the core enzyme. Thus, the holoenzyme can unwind a 2.3-kbp nicked plasmid in the presence of ICP8. The primase activity produces oligoribonucleotides 6 to 13 bases in length, and the preferred template sequence is 3'AGCCCTCCCA, with synthesis initiating at the first C.

DNA Polymerase

The HSV DNA polymerase has been studied extensively, partly as a result of its potential as a target for antiviral drugs. A new DNA polymerase activity was detected in HSV-infected cells in the 1960s (270), but formal genetic proof that it was virus encoded was not provided until the late 1970s when temperature-sensitive and drug-resistant mutations affecting the properties of the polymerase were isolated and mapped to the viral genome (469). The HSV DNA polymerase holoenzyme is a heterodimer of the 136-kd U_L30 protein complexed with the 65-kd U_L42 protein. The U_L30 protein contains the polymerase activity, and it contains three sequence motifs that are homologous and align with sequence motifs I, II, and III of other DNA polymerases (186). The U_L30 protein also has an intrinsic 3'-5'-exonuclease activity, which can serve as a proofreading activity. U_L42 increases the processivity of the U_L30 DNA polymerase. The interaction between U_L30 and U_L42 is essential for viral DNA replication *in vivo,* and these interaction sites are being investigated as possible targets for antiviral compounds.

The HSV DNA polymerase has a broader substrate specificity than cellular polymerases, and this has allowed the development of compounds that specifically inhibit the viral DNA polymerase. These compounds are discussed in Chapter 15 and Chapter 73.

Based on the available information, a model for HSV DNA replication (Fig. 8) has been formulated (reviewed in 37). The first steps in HSV DNA replication involve the binding of the U_L9 protein to the origin sequences and the looping and distortion of the origin sequences by U_L9. ICP8 then binds to U_L9 or ssDNA regions, and the U_L9 helicase activity unwinds the DNA. The helicase–primase complex is then recruited to the origin by interactions with U_L9 or ICP8. Leading-strand synthesis involves the unwinding of the DNA and synthesis of a primer by the HSV helicase–primase complex, from which leading-strand synthesis can be accomplished by the HSV pol-U_L42 holoenzyme. Alternatively, primers may be synthesized by the cellular polymerase a-primase. Lagging-strand synthesis is then accomplished by primer synthesis and pol-U_L42 extension of the DNA strand. Because the progeny DNA is largely head-to-tail concatemers (245), it is believed that although synthesis initiates from the theta form, it is rapidly converted to a rolling-circle replicative mechanism, by which concatemeric molecules can be synthesized.

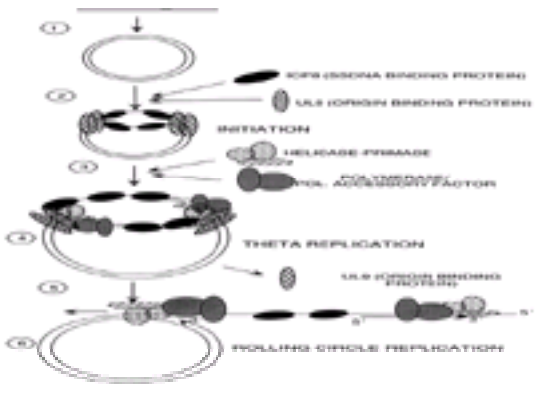

FIG. 8. Diagram of a model of HSV DNA replication, with the following steps: 1. Input DNA is circularized upon entry into the nucleus. 2. U_L9 (the origin-binding protein) initially binds to specific elements in the origin (either ori_L or ori_S) and begins to unwind the DNA. U_L9 then recruits ICP8 (the single-stranded DNA-binding protein) to the unwound single-stranded DNA. 3. U_L9 and ICP8 recruit the five remaining viral DNA replication proteins to the replication forks. 4. The helicase–primase proteins and the viral polymerase complex assemble at each replication fork for initial rounds of theta-form replication. 5. Replication switches from theta to rolling-circle mode by an unknown mechanism. U_L9 is not necessary for rolling-circle replication because it is not origin dependent. 6. Rolling-circle DNA replication produces long head-to-tail concatamers of viral DNA, which are cleaved into monomeric molecules during packaging. (Diagram courtesy of E. McNamee.)

Nonessential Viral Gene Products Involved in Viral DNA Synthesis and Postsynthesis Modification

Several other HSV gene products, including the thymidine kinase, ribonucleotide reductase, deoxyuridine triphosphatase, and uracil DNA glycosylase, are not essential for viral replication in cultured cells but are likely to be essential for nucleotide metabolism and viral DNA synthesis and repair in resting cells, such as neurons. The corresponding host cell enzymes are not expressed in resting cells, and it is likely that the virus has evolved to encode these enzymes to optimize its own DNA synthesis in these cells.

Thymidine Kinase

This enzyme was first identified as a deoxythymidine kinase (273), giving rise to its name. In fact, it phosphorylates pyrimidines and even purine nucleosides. In addition, it has a thymidylate activity. Its broad substrate specificity allows it to phosphorylate nucleoside analog molecules, which then can serve as antiviral compounds (172). The HSV TK consists of a homodimeric complex of the U_L23 protein product, the structure of which has been solved (47). HSV presumably

encodes a TK activity to provide nucleoside triphosphate precursors for DNA synthesis in resting cells, such as neurons, where the cellular enzyme is not expressed (see later). The viral enzyme leads to an increase in deoxythymidine triphosphate (dTTP) pools relative to that seen in uninfected cells or early in infection. This complicates the use of radioactive thymidine for labeling of viral DNA synthesis in infected cells because the specific activity of the labeled DNA will be lower at later times of infection.

Deoxyuridine Triphosphatase

Deoxyuridine triphosphatase (dUTPase) hydrolyzes dUTP to dUMP and pyrophosphate, preventing the incorporation of uracil into DNA and generating dUMP, the precursor of dTTP. The HSV enzyme is a monomer of the U_L50 protein product (464) and appears to be most essential for viral replication in the nervous system (473).

Ribonucleotide Reductase

Ribonucleotide reductase catalyzes the reduction of ribonucleoside diphosphates to the corresponding deoxyribonucleoside diphosphate. The HSV enzyme consists of a complex of the U_L39 and U_L40 proteins as an a_2b_2 tetramer (14). The HSV ribonucleotide reductase is not subject to the same allosteric controls as the cellular enzyme; thus, the HSV enzyme is not inhibited by the increased dTTP pools in HSV-infected cells. The HSV ribonucleotide reductase is required for viral replication in nondividing cells (194). The large subunit has an intrinsic serine-threonine kinase activity that is separable from the ribonucleotide reductase activity. The role of the protein kinase activity is not known, although there has been one report that the HSV-2 protein kinase activity is required for IE gene expression and virus growth (574).

Uracil N-Glycosylase

This enzyme removes uracil bases from DNA, bases that arise in DNA by the deamination of cytosine to form uracil, by the cleavage of the *N*-glycosidic bond linking uracil to the deoxyribose sugar. The site is then repaired so that a mutagenic event converting a G-C base pair to an A-T base pair does not occur. The HSV enzyme is encoded by the U_L2 gene (62). This gene product is not essential for replication in growing cells in culture, but it plays a role in viral pathogenicity and reactivation from latent infection (474).

Alkaline Nuclease

This enzyme is a phosphoprotein encoded by the U_{L12} gene (20,458), has endonuclease and exonuclease activities, and is active at pH 9.0 to 10.0 (270,271,625). As described later, this nuclease plays a role in DNA maturation and encapsidation. It is believed to interact with the ICP8 (625), possibly to allow the nuclease to act directly on viral replication intermediates or products. The HSV nuclease may be required to resolve concatenated viral DNA for packaging (553).

Viral DNA Recombination

Homologous recombination is very efficient in HSV-infected cells, and multiple crossover events between co-infecting viral genomes are apparent in progeny viruses, even between HSV-1 and HSV-2 genomes (396). Viral DNA replication is required for this high level of homologous recombination, and the time courses of DNA replication and recombination are parallel in cells transfected with viral *oriS* plasmids (133). The mechanism by which replication of the DNA promotes recombination is not known, but the single-stranded regions or the concatemeric molecules might be targets for cellular or viral recombination machinery. In addition, ICP8 is known to promote strand transfer; hence, it might play a role in recombination in infected cells.

Inversion of the genomic L and S segments also involves recombination between the terminal repeats and the internal inverted repeats. As described previously, HSV virion DNA contains four populations of molecules bearing the four orientations of the L and S components of the genome. This novel feature of the genome of HSV and certain other, but not all, herpesviruses (see Chapter 71) has long intrigued the field, and interest has been further piqued by the observation that viruses without internal repeats are viable, indicating that inversion is not essential for viral replication (253,446). These mutant viruses are less virulent, but the role of the internal repeats as protein-coding sequences versus their structural role as repeated sequences has not been separated. The L–S junction sequences and, in particular, the *a* sequences promote high-efficiency inversion in that insertion of a copy of these sequences at other sites in the genome leads to inversion of these sequences (83,387,388 and 389). Duplication of certain other viral sequences at a second site in the viral genome can lead to additional inversion events (448,663), but these events appear to be less efficient than *a* sequence–mediated inversion. The 95-bp Uc-DR1 sequence is specifically required for inversion at the *a* sequence (133), but it remains to be determined if this event involves site-specific recombination or a hot spot for recombination. This may be resolved by the further purification of the activity needed for inversion (49).

Activation of Late Viral Transcription

Once viral DNA replication has initiated, expression of g genes is increased (232), largely as a result of increases in their transcription (193,666,699). For some genes called g^1, early-late, or leaky-late genes, this represents an increase in expression that was already occurring under early conditions. These include the genes encoding ICP5 (U_L19), gB (U_L27), and gD (U_S6). Other genes, called g^2, late, or true-late genes, are transcribed at significant levels only after viral DNA synthesis. These include U_L38, *gC* (U_L44), U_S11, U_S9, and $U_L49.5$. Whereas g^2 genes are unambiguously defined as requiring the onset of viral DNA synthesis for their expression, the g^1 group lumps together all genes whose expression is enhanced by the onset of viral DNA synthesis but in reality contains a continuum of genes that either resemble g genes but are expressed late in infection or are partially expressed in the absence of DNA synthesis but kinetically are not

different from the g_2 genes.

Late transcription takes place in replication compartments within the infected cell nucleus, as evidenced by (a) the localization of ICP4 (280,481), pol II (323,488), and ICP22 (323) to replication compartments at late times; and (b) RNA-pulse labeling of replication compartments at late times (443). Thus, the transition from b to g gene transcription involves a change in the nuclear location of transcription from sites near ND10 domains to replication compartments. This is likely to play a significant role in this change in viral gene transcription.

Although the complete mechanism for stimulation of late viral gene expression has not been defined, it is known that transcription of late genes increases upon viral DNA synthesis (193), that the alteration in the viral DNA template is cis-acting (359), and that the viral proteins ICP4, ICP27, and ICP8 are required. The cis-acting effect on the template could be due to changes in the viral DNA molecules themselves by exposure of single-stranded regions or by conversion from a circular form to a linear form. Alternatively, the cis-acting effect could be due to proteins tightly bound to the viral parental DNA that do not exchange to other DNA molecules in the infected cell.

As a general rule, while sequences upstream of transcription initiation are sufficient to endow a reporter gene with the kinetics of b gene expression both in transfected cells and in the context of the viral genome (94,666), this is not generally true of g genes (359,565). In the context of the viral genome, expression of reporter genes as g_2 genes also requires regulatory elements present in the 5'-transcribed noncoding domains (229). Even then, such chimeras are expressed as b genes in cells transfected with the chimera and then superinfected with the virus (565).

The HSV g_1 promoters have not been studied as extensively as some of the other viral promoters, but the *ICP5* (*U_L19*) gene promoter elements have been defined (see Fig. 6). The essential elements of the minimal *ICP5* promoter are an SP1-binding site at –48, a TATA box at –30, and and an essential cis-acting element between –2 and +10 whose sequence resembles the human immunodeficiency virus (HIV) initiator element (238). A cellular factor that binds at the cap site has been identified (237). The g_1 gene promoters are heterogeneous in that the minimal *VP16* gene promoter from base pair –90 to +6 contains an E Box (CACGTG) at –85, a CAAT box at –77, and an SP1 site at –48 as well as a different initiator element (325).

Analyses of the g_2 viral gene promoters have shown that the upstream sequences consist of a TATA box with few other upstream transcription factor–binding sites (163,228,229,257) and with additional sequences needed for activation within the 5'-untranslated region (200,229,359,601,667). For example, the g_2 *U_L38* gene promoter (see Fig. 6) contains three elements: (a) an unusual TATA element with the sequence TTTAAA at –31, (b) a consensus initiator element at the transcriptional start site, and (c) a downstream activation sequence (DAS) from base pair +20 to +33 that is required for normal levels of gene expression (200). The DAS appears to increase transcriptional initiation (199), and several other HSV g genes, including *U_S11, gC (U_L44), gB (U_L27), L/ST,* and *U_L49.5*, have similar downstream control elements in their promoter (reviewed in 199). In addition, the *gC* gene DAS can partially substitute for the *U_L38* DAS (199), suggesting that common mechanisms may act on the different DAS sequences. One cellular protein purified on the basis of binding to the DAS has been identified as the DNA-binding subunit of the DNA-dependent protein kinase (440). Given that HSV infection leads to the degradation of the catalytic subunit of DNA-PK and loss of kinase activity (313), this effect may free up the DNA-binding subunit for interaction with viral DNA.

In addition to ICP4, g gene expression requires ICP27 (489,527). As described previously, ICP27 stimulates expression of viral DNA replication proteins and thereby viral DNA synthesis (639), but it is also specifically required for g gene expression (489). The mechanism by which ICP27 stimulates g gene expression has not been completely defined because there is evidence that its effects may be both transcriptional and posttranscriptional. Posttranscriptional effects of ICP27 were initially inferred from its stimulation of reporter gene expression in transfected cells in which the stimulation appeared to be dependent on sequences in the 3'-untranslated region of the reporter gene (72,535). Similarly, a late polyadenylation factor (LPF) was reported to be dependent on ICP27 (370). In infected cells, g viral transcription was not inhibited when cells infected with the ICP27 ts mutant *ts*LG4 were shifted to the nonpermissive temperature (575). Based on this result, it was concluded that ICP27 stimulated late gene expression by posttranscriptional mechanisms. Nevertheless, the *ts*LG4 ICP27 may not be thermolabile for transcriptional functions upon shift to the NPT.

In addition, ICP27 was shown to bind to RNA (46,242,377), and one report indicated sequence specificity in this binding activity (46), whereas others failed to observe this specificity (242,377). A portion of the nuclear ICP27 can shuttle from the nucleus to the cytoplasm in infected cells (376,442,579). This activity requires an RNA-binding sequence, an export sequence, and an export control sequence on ICP27 (580). A correlation has been reported between the ability of ICP27 to shuttle from the nucleus to the cytoplasm and its ability to stimulate gene expression, suggesting that ICP27 stimulates gene expression by shuttling late mRNAs from the nucleus to the cytoplasm (579).

Not all studies, however, support the hypothesis that the effect of ICP27 on viral gene expression is solely a consequence of posttranscriptional effects. ICP27 has been shown to bind to ICP4 (426), to alter the phosphorylation of ICP4 (485,613,687), and to localize to replication compartments (115). These properties are all consistent with effects on transcription of late HSV genes.

The ability of ICP27 to promote g viral gene expression is likely a distinct function derived from its ability to stimulate viral DNA synthesis because at least one mutant virus, *n*504, separates these two functions. This mutant is defective for g gene expression, in particular g_2 proteins, while maintaining normal levels of viral DNA synthesis (486). This unique mutant virus has been used further to demonstrate that ICP27 stimulates transcription of g genes independently of its role in stimulating b gene expression and viral DNA replication (252). This study found that ICP27 promotes transcription of at least two g_2 genes, *U_L44* and *U_L47*, in infected cells, as assayed by *in vivo* pulse labeling of RNA, without any apparent effects on transport or stability of these transcripts.

ICP27 has also been reported to stimulate the use of weak polyadenylation sites (365) and downstream polyadenylation

sites (203). Thus, ICP27 appears to have roles in transcription, processing, and transport of late mRNAs in infected cells, a multifunctional role similar to the HIV Rev protein. Interestingly, ICP27 has been reported to interact with the hnRNP K protein, which also plays a role in both transcriptional and RNA processing and transport events, and with casein kinase 2 (649). ICP27 may stimulate late transcription or RNA processing by binding to nascent RNA transcripts and promoting transcriptional elongation like HIV Tat protein or by altering the phosphorylation of viral and cellular proteins involved in transcription and RNA processing and transport.

ICP8 has also been found to stimulate g gene expression from progeny DNA templates (76,177). This ability to stimulate late gene expression correlates with the ability of the virus to form large replication compartments in infected cells (374). Thus, transcription of g_2 genes such as *gC* may require the movement of viral progeny DNA to new sites in the nucleus in a process promoted by ICP8.

Finally, the accumulation of a subset of g_2 proteins exemplified by U_S11, U_L41, and U_L38 is significantly reduced in the absence of the carboxyl-terminal portion of ICP22 or $U_S1.5$, or U_L13 proteins (421,452,471). The same two proteins, $U_S1.5$ and U_L13, are required for degradation of cyclins A and B and for the activation of cdc2. The connection may be a requirement for cdc2 for the expression of U_S11, and so forth, inasmuch as in cells transfected with dominant negative cdc2 and infected with wild-type virus, a, b and g_1 proteins are expressed, but U_S11 is not (6).

The ultimate goal of viral late gene expression is to express large amounts of viral structural proteins for assembly of progeny viral particles.

Viral Capsid Assembly

After synthesis of the g capsid proteins, they are localized into the infected cell nucleus, where capsid assembly occurs. Empty shells containing an internal scaffolding are assembled first, and the scaffolding is lost upon DNA encapsidation or insertion of viral DNA into the capsid. Our knowledge about the mechanisms of assembly of the HSV capsid has come from several lines of experimentation: (a) study of infected cell complexes and structures, (b) assembly of capsid structures from extracts of insect cells infected with baculoviruses expressing HSV scaffolding proteins, (c) study of protein localization using immunofluorescence, and (d) genetic analysis of the functions of capsid and scaffolding proteins. Each of these approaches has contributed important information to our understanding of this process (reviewed in 227 and 604).

Immunofluorescence studies have shown that the initial stages of assembly of at least some capsid proteins occur in the cytoplasm (412,491). VP5, the major capsid protein, VP26, the outer tip of hexons, and VP23, a triplex protein are incapable of nuclear localization on their own, but VP5 can be carried into the nucleus by VP19C, a capsid triplex protein, or pre-VP22a, a scaffolding protein. VP23 localizes into the nucleus with VP19C, consistent with their interaction in triplexes, and VP26 localizes into the nucleus only when it is expressed with both VP5 and VP19C or pre-VP22.

Electron microscopic studies have shown that the final assembly of capsids occurs in the nucleus. Three types of capsids, called *A-, B-,* and *C-capsids,* have been identified from infected cell nuclear extracts by sucrose density gradient ultracentrifugation (189). All three types of capsids are about 120 nm in diameter, with an outer shell consisting of hexons and pentons made up of VP5, the major capsid protein. The capsomers are linked by triplex structures composed of the two minor capsid proteins VP19C (U_L38) and VP23 (U_L18), each complex consisting of one molecule of VP19C and two molecules of VP23 (409). C-capsids contain viral DNA and can mature into infectious virions by budding through the nuclear membrane (434). A- and B-capsids lack DNA, but B-capsid cavities are filled with VP22a and VP21, the cleaved forms of the scaffolding protein, and a viral protease, VP24 (189,404). The internal proteins, including the scaffolding proteins and protease, are removed upon encapsidation of DNA (111,189). A-capsids are not filled with DNA or scaffolding protein and are believed to be abortive forms that result from failed attempts to package DNA.

In the nucleus, the VP5–pre-VP22a complexes come together as a result of self-interactions of pre-VP22a molecules. The triplex proteins are then added to form a partial capsid. As hexons and pentons are added, the partial capsid assembles into a round procapsid (406). The procapsid structures undergo a structural transformation and become angular and polyhedral (88,630,636). It is controversial whether the round or the polyhedral B capsids are the structure into which viral DNA is encapsidated (312,435,636). Much of our knowledge of the capsid assembly process has come from analysis of structures formed in insect cells infected with baculoviruses expressing HSV capsid or scaffolding proteins (621,631) and in extracts from these infected cells (408). In these studies, a series of baculovirus recombinants were constructed that each express one capsid or scaffolding protein, and B-capsids with normal structure were formed when insect cells were co-infected with viruses encoding VP5, VP19C, VP23, and U_L26 or $U_L26.5$ gene products. When the U_L26 and $U_L26.5$ gene products were left out, no intact capsids were formed, indicating that these gene products are needed to form a scaffold structure around which the shell proteins could form a closed capsid. Similar phenotypes were observed with HSV strains in which the U_L26 and $U_L26.5$ genes were mutated (124). In the baculovirus studies, when the U_L26 gene was omitted, large cored B-capsids were observed because in the absence of the maturational protease, the $U_L26.5$ protein is not cleaved. Thus, cleavage of the $U_L26.5$ scaffolding protein leads to condensation of the core. When the $U_L26.5$ gene was omitted, intact capsids were observed, but no core structure was apparent. Viruses mutated for $U_L26.5$ can still produce infectious virus, but progeny virus yields are reduced by 10^2- to 10^3-fold relative to wild-type virus (178). These data indicate that the U_L26 gene products can serve as scaffolding proteins, but they form a different core and one that is not as effective as cores containing $U_L26.5$ gene products.

In vitro assembly of B-capsids can occur in extracts when the insect cell extracts from cells individually infected with baculoviruses expressing VP5, VP19, VP23, U_L26, and $U_L26.5$ gene products are mixed and incubated (406). *In vitro* assembly of procapsids requires only the purified viral components VP5, VP19C, VP23, and a scaffolding protein; hence, assembly of procapsids does not require any cellular proteins (407). It has been hypothesized that procapsids may be

involved in the early stages of viral DNA packaging, much like the prohead structures of bacteriophages (227).

Although the other capsid proteins are encoded in separate transcriptional units (see Table 1), the scaffolding proteins and maturational protease are encoded by the overlapping *U_L26* and *U_L26.5* genes, which encode a complex set of gene products involved in formation of a core for capsid assembly and for capsid maturation (331,333,334,462). The *U_L26* gene encodes a 635–amino acid residue precursor protein with an intrinsic protease activity that cleaves either autoproteolytically or in trans after residues 247, the R site, and 610, the M site, in the precursor molecule. The amino-terminal 247-residue fragment is VP24, which retains protease activity. The fragment from residues 248 to 610 is VP21, which can serve as a scaffolding for capsid assembly. The *U_L26.5* gene mRNA initiates within the *U_L26* gene and encodes a protein that is read in the same reading frame as U_L26. The U_L26.5 protein, pre-VP22a, is equivalent to the C-terminal 329 residues of U_L26 and is also subject to cleavage by the U_L26 protease at the M site near its C-terminus to give a 304-residue protein, which is known as VP22a. The pre-VP22a protein functions as the major scaffolding protein for capsid assembly. The carboxyl-terminal 14 residues of pre-VP22a (and VP21) are recognized by VP5 during capsid assembly (233).

The protease activity encoded by the *U_L26* gene is a serine protease (332) whose activity is required for virus assembly (178). Cleavage at the R site is required for viral infectivity (496), and cleavage at the M site is believed to be involved in release of the scaffolding protein from the capsid interior. Mutagenesis studies have identified two histidines and two glutamic acid residues essential for proteolytic activity, but a conserved cysteine was dispensable in the 247–amino acid polypeptide (331,332). Proteases have been targets for drug development in many biologic systems, and considerable effort has been devoted to identifying specific inhibitors of the HSV protease as possible antiviral compounds. The crystal structures of the HSV-1 and HSV-2 proteases have been solved (234).

Assembly of capsids may take place within specialized infected cell nuclear structures called *assemblons* (403,658), or they may be assembled within replication compartments at sites near the sites of viral DNA replication (85,88,114,309,373). However, there is more general agreement that the next step in viral replication, encapsidation, occurs in replication compartments (15,309,658).

Encapsidation of Viral DNA

Encapsidation of HSV DNA involves a process in which cleavage of HSV progeny DNA concatemers into unit-length monomers and packaging of the monomers is linked, as originally shown for pseudorabies virus (304,305). This process is not well defined, but the concatemeric progeny molecules are likely fed into the capsid concomitant with displacement of the scaffolding molecules, VP21 and VP22a, from the capsid. The viral DNA concatemer is believed to be cleaved upon encapsidation of a length of DNA that fills the capsid or when a “headful” (a term that originated with bacteriophage head assembly) of DNA has been inserted. Varmuza and Smiley (645) first mapped signals for cleavage and packaging within the U_b and U_c domains of the *a* sequences, and Deiss and colleagues (118) mapped these precisely and designated the two DNA packaging elements as *pac1* and *pac2,* respectively.

Concatemers are cleaved into unit-length molecules during packaging (118,262,335,445,559,582,608,609,645). Cleavage occurs site specifically within the DR1 sequences of the *a* sequences (388) and involves two site-specific breaks at defined distances from the *pac1* and *pac2* packaging signals (118,571,645). The maturational process duplicates the sequences between these two cleavage sites, so that cleavage at sites bearing only one *a* sequence leads to two molecules with terminal *a* sequences (119,571,645). Several models have been proposed to explain the cleavage and metabolism of viral DNA during encapsidation (118,645). In general, these models propose that a packaging complex binds to the DNA and scans for a U_c sequence (Fig. 9). Cleavage occurs at a DR1 element proximal to the U_c sequence, and then the packaging complex scans the DNA as it is packaged until a directly repeated junction is encountered. Alternatively, two cleavages at L- and S-termini produce a monomer molecule. The amplification of the *a* sequence may occur by staggered nick-repair or gene conversion. The terminal *a* sequence generated by the cleavage may be recombinogenic in either a single-stranded or double-stranded form and promote inversions or *a* sequence amplification. In any event, the process must yield the virion form of the genome with an L-terminus containing one or more *a* sequences and a 3' single-base overhang, a unit-length genome with an L and S component, and an S-terminus containing a single *a* sequence and a 3' single-base overhang.

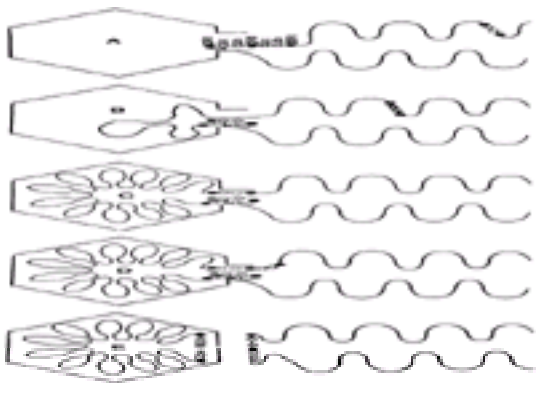

FIG. 9. Packaging of HSV-1 DNA. This general model predicts that (a) proteins attach to components of the *a* sequence, probably U_c; (b) empty capsids scan concatemeric DNA until contact is made in a specific orientation with the first protein-U_c sequence (capsid A); (c) the DNA is then taken into the capsid B until a “headful” or contact is made with a sequence whose nucleotide arrangement is in the same orientation (i.e., one genome equivalent in length away) is encountered (capsid C); (d) the packaging signal requires nicking of both strands from signals on opposite sites of a DR1 sequence. In the absence of two adjacent *a* sequences (capsid D), the juxtaposition of the *a* sequences would result in duplication of the *a* sequence (capsid E). (Model based on refs. 118 and 645.)

Encapsidation of viral DNA requires several viral gene products, including the *U_L6, U_L15, U_L25, U_L28, U_L32, U_L33, U_L36,* and *U_L37* gene products, but the mechanisms of this process remain to be defined. Several biochemical activities that may be involved in this process have been identified, including virus-encoded proteins that bind to the *pac2* site (79) and a virus-encoded endonuclease that introduces double-stranded cuts in the U_c domain of the *a* sequence (135,679).

Virion Assembly and Egress

After encapsidation of full-length viral genomic DNA molecules, the nucleocapsids are capable of budding through the inner nuclear membrane (648). Interactions between capsid and tegument proteins and between tegument proteins and viral glycoproteins in the inner nuclear membrane promote this budding process. It is clear that nucleocapsids acquire a tegument layer upon budding through the inner nuclear membrane, although the tegument of virions in the internuclear membrane space appears less dense than that of extracellular virions (184,596). This apparent change in the tegument during egress of the virions may be due to maturation or exchange of tegument layers, as discussed later. Some tegument proteins play essential roles in the assembly process. VP16 has been reported to be required for envelopment at the inner nuclear membrane (665) or for another step downstream of nuclear envelopment (397). In addition, the *U_L11* gene product increases the efficiency of envelopment (17,349).

Knowledge of the localization patterns of the tegument proteins could be informative as to the site of tegument assembly, but thus far, the results on tegument protein localization are complex. VP16 has been reported to localize to the cytoplasm and the nucleus (141) and at early times to the nucleus in diffuse patterns or replication compartments and later times also to a perinuclear distribution (303). Thus, VP16 could be available for nuclear or cytoplasmic assembly of tegument structures. The potential role for VP16 in replication compartments remains to be explored. The localization patterns of the VP22 tegument protein also show complex results, but this protein has displayed some novel properties. In some studies VP22, was shown to localize primarily to the cytoplasm in a perinuclear pattern in infected cells (141), whereas others have observed significant accumulations of VP22 in nuclei (451). The latter study found that nuclear VP22 is phosphorylated. Thus, VP22 could also assemble into tegument structures in either the nucleus or cytoplasm. Interestingly, VP22 has the property of intercellular transport in transfected and infected cells (142). VP22 is found in the cytoplasm of the cell where it is synthesized, but it is localized to the nucleus of the surrounding cells where it traffics. Intercellular trafficking occurs by a nonclassic, Golgi-independent mechanism apparently involving microfilaments. The function of this unique property in viral infection is not known, but applications of this property to delivery of proteins and other molecules inside of cells are being actively sought (127).

The route for egress of the virion particle from the space between the inner and outer nuclear membranes to the exterior of the infected cell is controversial. Two general pathways have been hypothesized for virion egress (Fig. 10), originally based on electron microscopic evidence. In pathway A, often called the *reenvelopment pathway,* the enveloped particle fuses with the outer nuclear membrane, resulting in deenvelopment of the nucleocapsid and its entry into the cytoplasm. The nucleocapsid then buds into the trans-Golgi network, and the enveloped particle is then released through secretory vesicles. The early electron microscopic evidence for this pathway came from observations of naked nucleocapsids in the cytoplasm of cells infected with HSV or a frog herpesvirus (566,596). In pathway B, called the *lumenal pathway* by Enquist and associates (144), the enveloped particle moves through the cytoplasm in the lumen of the endoplasmic reticulum (ER) or in vesicles either to the trans-Golgi network or Golgi vesicles where final maturation of the virion glycoproteins occurs. The early electron microscopic evidence for this pathway was that cytoplasmic viral particles largely showed enveloped particles in vesicles (109) or in tubular membrane structures (545). Further evidence interpreted in favor of this pathway came from studies involving monensin treatment of HSV-infected cells (256). Monensin, an ionophore that inhibits the secretory pathway, blocked viral egress and caused accumulation of virions in cytoplasmic vesicles. Thus, it appeared that egress involved the secretory pathway. Studies on the lipid content of virions have shown that virions are similar to cytoplasmic membranes rather than nuclear membranes, supporting the reenvelopment model (642); however, as noted earlier, the comparison is between virion envelopes and nuclear membranes of uninfected cells. The assumption underlying this comparison may not be tenable in light of the many modifications known to take place in the nuclear membrane.

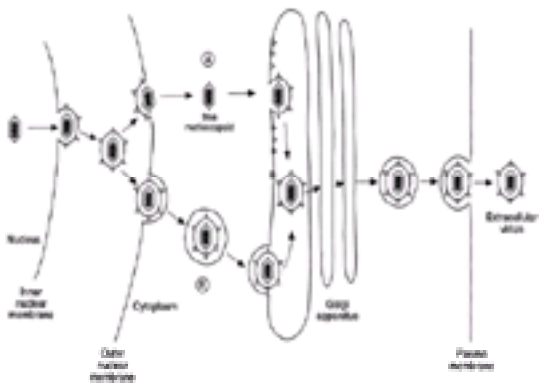

FIG. 10. Diagram of pathways of egress. HSV capsids bud through the inner nuclear membrane, forming an enveloped virion particle. Egress of the virions from the host cell may occur by either of two general pathways. **A:** The envelope fuses with the outer nuclear membrane, de-enveloping the capsid and releasing it into the cytoplasm. The capsid then buds into the Golgi apparatus, forming an enveloped virion, which is transported to the surface by vesicular transport. **B:** The virion particle buds through the outer nuclear membrane and is transported by vesicular movement through the Golgi apparatus to the exterior of the cell.

The major new type of evidence favoring the reenvelopment model comes from genetic studies of virus release in cells infected with viruses expressing viral glycoproteins with novel targeting signals. A virus encoding a mutant glycoprotein H with an ER retention signal released normal numbers of extracellular particles that contained no gH and that were not infectious (48). Similarly, viruses encoding gD molecules with ER retention or ER-retrieval signals produced 10- to 100-fold less extracellular virus, whereas viruses encoding gD molecules with Golgi-retention or Golgi-retrieval signals formed normal amounts of extracellular infectious virus (671). Preliminary results with a viral mutant encoding an ER-retained gD indicate that viral particles within the nuclear membranes contain gD, whereas extracellular virions do not (A. Minson, personal communication). These studies argue that virus acquires its final membrane in a compartment that contains Golgi-targeted gD but from which ER-retrieved gD is excluded. However, the published data have not shown that gD or gH reach the nuclear membranes.

Whatever scheme is eventually shown to be correct, it must take into account two additional observations. First, in many cell types, the Golgi apparatus is fragmented and dispersed, a phenomenon that may be related to rearrangement of the cytoskeleton (59,657). Curiously, the Golgi apparatus is not fragmented in cells infected with *syn*$^-$ mutants. The second observation is that the U_L20 gene product plays an important role in viral egress from the infected cell. In cells in which the Golgi apparatus is fragmented, virions accumulate in the space between the inner and outer nuclear membrane, whereas the glycoproteins are transported to the trans-Golgi network (18).

In addition to spreading from one cell to the next through the extracellular space, HSV can spread directly from cell to cell, likely through cell junctions. The gE and gI glycoproteins are required for this mode of spread (128), possibly because the gE–gI complex can target to cell junctions and mediate movement of virions through these junctions (129).

THE FATE OF THE INFECTED CELL

Viruses require living cells for their replication. The longer the infected cells remain alive, the more progeny viruses are made, and ultimately the more the virus spreads. From an anthropomorphic viewpoint, viruses, unlike most bacteria, benefit from maintaining the cell alive. Cells productively infected with herpesviruses do not survive. Cell death is the result of not only irreparable injury caused by viral replication but also cellular responses to infection. This section deals with changes induced by the virus. Almost from the beginning of the reproductive cycle, the infected cells undergo major structural and biochemical alterations that ultimately result in their destruction.

Structural Alterations

Changes in Host Chromatin

As described in detail elsewhere (509), one of the earliest manifestations of productive infection is in the nucleolus. In infected cells, the nucleolus becomes enlarged, is displaced toward the nuclear membrane, and ultimately disaggregates or fragments. Concurrently, host chromosomes become marginated, and later in infection, the nucleus becomes distorted and multilobed. The numerous protrusions and distortions have in the past been mistaken for amitotic division (263,546). Margination of the chromosomes may or may not be linked with the chromosome breakage reported by numerous investigators (reviewed in 509).

Virus-induced Alteration of Cellular Membranes

Duplication and Folding of Intracellular Membranes

Changes in the appearance of cellular membranes and, in particular, of nuclear membranes are characteristic of cells late in infection. Deposition of material (tegument proteins?) on the inner surface facing the nucleoplasm or cytoplasm, but not in the space between inner and outer lamella or in the cisternae of the ER, results in the formation of thickened patches along the membranes. Ultimately, the patches in the nuclear membrane coalesce and fold upon themselves to give the impression of reduplicated membranes (100,145,314,361,393,413,455,544,562,680).

Fragmentation and Dispersal of Golgi Stacks. HSV also causes a cell-type–dependent fragmentation and dispersal of Golgi vesicles. In cells in which this occurs, the Golgi vesicles fragment into myriad small vesicles that become dispersed throughout the cytoplasm (59). Disruption of microtubules is essential but not sufficient to induce the fragmentation of the Golgi apparatus. (13). In cells in which the Golgi apparatus is fragmented and dispersed, transport of virions from the nuclear membrane to the extracellular space requires the U_L20 gene product (18). In cells in which the Golgi stacks remain intact (e.g., in 143 TK-negative cells and in cells undergoing polykaryocytosis), the U_L20 protein plays a less prominent role in virion transport. In these cells, the Golgi stacks aggregate in what appears to be a central location. The distribution of viral glycoprotein D matches the distribution of the Golgi stacks, suggesting that the aggregated Golgi stacks funnel viral glycoproteins and viral particles to a limited region of the plasma membrane of the polykaryocytes rather than directing exocytic flow in a more dispersed fashion as seen in *syn*$^+$ (wild-type) virus-infected cells exhibiting fragmented and dispersed Golgi (657).

Insertion of Viral Proteins into Cellular Membranes. The first inkling that herpesviruses modify cellular membranes was based on the observation that mutant strains can differ from wild-type strains with respect to their effects on cells. For example, although wild-type viruses usually cause cells to round up and clump together, some mutant viruses cause cells to fuse into polykaryocytes (137,504). These observations led to the prediction that herpesviruses alter the structure and antigenicity of cellular membranes—a prediction fulfilled by the demonstration of altered structure and antigenic specificity (495,512,513,519) and the presence of viral glycoproteins in the cytoplasmic and plasma membranes of infected cells (217,517,518,587).

Polykaryocytosis. Both HSV-1 and HSV-2 cause infected cells to round up and adhere to each other. Some viral mutants

cause cells to fuse into polykaryocytes, and this fusion may be cell-type specific or cell-type independent (137, 225,526). Polykaryocytosis has been studied for several reasons: (a) as a probe of the structure and function of cellular membranes reflected in the “social behavior of cells,” (b) as a tool for analyses of the functions of viral membrane proteins, and (c) as a model of the initial interaction between HSV and susceptible cells that results in the fusion of the viral envelope and the plasma membrane (60,504,583,584). Cell fusion induced by HSV also requires conditions that favor processing of high mannose glycans to complex glycans, but in this regard, it is not clear whether complex glycans must be present only on viral glycoproteins present on the surface of the infected recruiter cells, or on both the recruiter cells and on the uninfected cells being recruited into polykaryocytes (60,583,584).

Polykaryocytosis can be viewed as an aberrant manifestation of the interaction of altered membrane domains of infected cells and unaltered membranes of juxtaposed cells (504). Genetic analyses have shown that syncytial (*syn*) mutations that confer the capacity to fuse cells map in at least five and possibly more loci within the viral genome (16,41,117,330,350,447,449,523,526,689). These loci map within the domains of the *gB, gK, gL, U_L24*, and *U_L20*. One interpretation of these observations is that the membrane proteins form complexes whose structure and conformation become altered by mutations in any of the component polypeptides, and that the changes in the conformation are similar to those that occur in the envelopes of virions interacting with the plasma membrane (526).

Rearrangement of the Microtubular Network

Changes in the microtubular network are apparent very early in infection. Thus, the microtubules at the junction of the network with the plasma membrane appear to be disrupted in cells exposed to either *syn^+* (wild-type) or *syn^-* virus either in the presence or absence of cycloheximide. The overall arrangement of microtubules, however, is similar to that of uninfected cells. Late in infection, microtubules rearrange to form parallel bundles surrounding the nucleus. In polykaryocytes induced by the virus, microtubules form parallel bundles extending along the axis of recruitment of new cells (657).

Formation of Intranuclear Inclusion Bodies

Electron microscopy of herpesvirus-infected cells showed electron-translucent intranuclear inclusions surrounded by marginated and compacted cell chromatin (108,545) (see Fig. 9 in Chapter 7). Light microscopic observation of nuclear inclusions shows an hourglass appearance of the inclusions at early times and an eosinophilic staining at later times (402,576). Immunofluorescence experiments using antibodies specific for HSV DNA replication proteins have shown that viral DNA replication proteins accumulate in intranuclear foci by 3 hours after infection and that these foci enlarge into globular nuclear structures called *replication compartments* (112,475). The replication compartments are likely to be equivalent to (a) the translucent nuclear inclusions seen by EM and (b) the early nuclear inclusions seen by light microscopy.

These replication compartments are located in the interior of the nucleus as shown by EM (108,545) and by confocal microscopy (113). Viral DNA synthesis, late gene transcription, capsid assembly, and DNA encapsidation may all occur within these nuclear factories. Thus, the accumulation of replication proteins, progeny viral DNA, and nucleocapsid components within these replication compartments may cause the nuclear cytopathic effect described as *nuclear inclusion bodies.*

Host Macromolecular Metabolism

Background

It has been known for many years that HSV shuts off host RNA, DNA, and protein synthesis rapidly after infection (511). Thus, host DNA synthesis is shut off (511), host protein synthesis declines rapidly (506,614,615), and glycosylation of host proteins ceases (572). Host macromolecular metabolism is altered in infected cells in at least four different ways: (a) mRNA present in infected cells at the time of infection is degraded, and this degradation continues for at least several hours; (b) transcription appears to be turned off; (c) cellular proteins are selectively degraded or stabilized; and (d) cellular proteins are redirected to perform novel tasks.

Shutoff of the Synthesis of Cellular Products

HSV host shutoff occurs in two stages: degradation of host mRNA and inhibition of further synthesis and processing of host mRNAs.

Virion Host Shutoff and Degradation of RNA

The existence and properties of a virion lost shutoff (*vhs*) function were documented in several stages. The first stage, documented initially by Fenwick and Walker (160) and by Nishioka and Silverstein (414,415 and 416), involves structural proteins of the virus and does not require *de novo* protein synthesis. Thus, HSV shutoff of host protein synthesis occurs in physically or chemically enucleated cells (158). Furthermore, the shutoff was effected by density gradient purified virus but not by purified virus inactivated by heating or neutralization with antibody. The shutoff is faster and more effective in HSV-2– than in HSV-1–infected cells, and this observation permitted the initial mapping of the genetic locus that confers upon HSV-1 × HSV-2 recombinants the accelerated shutoff characteristic of HSV-2 (157).

The second stage began with the isolation of *vhs^-* mutants that failed to shut off host polypeptide synthesis in HSV-infected cells (483). Viral mutants of HSV-1 that were defective for shutoff of host cell protein synthesis were identified. The *vhs* function was initially mapped to 0.52 to 0.59 map units (157). Isolation of a mutant defective in this function (483) allowed further mapping of the gene responsible. Mapping studies by Oroskar and Read (425) and Kwong and colleagues (301) have identified sequences mapping from 0.604 to 0.606 map units on the viral genome (*U_L41* ORF)

as being responsible for the *vhs*⁻ phenotype of the mutants. *U_L41* RNA is expressed as a g_1 gene (170). The products of *U_L41* are an abundant phosphoprotein of Mr 58,000 and a less abundant, more extensively phosphorylated protein of apparent Mr 59,500. Only the faster, migrating protein is found in virions (484). Conclusive evidence that vhs acts in the absence of other viral proteins emerged from studies of Zelus and associates (698), but the question of whether it acts directly as a ribonuclease or indirectly to activate a cellular nuclease remains unresolved. Virions have a ribonuclease activity that is inactivated by anti-vhs antiserum (698). The observation that vhs has weak sequence similarity to the fen-1 family of nucleases suggested that it has intrinsic nuclease activity. Consistent with this view, Elgadi and associates (138) reported that the vhs protein induces endoribonucleolytic cleavage of mRNAs *in vitro,* whereas Karr and Read (264) noted that vhs causes the degradation of the 5' end of mRNAs before that of the 3' end. Recently, it has been reported that vhs interacts with the translation factor eIF-4H and that this interaction is essential for the RNase activity and perhaps for targeting of vhs to polyribosomes for selective degradation of mRNAs (S. Read, personal communication; J. Smiley, personal communication). The complex appears to cause the decapping of cellular mRNAs from the 5' terminus.

In cells infected with a *vhs*⁻ mutant, host protein synthesis is not shut off, at least early in infection, and the duration of a and b protein synthesis is prolonged compared to wild type. Both of these effects have been shown to be due to a stabilization of host and viral mRNAs in cells infected by *vhs*⁻ mutants; thus, vhs protein accelerates the degradation of both cellular and viral mRNAs (300,425) and serves to inhibit translation of cellular mRNA. Combined with the viral effects of inhibition of host transcription and RNA splicing, the cellular mRNA pools are not replenished, and as viral mRNA accumulates, it is preferentially translated. It has been suggested that vhs serves to facilitate the transitions from a to b to g protein synthesis by shortening the life of viral mRNA (300,425). As infection progresses, the degradation of RNA by vhs appears to be reduced or blocked altogether. The most direct observation in support of this conclusion is that the half-lives of viral mRNAs increase with time after infection (159). A compelling rationale for the turnoff of vhs function is that the vhs protein accumulates in appreciable amounts late in infection. If the nascent protein were functional, it would be expected that it would totally degrade viral mRNA concurrent with its accumulation in the infected cell. VP16 and vhs interact (570), and this interaction blocks the degradation of RNA by vhs (308). Thus, assembly of vhs into tegument complexes not only allows the virion to bring vhs into the cell and inhibit host translation but also serves to modulate the activity of vhs at later times of infection when mostly viral mRNA is present in the cell. The conditions required for the dissociation of vhs and VP16 proteins at the outset of infection remain to be defined.

Shutoff of Transcription

To facilitate the transition from cellular to viral gene transcription, HSV infection causes a rapid decrease in host RNA synthesis (209,654). Transcription by all three cellular RNA polymerases declines to less than 50% of uninfected cell levels by 4 hours postinfection (460). Repression of host cell poll II transcription requires multiple HSV genes, the specific gene dependence varying with the cellular gene (593). HSV infection causes changes in the phosphorylation of RNA pol II (593) in some cell lines, and this effect on the host cell requires ICP22 and U_L13 protein kinase. However, the relationship of this change in pol II to inhibition of host gene transcription and promotion of viral gene transcription remains to be defined.

Inhibition of Splicing of Messenger RNA

Early in infection, some of the intranuclear ICP27 localizes to spliceosomes, causing a redistribution of host snRNPs (441,534). Two cellular snRNP proteins, U1 and a 70-kd protein, coprecipitate with ICP27, and ICP27 causes an increase in their phosphorylation (533). Phosphorylation of U1 protein impairs its ability to stimulate RNA splicing. Thus, this effect of ICP27 may contribute to its ability to inhibit RNA splicing. This effect on splicing has little or no effect on viral RNA synthesis because three of the genes encoding spliced RNAs are a genes (a *0*, a*22*, and a*47*). Late in infection, ICP27 is localized to replication compartments and shuttles to the cytoplasm, and at this stage, it may no longer repress RNA splicing, allowing U_L15 RNA to be spliced.

Selective Degradation of Cellular Proteins

Destruction or posttranslational modification of cellular protein is implied by the changes in microtubular network, nucleoli, mitochondria, Golgi apparatus, ND10 structures, and so forth. Recent studies have shown that HSV causes both accelerated destruction and stabilization of cellular proteins.

Accelerated destruction of specific proteins in infected cells was described earlier. These included PML, the kinetochore protein CENP-C (149), and cyclins A and B (4). The destruction of CENP-C is mediated by ICP0, whereas the destruction of cyclins A and B requires two functions, that of ICP22 and of U_L13 protein kinase (5). Additional evidence for selective destruction of cellular proteins is likely to emerge given the increasing prominence of viral–cellular protein interactions in current research. What differentiates normal turnover of cellular proteins from selective degradation is evidence that specific viral proteins mediate this degradation.

Selective Stabilization and Activation of Cellular Proteins

As noted earlier, ICP0 stabilizes cyclin D1 and D3 and activates cdc2 cell cycle kinase. The stabilization of cyclins D1 and D3 is mediated by ICP0 (269,644). Thus, wild-type ICP0 binds cyclin D3 and stabilizes it. Mutants lacking ICP0 or carrying an alanine substitution in place of aspartic acid 199 fail to bind cyclin D3 and are less pathogenic when administered to mice at a peripheral site (643). The D199A mutation is pleiotropic in the sense that both cyclin D3 and cyclin D1 are destabilized and degraded within a few hours after infection (643). Moreover, the D199A mutant is not transported from the nucleus into the cytoplasm (644). The stabilization of cyclin D3 and D1 is surprising in light of the observation that cdk2 is inactive (136). The pRB protein is hypophosphorylated, E2F-pRB and E2F-p107 complexes accumulate, E2F-dependent gene expression decreases, and E2F proteins are posttranslationally modified and inactive (5,6,136,223,423,581), all suggesting that S-phase genes are unlikely to be activated.

The hypothesis that HSV uses cyclins D1 and D3 for purposes other than to induce S phase is supported indirectly by another observation. Thus, 5 to 9 hours after infection, cyclins A and B are destroyed, but their catalytic partner, cdc2, is activated (5), prompting the question of how catalytic subunit regulation occurs in the absence of the normal cyclin subunit. In addition, cdc2 is required for the expression of a subset of g_2 genes exemplified by *U_S11* (6). More recent studies indicate that cdc2 can phosphorylate ICP0 and ICP22 *in vitro* and in the context of infected cells (S. J. Advani and B. Roizman, manuscript in preparation). Activation of cdc2 is mediated by ICP22 and the U_L13 protein kinase.

The conscription of cdc2 to phosphorylate viral proteins is not an isolated phenomenon. As noted elsewhere in this chapter, the $g_1$34.5 protein binds and redirects protein phosphatase 1 to dephosphorylate eIF-2a (215). As analyses of viral–cellular protein interactions progress, many more examples of diversion of cellular proteins to meet viral needs will emerge. Equally significant, posttranslational modifications of cellular proteins are also likely to be commonplace as more and more cellular proteins are studied in depth in the context of infected cells. The distinction between specific and nonspecific modification will depend on the viral genes that are involved in the process and evidence that they play a role in viral gene expression. A case in point is the phosphorylation of translation factor EF-1d in infected cells by the U_L13 protein kinase. The specificity of this reaction was reinforced by the observation that EF-1d is hyperphosphorylated in cells infected with representative alphaherpesviruses, betaherpesviruses, and gammaherpesviruses and that in cytomegalovirus (CMV)-infected cells, the phosphorylation of EF-1d is mediated by the U_L97 protein, the CMV homolog of U_L13 protein kinase (268). An additional example of the activation of cellular kinases is the activation of p38 and JNK stress-activated kinases, which augments viral yield (372,697).

Effects of Herpes Simplex Virus Infection on the Cell Cycle Machinery

HSV infection causes several changes in the cell cycle machinery. First, it causes a block in the cell cycle in either the G_2 (96) or the G_1 (112) phase of the cell cycle. The G_1 phase block is distinct from the viral inhibition of cell DNA synthesis because early to mid G_1 phase events are blocked, including pRB protein phosphorylation and induction of cyclins and cyclin-dependent kinases (136,581). The net effect of HSV infection on cells is to lower the level of G_1 phase–specific functions, including cyclin D3 protein levels (581) and cdk2 kinase activity (136). This is interesting in light of several reports indicating that HSV infection requires cyclin-dependent kinases (539,540 and 541). Clearly, we have much more to learn about the interactions of HSV with the cell cycle machinery.

VIRULENCE

Background

During infection of humans, viral disease includes primary and recurrent epithelial lesions as well as disseminated disease and encephalitis. In studies on the molecular basis of disease induced by HSV, the end point of the research objective—disease—is often taken to be synonymous with the destruction of central nervous system (CNS) tissue. In healthy, immunocompetent humans, encephalitis occurs rarely but with catastrophic results (672). In experimental animals, it is frequently a major component of the disease. Neurogrowth, the ability to grow in nervous system tissue, as measured solely by intracerebral inoculation of virus, is the most commonly measured aspect of virulence. Direct injection of virus into the CNS measures the capacity of the virus to destroy an amount of CNS tissue that will result in death before the immune system blocks further virus spread. Because in most instances destruction of the CNS and death are related to virus multiplication, in quantitative terms, the growth of the virus in the CNS is measured in terms of the amount of virus required to reach a specific level of mortality (50% of inoculated animals).

A second attribute of virulence is invasiveness—the capacity to reach a target organ from the portal of entry. To disseminate to the target organ, it is necessary for the virus to multiply at peripheral sites. In experimental systems, virulence is composed of (a) peripheral multiplication, (b) invasion of the CNS, and (c) growth in the CNS. Peripheral growth and invasiveness into the CNS can be quantified by measuring the amount of virus recovered at the peripheral site and in the CNS as a function of the quantity of virus inoculated at a peripheral site (e.g., footpad, eye, ear).

The sum total of events defined under the heading “virulence” reflects two distinct sets of viral functions. The first comprises viral genes responsible for access to and injury of the cells whose destruction is responsible for the disease. The second, less well appreciated, are viral genes and gene functions that turn off host responses to infection.

Viral Functions that Contribute to Viral Invasiveness and Replication

Several types of studies have been done to define genes required for neurovirulence or neuroinvasiveness. They may be summarized as follows:

1. An important question is whether the virus that causes adult encephalitis is different from that which establishes recurrent labial infections. Viral isolates taken either from CNS tissues of encephalitis patients, from facial or genital isolates of the same patients, or from normal individuals have been compared in mice inoculated intracranially or through peripheral routes with respect to neurogrowth. Although the encephalitis isolates appear to have slightly lower average PFU/LD_{50} values as compared with nonencephalitis strains, no correlation was apparent between encephalitis in humans and neurogrowth or neuroinvasiveness in experimental animals (R. J. Whitley, personal communication). However, as a variant of this approach, infection of neurons in culture has indicated that virus isolates from encephalitis cases are better able to infect and be transported to the cell body than isolates from peripheral lesions (25).
2. Numerous studies have been undertaken to assess the relative abilities of various viral mutants to grow in the CNS after direct intracerebral inoculation. What has emerged from the accumulated data is that so-called neurovirulence factors are not the exception, but the rule. Almost all virus mutants tested to date, including a number of HSV-1 ×

HSV-2 recombinants, many ts viruses, a variety of spontaneous mutants, and myriad recombinant viruses with deletions in one or more genes, exhibit LD_{50} values following intracerebral inoculation ranging from 100- to 100,000-fold higher than those of the parental strains. Experiments using nongenetically engineered viruses mapped loci implicated in “neurovirulence” to a number of regions, including the *tk* gene and sequences around the right terminus of the L component (68,161,249,250 and 251,282,465,524,598,626,627). Recombinant viruses with elevated intracerebral LD_{50} values include those with deletions in the genes encoding ICP22, U_S2, U_S3 protein kinase, U_L13, U_L16, U_L24, gG, gJ, gE, gI, ribonucleotide reductase, thymidine kinase, $g_134.5$, U_L55, and U_L56 (56,379,380,547,664,673; E. Kern, B. Meignier, J. Baines, R. J. Whitley, A. Sears, and B. Roizman, unpublished results). Most of the attenuated deletion mutants listed previously also exhibit impaired growth in peripheral tissues (e.g., cornea) as assayed either by the occurrence of epithelial lesions or by quantitation of infectious virus in the tissues, indicating that the genes deleted are required generally for growth in differentiated or polarized cells, not specifically for growth in neurons or in CNS tissues (44,246,247; A. Sears, B. Meignier, and B. Roizman, unpublished results). In fact, the only genes that have to date been shown *not* to be required for neurovirulence in the murine model are *gC, U_S9*, *U_S10*, *U_S11*, and a*47* (417; R. J. Roller, B. Roizman, unpublished data). Because the function of a*47* appears to be human cell specific (695), it is conceivable that if the *U_S9* to *U_S11* genes share in this property, their function will be inapparent in the mouse.

The conclusion that emerges is that all HSV genes are important in enabling optimal viral replication and viral spread in the CNS. The special importance of some genes is nevertheless obvious. Mutations in *gD* that restrict or expand the host range are likely to have a significant impact on viral pathogenicity. Another, as yet not fully defined function that plays a significant role in viral pathogenesis is that which enables capsid–tegument structures to be transported retrograde in axons leading to sensory neurons or the CNS.

Viral Functions that Block Host Responses to Infection

Of the 84 ORFs identified to date, more than half are dispensable for replication in cells in culture. Some (e.g., thymidine kinase) are not essential in dividing cells but must be present in nondividing cells to enable viral replication. A large number of the “dispensable” genes as well as some “essential” genes, however, appear to target host responses to infection. These genes may be divided into two groups: (a) those that block *de novo* synthesis of cellular gene proteins that may adversely affect viral replication, and (b) those that block the function of preexisting proteins residing in cells after infection. Examples of the former are vhs, the product of U_L41 gene, and ICP27. The former causes degradation of mRNA present in infected cells, whereas the latter mediates an inhibition of transcription and splicing during the initial stages of infection. Included in this list are the other viral gene functions that block transcription of cellular genes discussed earlier in the text. This section concerns viral gene functions that block the activation of proteins preexisting in the cell at the time of infection.

ICP34.5, U_S11 protein, and the RNA-dependent Protein Kinase (PKR)

One of the principal but easily defeated host defenses is PKR. This enzyme resides in small amounts in uninfected cells but its expression is induced by interferon. PKR is activated by some forms of dsRNA. Activated PKR causes the phosphorylation of the a subunit of eIF-2. Phosphorylated eIF-2a causes total shutoff of protein synthesis. In cells infected with a $g_134.5$-negative mutant, protein synthesis is shut off after the onset of viral DNA synthesis concomitant with the phosphorylation of eIF-2a and the appearance of complementary viral RNA capable of self-annealing to form dsRNA (80,248,288). All viruses that cause the synthesis of RNA with extensive secondary structure must block PKR from shutting off protein synthesis. The manner in which HSV does this is quite different from that of other viruses: ICP34.5 binds protein phosphatase 1a and redirects it to dephosphorylate eIF-2a (215). The virus totally ignores the activated PKR. The domain of ICP34.5 responsible for this function resides in the carboxyl terminus of ICP34.5 and exhibits two attributes. First, it contains the motif of the protein phosphatase accessory protein necessary to direct the phosphatase to specific targets. Mutagenesis of two key amino acids within this motif precludes ICP34.5 from causing the dephosphorylation of eIF-2a (214). Second, the carboxyl-terminal domain of ICP34.5 is highly homologous to the corresponding domain of a conserved mammalian protein known as growth arrest and DNA damage 34 (GADD34) protein. The GADD34 domain substitutes for the corresponding ICP34.5 domain in blocking the effects of PKR (213).

Mohr and Gluzman (391) serially passaged a $g_134.5$-negative mutant and obtained a phenotypic revertant. The revertant showed a spontaneous deletion of the coding sequence of a *47* and the adjacent promoter of *U_L11* gene such that the a promoter of a*47* became juxtaposed to the *U_L11* gene. The net consequence was that *U_L11* was expressed earlier in infection (212). Subsequent studies showed that PKR interacted physically with *U_L11 in vitro* and that the capacity of U_S11 protein to block activation of PKR was dependent on the time and order of additional U_S11 protein. Exposure of PKR to U_S11 protein before its activation was effective in precluding the phosphorylation of eIF-2d, whereas activated PKR responded poorly to added U_S11 protein (67).

As noted in Chapter 71, the *$g_134.5$* gene is conserved only in HSV-1, HSV-2, and simian B virus, the implication being that *$g_134.5$* gene is a late acquisition by these herpesviruses. Therefore, the HSV progenitor may have dealt with PKR differently, perhaps by U_S11 protein expressed earlier in infection.

Apoptosis

Several HSV-1 deletion mutants have now been shown to induce classic apoptosis, characterized by chromatin condensation, release of cytochrome C from mitochondria, fragmentation of cellular DNA, vacuolization, and blebbing of the cytoplasm. The mutants shown to cause programmed cell death in at least one cell line include a *4^-*, a*27^-*, *ts*B7 carrying a ts lesion in the U_L36 protein and maintained at the nonpermissive temperature, and *$(gD, gJ)^-$* mutant viruses. Conversely, wild-type HSV-1 blocks apoptosis induced by osmotic shock, thermal shock, Fas ligand, and TNF-a

(11,12,176,255,287,321,564). The salient features of the available data may be summarized as follows:

1. Apoptosis is cell-type dependent. For example, the *d*120 mutant lacking the a*4* gene induces apoptosis in all continuous cell lines (175,176) tested but not in human embryonic lung cells (175,701). *ts*B7 at the nonpermissive temperature induces programmed cell death in Vero cells but not in the human SK-N-SH cells derived from a malignant glioma (176).

   The pathway leading to programmed cell death is also cell-type dependent. For example, the *d*120 mutant induced caspase 3–independent apoptosis in SK-N-SH cells but caspase 3–dependent apoptosis in HEp-2 cells. Recently, a novel caspase-independent pathway mediated by a mitochondrial protein designated *apoptosis-inducing factor* (AIF) was described. In induced cells, AIF is translocated from mitochondria into the nucleus. In induced human embryonic cells, AIF is translocated into the nucleus, but apoptosis does not ensue.

   These observations suggest that different cells react differently to the same stimulus, that mutants differ in the stimuli they induce, and that wild-type virus blocks all viral activators of programmed cell death to achieve its optimal replication.
2. Little is known of the mechanism by which HSV mutants induce apoptosis. It has been reported that HSV degrades Bcl2 (355), and indeed overexpression of Bcl2 in HEp-2 cells blocks apoptosis induced by the *d*120 mutant (174). The delay in the cytopathic effects induced by wild-type HSV-1 suggests that the cytopathic effects observed in cells undergoing productive infection may at least in part be due to apoptosis. Consistent with this view is the observation that the cytopathic effect of *d*120 virus was more extensive than that caused by wild-type virus, whereas mutants lacking both a*0* and a*4* genes were far less cytopathic (531,684).
3. There is also a paucity of data on the mechanism by which HSV blocks apoptosis. One observation of particular interest was that in SK-N-SH cells treated with sorbitol, (osmotic shock) HSV blocked fragmentation of DNA but not activation of caspase 3 or release of cytochrome C (175,176). Viral genes shown to date to block apoptosis are *gD, gJ,* and the protein kinase U_S3 (254,322,700). ICP4 and ICP27 deleted from respective viruses most likely block apoptosis by enabling the synthesis of proteins made late in infection. The *gD* and *gJ* genes were able to block apoptosis only in cells infected with a mutant lacking both genes but not in cells exposed to TNF-a or Fas ligand (703); therefore, they may be necessary and sufficient in some circumstances but not in all systems studied to date.

In essence, cell death appears to be a complex phenomenon resulting in part from injury to the cell and in part from the cell response to infection. A major cause of cell death even in wild-type virus-infected cells may result from exhaustion of mitochondria and ultimately necrosis, if the levels of ATP have been totally exhausted, or apoptosis, if the cell can still react to the injury caused by viral gene products.

Herpes Simplex Virus and the Immune System

York and colleagues (695) were the first to report that HSV blocks the presentation of antigenic peptides by class I major histocompatibility complex (MHC) proteins. As the story unfolded, it became clear that ICP47, a small protein encoded by the a*47* (U_S12) gene binds to the transporter associated with antigen processing (TAP) and blocks the transport of peptides into the ER. ICP47 appears to have a high affinity for human and porcine TAP but not for murine homologs of the transport proteins. It may explain why the anti-HSV response in mice is so much more effective than in humans.

There is no current evidence that HSV blocks presentation by class II MHC proteins.

LATENCY

The ability of HSV to establish a lifelong latent infection in the human host is the most intellectually challenging aspect of HSV biology. The available data support the following sequence of events: The virus enters nerve endings and is transported retrograde to the nucleus of sensory nerves innervating mucosal epithelium (Fig. 11). In latently infected neurons, viral genomes acquire the characteristics of endless or circular DNA (167,381,497,498), and no replicating virus can be detected in the sensory ganglia innervating the site of inoculation. In a fraction of neurons harboring latent HSV, the virus is periodically reactivated. Infectious virus is carried anterogradely to peripheral tissues by axonal transport (97), usually to cells at or near the site of initial infection (65,106,195,502). Depending on several factors, including the host immune status, the reactivation may be asymptomatic or lead to a recurrent lesion, which may vary considerably in severity from punctate lesions that are invisible to the naked eye to severe, debilitating lesions in immunosuppressed individuals.

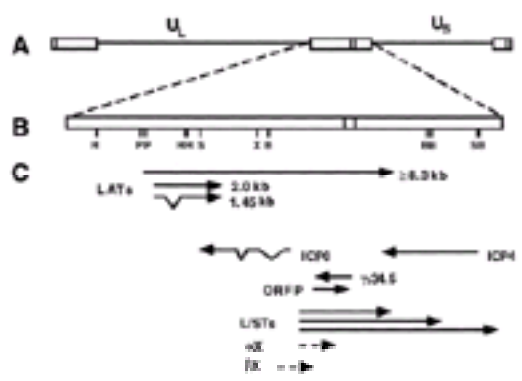

FIG. 11. Stages of HSV infection of the host. 1. HSV is introduced onto a mucosal surface or a break in the skin; it replicates productively in epithelial cells at the site of inoculation and spreads through the tissue. Virus enters sensory neuron axons and is transported to the cell body in a ganglion. 2. Virus either replicates productively or establishes a latent infection in the neuronal cell nucleus. Viral DNA is circular and in a nucleosomal form. Upon neuronal damage or activation, the virus reactivates and undergoes at least a limited productive cycle. Capsids are transported by

anterograde transport to the axonal termini and virions are released. 3. Reactivated virus causes a recurrent infection of the mucosal tissue, causing the shedding of virus.

Viral DNA fragments have been detected in CNS and other tissues; thus, to differentiate between presence of defective genomes and latent infections, the operational definition of latent infections has historically embodied the requirement that wild-type virus must be able to reactivate from latent state under appropriate experimental conditions. Operationally, this meant that virus could be detected after incubation of intact ganglionic tissue with suitable susceptible cells, but not by inoculation of the susceptible cells with homogenized ganglia (597). This definition obviously also included the ability to reactivate and replicate to detectable levels in the ganglia. Because virus has been reactivated from sensory and autonomic ganglia only, this definition restricts viral latency to only these tissues. More recently, the definition of latency was extended to include viruses that can be detected in sensory ganglia several weeks after infection by *in situ* hybridization (Fig. 12) with probes for latency-associated transcripts (described later) or by assays of viral DNA in ganglia (93,266,316,318,345,623). At the present time, the only technique for proving that a virus is incapable of establishing latent infections is the inability to detect viral DNA by PCR assays of DNA extracted from whole ganglia (378a, 478a). A possible new standard is the identification of neurons containing viral DNA by *in situ* PCR (143,600), although the results to date with this technique have been variable (378,478a). This redefinition of latent virus enables an assessment of the roles of specific genes in the establishment and maintenance of latency, separate from their roles in reactivation. The downside of the revised definition is that it equates the presence of viral DNA with a *bona fide* latent state defined biologically as at least capable of reactivation. Because viral DNA has been detected in the CNS and even at peripheral sites, the redefinition arguably extends the sites of viral latency beyond currently proven sites.

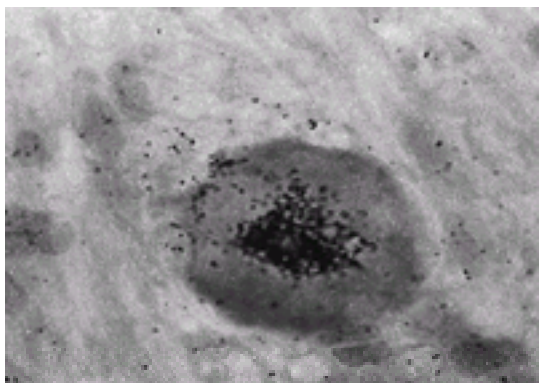

FIG. 12. Detection of HSV stable latency-associated transcript (LAT) RNA in latently infected murine trigeminal ganglion neurons by *in situ* hybridization. Mice were infected with HSV-1 after corneal scarification. At 30 days postinfection, the mice were sacrificed, and trigeminal ganglia were frozen and sectioned. The sections were hybridized with a ^{3}H-labeled DNA probe detecting the LAT RNA as described (93). (Micrograph courtesy of Magdalena Kosz-Vnenchak.)

The clinical aspects of latent infection and reactivation are discussed in Chapter 73. This section concerns the molecular biology of latency. The key issues are how the virus establishes latency, how it is maintained, and what makes it reactivate spontaneously.

Herpes Simplex Virus Latency in Experimental Systems

The Experimental Models

The most useful animal model systems are mice, guinea pigs, and rabbits. In all three species, inoculation of wild-type virus results in viral replication at the peripheral site, retrograde transport of virus to the nucleus of dorsal root neuron, followed ultimately by establishment of latency. In all three systems, a fraction of sensory neurons replicate the virus after entry into the neuron (274,275,276 and 277,366,367,466,467,637,656,678). It is not known whether acute viral replication also occurs in humans or whether this replication reflects the animal system, route of inoculation, induction of host transactivating factors, or the large amount of virus used in the inoculum to attain a high percentage of latently infected ganglia.

Explantation of dorsal root ganglia causes the latent virus to replicate and spread from cell to cell. There are several key differences in the animal models. In rabbits, both HSV-1 and HSV-2 reactivate spontaneously. The rabbit eye model is particularly useful for studies of spontaneous reactivation because the virus is readily detected in lacrimal secretions. The guinea pig is a useful model of HSV-2 genital infections. The virus reactivates spontaneously, causing lesions containing small amounts of virus, although the acute and recurrent phases are somewhat artificially defined. The virtues of the mouse model are twofold. First, highly inbred strains differ with respect to their susceptibility to infection, and knock-out mice have been particularly useful in studies of immune responses to infection (339). Second, spontaneous reactivations of virus resulting in the appearance of infectious virus either in ganglia or at peripheral sites are very rare (34,35,221,222,605). Here, the key issue is spontaneous reactivations resulting in abortive replication. As discussed later in the text, if HSV reactivates to cause abortive infections in dorsal root ganglia ever so rarely, it would have a significant impact on our understanding of the mechanism of reactivation. As in other systems, latent virus in mice can be induced to reactivate, leading to appearance of virus in sensory ganglia or at peripheral sites by peripheral tissue trauma, ultraviolet light exposure, hyperthermia, or administration of drugs that stimulate prostaglandin synthesis.

Establishment of Latency: Initial Stages

Studies on neurons cultured *in vitro* indicate that viral capsids are transported by retrograde axonal transport involving microtubules; thus, drugs that disrupt neuronal microtubule structures, or that are known to inhibit retrograde transport of certain compounds, also inhibit the ability of the virus to move from the peripheral endings of neurons to the nuclei (291). Electron microscopic studies indicate that in neurons infected in cell culture, the viral particle being transported is the unenveloped nucleocapsid or nucleocapsid–tegument structure (344,433).

Several important facets of latent infections relate to the role of virus multiplication, both at the portal of entry and in the neurons harboring the virus.

1. As noted previously, HSV must have access to the nerve endings to establish latency; therefore, it could be expected that the greater the number of peripheral cells that become infected and support virus multiplication, the larger the number of neurons that will harbor latent virus. The relevant phenomenon in humans is that the frequency of reactivations resulting in recrudescences of lesions is related to the severity of lesions caused by the first infection. In the model discussed subsequently, the frequency of recurrences would be determined in part by the number of neurons harboring virus.
2. Because wild-type viruses multiply in sensory neurons during the first 7 to 10 days after peripheral inoculation, most of the information available to date on the establishment of the latent state is based on studies done 2 weeks or more after infection and therefore adequately reflects maintenance rather than establishment. Studies with mutants lacking essential genes have been very revealing in several respects.

First, viruses lacking the essential a *4* and a*27* genes, totally unable to replicate in cultured cells in the absence of complementing viral genes, were shown to be able to establish and maintain latent infections but were unable to reactivate (266,552). The fact that no deletion mutant totally failed to establish latency raises the question of whether any viral gene is essential for this process and suggests that no viral function is absolutely required for the establishment of latency. Nevertheless, viral gene products may affect the levels of DNA persisting in latent viral ganglia. For example, recent studies have shown that an HSV-2 U_L5-negative, U_L29-negative mutant virus is defective for stable maintenance of viral DNA in trigeminal ganglia (107).

Second, either viral latency is determined by cellular functions or virion proteins and no viral gene function expressed *de novo* is required to establish latency, or viral DNA entering neurons is retained in an episomal form irrespective of its ability to express any function, and therefore at least some of the deletion mutants may not be truly latent but merely retained in dorsal root neurons. Differentiation between these two alternatives requires an analysis of dorsal root ganglia during the first few hours after infection. Alas, the small number of neurons harboring these mutants makes effective analyses of the early events in the establishment of latency very difficult. In essence, no gene has been identified as essential for establishment of latency based on analyses of latent virus present during the maintenance phase, although certain viral functions, such as the LATs and the missing functions in the *dl*5-29 mutant, appear to increase the efficiency of latent infection.

Function(s) of Latency-associated Transcripts

The major viral gene products expressed during latent infection are the LATs (606). This transcriptional unit is expressed from the *b* repeat sequences of the L component (Fig. 13), and the more than 8-kb transcript is antisense to ICP0 mRNA and possibly ICP4 mRNA. The viral promoter driving expression of this transcriptional unit functions efficiently in sensory neurons, and expression of LAT ensues rapidly after viral infection of sensory neurons (285,595). Latent infection is favored in certain subsets of murine trigeminal ganglion sensory neurons, as evidenced by expression of LATs, whereas productive infection is favored in other types of the sensory neurons, as evidenced by expressing of lytic antigens (351). LAT-negative mutant viruses exhibit increased acute expression of viral a, b, and g genes in sensory neurons as compared with rescued or wild-type viruses (180), suggesting that LATs in some way down-regulate lytic gene expression in neurons. The threefold increase in neurons expressing lytic genes with LAT-negative viruses correlates with the similar decrease in latently infected neurons with LAT-negative viruses (628). Thus, LAT may play a role in promoting latent infection by down-regulation of lytic gene expression. The mechanism of this effect could include antisense down-regulation of ICP0 or ICP4 mRNA, structural effects of the transcript on the viral genome, or expression of a protein product.

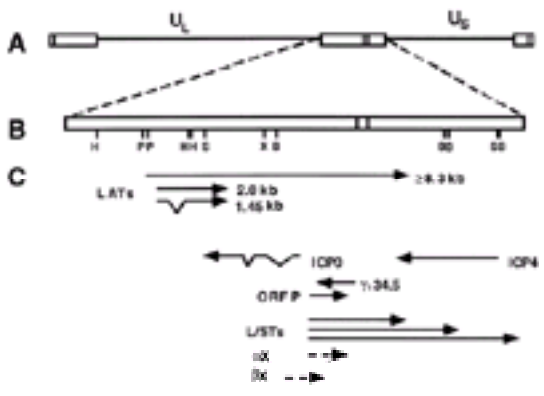

FIG. 13. Map of the latency-associated transcript (LAT) transcriptional unit. Map of the HSV-1 genome showing the LAT transcriptional unit. **A:** HSV-1 genome in the prototype orientation; U_L and U_S denote the unique sequences of the long (L) and short (S) components of the genome, respectively, and the *open boxes* denote repeat sequences. **B:** Expanded view of the L-S junction region with restriction endonuclease cleavage sites: B, BamHI; H, HpaI; P, PstI; S, SalI; X, XhoI. **C:** Locations and orientations of transcripts of the L-S junction region are denoted by *solid arrows* and include the LATs, ICP0, ICP4, $g_1$34.5 (78,82), ORF P (306), L/STs (693), and partially mapped transcripts (*dashed arrows*) aX and bX

(39,40).

A promising observation that did not live up to its expectation is that ORF P and ORF O were encoded in the domain transcribed by the 8.3-kb LAT. The transcript was detected late in infection and in nuclear runoff experiments, but not in cells treated with cycloheximide from the time of infection (40,693). The transcript or the protein it encodes has been detected early in infection in cells infected with a *4*-negative virus (693) or at 39°C, the temperature at which ICP4 of a wild-type virus is nonfunctional (306). Although attempts to detect the transcript in latently infected neurons have been unsuccessful (693), the results remain inconclusive because both the transcript and the protein are made in very small amounts. In addition, Yeh and Schaffer (693) failed to detect the 8.3-kbp LAT, which contains the sequences contained in the *ORF P* transcript. The transcription initiation site contains a high-affinity binding site for ICP4, and the genes are expressed only in the absence of functional ICP0 (480). Both ORF O and ORF P proteins are expressed from a single mRNA; thus, they share the amino-terminal 1 to 35 codons but diverge thereafter owing to RNA editing or undetected splicing. Overexpressed ORF P protein co-localized with spliceosomes and reduced the accumulation of ICP22 and ICP0, whereas the ORF O protein bound ICP4 and interfered with its binding to cognate sites on HSV DNA. Notwithstanding these attributes, mutagenesis of the initiator methionine, which abrogated the synthesis of ORF P and ORF O, had no effect on the ability of the virus to replicate in experimental animal systems and only a slight effect on the amount of virus recovered from latently infected ganglia (479). *ORF P* and *O* gene products may contribute to the establishment but are not key determinants of latency.

In the absence of detailed analyses of the events occurring during the first few hours after entry of viral DNA into dorsal root ganglia, one key hypothesis regarding the establishment of latency remains unchallenged. In essence, the hypothesis predicts that latency is established by default in the absence of initial sustained expression of a genes. The lack of a gene expression is likely explained by several mechanisms acting in combination: (a) lack of nuclear forms of host factors necessary for a gene transcription (298,640), (b) hormonally regulated repression of viral gene expression (674), and (c) LAT-mediated repression of a gene expression (180). The hypothesis that lack of a gene expression is central to latency is further supported by two sets of observations.

The first set stems from attempts to establish latency in cultured cells *in vitro.* Initial attempts were based on suppression of viral multiplication by high temperatures or antiviral drugs. Although these early attempts used nonphysiologic means and lacked the power of modern analytic tools, they did show that the HSV resident in these cells could be reactivated by superinfection with unrelated human CMV. More recent studies in so-called quiescent systems have yielded similar information, but in this instance, the power of the analytic tools applied to the system indicate that HSV does remain quiescent (nonreplicating) if a gene expression immediately after entry of the virus into the cell is repressed. The mechanism of repression after the initial stages of infection is unknown.

The second set of supporting data comes from two series of experiments. In chronologic order, the first was based on the hypothesis that the tegument protein aTIF or VP16 does not reach the neuronal nucleus. This possibility was tested using a recombinant virus that contained an insertion of a second copy of the a *TIF* gene under the control of the mouse metallothionein (MT) promoter (548). Despite expression of the chimeric a*TIF* gene in latently infected sensory neurons, latent infection continued. Furthermore, expression of the same chimeric gene in transgenic mice also failed to prevent establishment or maintenance of latency. *In situ* hybridization with probes specific for Oct-1 demonstrated detectable levels of Oct-1 mRNA in the sensory neurons of the MT–aTIF transgenics (V. Hukkannen and B. Roizman, unpublished data), indicating that the presence of both aTIF and Oct-1 was insufficient to prevent latent infection. A formal explanation as to why MT–aTIF failed to induce viral multiplication emerged from studies of Kristie and co-investigators (298), who showed that HCF or C1, the cellular cofactor required for enhancement of a gene expression, along with Oct-1 and aTIF, resides in the cytoplasm and is translocated into the nucleus only under conditions of reactivation, such as explantation of ganglia in culture.

Maintenance Phase of Latency: The Latency-associated Transcripts

Extensive studies on ganglia harboring latent HSV have been rewarded by an extreme paucity of evidence for viral gene expression. The only transcripts regularly detected in a large fraction of latently infected neurons have been designated as the LATs (606). They constitute a family of transcripts mapping to the inverted repeats flanking the U_L sequence (see Fig. 13). The full-length 8.3-kb transcript accumulates at low levels in latently infected neurons, whereas the 2.0- and 1.5-kb introns processed from a full-length transcript are abundant and accumulate in the nucleus (125,290,499,594,606,652,653,705). These introns are highly stable as a result of unusual lariat structures (156,500,685,696). The literature on LATs is enormous but fortuitously does lend itself to a brief summation. Viruses deleted in various domains of LATs have been reported to establish latency at normal levels (250,315,602) or at threefold reduced levels (628). Several studies have shown reduced explant reactivation of virus from ganglia latently infected with LAT-negative mutant viruses (31,220,250,315,551,602), although in many instances, LAT-negative mutant viruses show reduced replicative ability (31; Garber et al., manuscript in preparation; Lagunoff and Roizman, unpublished studies). The region of the LATs associated with decreased reactivation has been mapped to a 348-bp sequence in the 5' end of LAT (33,219).

Notwithstanding several reports (131,624), the stable 2.0- and 1.5-kb LATs have not been shown unambiguously to express ORFs. The functions attributed to LATs have been numerous and varied. Thus LATs, have been reported to (a) block productive infection gene expression by blocking the transcription of the gene encoding ICP0 located antisense or by other mechanisms (75,180), (b) enable reactivation of virus from latent state, and (c) maintain virus in latent state. Each of these putative mechanisms has been disputed (32,75,89,180,196,221,315,316,628,635). The most recent function attributed to LATs is that they protect neurons from apoptosis. Thus, a virus deleted for LAT was reported to induce apoptosis in rabbit trigeminal ganglia at slightly higher levels than the wild-type virus (438). The substance of the report is that LATs do spare the neurons from destruction but not the mechanism by which this takes place. This report

requires confirmation. If LATs do protect neurons from apoptosis, the question arises as to how RNA does this, and whether reactivation is the cause or consequence of failure of LAT to protect neurons from programmed cell death. Irrespective of the final determination of the functions of LATs, current data suggest that LATs exert a quantitative effect on latency rather than an absolute role.

Copy Number of Viral DNA in Latently Infected Neurons

In a different category from LATs is the observation that in trigeminal ganglia harboring latent virus, there are between 0.1 and 1 viral genome equivalents per cell genome (55,468,497,498). This datum posed an intriguing question. Heretofore, the number of neurons harboring virus was thought to be about 3% of total neurons. Rodahl and Stevens (501) indicated that under some circumstances, the number can be higher; however, neurons account for only about 10% of the total cells in a sensory ganglion. Unless viral genomes are contained in every single cell in a ganglion, including glial cells, it is obvious that, as was first calculated a number of years ago (516), each latently infected neuron must contain more than one viral genome.

Two series of experiments indicate that, as was predicted earlier (516), replication of viral DNA by viral enzymes is not necessary for the establishment of latent infection and is not responsible for the attainment of the high copy number. In these experiments (567,590,591), mice were infected by the footpad route, and assays of LAT, lytic antigens, and DNA copy number were done. Although there was a correlation between levels of lytic replication and the level of viral DNA per LAT-positive neuron, even those ganglia that showed little or no sign of viral antigen expression still had DNA copy numbers of greater than 20 viral genomes per LAT-positive neuron. To account for the high number of viral genomes per cell harboring latent virus, it is then necessary to postulate that (a) more than one viral genome can enter a single neuron during the establishment of latency, or (b) viral genomes are amplified by the cellular machinery during latency (516). In support of the second of these hypotheses, at least one host-dependent origin of DNA replication embedded within the viral genome has been identified (550). A second, symmetrically arranged copy was also found (A. E. Sears, personal communication). As discussed later, one hypothesis governing these studies is that one of the cellular polymerases amplifies resident viral genomes at a low rate. The dogma, however, has been that there is no DNA replication machinery in neurons.

On the other hand, evidence in favor of the high copy number being due to viral DNA replication functions includes (a) the constant level of viral DNA during latent infection by viruses incapable of viral DNA replication in neurons as determined by quantitative PCR (289,641) and (b) the general correlation between ganglionic replication and latent DNA load (629).

Reactivation of Virus from Latent State

The issues central to understanding viral reactivation from latent state are fivefold: (a) Do the events surrounding viral recrudescences in humans provide a clue to the events leading to reactivation? (b) Is there a specific viral gene whose function is unambiguously required for viral reactivation? (c) What is the order of expression of viral genes in the course of reactivation? (d) What is the significance of the observation that not all neurons harboring virus reactivate all at once? and (e) What is the fate of the neuron in which virus reactivated? It is convenient to consider these questions in the order stated.

a. In humans, latent virus is reactivated after local stimuli, such as injury to tissues innervated by neurons harboring latent virus, or by systemic stimuli, such as physical or emotional stress, hyperthermia, exposure to ultraviolet light, menstruation, hormonal imbalance, and so forth, which may reactivate virus simultaneously in neurons of diverse ganglia (e.g., trigeminal and sacral). In experimental systems, multiplication of latent virus has been induced by physical trauma to tissues innervated by the neurons harboring virus (10,204), by iontophoresis of epinephrine (299) or other chemicals or drugs (204,205,561), by transient hyperthermia (537,538), or by corneal scarification (640). The most plausible common denominator is that injury or stimulation of cells innervated by dorsal root neurons harboring latent virus is a common trigger of recrudescence of lesions caused by reactivated virus. The nature of the transduced signal is unknown.
b. It is a common practice to test deletion mutants for ability to establish latent infections and to reactivate. Not surprisingly, a large number of deletion mutants either failed to reactivate or reactivated poorly. Included in this list are virtually all of the genes essential for viral replication in cell culture but also mutants lacking thymidine kinase, ICP0, ribonucleotide reductase, $g_1$34.5, and so forth. A central problem with these claims is that neuronal cells harboring virus are relatively nonpermissive and devoid of enzymes necessary for viral nucleic acid metabolism. In the context of experimental tools based on explantation of sensory ganglia, it is virtually impossible to differentiate between genes required for optimal replication in tissues *in vivo* and those dedicated to reactivation of virus from latent state.
c. For years, the prevailing hypothesis concerning the regulation and order of gene expression during acute infection and reactivation was that it matched the program of viral gene expression taking place in infected cells in culture, that is, a genes are expressed first, followed by b and g genes. Recent evidence supporting the idea that a genes are expressed first is the rapid translocation (within minutes) of the HCF or C1 transcription factor from the cytoplasm to nucleus upon explantation of trigeminal ganglia (298). Nevertheless, theoretical arguments and experimental observations have suggested that viral gene expression may be regulated differently in neurons. Theoretical considerations have argued that HSV depends to a large extent on cellular factors for its gene expression, that the order of viral gene expression depends on available factors, and that in neuronal cells, the available factors differ from those of run-of-the-mill cultured cells (457). The experimental observations are of two kinds. First, Kosz-Vnenchak and associates (286) reported that high-level expression of a and b genes depended on viral DNA synthesis during acute ganglionic infection and in explanted ganglia. It was postulated that, in neurons, low levels of a and b gene expression preceded viral DNA synthesis and g gene expression, which then further activated a and b gene expression. The latter hypothesis was supported using reverse transcription PCR (RT-PCR) and PCR methods to detect viral RNA and DNA levels, respectively (289). Nevertheless, it has been argued that viral gene expression may not be detectable in the initial infected neuron and that viral spread amplifies the signal so that high-level a and b gene expression can be detected. By this hypothesis, viral DNA synthesis is

needed for progeny virus formation and spread and not direct induction of a and b gene expression. The currently available experimental data cannot rule out this alternative explanation for the *in vivo* data. However, one study of infections of sensory neurons in culture has supported the idea that viral gene expression is regulated differently in neurons. Nichol and colleagues (410) observed that, in HSV-infected sensory neurons in culture, viral DNA synthesis stimulates a and b gene expression. These results support the hypothesis of Kosz-Vnenchak and associates (286) that viral DNA synthesis stimulates a and b gene expression in neurons, but further studies are needed to rule out the possibility that viral spread accounts for the results *in vivo* and in explanted tissue. Second, Tal-Singer and colleagues (618) reported that they could detect b gene expression before a gene expression during explant reactivation. In this study, they used RT-PCR to detect viral transcripts, but they did not show that the assays for each of the transcripts was equally sensitive; therefore, it is conceivable that the differences in kinetics of appearance reflected sensitivity of the detection assay rather than the true order of appearance. The order of expression of HSV genes may be different during reactivation, but additional studies are needed to adequately document this.

d. Unlike the reactivation of varicella-zoster virus, not all neurons harboring latent HSV reactivate at once. The current consensus is that the recurrent lesions caused by reactivated virus are the reservoir for transmission of virus from person to person. Because transmission depends on physical contact between infected and uninfected individuals, frequent protracted recurrences would enhance transmission far more than a single synchronous transmission. One hypothetical model detailed elsewhere (45,515) that could explain asynchronous reactivation takes into account the DNA copy number per latently infected neurons. Briefly, the model is that each stimulus leading to reactivation causes an increase in the copy number of viral DNA. The stimulus may be local or systemic. At a certain point when the viral DNA copy number becomes very high, the virus reactivates either by diluting a repressor (copy number effect) or by competing more effectively for a scarce host factor necessary for basal level of viral gene expression (multiplicity effect). This model predicts that the decrease in recurrence rate reflects exhaustion of neurons that are stimulated to increase viral DNA copy number and, therefore, the larger the initial burden of latent virus, the more frequent or longer lasting interval of recurrences. This DNA level threshold could be achieved by host replicative mechanisms (516) or by viral replicative mechanisms (286).
e. The fate of the neurons after viral reactivation is a hotly debated topic. The proponents of the notion that neurons survive to reactivate again and again base their arguments on two observations. The first is that local anesthesia is not a sequelae in patients suffering from frequent recurrences at the same site. A formal rebuttal of this argument is that nerve endings from adjacent unaffected neurons grow into the healed area and reestablish a network. The second and more weighty observation is that women with recurrent genital lesions shed virus in the interim between clinically manifest lesions. The shed virus appears to originate from punctate, microscopic lesions that arise frequently and for long intervals. If each microscopic lesion arose from a reactivated neuron, there would not be enough neurons to support viral reactivation over many years if the neurons perished as a consequence of this process. The questions that have not been resolved yet is whether each lesion is the consequence of reactivation and whether chronic infections of mucosal tissues characterized by the observed microscopic lesions can be ruled out.

The studies on the molecular biology of viral replication and especially the effects of viral gene products on cellular structures and gene products detailed in this chapter do not support the hypothesis that neurons expressing viral gene products necessary for productive infection can survive and continue to function. A strange and unsupported model that satisfies the requirement that the neuron survive reactivation is that the neuron transport anterograde to peripheral sites not virions but viral DNA replicated by cellular enzymes.

CONCLUSIONS

There is an apocryphal story of three blind people asked to deduce the nature of an elephant. Each touched a different part and the identity became elusive. This probably was the case with herpesvirus research 50 years ago. In the interim, thousands of investigators explored every facet of HSV biology. We know what it consists of and the end result of infection: thousands of replicas and a very dead cell. The mass of data has produced a giant mosaic with huge gaps, but the designer's intent and general strategy of HSV design emerges. What is apparent is the following:

1. The overall strategy is total control of its own replication and of the cellular environment in which replication takes place.
2. A large fraction of viral coding sequence is devoted to changing the environment of the cell. The objectives of viral functions are the shutoff of *de novo* cellular gene expression, scavenging existing cellular proteins to redirect them to either block the host or to assist in viral replication, and complete dedication to the task of producing lots of viral progeny.
3. Many functions overlap. For example, several viral genes independently target *de novo* synthesis of cellular gene products. Many viral objectives are reached by accretion rather than by a single function of a viral gene.
4. Many, if not most, HSV proteins are multifunctional. In some instances, the functions can be mapped to blocks of amino acids. There is sufficient evidence to postulate that the function performed by individual proteins is determined by posttranslational modifications. Indeed, viral proteins are extensively posttranslationally modified.
5. Other members of the herpesvirus family with a much more restricted host range encode homologs of cellular genes. HSV encodes instead sequences that interact with and stabilize or redirect cellular proteins. The net effect is that whereas a homolog basically performs a single function, viral proteins containing amino acids blocks that redirect cellular proteins can perform multiple functions. This design presents a curious problem: It is much easier to identify a homolog than to detect the intent or function of an amino acid block that interacts with a similar cellular protein.
6. Latent infection of sensory neurons by HSV is likely to be a complex process in which numerous factors, including missing host cell factors, cellular repressor molecules, and viral functions, may each play a role in this alternative infection pathway.

Notwithstanding the many problems, the virus is no match to the effort, modern technology, and ingenuity of the blind investigators.

CHAPTER 73 Herpes Simplex Viruses

Richard J. Whitley

Knowledge of human herpes simplex virus (HSV) infections has increased dramatically since the initial historical descriptions of the disease in a variety of patient populations and the histopathology of induced lesions. Advances in our understanding of the natural history and pathogenesis of HSV infections have been paralleled by several major achievements. First, sensitive and specific serologic tests allow the distinction between HSV type 1 (HSV-1) and type 2 (HSV-2) infections. Two of these tests are now licensed. Second, antiviral drugs have proven to be selective and specific inhibitors of viral replication and are clinically efficacious. Such drugs as acyclovir, valaciclovir, and famciclovir have provided probes for assessing disease pathogenesis in both the normal and immunocompromised host. The unequivocal establishment of the value of therapy has had a major impact on altering the spectrum of human disease and has implications for long-range control of HSV infections. Third, polymerase chain reaction (PCR) detection of HSV DNA has contributed immensely to our knowledge of disease pathogenesis, as well as to the diagnosis of disease, particularly HSV infections of the brain. Furthermore, the ever-evolving knowledge of the molecular biology of HSV has been unusually striking over the past several years. This is best exemplified by the elucidation of the events of viral replication (especially induction of replication), including viral gene products and biologic functions, the translocation of proteins, gene regulation, membrane structure, and virus entry molecules. Our current level of biomedical knowledge sets a stage for (a) the application of molecular biology to the evaluation of human disease, (b) the development of genetically engineered vaccines, (c) the development of antiviral therapeutics predicated on newly identified site-specific molecular targets, and (d) the use of genetically engineered HSV for gene and tumor therapies (140,446). As with the study of other viruses, there is the potential for applying genetically engineered probes, which would make an understanding of the molecular pathogenesis of human disease even more attainable. This chapter will summarize the current status of our knowledge of HSVs as human pathogens.

HISTORY

HSV infections of humans have been documented since ancient Greek times (332,556). Records of human HSV infections began with descriptions of cutaneous spreading lesions thought to be of herpetic etiology, as noted in the writings of Hippocrates and reviewed by Nahmias and Dowdle (332). Scholars of Greek civilization define the word *herpes* to mean to creep or crawl, in reference to the spreading nature of the visualized skin lesions (43,556). The Roman scholar Herodotus associated mouth ulcers and lip vesicles with fever and defined this association as “herpes febrilis” (311). Most likely, many of these original observations were predicated on Galen's deduction that the appearance of such lesions was an attempt by the body to rid itself of evil humors, and this possibly led to the name of “herpes excretins” (556). These original descriptions of skin lesions probably show little resemblance to later reports (in the 19th and 20th

centuries) of these infections (312).

As noted by Wildy (556), Shakespeare was probably cognizant of recurrent HSV labial lesions. In Romeo and Juliet, Queen Mab, the midwife of the fairies, stated, “O'er ladies lips, who straight on kisses dream, which oft the angry Mab with blisters plagues, because their breaths with sweetmeats tainted are.”

In the 18th century, Astruc, physician to the king of France, drew the appropriate correlation between herpetic lesions and genital infection (203). By the early 19th century, the vesicular nature of lesions associated with herpetic infections was well characterized. However, it was not until 1893 that Vidal specifically recognized human transmission of HSV infections from one individual to another (556).

Several observations made at the beginning of the 20th century brought an end to the early era of imprecise descriptions of HSV infections. First, histopathologic studies described multinucleated giant cells associated with herpesvirus infections (517). Second, the unequivocally infectious nature of HSV was recognized by Lowenstein in 1919 (289). He demonstrated experimentally that virus retrieved from the lesions of humans with HSV keratitis or from the vesicles of HSV labialis produced lesions on the cornea of the rabbit. These corneal lesions were similar to those encountered in humans with eye infection. Furthermore, vesicle fluid from patients with herpes zoster failed to produce similar dendritic lesions in the rabbit eye model. These observations were actually attributed to earlier investigations by Grüter, who performed nearly identical experiments around 1910 but did not report them until much later (169).

Investigations reported between 1920 and the early 1960s focused on the biologic manifestations of HSV and the natural history of human disease. During the first four decades, the host range of HSV was expanded to include a variety of laboratory animals, chick embryos, and, ultimately, cell culture systems. Expanded animal studies demonstrated that transmission of human virus not only could occur with the rabbit, as noted, but also could lead to infections of either the skin or the central nervous system (CNS) (reviewed in refs. 127,346,543,545, and 550).

Host immune responses to HSV were first described in the early 1930s. The first studies were performed by Andrews and Carmichael and defined the presence of neutralizing antibodies to HSV in the serum of previously infected adults (14). Subsequently, some of these patients developed recurrent labial lesions, albeit less severe than those associated with the initial episode. This observation led to the recognition of a unique biologic property of HSV, namely, the ability of these viruses to recur in the presence of humoral immunity, a characteristic known as reactivation of latent infection. Only individuals with neutralizing antibodies developed these recurrent vesicular lesions, a paradoxical finding given the classic lessons of infectious diseases provided by measles and rubella, in which antibodies were normally associated with protection from subsequent episodes of disease. By the late 1930s, infants with severe stomatitis were reported to shed a virus thought to be HSV (126) and developed neutralizing antibodies during the convalescent period (71). Later in life, some of these children had recurrent lip lesions.

The medical literature of the 1940s and 1950s was replete with articles describing specific disease entities such as primary and recurrent infections of mucous membranes (e.g., gingivostomatitis, herpes labialis, and genital HSV infections, and such skin manifestations as herpetic whitlow or eczema herpeticum) (453), keratoconjunctivitis (159), neonatal HSV infection, visceral HSV infections of the immunocompromised host, and HSV encephalitis (474). Recently, the clinical spectrum of HSV infection was expanded to include Kaposi's varicella-like eruption, infections of the immunocompromised host, and an association with erythema multiforme.

Laboratory advances have provided a foundation for better understanding the epidemiology and natural history of infection. One significant advance was the detection of antigenic differences between HSV types. Although suggested by Lipschitz (282) on clinical grounds over 70 years ago and by others from laboratory observations (379,447), in 1968 antigenic and biologic differences were demonstrated between HSV-1 and HSV-2 by Nahmias and Dowdle (332). These investigators demonstrated that HSV-1 was more frequently associated with nongenital infection (infection above the belt), whereas HSV-2 was associated with genital disease (infection below the belt). Today, the principle of type specificity and location is not as predictable as it was 30 years ago. Nevertheless, this observation was pivotal for many of the early clinical, serologic, immunologic, and epidemiologic studies.

Other critical advances that have contributed to our understanding of the natural history of HSV infections include the following: First, successful antiviral therapy was established unequivocally for HSV encephalitis (552) and, subsequently, for genital HSV infections (63,108,109,112) and HSV infections in the immunocompromised host (313,433; reviewed in refs. 535 and 544). Second, differences between strains of HSV were demonstrated by restriction endonuclease technology—an important epidemiologic tool (66). Third, type-specific antigens have been applied to seroepidemiologic surveys (411). Fourth, an understanding of the genotypic properties HSV has been applied to phenotypic studies. Such efforts have advanced our understanding of latency, trophism, and virulence at a molecular level. Fifth, the engineering of HSV and the expression of specific genes are providing the technology for experimental vaccines (410), as well as for the use of such viruses for gene therapy. Finally, extensive effort has been devoted to the study of latency with incremental advances (defined in ref. 492, and reviewed in ref. 413).

INFECTIOUS AGENT

HSVs are members of a family of viruses whose genomes consist of a single large double-stranded DNA molecule, as reviewed in Chapter 72 (556). The herpes simplex virion consists of four components: (a) an electron-dense core containing viral DNA; (b) an icosadeltahedral capsid; (c) an amorphous, at times eccentric, layer of proteins, designated tegument, which surrounds the capsid; and (d) an envelope. The capsid consists of 162 capsomeres and is surrounded by the tightly adhering tegument. The envelope surrounds the capsid–tegument structure and consists of at least 10 glycosylated and several nonglycosylated viral proteins, lipids, and poly-amines. Viral DNA contains at least 152 kbp. The variability in size is due chiefly to the variation in the number of reiterations of specific terminal and internal sequences. The DNA of HSV-1 and HSV-2 DNAs consists of two covalently linked components, designated as L (long) and S (short). Each component is composed of unique sequences (U_L or U_S, respectively) flanked by relatively large

inverted repeats. The inverted repeat sequences flanking U_L are *ab* and *b'a'*, whereas those flanking U_S are *a'c'* and *ca*. The two components can invert relative to one another to yield four populations of DNA molecules differing solely in the relative orientation of these DNA sequences (414).

Current studies indicate that HSV-1 and, by extension, HSV-2 encode at least 84 different polypeptides (Table 1) (527). Of this number, 14 map in the U_S, four in each of the sequences flanking U_L, one in each of the sequences flanking U_S, and the remainder in U_L. The genes mapping in the repeats are present in two copies per genome.

TABLE 1. *Polypeptides encoded by herpes simplex viruses 1 and 2*

To initiate infection, HSV must attach to cell surface receptors, fuse its envelope to the plasma membrane, and allow the de-enveloped capsid to be transported to the nuclear pores. The DNA is released into the nucleus at the pore. The key events in viral replication that occur in the nucleus include transcription, DNA synthesis, capsid assembly, DNA packaging, and envelopment. Viral surface glycoproteins mediate attachment and penetration of the virus into cells. They also elicit host immune responses to the virus. Currently, at least 10 viral glycoproteins (designated gB, gC, gD, gE, gG, gH, gI, gK, gL, and gM) are known, and an eleventh (gJ) has been reported. Two, gC and gB, are required for attachment to the cell surface, whereas gD is required for entry of virus into cells. Two more, gE and gI, form a rather potent Fc receptor; gE is also required for basolateral transmission of virus in polarized cells and for efficient expression of late genes. It is of note that the deletion of gH allows only a single cycle of viral replication. This principle is being applied to the development of infectious vaccines.

The synthesis of viral gene products, both RNA and proteins, takes place in three sequential periods. The first set consists of six proteins known as a or immediate-early proteins. Of these, five regulate the reproductive cycle of the virus and one blocks the presentation of antigenic peptides on the infected cell surfaces. The a proteins are essential for the synthesis of the second set of viral gene products, known as b or early proteins. Most of the b proteins are responsible for viral nucleic acid metabolism and are the main target of antiviral chemotherapy (e.g., viral thymidine kinase, viral DNA polymerase). These enzymes are essential for activation of acyclovir and penciclovir and subsequent inhibition of viral replication (437). HSV viruses resistant to these medications have been described (115, and reviewed in ref. 545).

The third class of proteins (g or late) are for the most part the structural components of the virion. They assemble to form the capsid and the tegument, and they incorporate into nuclear membranes for eventual envelopment of virions. In the process of viral assembly, a procapsid is formed from scaffolding and capsid proteins. The scaffolding proteins consist of a protease and its substrate, with the protease cleaving the substrate during capsid assembly. The newly synthesized DNA is cleaved into unit-length molecules and packaged into the virions. Generally, envelopment favors capsids containing DNA. Capsids containing DNA attach to the nuclear surface of the inner nuclear membrane and are rapidly enveloped and released into the space between the inner and outer nuclear membranes. Here, the virions become encased in transport vesicles and are transported through vesicles formed by fragmented and dispersed Golgi stacks to the extracellular space. This process takes approximately 18 hours.

Several aspects of the viral replication cycle and of the viral proteins are relevant to the pathogenesis of human diseases, and to the present and future development of antiviral chemotherapy:

1. At least five viral proteins play a key role in ensuring a robust expression of viral genes and the mobilization of cellular proteins necessary for efficient synthesis of viral DNA and proteins. The first of these, aTIF (for trans-inducing factor) or VP16, is a protein, packaged in the tegument, that augments the basal level of expression of a genes. Like many other viral proteins, aTIF is both a transactivator and an essential structural protein of the virion.

The second, an a protein known as the infected cell protein (ICP4), binds directly to both high- and low-affinity sites on viral DNA. ICP4 acts both as a transactivator at low-affinity sites and as a potent repressor at high-affinity sites located at the transcription initiation sites of its own gene and that of a few others.

Another a protein, ICP0, acts a promiscuous transactivator of genes introduced by infection or transfection. It does not bind DNA. Recent studies indicate that it binds an array of cellular proteins. The functions of the interactive proteins suggest that ICP0 has at least two roles: (a) to stabilize important cell cycle regulatory proteins (e.g., cyclin D3), forcing the cell to the brink of the S phase (but not allowing cell division), and (b) to maintain a vigorous protein synthesis for its own use.

ICP27, another a protein, also has several functions. The most remarkable is control of posttranslational processing of RNA. Unlike cellular genes, the vast majority of viral genes lack introns. IPC27 blocks the splicing of mRNA. Although it

reduces the amounts of spliced viral mRNAs, the net effect is on host mRNAs and results in diminished cellular protein synthesis. In addition, ICP27 acts as a transporter for late RNA from the nucleus to the cytoplasm and, as a consequence, regulates the expression of late proteins. ICP22 is another multifunctional a protein. This protein has revealed few of its functions, but it appears to regulate the longevity of ICP0 mRNA. It also is involved in the use of specific splice acceptor sites of ICP0 mRNA.

2. The tegument proteins function to enhance the capacity of HSV to replicate efficiently. In addition to the aTIF described, two viral proteins play an important role in viral infection. The first, *vhs*, is the product of the gene U_L41. It induces an RNase activity, which degrades all mRNA. Because viral transcription occurs at a very high rate, viral protein synthesis is less affected than cellular protein synthesis. The tegument also includes a protein kinase encoded by U_L13. Although dispensable in cell culture, this kinase is essential for viral replication in experimental animal systems, and its substrate is both viral and cellular proteins.

3. Viral proteins interact with cellular proteins, either to stabilize them and redirect their function, or to block their function. For example, as noted, ICP0 binds to and prolongs the half-life of cyclin D3. The two other types of interactions of viral and cellular proteins are involved in blocking host cell response to infection. Small peptides derived from degradation of cellular DNA are normally transported through the endoplasmic reticulum to the cell surface. In the first of the two interactions that interfere with function, HSV blocks the presentation of antigenic peptides by encoding an a protein, ICP47, that binds to TAP1/TAP2, the proteins that bind to and translocate peptides into the endoplasmic reticulum.

A second antiviral host defense mechanisms is based on the activation of dsRNA-dependent protein kinase (PKR). Activated PKR phosphorylates the a subunit of a translation initiation factor (eIF-2a) and shuts off protein synthesis. Nearly all viruses make dsRNA, either as part of their replicative cycle or because both strands of the nucleic acid that are transcribed activate PKR, and all of them have evolved functions to block the shutoff of protein synthesis. HSV has evolved a totally different technique: The protein encoded by the viral $g_1 34.5$ gene binds protein phosphatase 1 and redirects its activity from common substrate to dephosphorylate eIF-2a. The rate of dephosphorylation of eIF-2a in cells infected with wild-type virus increases 3,000-fold compared to that of uninfected cells. Expression of several viral functions, including the stabilization and prolonged function of cyclin D3, is likely to induce apoptosis. HSV has evolved at least one gene, the protein kinase expressed by the U_S3 gene, to block apoptosis induced by the virus as well as that induced by other agents.

4. Viral replication is highly deleterious to the integrity of the infected cell. Cellular chromosomes are marginated to the nuclear membrane and degraded, the nucleolus falls apart, the Golgi is fragmented and dispersed, and the microtubules are rearranged. All of these events are designed to create the environment for viral DNA synthesis, to enhance the glycosylation and exocytosis of virions, and to prevent a host response to infection.

5. Of the 84 genes known to be encoded by HSV-1 and HSV-2, at least 45 are dispensable for growth in cells. These 45 include genes whose products enable the virus to attach and enter both apical and basolateral aspects of polarized cells, to fine-tune expression of individual genes, to provide efficient cell-to-cell spread, to sort proteins and viral exocytosis, to increase the precursor pool and repair viral DNA, and to block cellular and immune responses to viral infection. It should be stressed that these genes are not truly dispensable: Viruses lacking them have not been isolated from people, and viruses from which these genes have been deleted by genetic engineering frequently exhibit reduced capacity to multiply and spread in experimental animals. On the other hand, the observation that so many HSV genes are dispensable and can be replaced by non-HSV genes sustains the expectation that a live attenuated vaccine capable of acting as a vector for foreign gene expression is feasible.

PATHOLOGY AND PATHOGENESIS

Pathology

The pathologic changes induced by the replication of HSV are similar for both primary and recurrent infection but vary in the quantitative extent of cytopathology. The histopathologic characteristics of a skin lesion induced by HSV are shown in Figure 1. These changes represent a combination of virally mediated cellular death and associated inflammatory response. Changes induced by viral infection include ballooning of infected cells and the appearance of condensed chromatin within the nuclei of cells, followed by subsequent degeneration of the cellular nuclei, generally within parabasal and intermediate cells of the epithelium. Cells lose intact plasma membranes and form multinucleated giant cells. With cell lysis, clear (referred to as vesicular) fluid containing large quantities of virus appears between the epidermis and dermal layer. The vesicular fluid contains cell debris, inflammatory cells, and, often, multinucleated giant cells. In dermal substructures, there is an intense inflammatory response, usually in the corium of the skin, more so with primary infection than with recurrent infection. With healing, the vesicular fluid becomes pustular with the recruitment of inflammatory cells, and then it scabs. Scarring is uncommon but has been noted in some patients with frequently recurrent lesions. When mucous membranes are involved, vesicles are less likely to be prominent. Instead, shallow ulcers are more common because the vesicles rapidly rupture as a result of the very thin cornified epithelium. Nevertheless, the histopathologic findings of these shallow ulcers are similar to those of the skin.

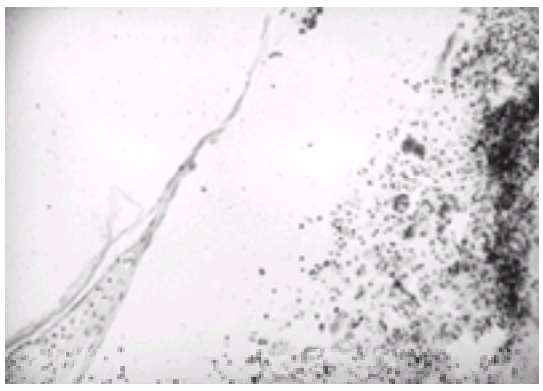

FIG. 1. Histopathology of an HSV infection.

Vascular changes in the area of infection include perivascular cuffing and areas of hemorrhagic necrosis (Fig. 2). These histopathologic findings become particularly prominent when organs of the body other than skin are involved, as is encountered with HSV encephalitis or disseminated neonatal HSV infection. In such cases, widespread areas of hemorrhagic necrosis, mirroring the area of infection, become most prominent. When the brain is involved, oligodendrocytic involvement and gliosis are common, as is astrocytosis, but these changes develop late in the disease course. Local lymphatics can show evidence of infection with intrusion of inflammatory cells, which allows the draining of infected secretions from the area of viral replication. The intensity of the inflammatory response is significantly less with recurrent disease. As host defenses develop, an influx of mononuclear cells can be detected in infected tissue.

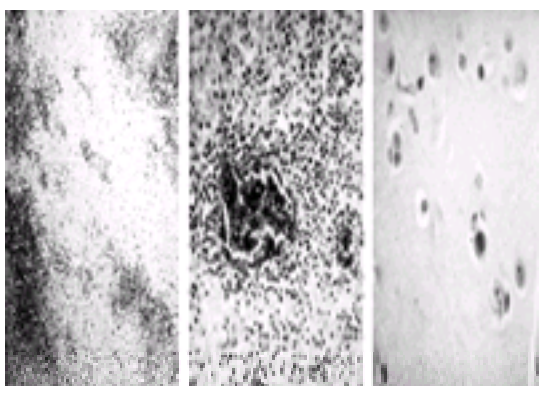

FIG. 2. Perivascular cuffing with areas of hemorrhagic necrosis of the brain.

Pathogenesis of Human Infection

The pathogenesis of HSV infections is understood through knowledge of the events of replication, including virulence, and establishment of latency in both animal models and humans. The pathogenesis of human disease depends on intimate, personal contact of a susceptible individual (namely, one who is seronegative) with someone excreting HSV. The trigeminal ganglion becomes colonized and harbors latent virus. Acquisition of HSV-2 infection is usually the consequence of transmission by genital contact. Virus replicates in the genital, perigenital, or anal skin sites with seeding of the sacral ganglia. An overview of these sites of infection appears in Figure 3.

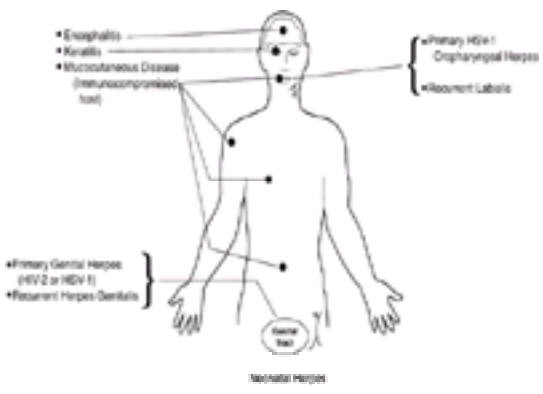

FIG. 3. Sites of HSV infection and disease.

Accumulated clinical experience suggests that after primary infection, replication of virus at the portal of entry, usually oral or genital mucosal tissue, results in infection of sensory nerve endings; the virus is transported to the dorsal root ganglia, as noted previously (32,34,493,495). Figure 4 illustrates the events of primary infection. The more severe the primary infection, as reflected by the size, number, and extent of lesions, the more likely it is that recurrences will ensue. However, experimental evidence to substantiate this hypothesis is lacking. In large part, this notion is attributed to the large quantity of virus present when primary disease is extensive and clinically overt as compared with those infections

that are asymptomatic and usually undetected. The resulting cutaneous lesions contain infectious virus.

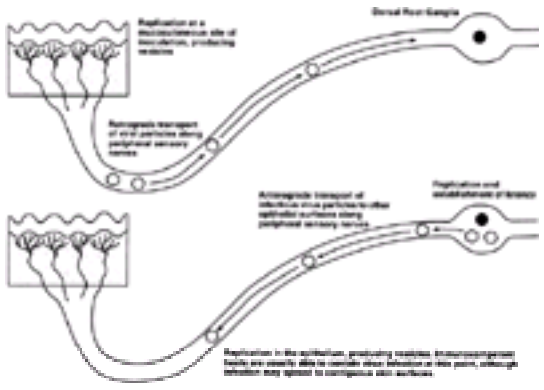

FIG. 4. Schematic diagram of an HSV infection.

Thus, virus must come in contact with mucosal surfaces or abraded skin for infection to be initiated. With viral replication at the site of infection, either an intact virion or, more simply, the nucleocapsid is transported by neurons to the dorsal root ganglia, where latency is established. These events were demonstrated in a variety of animal models (reviewed in ref. 194). Transport of the virion is by retrograde axonal flow (103). The fundamental principle of disease pathogenesis, then, is the propensity of virus to replicate at mucosal surfaces, to be transported to dorsal root ganglia, and to become latent. Although replication can sometimes lead to disease and can infrequently result in life-threatening CNS infection, the host–virus interaction leading to latency predominates. After latency is established, a proper stimulus will cause reactivation to occur; virus becomes evident at mucocutaneous sites (Fig. 5), appearing as skin vesicles or mucosal ulcers. Primary infection can spread beyond the dorsal root ganglia, thereby becoming systemic; however, this event is unusual. Such circumstances include disseminated neonatal HSV infection with multiorgan involvement, multiorgan disease of pregnancy, and, rarely, dissemination in immunosuppressed patients. It is likely that widespread organ involvement is the consequence of viremia in a host incapable of limiting replication to mucosal surfaces.

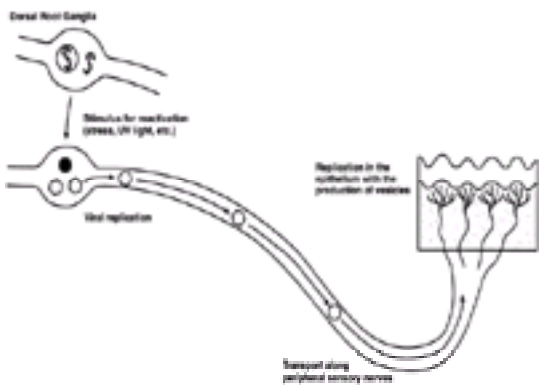

FIG. 5. Schematic diagram of latency and reactivation

Animal models provide insight into the transport of virus to the ganglia by retrograde axonal flow (103,195,261). Both histopathologic (using immunofluorescence staining of targeted cells) and electron-microscopic studies have unequivocally established axonal transport as a mechanism for translocation of the virus from a peripheral site to a central one. Virus is transported by the sensory nerves to central axons, where translocation of the capsid containing viral DNA occurs at a rate of approximately 10 mm/hr. This rate is similar to that of retrograde axoplasmic flow (104,261). If axonal flow is interrupted by severing the nerve or by chemical manipulation, translocation of virus from a peripheral mucocutaneous site to the associated ganglia will not occur.

After transport, virus replicates for several days in the associated sensory ganglia that innervate the site(s) of inoculation (103,193,194). Once replication in the sensory ganglia is complete, antiviral drugs have no effect on the elimination of virus from its latent state. Thus, one significant conclusion is that latent virus does not multiply; therefore, it is not susceptible to drugs that affect viral DNA synthesis. Numerous studies have attempted to eliminate latent HSV by treatment with nucleoside analogs, but all were unequivocal failures. It must be reemphasized that the mechanisms by which HSV establishes a latent state and maintains it are not yet well understood.

Operative definitions of the nature of the infection are of pathogenic relevance. Human definitions will be applied to both systems. For individuals susceptible to HSV infections (namely, those without preexisting antibodies), the first exposure to either HSV-1 or HSV-2 results in primary infection. The epidemiology and clinical characteristics of primary infection are distinctly different from those associated with recurrent infection, as will be noted later. After the establishment of latency, a recurrence of HSV is known as recurrent infection. This form of infection results in vesicular lesions of the skin such as HSV labialis or recurrent HSV genitalis. An individual with preexisting antibodies to one type of HSV (i.e., HSV-1 or HSV-2) can experience a first infection with the opposite virus type (i.e., HSV-2 or HSV-1, respectively) at a different site. Under such circumstances, the infection is known as an initial infection rather than as a primary infection.

An example of an initial infection occurs in those individuals who have preexisting HSV-1 antibodies (acquired after HSV gingivostomatitis) and then acquire a genital HSV-2 infection. Reinfection with a different strain of HSV can occur,

although it is extremely uncommon in the normal host. When this does occur, it is called exogenous reinfection.

A fundamental question that arises from the appearance of recurrent lesions, either of the lip or of the genital tract, is, Can exogenous reinfection with the same or opposite strain of virus account for “apparent” recurrent HSV infections? Clinical evidence, as early as 1968, had suggested that this was a possibility (332). However, in 1979, further speculation regarding exogenous reinfection was clarified by an important observation in an animal model. Namely, it was possible to reinfect both mice and *Cebus* monkeys with HSV-2 by the genital route after they had recovered from prior genital infection at the same site and with the same virus type (284). Unequivocal demonstration of exogenous reinfection became possible only after the development of restriction endonuclease technology, as described later.

UNIQUE BIOLOGIC PROPERTIES OF HSV

HSV has two unique biologic properties that influence human disease: neurovirulence and latency. The propensity of HSV to invade and replicate in nervous system tissue can result in profound disease with severe neurologic devastation. This is especially the case for HSV encephalitis. Alternatively, virus can infect sensory ganglia without resulting in significant disease. When this occurs, latency is established, thus providing a reservoir for virus and allowing its transmission to susceptible persons if reactivated.

Neurovirulence

Neurovirulence encompasses both neuroinvasiveness from peripheral sites and the ability of HSV to replicate in neuronal cells. While this property may be the function of numerous genes, the deletion of one gene in particular, $g_1$34.5, removes the ability of HSV to both invade and replicate in the CNS (93). The molecular basis for the failure of $g_1$34.5-deleted mutants to multiply in CNS is unclear and probably different from the function of the protein in directing the dephosphorylation of eIF-2a. Regardless, the inability of viruses with this gene deletion to replicate in the CNS and their significantly decreased ability to establish latency provide a foundation for the use of this virus as a vector for gene therapy and the development of a genetically engineered vaccine.

Mutations affecting neuroinvasiveness have also been mapped in genes encoding glycoproteins. These findings are not unexpected. Access to neuronal cells from usual portals of entry into the body requires postsynaptic transmission of virus and, therefore, a particularly vigorous capacity to multiply and to sort the virions to appropriate membranes. In addition, because neuronal cells do not make cellular DNA, they lack the precursors for viral DNA synthesis that are also encoded by those viral genes that are dispensable for replication in cell culture.

Latency

The ability of HSV to establish latency has been recognized biologically since the beginning of the 20th century. Following entry and infection of nerve endings, both HSV-1 and HSV-2 are transported by retrograde movement to the nuclei of sensory ganglia (494). The available evidence indicates that the virus multiplies in a small number of sensory neurons. In the majority of the infected neurons, the viral genome remains in an episomal state for the entire life of the individual. Reactivations occur following a variety of local or systemic stimuli such as physical or emotional stress, fever, exposure to ultraviolet (UV) light, tissue damage, and immune suppression.

Little is known regarding the mechanisms by which the virus establishes and maintains a latent state or is reactivated. In fact, disagreements exist on the fate of neurons in which latent virus becomes reactivated (reviewed in ref. 412). The relevant issues may be summarized as follows:

1. Sensory neurons harboring virus contain nuclear transcripts arising from the sequences *ab* and *b'a'* flanking U_L. To date, two sets of transcripts, designated latency-associated transcripts (LAT) have been detected. The most abundant transcripts arise from 2.0 domain mapping 3' to the gene encoding ICP0. This domain encodes two RNAs, a 2.0-kb and a 1.5-kb RNA. Both RNAs are nuclear and both have characteristics of stable introns. They do not appear to encode proteins. The other RNA detected to date is an 8.5-kb species of much lower abundance. This species appears to include the 2.0-kb sequence contained in the stable intron. The issue then is if the 2.0-kb RNA and the 1.5-kb RNA are introns, where is the product of the splicing event? Furthermore, deletion of the domain of the 2.0-kb RNA or of its promoter decreases the number of neurons harboring latent virus and the frequency of reactivation, but it does not abolish either process.

Recent studies on the 8.5-kb DNA domain transcribed during latency led to the discovery of two open reading frames (ORFs) totally repressed by ICP4 during productive infection. These ORFs, designated ORF P and ORF O, are antisense to the $g_1$34.5 gene. ORF P protein has been shown to bind p32, a protein involved in splicing. In cells in which ORF P is derepressed, ICP0 and ICP22, two proteins made from spliced mRNAs, are grossly underproduced early in infection. Late in infection, these two proteins accumulate concomitant with extensive posttranslational processing of ORF P protein. The ORF O protein binds to ICP4 and blocks it from binding its cognate site on DNA *in vitro*.

The mechanism whereby HSV establishes latency remains obscure, but probably not for long. It is likely that establishment of latency is based on several events occurring simultaneously. These could well be expression of viral genes that block a proteins from being made, absence of factors that enable high-level expression of a genes, and cell factors that do not favor or actually participate in the repression of viral gene expression.

2. As noted before, replication of HSV-1 and HSV-2 results in the destruction of the infected cell. It has been suggested that reactivation of latent virus in sensory neurons does not destroy the neuron harboring the virus. This suggestion is based on the observation that patients do not suffer from local anesthesia at the site of frequent, multiple recurrences. Alternatively, nerve endings from adjacent tissues innervated by other neurons could extend into the site of the healed lesion. Finally, it has also been suggested that small amounts of virus could remain latent in peripheral tissues. The

answer to this puzzle has not been forthcoming.

Further study of the biology of latency is indicated. Patients treated for trigeminal neuralgia by sectioning a branch of the trigeminal nerve can develop herpetic lesions along the innervated areas of the sectioned branch (117). This association was also suggested by Goodpasture (166). Carlton and Kilbourne (78), Pazin et al. (375,376), and others (141) have demonstrated that microvascular surgery of the trigeminal nerve tract, performed to alleviate the pain associated with tic douloureux, resulted in recurrent herpetic lesions in over 90% of seropositive individuals.

Latent virus has been retrieved from the trigeminal, sacral, and vagal ganglia of humans (29,30,32,34). In humans, the frequency of isolation of HSV from ganglia was described by Baringer (29,30,32) and others (34,528). In one study, virus isolation was attempted from the trigeminal ganglia of 90 cadavers and was documented in 44 individual situations. In 26 of these cases, HSV was isolated bilaterally from both ganglia. The retrieval of virus from the trigeminal ganglia helps explain the observation of vesicles that recur at the same site in humans, usually the vermilion border of the lip. Similarly, when 68 sacral ganglia were co-cultivated, only nine were positive and all for HSV-2. Baringer extended these observations to successfully retrieve virus from the thoracic ganglia of one patient whose trigeminal ganglia yielded HSV-1 bilaterally (29,30,32). A model of reactivation appears in Figure 5.

Reactivation of latent virus appears to depend on an intact anterior nerve route and peripheral nerve pathways. Induction of viral replication by axonal injury was reported by Walz et al. (526). They reactivated latent ganglionic infection by sectioning a peripheral nerve, resulting in the appearance of virus within the ganglia 3 to 5 days after the surgical manipulation. Not surprisingly, if an attempt is made to excise the lesions induced by HSV, vesicles will still recur adjacent to the site of excision (234,526). Recurrences occur in the presence of both cell-mediated and humoral immunity. Recurrent herpes labialis is three times more frequent in febrile patients than in nonfebrile controls.

At present, no data support the contention that recurrent infections are the result of chronic viral production at the site of recurrence. Skin biopsies performed at the site of recurrent lesions, but between episodes of disease, for purposes of virus isolation have not resulted in the retrieval of virus by standard laboratory procedures, as noted previously (412). However, during the prodrome of recurrent HSV labialis, virus can be retrieved by needle biopsy or cell scrapings from apparently normal tissue (483).

Models of Disease Pathogenesis

Animal models have been used to study the pathogenesis of HSV infections, especially in the evaluation of latency, vaccines, and antiviral agents. Although these models have used routes of infection encountered in human disease (i.e., mucosal and skin inoculation), only a select few approximate the pathogenesis of human disease. Human models of disease have been reported as well.

Animal model studies become the only system in which the pathogenesis of infection outside the human can be delineated; however, herein lies a series of fundamental problems. These studies were reviewed by Kirchner and Kern, among others (229,230,241). The animal species (indicative of susceptibility), virus type, route of infection, state of immune competence, and specific viral strain will all influence disease pathogenesis (314,316). Disease progression alone can be selectively modulated by the specific strain of animal selected. The route and site of inoculation become especially important in distinguishing one disease state from another. Models of primary HSV infection vary from system to system (e.g., susceptibility of the mucosa for replication of HSV). The strengths and weaknesses of the most common models are summarized next.

Both encephalitic (virulence) and latency models have been defined for inoculation of HSV-1 by the eye route, which is the best route to study latency. However, the end points of virulence and latency have distinctive differences for predicting human disease. After ocular inoculation by corneal scarification, replication of virus in the eye peaks within 48 hours and declines over the next 6 days. Virus appears in the trigeminal ganglia approximately 1 day after inoculation, with peak replication occurring 4 to 6 days after inoculation. If a sufficient quantity of virus and/or a virulent strain of virus is inoculated onto the eye, brain infection follows replication of virus within the trigeminal ganglia. The extent of disease (localized to the eye and trigeminal ganglia, not invasive disease) depends on a variety of factors, as noted earlier. Invasive brain infection is a rare event, if it has ever occurred, after human eye infection. Nevertheless, the trigeminal ganglion is routinely involved with human eye infection (239,247).

For HSV-1 infections of the skin, mice (particularly the hairless mouse) (516) and rabbits or guinea pigs with abraded or punctured skin were used to study the events of replication and disease pathogenesis and, more frequently, to evaluate antiviral therapies. Although in each system the nature, duration, and histopathology parallel human infection, there are notable differences. The hairless mouse, guinea pig, and rabbit are all artificial models of human infections, particularly for recurrent infections of humans. Regardless, as a screen for antiviral drug evaluations, they are of value.

HSV-2 mucosal infections have been studied most extensively in the guinea pig model. Both HSV-1 and HSV-2 have been used in this model. Intravaginal inoculation of HSV into female Hartley guinea pigs appears to be the most predictive of all the animal models for human disease, although not totally so. Reasons for these inconsistencies include endogenous host defenses, the artificial nature of infection, and viral strain differences. Moreover, these animals tend to experience continual recurrences of lesions, but retrieval of HSV from these lesions is most variable. This propensity for an enhanced frequency of recurrent lesions that are usually culture negative for virus has raised questions regarding the validity of the model for studies of the pathogenesis and molecular basis of latency of HSV-2. Nevertheless, it is the best available model.

Models of life-threatening disease have been developed for both HSV-1 and HSV-2. Intranasal inoculation of HSV-1 or HSV-2 into young (3-week-old) BALB/c mice leads to CNS and visceral (usually lung) disease, which is considered similar to neonatal HSV infection. However, inoculation of older mice with similar quantities of either of these two viruses may not result in any evidence of disease, or, if it does lead to disease, it might be encephalitis but certainly not

overwhelming multiorgan disease. Intracerebral inoculation of virus provides an unnatural route of infection even for the study of antiviral therapeutics; however, it is used to screen new drugs.

Accurate and predictive models of human HSV encephalitis have been described using rabbit (440,441) and mouse models. The resultant disease leads to focal localization of infection in the rabbit brain, as compared with diffuse pancortical infection of the CNS. Virus is inoculated directly into the olfactory bulb or upon abraded nasal epithelium of the rabbit over the nerves from the olfactory bulb. Virus can be traced along the olfactory tract to the anterior-frontal region of the rabbit brain. This region correlates with the temporal lobe of humans. Immunosuppression after subclinical infection can result in focal reactivation (498).

Over the past several years, human models of both labial and genital herpes have been reported. Spruance et al. have induced reactivation of HSV labialis by exposure of the vermilion border of the lip of seropositive individuals to UV light (482). The resulting lesions and course of infection are similar to those that occur in nature. Lesions develop in approximately 70% of UV-exposed volunteers after approximately 3 days. This model has been exploited for the evaluation of antiviral therapies (415).

A UV model was developed by Rooney et al. for individuals with HSV-2 infection of the buttocks and thigh. The incidence of reactivation is lower, approximately 35%, and the incubation period longer, about 5 days (416).

EPIDEMIOLOGY

Orolabial HSV Infections

HSV disease ranges from the usual case of mild illness, undiscernible in the majority of patients, to a few cases of sporadic, severe, and life-threatening disease in infants, children, and adults. Although HSV-1 and HSV-2 are usually transmitted by different routes and involve different areas of the body, there is a great deal of overlap between the epidemiology and clinical manifestations of infections. HSV infections are distributed worldwide and have been reported in both developed and underdeveloped countries, including remote Brazilian tribes (46). Animal vectors for human HSV infections have not been described; therefore, humans remain the sole reservoir for transmission of these viruses to other humans. Virus is transmitted from infected to susceptible individuals during close personal contact. There is no seasonal variation in the incidence of infection. Because infection is rarely fatal and because these viruses become latent, over half of the world's population probably has recurrent HSV infections and, therefore, the capability of transmitting HSV during episodes of productive infection.

Primary HSV-1 infections usually occur in the young child, less than 5 years of age, and are most often asymptomatic. The mouth and lips are the most common sites of HSV-1 infections; however, any organ can become infected with this virus. With clinical illness, gingivostomatitis usually is the manifestation. Primary infection in young adults has been associated with only pharyngitis and a mononucleosis-like syndrome (163,303).

After the implication of HSV as the etiologic agent responsible for gingivostomatitis (126) and its confirmation by Burnett and Williams (71), virologic screening became a useful tool for epidemiologic surveys. Dodd et al. (126) determined that primary infection led to the shedding of virus in mouth and stool and from the former site for as long as 23 days (average, 7 to 10 days). This observation has been recently confirmed in a controlled trial of acyclovir for gingivostomatitis (9). Neutralizing antibodies begin to appear between days 4 and 7 after the onset of disease and peak in approximately 3 weeks. In these studies, virus could be isolated from the saliva of asymptomatic children (68). Viral shedding was documented in approximately 20% of the children in the age range of 7 months to 2 years. Despite no overall race or sex differences in the study, the young African-American children had higher rates of both neutralizing antibodies and virus isolation than did their white counterparts. Virus shedding in children less than 6 months of age was uncommon, as has been noted in more recent studies (216). In older children, 3 to 14 years of age, presumed asymptomatic shedding was documented in 18%. Virus retrieval decreased with advancing age; in individuals over 15 years of age, the frequency of excretion was 2.7%. These frequencies of shedding are similar to contemporary cross-sectional surveys, ranging from 2% to 5% (83,129,246,257,280,365,491,567).

The influence of age is underscored by the results of two other studies (121,133). A thorough clinicoserologic study of primary herpetic oral infection was performed in Yugoslavia. Of the 18,730 children attending outpatient clinics, evidence of oral herpetic infection was found in approximately 13% over a 10-year period. Children 1 to 2 years of age were most commonly afflicted, accounting for over half of all cases. Neither difference in sex nor seasonal variation was detected.

Most children experience asymptomatic infection. Cesario et al. (83) reported a study of 70 seronegative children who had evidence of primary infection. Only 6 of the 70 children, or less than 10%, had clinical symptoms associated with illness. In an Australian study, Anderson and Hamilton (12) found that 67.4% of seronegative children (29 of 43) developed HSV antibodies over a period of 1 year; but less than one third of these children had symptomatic infections.

Geographic location, socioeconomic status, and age are the primary factors that influence the acquisition of HSV infection, regardless of the mode of assessment (126,397,450,489,505). In developing countries, seroconversion occurs early in life, but with some minor differences between selected populations. When classic antibody assays have been used to assess status of infection among Brazilian Indians and children of New Orleans, HSV antibodies were found in over 95% of children by 15 years of age (26,47). In Uruguay and lower socioeconomic populations of the central United States, the appearance of antibodies occurred at similar but lower frequencies (47). These lower rates of acquisition were particularly evident in the poor African-American communities of Atlanta and Houston (334,335,402). By 5 years of age, approximately one third of patients seroconverted; this frequency increased to 70% to 80% by early adolescence. Predictably, presumed middle-class individuals of industrialized societies acquire antibodies at a later age. Seroconversion occurred over the first 5 years of life in 20% of children, followed by no significant increase until the second and third decades of life, at which time the prevalence of antibodies increased to 40% and 60%, respectively (434,531), as noted in other studies (163,300,472). Seroconversion of susceptible university students occurs at an annual

frequency of approximately 5% to 10% (161,163).

Using type-specific serologic assays, the seroprevalence of HSV-1 and HSV-2 infections was redefined using sera obtained from two randomized National Health and Nutrition Examination Surveys (NHANES) (148,331,340). The seroprevalence of HSV-1 is more common than its counterpart HSV-2. For the United States, a summary of these HSV-1 seroprevalence appears in Figure 6. These data indicate that by 5 years of age, over 35% of African-American children versus 18% of white children are infected with HSV-1. There were no significant differences in seroprevalence between the two NHANES studies performed on sera collected in 1978 and then again in 1988 to 1994. Subsequently, through adolescence, African-Americans had approximately a twofold higher prevalence of antibodies to HSV-1 than did whites, and females had a slightly higher prevalence of HSV-1 antibodies than did males. Furthermore, the female prevalence was slightly higher for HSV-1 antibodies than the male. By 40 years of age, both African-Americans and whites had similarly high prevalences of antibodies, which may be the consequence of a cohort effect; that is, these individuals had a higher rate of acquisition of HSV-1 earlier in life.

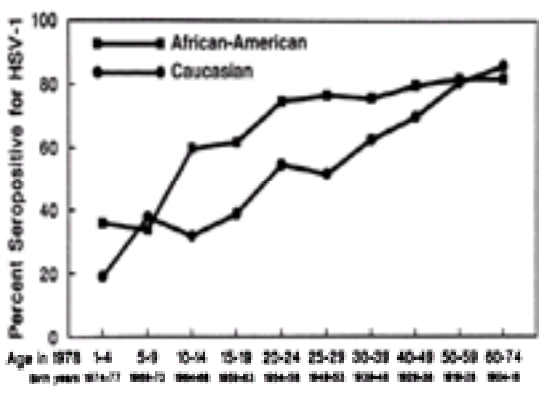

FIG. 6. Seroprevalence of HSV-1 by age.

When similar analyses were performed on populations from a variety of countries around the world, notable differences were detected. For example, only 5 of 18 countries surveyed had an HSV-1 antibody prevalence of less than 70%. These included white individuals in the United States (U.S. NHANES participants) as well as selected populations residing in Pittsburgh, Pennsylvania; Birmingham, Alabama; Atlanta, Georgia; Japan; Lyon, France; and Sweden. An antibody prevalence in excess of 95% was detected in Spain, Italy, Rwanda, Zaire, Senegal, China, Taiwan, Haiti, Jamaica, Uganda, and Costa Rica. Seroprevalence was determined for adults between the ages of 20 and 40 years. Thus, a high prevalence of antibodies to HSV-1 exists worldwide and, therefore, a high rate of infection, but there is significant country-to-country variation (545).

In summary, these studies demonstrate a significantly lower prevalence of antibodies during childhood, adolescence, and even later in life among relatively middle and upper socioeconomic classes. Primary infection occurs much earlier in life, generally very early, in children of underdeveloped countries as well as in those of lower socioeconomic classes, whereas in developed countries and more affluent classes, primary infection may be delayed until adolescence or perhaps even adulthood. The frequency of direct person-to-person contact, indicative of crowding encountered with lower socioeconomic status, appears to be the major mediator of infection.

Recurrent HSV-1 Infection

The largest reservoir of HSV-1 infections in the community is recurrent herpes labialis. Studies performed to assess the frequency and severity of recurrent infection in the immunocompetent host are limited. Baseline frequencies for recurrent herpes labialis have been defined from a study performed in Philadelphia. A positive history of recurrent herpes labialis was noted in 38% of 1,800 graduate students (460,461). New lesions occurred at a frequency of one per month in 5% of the students and at intervals of 2 to 11 months in 34% of the students. Recurrences of one per year or less often were found in 61%. The predictable frequency of recurrence is relatively constant, approximately 33% in several studies (156,458,459). Exceptions to this rate of recurrence were reported by Young et al. (567) and others (129), who reported lower frequencies of recurrences of approximately 16%, but under vastly different (namely, lower) socioeconomic conditions. Ironically, one other study found that recurrences occur more frequently among the more socially privileged (459), suggesting more attention to relatively trivial medical illnesses.

Recurrent infection may occur in the absence of clinical symptoms. Asymptomatic excretion of HSV in normal children after recurrence is about 1% (183,186) and varies from approximately 1% to 5% in the normal adult (163,180,181,280,456). Nearly 1% of pregnant women and nursery personnel excrete HSV at any time (181), providing a source of virus for transmission to the newborn. Asymptomatic excretion of virus is not limited to the healthy adult; excretion of HSV in renal transplant recipients, without signs or symptoms of disease, occurs in nearly one third of seropositive patients (372,373). Studies of closed populations have documented a high frequency of recurrent HSV excretion in the absence of symptoms (83). A summary of seroprevalence of HSV-1 infections by geographic locale and over time is illustrated in Figure 7.

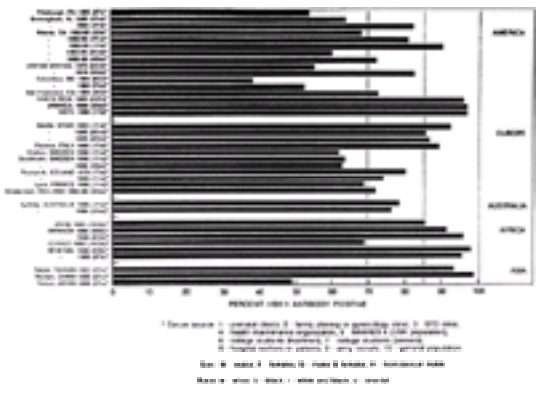

FIG. 7. Seroprevalence of HSV-1 by specific populations.

Unusual Epidemiologic Infections

Clustered outbreaks of human HSV infections have been reported (216,450); however, there is no indication from either clinical or molecular epidemiologic studies that these viruses cause epidemic diseases. Most of the studies reported involve families in which several individuals within the family had HSV infection at approximately the same time. No index case could be identified, although recurrent labial lesions of one family member were frequently incriminated.

Outbreaks within hospitals have been identified; however, here also no clear epidemic nature of the disease could be determined. The frequent occurrence of HSV infections among renal transplant recipients within the 4-week period immediately after surgery was reported (373). Pugh et al. (386) described an outbreak of eczema herpeticum in a large group of hospitalized patients within an 8-day period; in this case, hospital conditions (particularly the lack of attention to nursing details, such as hand-washing) were incriminated as being responsible for virus transmission.

Outbreaks of herpetic stomatitis have been reported within orphanages (172,216), where the attack rate for clinically apparent primary infections was approximately 75% of the susceptible patients. Similarly, an outbreak of a larger number of cases than expected of HSV encephalitis was recognized in Boston; however, no common virus was identified (174). Interestingly, increased transmission of HSV in day care centers has not yet been reported to be a problem (444).

Genital HSV Infections

Because infections with HSV-2 are usually acquired through sexual contact, antibodies to this virus are rarely found before the age of onset of sexual activity. Although most genital HSV infections are caused by HSV-2, a recognizable and ever-increasing but variable proportion is attributable to HSV-1 (107,221,473,559). The distinction in virus type is not insignificant, because genital HSV-1 infections are usually both less severe clinically and less prone to recur (107,404). Sexual transmission is the primary route of the spread of HSV-2 (120,213,214 and 215,368).

Clinics treating sexually transmitted diseases (STDs) provide one setting for acquiring prevalence data on genital HSV infections, particularly those in the United States, England, and Sweden (36,142,215,343). The number of new cases of genital HSV infections has been conservatively estimated to be approximately 500,000 individuals per year (343). Because genital HSV infections are not reportable diseases in the United States, these rates are estimates (205). The number of new cases of recognized STDs was used to determine estimates of the number of cases of genital herpes. If the incidence of new cases is calculated from a ratio of 5 to 10 cases of gonorrhea to every 1 case of genital HSV infection, approximately 300,000 new cases would occur yearly in the United States (210,211,343). A report by Corey et al. (110) suggests a much higher rate of infection, namely, a ratio of 1 case of genital herpes infection to 2.2 cases of gonorrhea. Such estimates would increase the frequency of primary disease. Current estimates of individuals with genital herpetic infection in the United States alone range from as low as 10 million to as high as 30 to 40 million (110,205). Predicated on newer serologic methods for detection of prior HSV-2 infection, as will be described later, a more accurate estimate range is 40 to 60 million infected individuals in the United States (293).

Cytopathologic screening by Papanicolaou staining of cervical scrapings or virus isolation from cervicovaginal swabs has determined the prevalence of genital HSV infection to range from 0.09% to 0.24% in normal women (127,129,213,244,346,519,558). In contrast, rates of infection in individuals routinely attending clinics for STD clinics vary between 0.002% and 3.3% and even 7.0%, depending on the population studied (130,346). These studies were performed over a decade ago, when the prevalence of the disease was much lower.

Women were reported to have higher rates of infection than were men, particularly prostitutes and others with multiple sex partners. Several studies estimate that the risk of susceptible females for contracting HSV from infected males is 80% after a single contact (333,381,398,399). However, the best data that define the rate of transmission emanate from couple studies of promising vaccines. In putative monogamous relationships, the risk of transmission from a seropositive male to a seronegative female is approximately 20% annually (59). If the female is seropositive for HSV-1, the risk is somewhat diminished to 15%. On the other hand, the risk of transmission from an HSV-2 seropositive female to a seronegative male is about 50% annually. The risk decreases to 5% if the male is HSV-1 seropositive (309). These data suggest that preexisting HSV-1 antibodies influence the frequency of HSV-2 acquisition. An interesting observation was made that relates the frequency of HSV shedding to the age of the prostitutes. The most active prostitutes (age range, 20 to 29 years) were most likely to excrete HSV (12%), whereas those in the older age groups had a decreased frequency (6%) of viral excretion. As would be expected, one study found that the incidence of genital HSV infections in both indigent women and those of middle and upper socioeconomic classes appeared significantly lower (0.3% and 0.2%, respectively) (354) than that found among women attending STD clinics.

As with HSV-1 infections of the mouth, HSV-2 can be excreted in the absence of symptoms at the time of primary, initial, or recurrent infection (138,392), provided a reservoir exists for transmission of infection. Among women evaluated prospectively after their first episode of genital herpes, asymptomatic shedding was detected in approximately 12%, 18%, and 23% of those with primary HSV-1, primary HSV-2, and nonprimary HSV-2 infection, respectively (248). Among women with established genital HSV-2 infection, asymptomatic shedding was detected on 1% of all days cultures were obtained (57). Shedding of virus occurs more frequently in the first year following genital infection than in subsequent years (524). Thus, asymptomatic shedding provides a significant source for virus transmission. The use of PCR to detect virus shedding markedly increases these rates, as is discussed later.

The appearance of type-specific HSV-2 antibodies correlates positively with the onset of sexual activity (3,335,402). Crowded living directly parallels increased antibody prevalence, as well (35,346). Historically, if HSV-2 antibodies are sought in healthy women, there is a wide discrepancy in prevalence, ranging from 10% in individuals in the United States to 77% in Ugandans (394). However, overall in the United States, the seroprevalence of HSV-2 is about 22%, a 30% increase over the past decade (148). As many as 50% to 60% of women at lower socioeconomic levels in the United States and elsewhere develop antibodies to HSV-2 by adulthood (148,341). Antibodies to HSV-2 are virtually nonexistent in nuns (335,397,558). This compares with similar data from Birmingham, Alabama, of 11.4% in 1985 and 28% in 1990. Sera collected from pregnant women in the mid 1980s from Padova, Italy; Orebro, Sweden; and Stockholm, Sweden, showed seroprevalence rates varying between 8% and 28%. Relevant to the importance of these serologic observations is the potential for these women to reactivate HSV-2 at the time of delivery and transmit infection to their infants. In contrast, 10% to 20% of women in higher socioeconomic groups are seropositive (18,300). Seroprevalence continues to increase over time, indicating widespread acquisition of HSV-2 infection.

Using type-specific antigens for HSV-2, antibodies were demonstrated in 35% of middle-class women receiving care through the Atlanta Health Maintenance Organization (274,336). Seroprevalence of HSV-2 increases from 6.9% at 15 to 29 years of age, to 23.4% by 60 years of age. When the populations are analyzed according to race, these same percentages were 4.6% and 19.7% for whites and 21.8% and 64.7% for African-Americans, respectively. Factors found to influence acquisition of HSV-2 include gender (greater for women than men), race (more frequent among African-Americans than whites), marital status (more for divorced individuals than single or married individuals), and place of residence (more in the city than in the suburbs). Importantly, the number of sexual partners greatly influences acquisition of infection (398,399 and 400). A recent NHANES III study has clarified the seroprevalence of HSV-2 in the population of the United States (Table 2 and Table 3). For all classes, the seroprevalence of HSV-2 was 21.9%. This represents an increase of 30% over a 10-year period (Table 3); it is graphically illustrated in Figure 8.

Variable	Overall[a]		Whites		Blacks		Mexican-Americans	
	Sample size	Percent prevalence (95% CI)	Sample size	Percent prevalence (95% CI)	Sample size	Percent prevalence (95% CI)	Sample size	Percent prevalence (95% CI)

TABLE 3. *Changes in age-adjusted HSV-2 seroprevalence between NHANES II (1976 to 1980) and NHANES III (1988 to 1994)*[a]

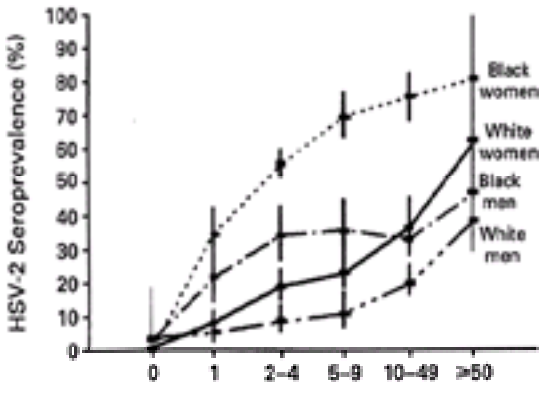

FIG. 8. Seroprevalence of HSV-2 by specific populations.

The highest prevalence of antibodies to HSV-2 in the United States was identified in female prostitutes (75%), as would be expected, a rate almost identical to that of prostitutes in Tokyo (340). Seropositivity among female prostitutes in Dakar, Senegal, was even higher, 95.7% in 1985. Homosexual men have seroprevalence rates to HSV-2 varying from a high of 83.1% in San Francisco (1985 to 1986) to lows of 21.6% in Seville, Spain (1985 to 1986); 24.2% in Tokyo (1988); and 50.0% in Amsterdam (1986). A comparison of HSV-1, HSV-2, or dual-antibody assessments by population is shown in Figure 9. Numerous seroprevalence studies have recently been reported (56,259,340,361,429).

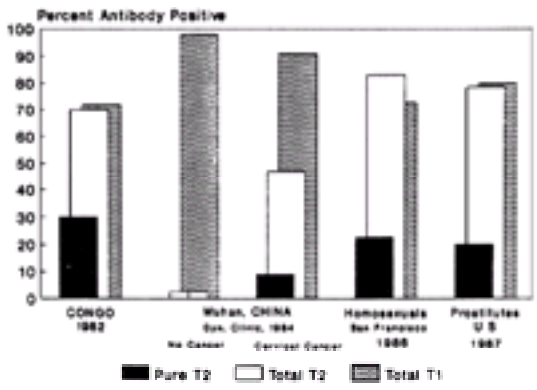

FIG. 9. Seroprevalence of HSV-1 and HSV-2 by selected country.

Some countries have surprisingly low HSV-2 seroprevalence rates. For example, in Italy, the seroprevalence was high in STD clinics (26%), but it was significantly lower in obstetric populations of Modena (5.3%) (118). These figures are in sharp contrast to data from the United States.

As noted, the number of different sexual partners has been found to correlate directly with acquisition of HSV-2, as shown in Figure 10. For heterosexual women living in the United States having one partner, the probability of acquisition of HSV-2 is less than 10%. The probability increases to 40%, 62%, and greater than 80% as the number of lifetime sexual partners increased to 2 to 10, to 11 to 50, or to greater than 50, respectively. For heterosexual men, similar data are 0% for one lifetime sexual partner and 20%, 35%, and 70% for each of the subsequent three risk groups. In contrast, for homosexual men, seroprevalence increases from greater than 60% to 90% for those with 11 to 50 and more than 50 partners. Thus, multiple sexual partners (“polypartnerism”), irrespective of sexual preference, correlates directly with acquisition of HSV-2 infection (340).

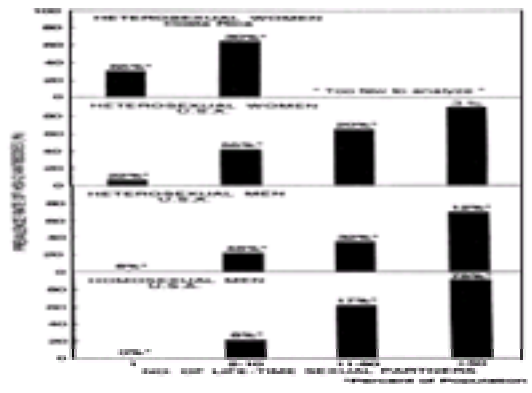

FIG. 10. Seroprevalence of HSV-2 as a function of the number of sexual partners.

The incidence of HSV-2 infection has been assessed prospectively. Among low-risk individuals, namely college students, the rate of acquisition was approximately 2% per year over 4 years, compared with 4% per year for homosexual men in San Francisco (340). The incidence of HSV-2 infection during pregnancy is about 2.5% per gestation but was reported by other investigators to be as low as 0.58% (53). Acquisition of HSV-2 infection between monogamous sexual partners with

discordant infection status is 10% to 15% yearly (309).

HSV-2 infection, by the nature of its being an ulcerative disease, is associated with the acquisition of both human immunodeficiency virus type 1 (HIV-1) and human T-cell lymphotropic virus type 1 (HTLV-1). Several case-control studies performed in Baltimore, San Francisco, Seattle, and Central and South Africa indicated increased risk ratios by one-and-one-half- to over twofold (54,88,97,200,201,226,340,484). One study, however, refutes this conclusion (238). The association between acquisition of HIV-1 and HSV-2 has been documented in heterosexual populations, as well (201).

Recurrent HSV-2 Infection

As with orolabial lesions, recurrent genital infection is the largest reservoir of HSV-2. Factors responsible for reactivation of genital HSV infections cannot be unequivocally gleaned from retrospective studies. Recurrent HSV-2 infection, like HSV-1, can be either symptomatic or asymptomatic. A recurrence is usually associated with a shorter duration of viral shedding and fewer lesions (107). The frequency of recurrences varies somewhat between men and women, with calculations of 2.7 and 1.9 per 100 patient-days, respectively (107). The actual number of days of viral excretion has been clarified in studies assessing detection of HSV DNA by PCR. Wald and colleagues (525) documented viral excretion in a select group of motivated women to be about 6% annually. Utilizing PCR, DNA could be detected in nearly 18% of days—a threefold increase over viral culture. Notably, there was an association between detection of virus by PCR (but not by culture) and person-to-person transmission.

Overall, several studies have reported a frequency of recurrence as high as 60% (3,85). The type of genital infection (HSV-1 or HSV-2) is predictive of the frequency of recurrence (91,404). HSV-1 infection recurs less frequently than does HSV-2 infection for reasons that are entirely unclear (37,267). The changing prevalence of HSV-2 infections is illustrated by surveys of representative populations (Table 4).

Site of study	Year of study	Prevalence of HSV-2 antibodies (%)
Different individuals		
Reykjavik, Iceland (pregnant women)	1970	4.1
	1985	23.4
Lyon, France (pregnant women)	1977–1978	10.7
	1985	17.3
Orebro, Sweden (pregnant women)	1982	11.8
	1985	16.1
Zaire		
Kinshasa	1959	21
	1985	60
Rural areas	1959	6
	1985	33
Same individuals		
Alabama (pregnant women)	1985	6-mo acquisition rate = 2%
South Carolina (university students)	1983	0.4 (acquisition rate = 2%/year)
	1987	7.0
San Francisco (homosexual men)	1978	44 (acquisition rate = 4%/year)
	1985	72

TABLE 4. *Prevalence of HSV-2 antibodies in different populations*

Molecular Epidemiology

Hayward et al. (184) found that fragments resulting from the cleavage of HSV DNA by restriction endonuclease enzymes define fingerprints for the virus. Analyses of numerous HSV-1 and HSV-2 isolates from a variety of clinical situations and widely divergent geographic areas demonstrated that epidemiologically unrelated strains yielded distinct HSV DNA fragment patterns. In contrast, fragments of HSV DNA derived from the same individual obtained years apart, such as monogamous sexual partners, or after short and long passages *in vitro*, had identical fragments after restriction endonuclease cleavage.

This technique has been applied to specimens collected from a variety of patients with a genital HSV infection in order to assess potential strain differences or similarities after digestion with various endonucleases. Analyses of patterns of HSV DNA fragments showed that isolates from the same patient or their respective sexual partners could be either the same or different (66,67). Stated differently, a given patient might well have nonidentical isolates obtained from lesions at adjacent sites. This finding indicates that an individual can be infected with multiple, different strains. No doubt, similar findings will become apparent for orolabial HSV-1 infections when properly studied. The use of endonuclease restriction enzymes has unequivocally demonstrated that a target organ, in this case the genitalia, is not immune to reinfection. The frequency of this occurrence in large-scale studies is low (269,443). From a public health viewpoint, this is an extremely important issue. If exogenous reinfection occurred frequently (regardless of the actual incidence), both the potential of vaccination and the methods for vaccination would have to be seriously reassessed to provide immunity to target organs. Protection of mucosal sites from the initiation of replication after primary infection becomes exceedingly important. Clearly, an exogenous source of virus does not explain the majority of instances of apparent reactivation.

Maternal Genital HSV Infections

Genital HSV infection in the pregnant woman is as common as in age-matched, nonpregnant women. However, it must be considered separately from nonpregnant populations because of the risk to the fetus and newborn, as was recently reviewed (540).

An uncommon problem encountered with HSV infections during pregnancy is that of widely disseminated maternal disease. As first reported by Flewett et al. (149) in 1969 and by others subsequently (10,167,190,377,566), HSV disease can involve multiple visceral sites, in addition to cutaneous dissemination. In a limited number of cases, dissemination after primary oropharyngeal or genital infection has led to life-threatening disease, such as necrotizing hepatitis with or

without thrombocytopenia, leukopenia, disseminated intravascular coagulopathy, and encephalitis. The mortality rate among these pregnant women is reported to be greater than 50%. Fetal deaths also have occurred in more than 50% of cases, although mortality did not necessarily correlate with the death of the mother. Surviving fetuses were delivered by cesarean section either during the acute illness or at term, and none had evidence of neonatal HSV infection. Cumulative experience suggests that factors associated with pregnancy may place both mother and fetus at increased risk for severe infection, possibly because of altered cell-mediated immunity (378,509). Fortunately, with the advent of safe antiviral therapy, specifically the availability of acyclovir, if HSV disease appears progressive in the pregnant woman, treatment is initiated.

From several prospective trials, the major risk to the fetus is maternal primary or initial genital HSV infection (58,262). Thus, identification of the woman at risk for primary infection (seronegative for HSV-2) is of paramount importance. Studies of the discordant serologic status of sexual partners and rates of acquisition of genital HSV-2 infection begin to define this problem, as recently summarized (383). With primary or initial genital infection occurring at rates from 0.5% to 10% per year, precise risks are not clear (62,383); however, incidence according to maternal infection is becoming clearer. If a pregnant woman experiences initial or primary genital infection in the last trimester of gestation, the likelihood of transmission varies between 30% and 50%. On the other hand, recurrent maternal infection is associated with a transmission of 3% or less (59). These different rates of transmission have direct implications on strategies to prevent neonatal disease or at least ameliorate it if the child is inadvertently delivered through an infected birth canal.

Maternal primary infection before 20 weeks gestation in some women has been associated with spontaneous abortion (336). Although the original estimate of spontaneous abortion after a symptomatic primary infection during gestation was thought to be as high as 25%, it is likely that this calculation is high because of the very small number of women followed. Precise data indicating the true risk of spontaneous abortion after primary infection during gestation are not available at this time. Furthermore, the contribution of primary maternal genital infection to spontaneous abortion must be weighed above that of a routine rate of fetal loss of approximately 20%. Infection that develops later in gestation has not been associated with the termination of pregnancy (168,178,338). Notably, morbidity of the fetus born to a woman with primary infection was documented with manifestations of either neonatal HSV disease or severe intrauterine growth retardation as compared with controls (60).

Recurrent infection is the most common form of infection during gestation. The frequency of HSV recurrences during gestation should be of concern for women with a known history of infection. Transmission of infection to the fetus is most frequently related to the actual shedding of virus at the time of delivery. Because HSV infection of the fetus is usually the consequence of contact with infected maternal genital secretions at the time of delivery, the determination of viral excretion at this time is important. The actual incidence of viral excretion at delivery was suggested to be 0.01% to 0.39% for all women, irrespective of past history (338,392,504,521), and perhaps as high as 0.6% (16,58).

Several prospective studies have evaluated the frequency and nature of viral shedding in pregnant women with a known history of genital herpes. In a predominantly white, middle-class population, documented recurrent infection occurred in 84% of pregnant women with a history of recurrent disease (521). Moreover, asymptomatic viral shedding occurred in at least 12% of the recurrent episodes. Viral shedding from the cervix occurred in 0.56% of symptomatic infections and in 0.66% of asymptomatic infections. These data are similar to those obtained in other populations (16,51,392). The incidence of cervical shedding in pregnant women with asymptomatic HSV infection was reported to average approximately 3% (182). However, the observed rate of shedding among pregnant women with asymptomatic infection has varied more than that among nonpregnant women (from 0.2% to 7.4%), depending on the study population and trial design (51,168,170,179,392). The frequency of recurrences has not been shown to be different from one pregnancy to the next for a given woman (179). Overall, these data indicate that the frequency of cervical shedding is low, rendering the risk of transmission of virus to the infant similarly low when the infection is recurrent in nature (338). The frequency of shedding does not appear to vary by trimester during gestation (179,521). No increased incidence of premature onset of labor is apparent in these prospective studies. Regardless, given the high seroprevalence of infection, a significant degree of protection for the fetus must exist, or the incidence of neonatal disease would be significantly higher.

Importantly, most infants who develop neonatal disease are born to women who are completely asymptomatic for genital HSV infections at the time of delivery and have neither a past history of genital herpes nor a sexual partner reporting a genital vesicular rash (338,543,551,555). These women account for 60% to 80% of all women whose infected children become clinically ill. An analysis of demographic characteristics of those women delivering children who developed neonatal HSV infection has been summarized (543). Only 27% of these women had either a history of or evidence of recurrent lesions indicative of HSV infection during the current pregnancy. Furthermore, only half of this latter group of women reported genital HSV infection in their sexual partners.

HOST IMMUNOLOGIC RESPONSE

The natural history of HSV infections is influenced by both specific and nonspecific host defense mechanisms, as recently reviewed (287). Animal models have provided the majority of data that address the relationship between host defense and disease pathogenesis. Host genetic background, macrophages, natural killer cells, specific T-cell subpopulations, specific antibodies, and lymphokine responses have been implicated as important host defenses against HSV infections. Notably, the relative value of each varies according to the route of viral inoculation, among other factors. Specifically, intraperitoneal and intracerebral inoculation most likely require host defense mechanisms that are different from those needed for the control of ocular infections.

Studies performed by Lopez (285,286) have confirmed the relative importance of host genetics on disease pathogenesis when virus is inoculated by the peritoneal route to inbred strains of mice. Differences in outcome are notable according to the virus type studied (80). For example, when HSV-1 was inoculated into inbred strains of mice, resistance was inherited as a dominant trait, involving two loci, and not restricted to the histocompatibility complex. If HSV-2 was used, however, resistance patterns were less apparent and implicated macrophage replication of virus as the major determinant of

outcome (319,320,321,322 and 323).

Experiments on macrophage function in response to HSV infection in animal models have been conducted for some time. Macrophage activation and inactivation experiments can either reduce or increase mortality, respectively (241,299,326,448,488,571). Such findings have been particularly well characterized in a newborn mouse model. However, the relevance of these observations to the pathogenesis of human infection remains to be established, particularly for neonatal HSV infection. Macrophage responses are dependent on lymphokine modulation, at least after intraperitoneal inoculation.

Both animal model and human studies have provided a basis for understanding humoral and specific cell-mediated immune responses. With the appearance of nonspecific inflammatory changes, paralleling a peak in viral replication, specific host responses can be quantitated but vary from one animal system to the next (247,260,358). In the mouse, delayed-type hypersensitivity responses can be identified within 4 to 6 days after disease onset, followed by a cytotoxic T-lymphocyte (CTL) response and by the appearance of both immunoglobulin (Ig)M- and IgG-specific antibodies (223,245,247,352,560,569). Host responses in humans tend to be more delayed, developing approximately 7 to 10 days later than in the mouse. Immunodepletion studies identified the importance of CTLs in resolving cutaneous disease (240,350). Adoptive transfer of CD8+ or HSV-immune CD4+ T cells also reduced viral replication or provided protection upon challenge (52,278,350,454). Furthermore, the characterization of the CD8+ immune response in genital lesions has been correlated with disease resolution.

T-cell lymphocyte subsets were examined for host susceptibility to infection, including those responsible either for H2-restricted cytotoxicity or for *in vitro* or adoptive transfer of delayed-type hypersensitivity (256,352,353,387). These latter cells have a requirement for both the IA and the H2 K/D regions (351). Similar specific T cells are under investigation in humans. Notably, studies using a specific infected cell polypeptide product (ICP4) have identified its requirement for mediation of T cells (297). Humoral immunity to HSV infection was evaluated exhaustively in disease pathogenesis. An increasing body of data suggests that prior HSV-1 infection, with its subsequent host response, has a somewhat protective effect on the acquisition of HSV-2 infection (309). Polyclonal antibodies were used to alter disease lethality, particularly in the newborn mouse (58,125,212,223,255,263,302,360,403,463). In addition, these antibodies were used to limit progression of both neurologic and ocular disease (119,223,302,359,360). With the development of monoclonal antibodies to specific infected cell polypeptides, especially the envelope glycoproteins, protection from lethality (27,125,311,403) can be achieved. As an aside, human trials of a human monoclonal antibody in combination with antiviral drugs will be explored for neonatal herpes. Success in the animal model was accomplished with both neutralizing and nonneutralizing antibodies. Antibody-dependent cell-mediated cellular cytotoxic host responses also have correlated with improved clinical outcome, as will be noted later for neonatal HSV infections. Taken together, these observations are extremely relevant for vaccine development.

The dissection of all arms of host immune responses during human disease has resulted in intense investigative efforts to attempt to develop effective vaccines. Clearly, an understanding of host immune responses must weigh the clinical observation of recurrent lesions in the presence of both humoral and cell-mediated immunity against the shortened duration of recurrent lesions. There is no resolution of this enigma at this time.

As with studies of strains of disease susceptibility in inbred strains of mice, a plethora of reports have incriminated or refuted human leukocyte antigen (HLA) associations with HSV infections (48,276). For recurrent fever blisters, these studies have included HLA-A1, HLA-A2, HLA-A9, HLA-BW16, and HLA-CW2 (48,84,98,352,570). Recurrent ocular HSV infections were associated with HLA-A1, HLA-A2, HLA-A9, and HLA-DR3 (98,314,315). These confusing and conflicting associations can be faulted by population selection bias, as reviewed by Rawls (393).

Humoral antibody responses of humans appear to parallel those documented after systemic infection of mice and rabbits. As classically described, IgM antibodies appear transiently and are followed by IgG and IgA antibodies, which tend to persist over time (42,139,157,220,264). Neutralizing and antibody-dependent cellular cytotoxic antibodies generally appear 2 to 6 weeks after infection and persist for the lifetime of the host (249,250,324,391,399,401). Analyses of antibody responses by immunoblot and immunoprecipitation have elucidated host responses to infected cell polypeptides and correlated these responses with the development of neutralizing antibodies (17,38,40,41,134,315 and 136,536,572). Soon after the onset of infection, antibodies to structural proteins are followed by those directed against gD, gB, ICP4, gE, gG-1 or gG-2, and gC (218). Both IgM and IgG antibodies can be demonstrated, depending on the time of assessment after disease onset.

When attempts are made to define the basis for frequent recurrences, research efforts have focused on cell-mediated immune responses. Lymphocyte blastogenesis studies demonstrate reactivity within 4 to 6 weeks after the onset of infection and sometimes as early as 2 weeks (113,371,391,423,424,425 and 426,457,487,499). With recurrences, boosts in blastogenic responses can be promptly defined; however, these responses, as after primary infection, decrease with time. Nonspecific blastogenic responses do not correlate with a history of recurrences. As noted, HSV-1 and HSV-2 antigens are cross-reactive in these assays. Specific CTL responses are under investigation. It has been suggested but not confirmed that cytotoxic cells are depressed in patients with frequent recurrences (510). Nevertheless, a similar case can be made for depression of natural killer cells. As noted, recent studies have demonstrated a role of envelope glycoproteins in the establishment of cell-mediated immunity (512). As with humoral responses, the appearance of lesions correlates with a boost in cytotoxic responses.

Lymphokine production was incriminated in the pathogenesis of frequently recurrent genital and labial HSV infection. Notably, several investigators have recognized a decrease in both gamma-interferon production and natural killer cells during the disease prodrome (116,366,455). No reproducible data from selected populations confirm these observations.

Host response of the newborn to HSV must be defined separately from that of older individuals. Impairment of host defense mechanisms is a cause of the increased severity of some infectious agents in the fetus and the newborn. Factors that must be considered in defining the host response of the newborn include the mode of transmission of the

agent (viremia versus mucocutaneous infection without blood-borne spread), and the time of acquisition of infection. Two broad issues are of relevance: (a) protection of the fetus by transplacental antibodies and (b) definition of host response of the newborn.

Host response to HSV infection may well influence (a) the acquisition of disease, (b) the severity of infection, and (c) host resistance to the development, maintenance, and subsequent reactivation of HSV. Clearly, humoral immunity does not prevent either recurrences or exogenous reinfection. Thus, it is not surprising that transplacentally acquired antibodies from the mother are not totally protective against newborn infection but with conflicting results (219,256,499,500,555,562). Furthermore, the quantity of neutralizing antibodies is higher in those newborns who do not develop infection when exposed to HSV at delivery (384,562). The key issue, then, is to what extent these antibodies are protective and whether specific antibody classes or subclasses provide greater protection than others. Transplacentally acquired neutralizing antibodies seem to either prevent or ameliorate infection in exposed newborns, as do antibody-dependent cell-mediated cytotoxicity antibodies (384,562). Nevertheless, the presence of antibodies at the time of clinical presentation with disease does not necessarily influence the subsequent outcome (219,543,551).

Humoral responses of IgM and IgG antibodies have been well characterized. Infected newborns produce IgM antibodies (as detected by immunofluorescence) specific for HSV within the first 3 weeks of infection. These antibodies increase rapidly during the first 2 to 3 months, and they may be detectable for as long as 1 year after infection. The most reactive immunodeterminants are the surface viral glycoproteins, specifically gB and gD. Humoral antibody responses were elaborated recently using contemporary immunoblot technology, and the patterns of response are similar to those encountered in adults with primary infection (219,499). These immunoblot studies indicate that the severity of infection correlates directly with the number of antibody bands to defined polypeptides. Children with more limited infection—namely, infection of the skin, eye, and/or mouth—have fewer antibody bands than do children with disseminated disease. Total neutralizing antibodies in babies with disseminated infection are low (499).

Cellular immunity is considered important in neonatal host response to HSV infection. Newborns with HSV infections have a delayed T-lymphocyte proliferative response compared with that of older individuals (499). Most infants had no detectable T-lymphocyte responses to HSV 2 to 4 weeks after the onset of clinical symptoms (390,499). Other investigators have observed delayed blastogenic responses to HSV (371). The correlation between these delayed responses may be of significance in evaluating outcome to neonatal HSV infection. Specifically, if the response to T-lymphocyte antigens in children who have disease localized to the skin, eye, or mouth at the onset of disease is significantly delayed, disease progression may occur at a much higher frequency than it does in babies with a more appropriate response (90,499).

Infected newborns have decreased alpha-interferon production in response to HSV antigen when compared with adults with primary HSV infection (499). The importance of the generation of alpha-interferon on the maturation of host responses, particularly the elicitation of natural killer cell responses, remains to be defined (64,252). Lymphocytes from infected babies have decreased responses to gamma-interferon generation during the first month of life (69,252,499). These data taken together would indicate that the newborn has a delayed immune response by assessment of both cell-mediated immunity and lymphokine generation.

Antibodies plus complement and antibodies mixed with killer lymphocytes, monocytes, macrophages, or polymorphonuclear leukocytes will lyse HSV-infected cells *in vitro* (418). Antibody-dependent cell-mediated cytotoxicity has been demonstrated to be an important component of the development of host immunity to infection (251). However, the total population of neonatal killer lymphocytes seems lower than that found in older individuals. The type and quantity of antibodies present, as well as the immaturity of monocytes and macrophages of human neonates, are greater than those of adults (15,198,253,254,288,317,514,570). These findings are supported by data from animal models.

CLINICAL MANIFESTATIONS OF DISEASE

Primary/Recurrent Oropharyngeal Disease

The clinical symptomatology of primary HSV-1 infections varies greatly. Manifestations of infection range from totally asymptomatic to any combinations of fever, sore throat, ulcerative and vesicular lesions, gingivostomatitis, edema, localized lymphadenopathy, anorexia, and malaise. Asymptomatic infection is the rule rather than the exception. The incubation period ranges from 2 to 12 days, with a mean of approximately 4 days.

Symptomatic disease in children is characterized by involvement of the buccal and gingival mucosa (Fig. 11). The duration of clinical illness may be from 2 to 3 weeks, with fever of 101°F to 104°F. Children with symptomatic primary infection are often unable to swallow liquids because of the significant edema of the mucosal membranes and the associated pain. Lesions within the mouth evolve from vesicles, oftentimes not witnessed with intraoral disease, to shallow ulcerations on an erythematous base. They then slowly heal. In contrast to cutaneous lesions, intraoral lesions are not generally associated with the development of scabs. Submandibular lymphaden-opathy is commonly associated with primary HSV gingivostomatitis but rarely with recurrent infections. Other findings include sore throat and mouth, malaise, tender cervical lymphadenopathy, and an inability to eat. A clinical distinction should be drawn between intraoral gingival lesions and lip lesions, which are indicative of presumed primary and recurrent infections, respectively.

FIG. 11. Herpes simplex gingivostomatitis.

With the onset of primary HSV infections later in life, a common finding is HSV pharyngitis in association with a mononucleosis syndrome. Under such circumstances, ulcerative tonsilar lesions on an erythematous base with associated submandibular lymphadenopathy are common (163). The differential diagnosis of both primary HSV gingivostomatitis and pharyngitis focuses on other mucosal lesions of the oropharynx. These would include herpangina (caused by coxsackieviruses), candidal infections of the mouth, Epstein-Barr virus–induced mononucleosis, lesions induced by chemotherapy or radiation therapy, and Stevens-Johnson syndrome.

The onset of recurrent orolabial lesions is heralded by a prodrome of pain, burning, tingling, or itching, which generally lasts for less than 6 hours followed within 24 to 48 hours by vesicle formation (480,481,483,567). The natural history of recurrent herpes labialis is illustrated in Figure 12 (479). Vesicles appear most commonly at the vermilion border of the lip and persist in most patients only 48 hours at the longest (Fig. 13). Vesicles generally number three to five. The total area of involvement usually is localized, being less than 100 mm^2, and lesions progress to the pustular or ulcerative and crusting stage within 72 to 96 hours. Pain is most severe at the outset and resolves quickly over 96 to 120 hours. Similarly, the loss of virus from lesions decreases with progressive healing over 2 to 3 days (26,483). Healing is rapid, generally being complete in 8 to 10 days. The frequency of recurrences varies among individuals (483). The factors responsible for recurrences in humans are both highly variable and poorly defined but include fever, stress, and exposure to UV light (452,459).

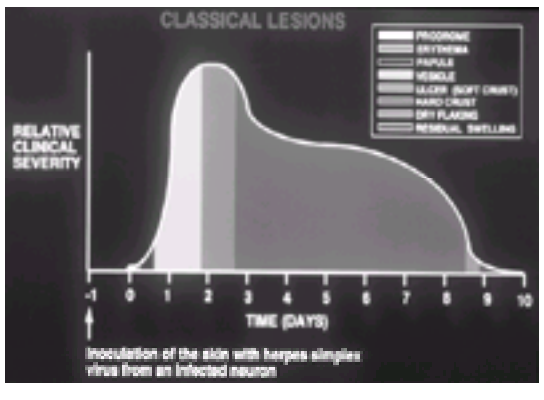

FIG. 12. The natural history of herpes simplex labialis.

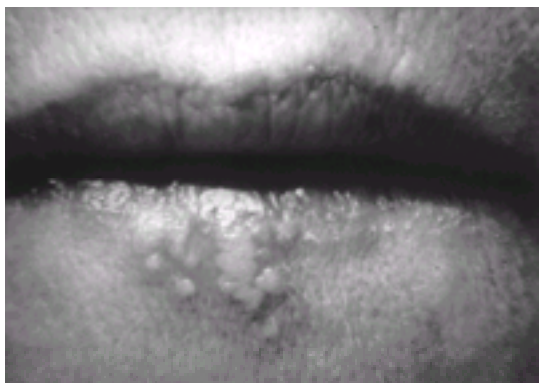

FIG. 13. Recurrent herpes simplex labialis.

Primary/Initial/Recurrent Genital Disease

The most severe clinical expression of genital herpes is encountered with primary infection. After acquisition of HSV infection at an abraded site, macules and papules, followed by vesicles, pustules, and ulcers, appear. The duration of lesions averages 3 weeks. There are both similarities and differences in the clinical symptomatology between men and women with infection (105,107).

Primary infection is associated with (a) larger quantities of virus replicating in the genital tract (more than 10^6 viral

particles per 0.2 mL of inoculum) and (b) a period of viral excretion that may persist for an average of 3 weeks. Systemic complications in men are relatively uncommon; however, aseptic meningitis can develop. Paresthesias and dysesthesias that involve the lower extremities and perineum can result from genital herpetic infection. Primary infections can be associated with fever, dysuria, localized inguinal adenopathy, and malaise in both men and women. The severity of primary infection and its association with complications are statistically higher in women than in men, for unknown reasons (63,107). Systemic complaints are common in both sexes, approaching 70% of all cases. Extragenital lesions are common.

In women with primary infection, lesions appear on the vulva and are usually bilateral (Fig. 14), with the cervix being invariably involved (Fig. 15). The actual frequency of primary cervical infection in the absence of vulvar infection is unknown. Lesions usually are excruciatingly painful, associated with inguinal adenopathy and dysuria, and may involve the vulva, perineum, buttocks, cervix, and/or vagina. A urinary retention syndrome occurs in 10% to 15% of female patients, and as many as 25% of women will develop aseptic meningitis.

FIG. 14. Genital HSV infection (female).

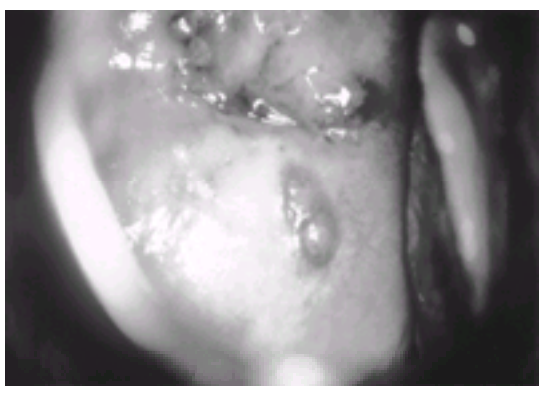

FIG. 15. Cervical HSV infection.

In men, primary genital HSV infections are most often associated with vesicular lesions superimposed on an erythematous base, usually appearing on the glans penis or the penile shaft (Fig. 16). The total number of lesions can vary significantly from six to 10 to many more. Extragenital lesions of the thigh, buttocks, and perineum can occur.

FIG. 16. Genital HSV infection (male).

Complications after primary genital herpetic infection have included sacral radioculomyelitis, which can lead to urinary retention, neuralgias, and meningoencephalitis (74,191,197,468,507). Primary perianal and anal HSV-2 infections, as well as associated proctitis, are common in male homosexuals (165,207). Like HSV-1 infections, many primary HSV-2 illnesses are subclinical, involving the mouth (172) or the uterine cervix (213,214,564).

Nonprimary but initial genital infection (i.e., occurring in an individual with preexisting antibody) is less severe symptomatically and heals more quickly than primary infection. The duration of disease is closer to 2 weeks. The number

of lesions, severity of pain, and likelihood of complications are significantly decreased. Preexisting antibodies to HSV-1 have an ameliorative effect on disease severity of HSV-2 (8,110,224,267,399,400,443,525) but do not appear to prevent infection (111,525).

Recurrent genital herpes is the mildest form of disease. With recurrent genital herpetic infection, a limited number of vesicles, usually three to five, appear on the shaft of the penis in men or as simply a vulvar irritation in women (6). The duration of disease, approximately 7 to 10 days, parallels that encountered with recurrent HSV labialis. Neurologic or systemic complications are uncommon with recurrent disease; however, paresthesias and dysathesias occur.

The virologic manifestations are also different for recurrent infection compared with primary infection. Virus is shed for an average of only 2 to 5 days and at lower concentrations (approximately 10^2 to 10^3 per 0.2 mL of inoculum in tissue culture systems) in women with recurrent genital infection. Recurrent genital herpetic infection in both men and women is characterized by a prodrome (which is a useful marker for therapeutic trials) (290) and localized irritation.

The major problem with recurrent genital HSV infection is the frequency of the recurrences, which varies from one individual to the next. Anecdotally, the severity of primary infection correlates directly with the frequency of recurrences; that is, the more severe the primary infection, the more likely and frequent the recurrences. Notably, all patients suffer from recurrences. One third of patients are estimated to have recurrences in excess of eight or nine times per year, one third will have two to three per year, and the remaining third will have four to seven (107). Clearly, with recurrences, either symptomatic or asymptomatic, transmission of infection to sexual partners can occur with intimate contact. Recent studies suggest that HSV DNA can be detected by PCR (99,496) three to five times more frequently than the isolation of virus. The implications of these data forces a reanalysis of our understanding of subclinical recurrences, especially the education of our patients, including behavioral interventions and use of condoms to prevent transmission of infection.

Neonatal HSV Infections

Incidence of Newborn Infection

Although centers caring for infants with neonatal HSV infections have observed fluctuations in disease incidence, the estimated rate of occurrence is approximately 1 in 3,000 to 1 in 5,000 deliveries per year (338,339). An increase in the number of cases of neonatal HSV infection has been noted in some areas, with rates approaching 1 in 1,500 deliveries (502), but this is unusual. Neonatal HSV infection occurs far less frequently than do genital HSV infections in the adult child-bearing population. Several countries do not appear to recognize a significant number of cases of neonatal HSV infection, probably reflecting their low overall prevalence of HSV-2 infection. As a contrast, serologic studies in central Africa indicate that women have a high frequency of antibodies to HSV-2, but the first case of neonatal herpes was reported only relatively recently (5,505). On the other hand, in the United Kingdom, the seroprevalence of HSV-2 is relatively low and, in parallel, so is the incidence of neonatal HSV infection. Why the United Kingdom has a distinctly lower seroprevalence of HSV-2 is not well understood.

Factors That Influence Transmission of Infection to the Fetus

At least four factors influence transmission of infection from mother to fetus. First, the type of maternal genital infection at the time of delivery is crucial. The duration and quantity of viral excretion and the time to total healing vary with primary, initial, and recurrent maternal genital infection: Primary infection is most and recurrent infection is least severe (105,107). Data generated from investigators in Seattle and supported by two other investigative teams suggest a risk of transmission of 30% with maternal primary or initial infection, compared with 3% or less with recurrent infection (58). In part, this reflects prolonged viral excretion during the third trimester of gestation, as well as an inadequate transplacental antibody response. Second, paralleling the type of maternal infection, the mother's antibody status to HSV at delivery influences the severity of infection as well as the likelihood of transmission. Transplacental maternal neutralizing and antibody-dependent cell-mediated cytotoxic antibodies appear to have at least an ameliorative effect on acquisition of infection for babies inadvertently exposed to virus at delivery (21,338,384,561,562). Third, the duration of ruptured membranes is an important indicator of risk for acquisition of neonatal infection. Observations by Nahmias et al. (338) indicate that prolonged rupture of membranes (longer than 6 hours) increases the risk of acquisition of virus, probably the consequence of ascending infection from the cervix. Fourth, certain forms of medical intervention in the labor and delivery suites may increase the risk of neonatal HSV infection. Specifically, fetal scalp monitors can be a site of inoculation of virus (225,369). Such devices should be relatively contraindicated in women with a history of recurrent genital HSV infection.

Times of Transmission of Infection

Infection of the newborn can be acquired at one of three times: *in utero*, intrapartum, or postnatally. Certainly, the mother is the most common source of infection for the first two of these routes of transmission of infection to the newborn. Although intrapartum transmission accounts for 75% to 80% of all cases, the other two routes must be considered in a child with suspect disease, for both public health and prognostic purposes. The first group of babies become infected *in utero* (28,150,176,204,477). Using stringent diagnostic criteria (namely, identification of infected babies within the first 48 hours of life who have virologic confirmation of infection), over 30 babies have been identified in the world's literature with symptomatic congenital disease. Other reports have included, as evidence for *in utero* acquisition of disease, the presence of HSV lesions at birth, detection of elevated IgM in cord blood, and neonatal viremia (1).

In utero infection can occur as a consequence of either transplacental or ascending infection. Placental necrosis and inclusions in the trophoblast can occur (158,160,557). Ascending infection, with histopathologic evidence of chorioamnionitis, was identified as an alternative route for *in utero* infection.

The second and most common route of infection is that of intrapartum contact of the fetus with infected maternal genital secretions. Most likely, 75% to 80% of infected babies acquire HSV infection by this route. Factors favoring intrapartum

transmission of infection were noted ealier.

The third route of transmission is postnatal acquisition. Even though HSV-1 is associated with genital lesions, postnatal transmission of HSV is increasingly suggested because 15% to 20% of neonatal HSV infections are caused by this virus type (338). In fact, more recent data from the National Institutes of Allergy and Infectious Diseases (NIAID) Collaborative Antiviral Study Group (CASG) indicate that the frequency of babies with neonatal HSV-1 infections has increased to nearly 30% (543). This observation should be weighed against the recognition that HSV-1 infections are becoming increasingly common in the United States and now account for about 25% to 30% of new cases of genital herpes. Regardless, relatives and hospital personnel with orolabial herpes are a reservoir of virus for infection of the newborn. The documentation of postnatal transmission of HSV by molecular epidemiologic tools has focused attention on such sources of virus for neonatal infection (128,133,152,175,233,279,281,503). The documentation of identical isolates from babies born to different mothers in a nursery by restriction endonuclease technology is troublesome (175) but, fortunately, rare. Postnatal transmission from mother to child was documented as a consequence of nursing on an infected breast (133,233,431,503). Father-to-baby transmission was documented from lesions of herpes labialis (128,563).

Clinical Presentation

Clinical presentation of babies with neonatal HSV infection is a direct reflection of the site and extent of viral replication. Although reported cases of asymptomatic infection in the newborn exist, neonatal HSV infection is almost invariably symptomatic and frequently lethal. Classification of newborns with HSV infection is mandatory for prognostic and therapeutic decisions. Babies with congenital infection should be identified within 48 hours after birth. Babies who are infected intrapartum or postnatally with HSV infection can be divided into three categories: those with (a) disease localized to the skin, eye, and mouth; (b) encephalitis with or without skin involvement; and (c) disseminated infection that involves multiple organs, including the CNS, lung, liver, adrenals, skin, eye, and/or mouth (334,553).

Intrauterine Infection

Intrauterine infection results in a group of severely afflicted babies; disease is apparent at birth and is characterized by the triad of skin vesicles or skin scarring, eye disease, and the far more severe manifestations of microcephaly or hydranencephaly. Often, chorioretinitis alone or in combination with other eye findings, such as keratoconjunctivitis, is a component of the clinical presentation. The frequency of occurrence of these manifestations has been estimated to be about 1 in 200,000 deliveries (28).

A small group of children will have skin or eye lesions that are present at the time of delivery. These children are frequently born to women who have had prolonged rupture of membranes. The babies have no other findings of invasive multiorgan involvement. The mothers of these babies often had prolonged rupture of membranes for as long as 2 weeks before the onset of labor and delivery. The prognosis for successful antiviral therapy in this group of babies is better than in the children who are born with hydranencephaly.

Disseminated Infection

Table 5 summarizes the disease classification of 291 babies with neonatal HSV from the NIAID CASG studies (see also Fig. 17). Babies with the worst prognosis for both mortality and morbidity have disseminated infection. Children with disseminated infection are usually brought to tertiary care centers for therapy at 9 to 11 days of age; however, signs of infection usually begin an average of 4 to 5 days earlier. Historically, this group of babies has accounted for approximately one half to two thirds of all children with neonatal HSV infection. However, with the early introduction of antiviral therapy, this figure was reduced to about 23% (see Fig. 16).

	Disease classification		
	Disseminated (%)	CNS (%)	SEM (%)
No. of babies	94 (32)	101 (34)	102 (34)
Male/female	66/28	81/20	63/39
Race: white/other	80/24	76/25	76/26
Premature (<37 weeks)	42 (45)	38 (38)	32 (31)
Gestational age (weeks ± SE)	38.5 ± 0.4	37.9 ± 0.4	37.8 ± 0.3
Enrollment age (days ± SE)	11.6 ± 0.7	17.4 ± 0.8	12.3 ± 1.1
Maternal age (years ± SE)	21.7 ± 0.5	23.1 ± 0.6	22.7 ± 0.5
Clinical findings

TABLE 5. *Demographic and clinical characteristics of infants enrolled in NIAID collaborative antiviral study*

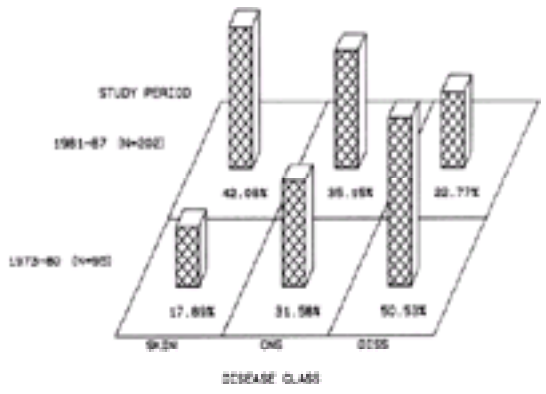

FIG. 17. Change in disease classification of neonatal HSV infection. Patients were enrolled in the NIAID Collaborative Antiviral Study Group and grouped according to disease class.

The principal organs involved after disseminated infection are the liver and adrenals. Infection can involve multiple other organs, including the larynx, trachea, lungs, esophagus, stomach, lower gastrointestinal tract, spleen, kidneys, pancreas, and heart. Constitutional signs and symptoms include irritability, seizures, respiratory distress, jaundice, bleeding diatheses, shock, and, frequently, the characteristic vesicular exanthem, which is often considered pathognomonic for HSV infection. Encephalitis appears to be a common component of this form of infection, occurring in about 60% to 75% of children with disseminated infection. The vesicular rash, as described later, is particularly important in the diagnosis of HSV infection. However, over 20% of children having disseminated infection will not develop skin vesicles during the course of their illness (19,543). Mortality in the absence of therapy exceeds 80%; all but a few survivors are impaired. The most common cause of death in babies with disseminated disease is either HSV pneumonitis or disseminated intravascular coagulopathy.

Encephalitis

Babies with infection of the CNS alone or in combination with disseminated disease present with the findings indicative of encephalitis in the newborn. Overall, nearly 90% of babies with disseminated disease have evidence of acute brain infection. Brain infection can occur in one of two fashions: either as a component of multiorgan disseminated infection or only as encephalitis with or without skin, eye, and mouth involvement. Nearly one third of all babies with neonatal HSV infection have only the encephalitic component of disease. The pathogenesis of these two forms of brain infection is very likely different. Babies with disseminated infection probably seed the brain by a blood-borne route, resulting in multiple areas of cortical hemorrhagic necrosis. In contrast, babies who present with only encephalitis probably develop brain disease as a consequence of retrograde axonal transport of virus to the CNS. Two pieces of data support this contention. First, babies with disseminated disease have documented viremia and are hospitalized earlier in life than are those with only encephalitis: at 9 to 10 days versus 16 to 17 days, respectively. Second, babies with encephalitis are more likely to receive transplacental neutralizing antibodies from their mothers, which may prevent viremia, allowing only intraneuronal transmission of virus to the brain.

Clinical manifestations of either encephalitis (alone or in association with disseminated disease) include seizures (both focal and generalized), lethargy, irritability, tremors, poor feeding, temperature instability, bulging fontanelle, and pyramidal tract signs. Whereas babies with disseminated infection often have skin vesicles in association with brain infection, the same is not true for the baby with encephalitis alone. This latter group of children may have only skin vesicles in approximately 60% of cases at any time in the disease course (19,501,537,543,563). Cultures of cerebrospinal fluid yield virus in 25% to 40% of all cases. Anticipated findings on cerebrospinal fluid examination include pleocytosis and proteinosis (as high as 500 to 1,000 mg/dL). Although a few babies with CNS infection demonstrated by brain biopsy were reported to have no abnormalities of their cerebrospinal fluid, this occurs only rarely. Death occurs in 50% of babies with localized CNS disease who are not treated, and it is usually related to brain system involvement. With rare exceptions, survivors are left with severe neurologic impairment (537,546).

The long-term prognosis, after either disseminated infection or encephalitis, is particularly poor. As many as 50% of surviving children have some degree of psychomotor retardation, often in association with microcephaly, hydranencephaly, porencephalic cysts, spasticity, blindness, chorioretinitis, or learning disabilities. It is unclear at this time whether visceral or CNS damage can be progressive after initial clearance of the viral infection, a possibility suggested by long-term assessment of children with skin, eye, or mouth disease (338,543,550) and, more recently, in a group of babies with more severe disease (171).

Recently, subclinical infection of the CNS has been detected in babies with disease apparently localized to the skin, eye, and mouth. These children had normal cerebrospinal fluid assessments but PCR-detectable HSV DNA at the onset of disease (235). Subsequently, a subset of these children developed neurologic impairment. These findings stress the often subtle presentation of CNS disease.

A comment regarding the diagnosis of encephalitis is indicated. In as many as 40% of children with disease localized to the CNS (e.g., the 2- to 3-week-old baby with cells and protein in the cerebrospinal fluid), other diagnostic clues, such as skin vesicles (the classic sign of HSV disease) may not be present. For the neonate with cerebrospinal fluid findings indicative of infection, HSV must be considered along with bacterial pathogens (e.g., group B *Streptococcus*, *Escherichia coli*). A reasonable diagnostic approach, if all antigen and Gram stain studies are negative and so are the PCR evaluations, would be serial cerebrospinal fluid examinations to document progression in protein and mononuclear cell counts.

Skin, Eye, and Mouth Infection

Infection localized to the skin, eye, and/or mouth is associated with lower mortality, but significant morbidity can occur. When infection is localized to the skin, the presence of discrete vesicles remains the hallmark of disease. Clusters of vesicles often appear initially on the part of the body that was in direct contact with the virus during birth. With time, the rash can progress to involve other areas of the body as well, particularly if viremia occurs. Vesicles occur in 90% of children with skin, eye, or mouth infection. Children with disease localized to the skin, eye, or mouth generally present at about 10 to 11 days of life. Babies with skin lesions invariably will experience recurrences over the first 6 months (and longer) of life, regardless of whether therapy was administered. Although death is not associated with disease localized to the skin, eye, and/or mouth, approximately 30% of these children eventually develop evidence of neurologic impairment (537,546,550). The skin vesicles (Fig. 18) usually erupt from an erythematous base and are usually 1 to 2 mm in diameter. Other manifestations of skin lesions have included a zosteriform eruption (329).

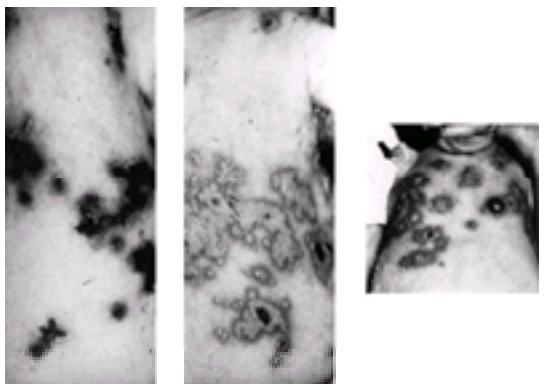

FIG. 18. Vesicular rash of neonatal HSV infection.

Infections involving the eye may manifest as keratoconjunctivitis or, later, as chorioretinitis. The eye may be the only site of HSV involvement in the newborn (546). These children present with keratoconjunctivitis or, surprisingly, evidence of microphthalmia and retinal dysplasia.

Long-term neurologic impairment has been encountered in children whose disease appeared to be localized to the skin, eye, and/or mouth. The significant findings include spastic quadriplegia, microcephaly, and blindness. Important questions regarding the pathogenesis of delayed-onset neurologic debility are raised by such clinical observations. Despite normal clinical examinations in these children, neurologic impairment has become apparent between 6 months and 1 year of life. As noted earlier, these children had detectable HSV DNA in the cerebrospinal fluid at presentation, implying subclinical infection of the CNS. The clinical presentation occurs in a manner similar to that associated with congenitally acquired toxoplasmosis or syphilis.

Prognostic Factors

Recently, the NIAID CASG completed an assessment of factors that predict long-term prognosis (Table 6) (541). The most significant predictors of both mortality and morbidity were disease classification: Babies with the most severe disease had the worst outcome. A low level of consciousness also predicted a more severe outcome. By disease classification, the poorest prognostic factors for babies with disseminated disease were, in addition to the preceding, the development of HSV pneumonia or disseminated intravascular coagulopathy. With encephalitis, prematurity and seizures predicted a poor outcome. Finally, for babies with skin, eye, or mouth disease, frequently recurrent HSV-2 cutaneous lesions defined a group at risk for a poor neurologic outcome.

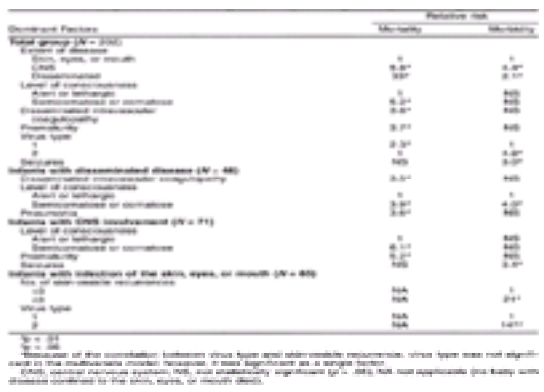

TABLE 6. *Prognostic factors identified by multivariate analyses for neonates with HSV infection*

Herpes Simplex Keratoconjunctivitis

Viral infections of the eye are usually caused by HSV-1 beyond the newborn age (45,364,449). Approximately 300,000 cases of HSV infections of the eye are diagnosed yearly in the United States. These infections are second only to trauma as the cause of corneal blindness in this country. Primary herpetic keratoconjunctivitis is associated with either unilateral

or bilateral conjunctivitis, which can be follicular in nature, followed soon thereafter by preauricular adenopathy. HSV infection of the eye is also associated with photophobia, tearing, eyelid edema, and chemosis, accompanied by the pathognomonic findings of branching dendritic lesions (Fig. 19). Less commonly, with advanced disease the infection is associated with a geographic ulcer of the cornea (Fig. 20). Healing of the cornea can take as long as 1 month, even with appropriate antiviral therapy.

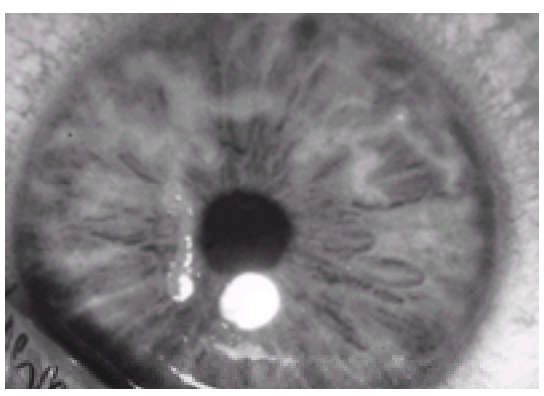

FIG. 19. Dendritic lesions of herpes simplex keratoconjunctivitis.

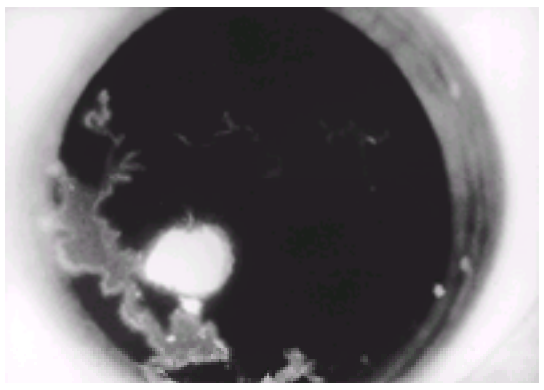

FIG. 20. Geographic corneal ulcer caused by HSV infection.

Recurrent HSV infections of the eye are common. Recurrences parallel that described for herpes labialis. Most frequently, recurrences are unilateral in involvement, but a small percentage of cases involve both eyes. Characteristically, either dendritic ulceration or stromal involvement occurs. Visual acuity is decreased in the presence of the ulcers; with progressive stromal involvement, opacification of the cornea may occur. Repeated individual attacks may last for weeks or even months after appropriate antiviral therapy. The route and pathogenesis of infection remain unknown. Progressive disease can result in vision loss and even rupture of the globe.

Skin Infections

Skin infections caused by HSV generally manifest as eczema herpeticum in patients with underlying atopic dermatitis (386,506,533). The lesions can be either localized, resembling herpes zoster with a dermatomal distribution, or disseminated. The latter occurs commonly in Kaposi's varicella-like eruption (422). HSV infections of the digits, known as herpetic whitlow, have been reported and are particularly common among medical and dental personnel (417). Herpetic infections of the hand have been described since 1909 and are particularly problematic for hospital personnel. The estimated incidence is 2.4 cases per 100,000 population per year, and the cause may be HSV-1 or HSV-2. An increasing incidence of HSV-2 herpetic whitlow has been recognized among health care professionals (162).

The prevalence of HSV skin infections in Skaraborg, Sweden, was assessed among approximately 7,500 individuals over 7 years of age and was found to be about 1% (186). In another Swedish study performed in dermatology clinics, 2% of men and 1.5% of women attending clinics in Gothenburg over a 6-year period had evidence of herpetic skin infections (137). In addition to individuals with atopic disease, patients with skin abrasions or burns appear particularly susceptible to HSV-1 or HSV-2 infections, and some may develop disseminated infection (151). Disseminated HSV infections were also reported among wrestlers, and this is referred to as herpes gladitorium (534). Other skin disorders associated with extensive cutaneous lesions include Darier's disease and Sezary's syndrome (185,199). As would be predicted, localized recurrences followed by a second episode of dissemination were observed (363). HSV infections of either type were found to trigger erythema multiforme (532). The association of HSV DNA in skin lesions of erythema multiforme is as high as 80%.

Infections of the Immunocompromised Host

Patients compromised by either immune therapy, underlying disease, or malnutrition are at increased risk for severe HSV infections. Renal, hepatic, bone marrow, and cardiac recipients are all at particular risk for increased severity of transplant HSV infection (283,327,372,554). An example of cutaneous dissemination after shaving, in a renal transplant recipient, is shown in Figure 21. Virus was most likely autoinoculated to multiple skin sites by the razor blade. In organ transplant recipients, the presence or quantity of HSV antibodies before treatment predicts the individual at greatest risk for recurrence (373). These patients may develop progressive disease involving the respiratory tract, esophagus, or even

the gastrointestinal tract (258,325). The severe nature of progressive disease in these patients appears to be directly related to the amount of immunosuppressive therapy (389). Esophagitis is a common occurrence in the immunocompromised host and can be caused by HSV, cytomegalovirus, or *Candida albicans.* Notably, acyclovir-resistant HSV disease will occur in the immunocompromised host and can be progressive. Reactivation of latent HSV infections in these patients can occur at multiple sites, and healing in these patients with severe progressive disease occurs over an average of 6 weeks (549).

FIG. 21. Cutaneous dissemination of HSV infection in an immunosuppressed host.

Since the first reports of acquired immunodeficiency syndrome, the severity of HSV clinical disease in these severely immunocompromised hosts was noted (294). Herpetic disease, even more exaggerated than in the cancer patient, has been reported and is an essential target for antiviral therapy. Although conflicting reports have suggested no enhanced severity of HSV infection in these patients (428), disease appears to occur more frequently and can lead to resistance with requisite therapy.

Asymptomatic excretion of HSV can occur even in the immunocompromised host, as is best exemplified in HIV-infected individuals (435,436,525). Parenthetically, ac-quisition of HSV infection from a transplanted organ (kidney) has been reported (131).

Infections of the Central Nervous System

Herpes simplex encephalitis is one of the most devastating of all HSV infections (Fig. 22), being the most common cause of sporadic, fatal encephalitis in this country (362). The Centers for Disease Control estimate the incidence of herpes simplex encephalitis to be approximately 40 to 50 cases per year; however, disease occurrence is undoubtedly higher (553). From data collected prospectively, the incidence of severe hemorrhagic focal encephalitis is approximately 1 in 200,000 individuals per year, for a national annualized rate of approximately 1,250 cases in the United States.

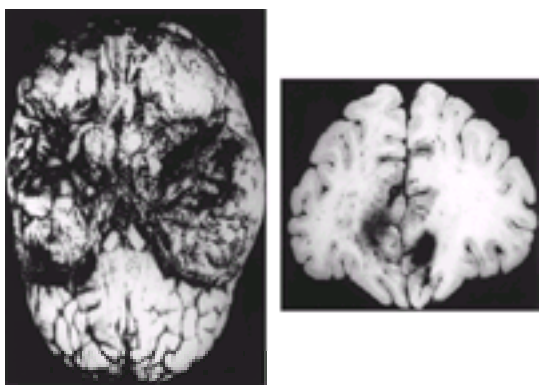

FIG. 22. Coronal section of brain from a patient with herpes simplex encephalitis.

The manifestations of HSV encephalitis in the older child and adult are indicative of the areas of pathology in the brain. These include primarily a focal encephalitis associated with fever, altered consciousness, bizarre behavior, disordered mentation, and localized neurologic findings. These clinical signs and symptoms generally are associated with evidence of localized temporal lobe disease, as demonstrated by neurodiagnostic procedures (552,553). There are no characteristic series of findings pathognomonic for herpes simplex encephalitis; however, a progressively deteriorating level of consciousness, fever, an abnormal cerebrospinal fluid formula, and focal neurologic findings in the absence of other causes should make this disease highly suspect. Other diagnostic evaluations should be initiated immediately because other treatable diseases mimic HSV encephalitis (542). Mortality in untreated patients is in excess of 70%, and only 2.5% of all patients return to normal neurologic function.

Pathogenesis

The pathogenesis of HSV encephalitis, particularly as it relates to the source of virus responsible for brain disease, has been considered for some time. HSV isolates obtained from both the brain and the lip or mouth of patients with virologically confirmed HSV encephalitis were examined by restriction endonuclease analyses for identity (548). These studies demonstrated that only approximately 65% of patients excreting virus from two sites had identical isolates. When

the viruses were proven identical, invariably the patient was experiencing a primary infection (as defined serologically). Thus, virus excreted from the mouth of patients with HSV encephalitis may be identical to that of the brain or may be entirely different. The NIAID CASG observed that approximately half of the patients with HSV encephalitis (confirmed by brain biopsy and virus isolation) appear to have primary infections and that the remaining patients appear to have recurrent infections (523,546,548).

Diagnosis

Standard neurodiagnostic procedures are used in the evaluation of patients with suspect HSV encephalitis and include cerebrospinal fluid examination, electroencephalogram, and one or more scanning procedures such as technetium, computed tomography, or magnetic resonance imaging. Characteristic abnormalities of the cerebrospinal fluid include elevated levels of cells (usually mononuclear) and protein. Red blood cells are found in most (but not all) cerebrospinal fluids obtained from patients with HSV encephalitis. Upon serial cerebrospinal fluid examination, protein and cell counts increase dramatically. The electroencephalogram generally localizes spike and slow-wave activity to the temporal lobe. A burst suppression pattern is considered characteristic of HSV encephalitis. Imaging will allow for localization of disease to the temporal lobe. Early after onset, only evidence of edema is detectable, if at all. This finding is followed by evidence of hemorrhage and a midline shift in the cortical structures.

One of many areas for further investigation is the elucidation of the spectrum of HSV infections of the brain. Historically, diagnosis of CNS infections was accomplished only by brain biopsy (542); however, PCR assessment of the cerebrospinal fluid has replaced this diagnostic approach. Serologic procedures performed on serum or cerebrospinal fluid are not helpful early in the disease course when therapeutic decisions are mandatory (344). Therefore, noninvasive diagnostic procedures have been developed. Such procedures used in the past have included detection of HSV-specified thymidine kinase, DNA polymerase, and DNase (89) or detection of HSV-excreted glycoproteins (87) in the cerebrospinal fluid (270). The detection of viral DNA by PCR is now the diagnostic method of choice, but it must be performed by a reliable laboratory. Its utility will be described later in the section, Diagnosis. The spectrum of HSV infection of the CNS will be defined with the availability of such assays as PCR.

Other Neurologic Syndromes

In addition to encephalitis, HSV can involve nearly all anatomic areas of the nervous system. Crain and Nahmias (114) have reviewed the association of HSV with meningitis, myelitis, and radiculitis, among others. Aseptic meningitis is a common occurrence in individuals with primary genital HSV infections. The relationship between HSV infections of the brain and chronic degenerative disease, psychiatric disorders, or Bell's palsy requires further definition (31,95,102,299,328).

Other Forms of Infection

Other forms of infection should be noted briefly. HSV was isolated from the respiratory tract of adults with adult respiratory distress syndrome and acute onset bronchospasm (515). Both were associated with increased mortality and morbidity.

Association with Malignancy

Over a century ago, it was recognized that cervical carcinoma rarely developed in nuns and that it occurred at a much higher rate in married versus single women (407). Nahmias et al. associated HSV-2 with cervical squamous cell carcinoma, as have other investigators (2,4,23,72,93,155,222,301,335,341,345,395,396,409,420,421). This subject was reviewed extensively (308,342,408,427). These observations were predicated on (a) the site of cancer and the known propensity of HSV-2 to infect this site and (b) a plethora of antibody determinations that support the association (3,7,81,82,91,94,147,206,208,232,298,370,470,471). These serologic studies often failed to consider other STDs (154,231). Thus, HSV-2 infection is only a marker of behavior that predisposes to human papillomavirus infection, the more obvious cause of cervical carcinoma.

DIAGNOSIS

The appropriate use of laboratory tools is essential if a diagnosis of HSV infection is to be achieved (reviewed in ref. 106). Virus isolation remains the definitive diagnostic method. If skin lesions are present, a scraping of skin vesicles should be made and transferred in appropriate virus transport media to a diagnostic virology laboratory. Clinical specimens should be shipped on ice for inoculation into cell culture systems (e.g., foreskin fibroblasts, Vero cells) that are appropriate for the demonstration of the cytopathic effects characteristic of HSV replication (446). Cytopathic effect tends to develop within 24 to 48 hours after inoculation of specimens containing infectious virus. The shipping and processing of specimens should be expedited.

In addition to skin vesicles, other sites from which virus may be isolated include the cerebrospinal fluid, stool, urine, throat, nasopharynx, and conjunctivae. In infants with evidence of hepatitis or other gastrointestinal abnormalities, it also may be useful to obtain duodenal aspirates for HSV isolation. The virologic results of cultures from these anatomic sites should be used in conjunction with clinical findings to define the extent of disease in the newborn and immunocompromised host.

Typing of an HSV isolate can be accomplished by one of several techniques, which may not be routinely available. Because outcome with treatment does not appear to be related to the virus type, identification is only of epidemiologic and pathogenetic importance and, therefore, not usually necessary.

Every effort should be made to confirm infection by viral isolation. Today such efforts are both reasonable and the expected standard of care. In the absence of diagnostic virology facilities, cytologic examination of cells from the

maternal cervix or from the infant's skin, mouth, conjunctivae, or corneal lesions may be useful in making a presumptive diagnosis of HSV infection. These methods have a sensitivity of only approximately 60% to 70% and therefore should not be the sole diagnostic determinant for infection in the newborn (50,341). Similar methods in adults with genital herpes have a slightly higher sensitivity and specificity (268). Cellular material obtained by scraping the periphery of the base of the lesions should be smeared on a glass slide and promptly fixed in cold ethanol. The slide can be stained according to the method of Papanicolaou, Giemsa, or Wright before examination by a trained cytologist. Deployment of either a Giemsa or a Tzanck smear most likely will not demonstrate the presence of intranuclear inclusions. The presence of intranuclear inclusions and multinucleated giant cells are indicative, but not diagnostic, of HSV infection. Electron-microscopic assays are continuing to be developed (275). PCR, as described later, is used to detect HSV DNA in lesions or genital and swabs.

Serologic diagnosis of HSV infection is not of great clinical value. Therapeutic decisions cannot await the results of serologic studies. Until recently, the inability of the commercially available serologic assays to distinguish between antibodies to HSV-1 and HSV-2, as well as to denote the presence of transplacentally acquired maternal IgG, as opposed to endogenously produced antibodies, makes the assessment of the neonate's antibody status difficult during acute infection. Serial antibody assessment may be useful if a mother without a prior history of HSV infection has a primary infection late in gestation and transfers little or no antibody to the fetus. The most commonly used tests for measurement of HSV antibodies are complement fixation, passive hemagglutination, neutralization, immunofluorescence, and the enzyme-linked immunosorbent (ELISA) assays. The more recent development of type-specific antibody assays will very likely replace many of the older systems. Recently, two tests have been licensed by the Food and Drug Administration that utilize detection of antibiotics to gG-2 as the basis for type specificity (22). Importantly, however, diagnostic tests for such life-threatening disease as HSV encephalitis will require improvement.

The experience with PCR indicates that it is a useful tool for diagnosis of HSV encephalitis (11,24,25,122,236,237,385,419,513). Using primers from an HSV DNA sequence that was common to both HSV types 1 and 2 (either the glycoprotein B or the DNA polymerase gene), successful identification of HSV DNA in the cerebrospinal fluid has been reported by several investigators. The largest clinical study to date has used cerebrospinal fluid specimens obtained from patients undergoing brain biopsies for HSV encephalitis. This study conclusively supports PCR as the diagnostic method of choice for CNS infection (271).

Importantly, PCR evaluation of cerebrospinal fluid can be used to follow therapeutic outcome in patients with HSV encephalitis. A recent publication (237) identified persistence of HSV DNA in the cerebrospinal fluid of newborns with suspect HSV encephalitis as a predictor of neurologic outcome. These data taken together suggest the utility of PCR for diagnosing HSV encephalitis. The evaluation of cerebrospinal fluid specimens obtained from patients with biopsy-proven HSV encephalitis and those with other proven diseases indicates a sensitivity of more than 95% at the time of clinical presentation, and a specificity that approaches 100% (271). Presumptive false-positive PCR evaluations were encountered when the site of disease was not properly determined via biopsy. Similarly, false-negative assessments can be found when there is contamination of hemoglobin in the cerebrospinal fluid or the presence of inhibitors.

PCR also has been used to detect HSV DNA in lesions. It has a sensitivity and a specificity that warrant careful evaluation under these conditions (100,101,177). The results of all control subjects were negative in this assay system. Additionally, PCR analyses of cerebrospinal fluid specimens will redefine the spectrum of HSV infections of the CNS (271,438,439).

PREVENTION: CONTROL OF HSV INFECTIONS

Two avenues exist for the control of HSV infections. One approach is that of antiviral chemotherapy. It is discussed in detail in Chapter 72. The alternative approach is one of prevention. For the purposes of this discussion, prevention will be considered from two perspectives. The first is an evaluation of the practical issues that surround the prevention of neonatal HSV infections. The second perspective is a discussion of the current developments in vaccines to prevent primary HSV infection or to influence the course of frequently recurrent disease.

Genital HSV Infections

Because of the rising incidence of genital herpes and neonatal herpes, and the increasing association of herpes with acquisition of HIV, every effort should be made to prevent HSV-2 infections. Until a vaccine is proven efficacious, educational efforts must be developed for adolescents and those at greatest risk. The use of condoms should be promoted.

Neonatal HSV Infection

With the increased awareness of neonatal HSV infection as a consequence of genital herpes, along with its recognition as a cause of severe and often fatal disease, methods of prevention have attracted particular attention. Surgical abdominal delivery is associated with decreased transmission of infection when membranes are ruptured less than 4 hours, but cesarean section has not been proven efficacious when membranes are ruptured for longer periods of time. Nevertheless, when membranes are ruptured up to 24 hours, there is still a time frame within which cesarean section may be of value. Although the recommendation seems logical, no data exist from adequately performed clinical trials to fully support it.

For women with a past history of genital HSV infection, a careful vaginal examination at presentation to the delivery suite is of paramount importance. Although visualization of the cervix is often difficult, speculum examination for documentation of recurrent lesions is extremely important and should be attempted in all women.

Clearly, identifying the women who excrete HSV at delivery and then optimizing either prophylactic protocols with safe and acceptable antiviral agents or delivery by cesarean section remains the optimal way to manage genital infection at

the time of delivery. Unfortunately, at the present time only isolation of virus in tissue culture will document the excretion of virus. Alternative and nontissue culture–based diagnostic approaches are being developed to expedite identification of women at risk for delivering an infected baby (96,406), including PCR detection of HSV DNA. Those at greatest risk should be identified. The detection of type-specific antibodies to gG-2 will be of value in identifying those women at greatest risk (337). Importantly, assessing discordant serologic status between sexual partners may assist in prevention of maternal primary infection.

Hospital Staff

At many institutions, a policy that requires transfer or provision of medical leave for nursery personnel who have a labial HSV infection is impractical and causes an excessive burden to be placed on those attempting to provide adequate care. Temporary removal of personnel who have cold sores is advocated for some clinical services. As noted previously, individuals with herpetic whitlow carry a high risk of viral shedding. These individuals should be removed from the care of newborns at risk for acquiring neonatal HSV infection because even gloves may not prevent transmission of infection. Education regarding the risk of transmission of virus and the importance of hand washing when lesions are present should be repeatedly emphasized to health care workers. In addition, hospital personnel should wear masks when active lesions are present.

Prevention of Other HSV Infections

At the present time, the only mechanism for prevention of mucocutaneous HSV infection is to avoid contact with infected secretions. There are no proven effective postexposure antiviral therapies or vaccines.

VACCINE DEVELOPMENT

Vaccination remains the ideal method for prevention of viral infection; however, prevention of HSV infections introduces unique problems because of recurrences in the presence of humoral immunity. Nevertheless, protection from life-threatening infection can be achieved in animal models with avirulent, inactivated, or subunit glycoprotein vaccines, each of which has unique differences. Excellent reviews summarize HSV vaccine development (539).

Human HSV Vaccine Development

Only in the past 10 years has there been a resurgence in the vaccine effort directed against HSV infections. These recent efforts have focused on the application of molecular techniques to antigen preparation and delivery. Three of the more promising HSV vaccines continue to be assessed. The first is based on the production of sufficient quantities of recombinant HSV-2 gB or gD to be used as subunit vaccines. The second is a genetically engineered, live, attenuated HSV-2 deletion mutant with carefully selected gene deletions to remove putative neurovirulence sequences. The third deletes an essential glycoprotein, gH, which allows only a single cycle of infectious virus replication.

Although the development of these vaccines is exciting, it has taken much effort. Earlier investigations provided important lessons from which future human trials will benefit; they will be reviewed before considering the newer, genetically engineered products. These approaches include the use of (a) wild-type virus, (b) inactivated or killed virus, (c) subunit vaccines, and (d) live vaccines. Each will be discussed.

Wild-Type Virus Vaccines

Numerous clinical investigators have attempted to alter the pattern of recurrences by inoculation of (a) autologous virus, (b) virus from another infected individual, or (c), in one set of experiments, virus recovered from an experimentally infected rabbit (356,357,374). In each circumstance, the inoculation of virus led to evidence of infection at the site of injection in as many as 40% to 80% of patients (146,291). Efficacy was reported with limited numbers of patients but without the use of matched controls (164,291,367). In some of these cases, inoculation led to recurrences of latent infection (49,273,356,374). In large part, live viruses were abandoned as immunogens on the grounds that many patients failed to develop lesions at the site of inoculation; therefore, it was concluded that the virus did not produce an “adequate take” (44,55,153). The analogy that was used was the cutaneous “take” required after smallpox immunization. At the present time, inoculation of either autologous or heterologous virus is considered unacceptable.

Inactivated (or Killed) Virus Vaccines

Killed viruses have been used as vaccines in a variety of animal model systems, often with good results, as reviewed elsewhere (123,173,304). Unfortunately, when these vaccines were administered to patients with preexisting HSV infection in order to alleviate recurrences, most studies failed to include an appropriate control group. Under such circumstances, significant bias can be introduced because patients may experience 30% to 70% decrease in the frequency of recurrent lesions, as well as improvement in severity, simply from having received placebo (39,209,227,228,490,518).

The initial inactivated vaccines were made from phenol-treated tissues obtained from infected animals (44,55,153). Because of the potential for demyelination after the administration of animal proteins, these vaccines attracted little biomedical attention. Subsequently, UV light inactivation of purified virus derived from tissue culture experiments provided greater impetus for the vaccine field. During the past 20 years, numerous reports have appeared in the literature regarding either the success or failure of such approaches. As reviewed by Meignier (304), viral antigens obtained from amniotic or allantoic fluid, chorioallantoic membranes, chick cell cultures, sheep kidney cells, and rabbit kidney cells that were inactivated either by formalin, UV light, or heat were used in a series of vaccine studies in thousands of patients (33,61,65,86,123,132,143,187,188,202,209,242,292,330,347,348 and 349,382,432,442,445,462,475,520,529). With one exception (330), each of these studies reported significant

improvement in as many as 60% to 80% of patients (132,347,348 and 349). Notably, however, no controls were used.

As these studies progressed, several important observations were made. First, despite repeated inoculations, antibody titers (as measured by neutralization or complement fixation) remained unchanged in the majority of patients (65,188,405) or demonstrated only slight increases (475,520). Second, although few side effects were reported, some authors noted concern that, in patients with keratitis, autoimmune phenomena might make the herpetic disease worse (189,277,382,445,476).

Placebo-controlled studies that have used inactivated vaccines are few (13,228,476,530). The results from these studies differ widely, even when the same vaccine was used. A conclusion from these investigations was that there may be some initial benefit for patients with recurrent infection; however, long-term benefit could not be established.

The only prospective study of prevention of HSV infections using this vaccine approach was performed by Anderson et al. in children living in an orphanage (13). In this study, 10 children received vaccine and 10 the placebo; nevertheless, HSV gingivostomatitis developed in an equal number of patients in both groups on long-term follow-up.

In summary, the perception of the biomedical research community was that these vaccines did not meet accepted standards for licensure. Very likely, the potential risks of inactivated vaccines, especially as a cofactor in the development of cervical carcinoma—a prevalent notion at the time of these studies—may have contributed to the abandonment of this approach. Finally, new techniques in recombinant DNA technology have made these vaccines obsolete.

Subunit Vaccines

Subunit vaccines evolved from attempts to remove viral DNA and eliminate the potential for cellular transformation, to enhance antigenic concentration and induce a stronger immunity, and, finally, to exclude any possibility of contamination with residual live virus (145). Available subunit vaccines were prepared using a variety of methods for antigen extraction from infected cell lysates by detergent and subsequent purification.

The immunogenicity of envelope glycoproteins, free of viral DNA, was demonstrated in animals (76,77,310,465). The results of studies in humans are disappointing. As recently reported, envelope glycoproteins do not convey protection to uninfected sexual partners of individuals with genital HSV infection (20,111,568).

These subunit vaccines, as well as others, have been studied in a variety of animal models, including mice (124,243,245,266,272,305,469), guinea pigs (265,485,486,511,522,565), and rabbits (75). Neutralizing antibodies can be detected in these systems in varying amounts, as can ELISA antibodies in some systems (192). In these systems, the quantity of neutralizing antibody appears to correlate with the degree of protection upon challenge. Challenge in the experimental systems was accomplished in mice (68,192,243,245,266,305,464,469), rabbits (75,79,388,451), and guinea pigs (451,485,486,511). Each of these systems used a variety of different routes of challenge as well as dosages. Challenge sites included skin, lip abrasion, intravaginal tissue, intradermal ear pinna, intradermal tissue, foot pad, intraperitoneal tissue, ocular tissue, and subcutaneous sites. Thus, interpretation of these results is extremely difficult, especially in light of the lack of clinically efficacious data in humans. Although there are many conflicting studies, generally the subunit vaccines elicited some protection, as evidenced by the amelioration of morbidity and reduction in mortality in the immunized animals. The predictability of these models for human studies is most disappointing. Furthermore, several injections are required to induce protection, and they must include adjuvant. The necessity for an appropriate adjuvant has recently been emphasized (430,508). Protection in the rodent is significantly easier than in higher primate species, as previously noted. This may be because HSV is not indigenous to rodent species; therefore, the protection studies may be totally irrelevant when evaluating human responses.

Vaccination of primates, specifically rhesus monkeys (75), chimpanzees (75,76), and *Cebus* monkeys (196), can induce neutralizing antibodies, which can lead to an anemnestic response after subsequent injection months later. The degree of protection in these animals remains unclear.

Subunit vaccines have failed in human experiments despite initial promising results. Both HSV-1 and HSV-2 antigens have been prepared in human diploid cells and chicken embryo fibroblasts cells for vaccine purposes. At least two studies have led to evidence of protection as defined by immune responses (466,467). Nevertheless, other experiments have suggested that these vaccines offer very little benefit (20,76,568).

Extensive vaccine experience was reported for individuals receiving the Merck Sharpe & Dohme (196) glycoprotein envelope subunit vaccine (20,568). In this study, conducted in sexual partners of patients known to have genital herpes, the number of individuals developing herpetic infection was nearly the same for both placebo and vaccine recipients, indicating that the vaccine was not effective.

Studies have been completed with one of two gB and/or gD recombinant vaccines in humans. Initially, the gD-2 construct was administered to 24 human volunteers at the National Institutes of Health for reactogenicity and immunogenicity. These studies demonstrated an increase in the geometric mean antibody titer to gD-2; however, lymphocyte blastogenic responses were not consistent between populations. Either 30 µg or 100 µg of purified gD-2 was used as the immunogen with alum (497). Extensive rodent experiments using the guinea pig genital herpes model have explored the utility of using viral glycoproteins gB and gD as vaccine components. If the dose is optimal, a mixture of gB and gD can protect against both primary and spontaneous recurrent disease after intravaginal viral inoculation (485). However, to demonstrate this effect it was necessary to use complete Freund's adjuvant, a component not acceptable for human administration. More recently, investigators demonstrated that gD combined with a lipophilic muramyl tripeptide affords a high level of protection from HSV disease (70,430); however, this adjuvant was abandoned because of reactogenicity. In a series of experiments, investigators were able to demonstrate that the amount of antigen in the vaccine affects the host response. An important observation from these studies is that the quantity of neutralizing antibodies elicited by

immunization and the total HSV antibody titer (as measured by ELISA) were higher after vaccination than after natural infection and, furthermore, that these antibody titers correlated with protection from disease (217,485).

These initial studies were expanded by further experiments using muramyl tripeptides with gB and gD, to determine protective effects against recurrent infection. These studies show the development of immune responses similar to those of natural infection (497). The use of these subunit vaccines for therapy of recurrent genital herpes appeared to decrease the frequency of recurrence (538). Unfortunately, the failure of the gB and gD vaccine in a well-performed clinical trial is most disappointing (111) and has resulted in one vaccine company abandoning the approach.

Live Virus Vaccines

For decades, live virus vaccines have been considered most likely to provide a high level of protection, as was the case with numerous viral pathogens such as measles, mumps, and rubella. The rationale for the selection of live virus vaccines is that because they replicate in the recipient, the resulting immunity should be longer lasting. Moreover, these vaccines usually require smaller quantities of antigen and, therefore, should be more economical. Several approaches to live virus vaccines have been attempted, including HSV mutants, heterologous herpesviruses, antigens expressed in non-HSV viral vectors, and genetically engineered viruses.

Genetically Engineered HSV

Molecular biology makes it possible to modify, almost at will, the genome of large DNA viruses and to construct genetically engineered attenuated live viruses (410). The technology developed by Post and Roizman (318,380) has been used to construct recombinant HSV as a prototype of herpes vaccines (306). These vaccines were engineered with the objectives that they should be attenuated for both primary inoculation and reactivation of latent virus; they should protect against HSV-1 or HSV-2 infections; they should provide serologic markers of immunization distinct from wild-type infections; and they should serve as vectors to express immunogens of other human pathogens.

The construction of these viruses was based on the use of a type 1 HSV, HSV-1(F), as a backbone to avoid the presence of the sequences of HSV-2 reported to be associated with transformation in cell cultures. The genome was deleted in the domain of the viral thymidine kinase gene and in the junction region of the U_L and U_S segments in order to excise some of the genetic loci responsible for neurovirulence as well as to create convenient sites and space within the genome for insertion of other genes. Finally, a type 2 HSV DNA fragment encoding the HSV-2 glycoproteins D, G, and I was inserted in place of the internal inverted repeat. The purpose of the type 2 genes was to broaden the spectrum of the immune response and to create a chimeric pattern of antibody specificities. The resulting recombinant, designated as R7017, was further altered by insertion of the thymidine kinase gene next to the HSV-2 DNA fragment (R7020). Because this virus expresses thymidine kinase, it is susceptible to antiviral chemotherapy with acyclovir. When analyzed by restriction enzyme digestion, the DNA of the recombinants has a unique pattern that facilitates their unambiguous identification.

When evaluated in rodent models, the two constructs appeared considerably attenuated in their pathogenicity and ability to establish latency and were capable of inducing protective immunity. The recombinants did not regain virulence, nor did they change DNA restriction enzyme cleavage patterns when subjected to serial passages in the mouse brain (336). It is remarkable that the thymidine kinase–negative virus R7017 behaved similarly to the thymidine kinase–positive virus R7020.

These results were corroborated by studies in owl monkeys (*Aotus trivirgatus*) (380). Although administration of 100 plaque-forming units of wild-type virus by peripheral routes was fatal to the monkeys, recombinants given by various routes in amounts at least 10^5-fold greater were innocuous or produced mild infections, even in the presence of immunosuppression by total lymphoid irradiation (307).

When R7020 was evaluated in humans in a reactogenicity study, human immune responses were elicited at low levels (73). Unfortunately, production difficulties precluded the development of higher dosages of vaccine.

The application of these principles to HSV-2 constructs has been undertaken and assessed in animal models (478). The definition of the $g_1$34.5 gene of HSV-1 as a mediator of CNS replication provides a potential vaccine construct (92,547). Furthermore, deletions of $g_1$34.5 significantly decrease the ability of this construct to establish latency (547). Because a homologous $g_1$34.5 gene exists in HSV-2, the opportunity to create an HSV-2 vaccine exists. Other creative approaches to the manipulation of HSV are underway for vaccine development (144,307,355,478).

More recently, a vaccine deleted in gH has been studied in phase I studies in the United Kingdom. This vaccine, known as the HSV-DISC vaccine, undergoes a single cycle of replication. Because gH is deleted, no further replication is possible. The results of this phase I study have not been reported at this time.

CONCLUSION

Tremendous progress has been made in our understanding of the molecular biology, natural history, and therapy of HSV infections; however, it is apparent that a great deal remains to be learned. The molecular pathogenesis of these infections, along with the prevention of resultant disease by means of molecularly derived vaccines, remains a principal goal for future research efforts. The prevention of HSV disease remains a high priority, especially in light of the failure of one of two subunit vaccines. Furthermore, as we learn about the role of HSV infection in programmed cell death, new avenues of advance will occur. One such avenue is the use of HSV and its genes for the treatment of brain tumors (295,296).

CHAPTER 74 Epstein-Barr Virus and Its Replication

Elliott Kieff and Alan B. Rickinson

CLASSIFICATION

Epstein-Barr virus (EBV) was discovered in 1964 (192). Beginning in the 1940s, Denis Burkitt, a British missionary surgeon, observed and treated children with previously undescribed extranodal lymphomas. He noted that the lymphomas were frequent in regions of equatorial Africa with holoendemic malaria and rarely occurred elsewhere. Burkitt wrote and spoke widely about the unusual epidemiologic and clinical features of this lymphoma, raising the specter of an infectious etiology (81). After hearing Burkitt speak about this new disease at Bristol University, Tony Epstein arranged collaborations to obtain tumor biopsies and succeeded in culturing the lymphoma cells. Epstein, Achong, and Barr identified a herpesvirus in electron micrographs of the tumor cells growing in culture. They showed that the virus differed from the known human herpesviruses in being unable to replicate in other cultured cells and in being nonreactive with antibodies to other known human herpesviruses. EBV became the first candidate human tumor virus.

EBV is now the prototype of the gamma subfamily of potentially oncogenic herpesviruses. The gamma herpesvirus subfamily includes both the gamma 1, or *Lymphocryptovirus* (LCV), and gamma 2, or *Rhadinovirus* (RDV), genera. EBV is the only human LCV, and the recently discovered Kaposi's sarcoma–associated herpesvirus (KSHV) is the only human RDV (93). Herpesvirus saimiri (HVS), an RDV that was discovered in New World primates and found to cause lymphomas in experimental infection, was the previous prototype RDV (10). Many Old World primate species have their own endemic LCV, and recent evidence suggests that some New World primate species also have endemic LCVs (61, 207, 244, 246, 313, 457, 474, 676). In contrast, RDVs have been identified not only in many primate species but also in many subprimate mammalian species (9, 11, 188, 858). At this stage of accumulation of LCV and RDV DNA sequences, RDV DNAs are more diverse than LCV DNAs. The endemicity of RDVs in a broader range of mammalian species and their greater genome divergence are evidence that RDVs evolved earlier than the LCVs. Given the many similarities of the LCV and RDV genomes and the restriction of LCVs to primates, LCVs are likely to have evolved from an early primate RDV. This would explain the presence of LCVs only in primates.

The LCV genomes are very similar to each other in structure and gene organization. In general, their DNAs are composed of colinearly homologous sequences. The EBV genome organization is shown in Figure 1 and compared to that of KSHV. The schematic diagram is based on the published analyses of KSHV DNA sequences. The LCVs share structural features such as similar 0.5-kbp terminal (TR), 3-kbp internal (IR1), and short internal (IR2, IR4) tandem direct repeats (142, 143, 313, 314, 316, 474, 714). The LCV open reading frames (ORFs) also encode colinearly homologous, antigenically related, structural and nonstructural proteins (384, 648, 690).

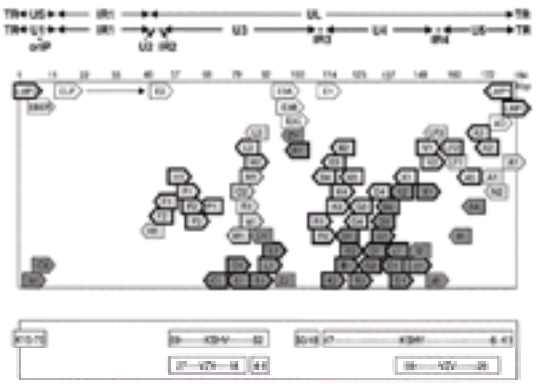

FIG. 1. Schematic depiction of the linear EBV genome, and comparison with the genomes of KSHV (712) and VZV (154, 155). At the *top* of the figure, the terminal repeat (TR), internal repeat (IR1-4), and the largely unique sequence domains (U1-U5) of the EBV genome are depicted in proportion to their overall size. The position of the cis-acting element for episome maintenance and replication in latent infection, oriP, is indicated. The origins for EBV DNA replication in lytic infection are in U3 and U5 just to the right of IR2 and IR4. The P3HR-1 EBV strain is deleted for DNA between 45 and 52 kbp in the indicated map. EBV open reading frames (*ORFs*) are indicated based on the size of the encoding *Bam*HI fragment (A, B, C, etc., in decreasing size), using the convention of Barrell et al. (36, 209). The origins and direction of the reading frames are indicated in the *large panel* according to scale. However, the size of the text box

and end of the ORFs are not to scale. ORFs expressed in EBV latent infection are in *clear text boxes*, immediate-early in *dark gray*, early in *light gray*, and late in *medium gray.* ORFs that are conserved in KSHV are indicated by *thick outline* and by blocks shown in the *lower panel.* The numbers in the lower panel refer to homologous ORFs of KSHV (712) r VZV (154), which are displayed by their corresponding EBV map location.

LCV genomes include genes that are shared by most herpesviruses, genes that are shared among gamma herpesviruses but not with other herpesviruses, and a number of genes that are characteristic only of LCVs (see Fig. 1). The genes that are shared with most herpesviruses include genes that encode for proteins that are involved in nucleotide metabolism, genes that encode for proteins that replicate viral DNA, genes that encode for proteins that comprise the structural components of the virion, and genes that encode for proteins that package viral DNA, modify the infected cell, and enable the virus envelope to fuse with the cell membrane. Despite base compositions ranging from 43% guanine plus cytosine for varicella-zoster virus (VZV) to 71% guanine plus cytosine for herpes simplex virus (HSV), herpesvirus DNAs have large regions with colinear, distant homology at the predicted protein level (see Fig. 1) (36,154,155,442). For example, one large conserved domain, homologous to VZV ORFs 28 to 59 (see Fig. 1), encodes for the major DNA binding protein, DNA polymerase, glycoprotein (gp) B (gB), thymidine kinase (TK), and gH. Similarities notwithstanding, base-pair conservation even in the homologous domains is inadequate to permit EBV DNA to hybridize to the homologous HSV, VZV, cytomegalovirus (CMV), or even KSHV DNAs. Furthermore, antigenic cross-reactivity between EBV and other human herpesviruses is rare, even among proteins encoded by the most conserved genes. The genes that are shared among the gamma herpesviruses and have more limited or less obvious representation in the genomes of other herpesviruses include genes that encode several immediate-early or early regulators of viral gene expression, an antiapoptotic Bcl-2 homolog, and two integral membrane proteins that in EBV are designated LMP1 and LMP2. LCVs and RDVs also have analogous, but nonhomologous, cis-acting DNA sequences and transacting nuclear proteins that are necessary and sufficient for persistence of the genomes as episomes in dividing cells (41,910). The genes that are well conserved among only LCVs include a set of genes that encode nuclear and integral membrane proteins that are important for latent B-lymphocyte infection and cell growth transformation, genes that encode two small nonpolyadenylated RNAs, genes that encode an interleukin (IL)-10 homolog, and a gene that encodes a glycoprotein that binds to a B-lymphocyte surface protein, CD21.

Overall, the LCV and RDV genomes are much more closely related to each other than to the genomes of the alpha or beta herpesviruses (36,154,155,712). Of the 75 KSHV predicted ORFs, 54 are colinearly homologous to ORFs of EBV (see Fig. 1). Only one of these 54 is out of place relative to its position in EBV. The mean amino acid identity to EBV among the 54 KSHV ORFs is 35%, with only two less than 21%.

Nevertheless, LCV and RDV are clearly distinct genera. The sequence homology between EBV and KSHV is insufficient to detect significant cross-reactive antibody or T-cell responses. Primates including humans can be persistently systemically infected by viruses of both genera. Whereas LCVs are able to efficiently immortalize B lymphocytes of their natural host, RDVs lack similar activity. At the genome level, RDVs have very highly reiterated terminal direct repeats and lack long internal direct repeats. Most RDVs have a common set of cellular genes that include dihydrofolate reductase, interferon regulator factors, G-protein coupled receptors, chemokine analogs, and a cyclin homolog, none of which have been found in LCVs.

The gamma herpesvirus subfamily classification was initially established not on the basis of similarity in genome organization but on the basis of similarity in biologic properties. EBV and KSHV have particularly limited host ranges for *in vitro* infection and are associated with human malignancies. Much of the interest in these viruses is because of their association with cancer. These and other gamma herpesviruses also establish latent infection in lymphocytes, but they are not unique in this regard; beta herpesviruses such as HHV-6, HHV-7, and CMV latently infect lymphocytes. Although the oncogenic properties of LCVs and RDVs were historically important in segregating them into the gamma herpes subfamily, the nucleotide and protein sequence relationships provide a more enduring basis for phylogenetic classification.

Taxonomists have renamed EBV as human herpesvirus 4 (HHV4). Although most authors still use the name EBV, some indexing services have adopted HHV4, so both entries should be used when doing bibliographic searches.

VIRUS STRUCTURE

Like other herpesviruses, EBV has a toroid-shaped protein core that is wrapped with DNA, a nucleocapsid with 162 capsomeres, a protein tegument between the nucleocapsid and the envelope, and an outer envelope with external glycoprotein spikes (172,173,192,659). The major EBV capsid proteins are 160, 47, and 28 kd, similar in size to the major HSV-1 capsid proteins (172,173). EBV has a range of envelope glycoproteins, including several that are homologs of relatively well conserved herpesvirus glycoproteins. These include homologs of HSV gH, gL, gB, gM, and gN, which are also known as EBV gp85 or BXLF2, gp25 or BKRF2, gp110 or BALF4, gp84/113 or BBRF3, and gp15 or BLRF1, respectively. However, the most abundant EBV envelope and tegument proteins are 350/220 and 152 kd, respectively, and these are not homologous to major envelope and tegument proteins of HSV-1 (172,173,597,668,669,820,822).

GENOME STRUCTURE

The EBV genome is a linear, double-stranded, 184-kbp DNA composed of 60 mole percent guanine or cytosine (see Fig. 1) (36,142,253,254 and 255,379,405,662,663,673). The characteristic features of EBV and most other LCV genomes include the following (see Fig. 1): (a) a single overall format and gene arrangement (142,147,253,254 and 255,671); (b) tandem, reiterated, 0.5-kbp direct repeats of the same sequence at both termini (TR) (255,304,430); (c) six to 12 tandem reiterations of 3-kbp, internal direct repeats (IR1) (103,104,253,254,305), and (d) short and long, largely unique sequence domains (U_S and U_L) that have almost all of the genome coding capacity. Although largely unique DNA, U_L and

U_S include perfect and imperfect tandem DNA repeats, most of which are within ORFs. A duplicated region, D_L, near the left end of U_L, consists of multiple, highly conserved, G-C-rich, tandem 125-bp repeats and 2 kbp of adjacent unique DNA, all of which have extensive homology to the D_R region, near the right end of U_L. D_R consists of multiple, highly conserved, G-C-rich, tandem, 102-bp repeats and 1 kbp of nearby unique DNA (149,311,313,314,316,351,378,463). The D_L and D_R repeats are within ORFs. Because the D_L repeat is 125 bp and not divisible by three, sequential iterations are translated in different reading frames, resulting in an unusual protein. D_L and D_R also include the origins for initiation of viral DNA replication in lytic infection.

The reiteration frequency of the EBV tandem perfect repeats becomes variable during viral DNA replication, with the average number of repeats being identical to the parent genome, and most of the progeny having a number of repeats that is identical or similar to that of the parental genome. When EBV infects a cell, the genome becomes an episome with a characteristic number of TRs, dependent on the number of TRs in the parental genome, with variation introduced during viral DNA replication and the unique cleavage and joining events of the single infecting viral genome. If the infection is nonpermissive for viral replication and permissive for latent infection and continued cell growth, each EBV episome in progeny infected cells will usually have the same number of TRs as the parent cell. Homogeneity or heterogeneity in the number of TRs is therefore useful in determining whether a group of latently infected cells arose from a single common progenitor infected cell or from multiple progenitors (76,674). The number of 3-kbp IR1 repeats also varies among EBVs and among progeny of EBV replication, but this is more difficult to assess as a marker of heterogeneity because of the 18- to 30-kbp size of the total IR1 element. Other, smaller, imperfect or less highly reiterated repeats within ORFs are more stable during replication but differ sufficiently among different virus isolates that the size of the encoded proteins can be used to uniquely identify each isolate.

Because of the limited host range for EBV replication *in vitro* and the difficulty in obtaining large amounts of viral DNA for molecular biologic investigation, EBV was the first herpesvirus whose complete genome fragments were cloned into *Escherichia coli* (33,77,142,216,656,673). EBV was also the first herpesvirus to be completely sequenced (36,301,632). Since the EBV genome was sequenced from a *Bam*HI fragment library, genes, promoters, ORFs, and polyadenylation sites are frequently referenced to the corresponding *Bam*HI fragment (36). Thus, the EBV DNA polymerase gene is frequently referred to as BALF3 for *Bam*HI A fragment, third leftward ORF. Exons of spliced mRNAs are also frequently designated by the *Bam*HI DNA fragment that encodes the exon.

Two EBV types circulate in most populations. The two types are now usually designated 1 and 2, although A and B were widely used in the past. Type 1 is far more common in most populations. EBV type 2 is nearly as common as type 1 in equatorial Africa and New Guinea, and it is also not infrequent among people infected with human immunodeficiency virus (HIV) (4,30,144,147,206,288,311,419,426,549,710,725,740,741,761,901,903,904,920). The only significant differences between the genomes of the two types are in the genes that encode for the EBV nuclear proteins [or antigens (EBNA)] LP, 2, 3A, 3B, and 3C. The type 1 and 2 alleles for EBNA-2, -3A, -3B, and -3C differ in predicted primary amino acid sequence by 47%, 16%, 20%, and 28%, respectively (4,144,723). EBNA-LP differs less overall (144,381). Other than these differences, the genomes of various isolates of type 1 or type 2 EBV strains from widely different geographic areas have single base changes and repeat reiteration frequency differences from prototype genomes, with an overall difference in nucleotide sequence between type 1 and type 2 isolates outside of the EBNA-LP, -2, -3A, -B, or -3C ORFs of less than 4%. Differences among individual type 1 or type 2 isolates are more in the range of 1% (266,267 and 268,269,288,419,549). Similarities in the numbers of DNA repeats at various sites in the EBV genome among EBV isolates from a given geographic area have been used to group isolates into strains and to epidemiologically track EBV infection. Similar strain variations have been noted among both type 1 and type 2 isolates, consistent with the notion that these polymorphisms evolve regularly in nature. Persistent infection with more than one EBV type or strain is not unusual, particularly for more promiscuous and immunocompromised people. Intertypic recombinants have been identified in the oropharynx and lymphocytes of immunocompromised people and less commonly from otherwise healthy people (5,266,269,288,419,549,761,860,861,862 and 863,901,903).

GENERAL ASPECTS OF EBV INFECTION OF CELLS *IN VITRO*

The *in vitro* host range for efficient EBV infection is restricted to primary human B lymphocytes (323,660). EBV readily infects B lymphocytes derived from peripheral blood, tonsils, or fetal cord blood (29,319,403,697,883,897,921). B lymphocytes at earlier stages of development from adult or fetal bone marrow or fetal liver, as well as leukemic and non-EBV-infected Burkitt's lymphoma (BL) cell lines, can also be infected, although the efficiency of infection is lower than with peripheral blood (20,35,85,87,175,195,294,435,528,529,815). Fully differentiated plasma cells cannot be infected. The outcome of infection of primary human B lymphocytes with EBV is nonpermissiveness for virus replication and conversion of the infected cells to continuous proliferation into long-term lymphoblastoid cell lines (LCLs) (323,660). The seminal observation that latent EBV infection efficiently causes perpetual B-lymphocyte proliferation was critically important in establishing that EBV has oncogenic potential (323,563,607,608,660).

EBV can also establish latent infection in other cell types, including T or natural killer (NK) cells, although the efficiency is low, even compared to non-EBV-infected BL cells, which are usually 10-fold less susceptible to infection than primary B lymphocytes (397,398,745). Primary epithelial cells (763,918) are also relatively resistant to infection, whereas some epithelial cell lines, including HEK293 (213), gastric carcinoma cell lines (916), and biliary, laryngeal, hepatocellular, colon, and bladder carcinoma cell lines (365), can be infected with efficiencies that approach those of BL cells.

Wild-type virus can be obtained from human saliva or from infected human B lymphocytes growing in culture. Most adults have been infected by EBV and intermittently shed virus in saliva (245,902). They also have EBV in a latent state in approximately 1 in 10^5 to 10^6 of their peripheral blood B lymphocytes (608). When 10^6 to 10^7 peripheral blood B lymphocytes from an EBV-seropositive person are put in culture in the absence of functional T lymphocytes, EBV-infected B lymphocytes are likely to grow out, without adding exogenous virus (608,685,821). These cell lines are then a source of infectious EBV. Interestingly, the recovery of EBV-infected cells from such cultures in the absence of exogenously added virus can be blocked by inhibitors of virus replication or the addition of neutralizing antibody (687,819). Explantation to culture can apparently cause a rare EBV infected cell to become permissive for virus

replication. The newly replicated virus can then infect other B cells in the culture, and thereby initiate a latent, immortalizing infection, whereas the *in vivo* latently infected cell cannot spontaneously convert to a transformation type of latent infection. Virtually all cell lines that arise from cultures of normal blood cells are EBV immortalized B LCLs.

EBV infection of primary B cells, *in vitro*, results in about 10% of the cells becoming latently infected and proliferating as immortalized or “transformed” latently infected LCLs (319,783). Virus replication in LCLs is usually minimal or undetectable. The presence of the “latent” virus in each of the infected cells can be readily detected using antibodies to any of the eight different virus proteins that are characteristically expressed in LCLs. The eight viral encoded proteins include six nuclear proteins (the EBNAs) and two integral membrane proteins (the LMPs) (Fig. 2). In this context, the virus genome is hardly inactive and the infection is latent only in the absence of lytic virus infection.

	I	II	III
EBNA-1	Qp	Qp	Wp, Cp
EBNA-2, LP, 3A-C	-	-	+
LMP1, LMP2	-	+	+
EBERs	+	+	+
BARTs	+	+	+
Example	EBV-BL	HD, NPC	LCL, EBV-BL

FIG. 2. Types of EBV latent infection observed in Burkitt's lymphoma (*BL*) cells growing in culture (types I or III), or in nasopharyngeal carcinoma or Hodgkin's disease cells *in vivo* (type II). Type III latency is also characteristic of human B lymphocytes that have been infected with EBV and are proliferating as a consequence of latent EBV infection.

The standard conditions for clonal infection of primary B lymphocytes with EBV are to add less than 50 transforming units of EBV to 10^7 T-cell-depleted lymphocytes, and to then plate the infected cells in 96 wells of a microtiter tray in 0.1 to 0.15 mL of a complete growth medium consisting of the defined constituents of RPMI 1640 (Sigma Chemical Company, St. Louis, MO) and 10% to 20% fetal calf serum. Each infectious virus will give rise to a macroscopically visible cell line by 5 weeks of incubation. The virus titer is usually defined by this most sensitive assay of EBV infection. If the purpose is to study the biochemical events of primary infection, lymphocytes are infected with three transforming units of virus per cell and kept in bulk culture. Higher multiplicities are rarely used because of the practical difficulty of obtaining high-titer EBV preparations. For the cloning of virus or latently infected cells, putatively infected cells are fed every 2 weeks, and the assay is scored after 6 to 8 weeks, by which time an infected cell will usually have multiplied into more than 10^5 progeny cells. The cloning efficiency can be modestly improved by culturing the infected lymphocytes on irradiated human diploid fibroblasts, which enriches the culture conditions beyond those provided initially by the 10^5 uninfected lymphocytes, residual macrophages, and complete growth medium.

In latently infected B lymphocytes, EBV expresses not only the six EBNAs and two LMPs but also two small nonpolyadenylated RNAs (or EBERs) and highly spliced *Bam* A rightward transcripts, or BARTs (see Fig. 2). These viral gene products maintain the latent infection and cause the previously resting B lymphocytes to enter cycle and continuously proliferate. The effect on cell growth is immediate, and most infected B cells enter the first round of cell DNA synthesis 48 to 72 hours after EBV infection (12,594,595 and 596). The target cell that is most amenable to conversion to an LCL has a resting B-lymphocyte phenotype (22).

Aside from the presence of the EBV genome and its gene products, the EBV-infected proliferating B lymphocytes are similar to lymphocytes proliferating in response to antigen, mitogen, or IL4 and anti-CD40 in their expression of a similar repertoire of “activation”-associated proteins, their secretion of immunoglobulin (Ig), their high level of expression of adhesion molecules, and their adherence to each other (42,67,85,86 and 87,363,635,636,785,826,828,867,868 and 869). EBV-infected B lymphocytes may continue to secrete immunoglobulin for months or even years in culture. Some cells can continue to differentiate and undergo class switching in culture when exposed to IL4 (243,373).

Most non-EBV-infected BL cell lines can be infected with EBV *in vitro* (85,87). The growth of non-EBV-infected BL cells *in vitro* is substantially the result of a characteristic reciprocal chromosome translocation involving the c- *myc* and Ig heavy or light chain loci. This results in constitutive c- *myc* expression (141; for review see ref. 531). Other changes are presumed to be necessary for the development of BL *in vivo*, including changes in chromosome 1 (52). Still other genetic changes occur in BL cells during growth *in vitro*. BL cells frequently grow as single cells and can regrow from true single-cell end-point dilution. They are similar to germinal-center B lymphocytes in their expression of surface markers including IgM, and they differ from LCLs in their high-level expression of Bcl-6 and CD10 and low-level expression of activation markers and adhesion molecules. When EBV infects BL cells *in vitro*, the virus usually initially expresses the same program of latency as in LCLs. This type of latency, characteristic of LCLs and marked by the expression of the six EBNAs, two LMPs, two EBERs, and BARTs, is termed latency III (21,271,708) (Fig. 2 and Fig. 3). Latency III EBV gene expression causes the cells to grow in tight clumps, express activation markers, down-regulate Bcl-6 and CD10, and otherwise assume the phenotype of LCLs (1,57,133,134,321,453,527,867,868 and 869,871,873). Over the ensuing months of culture, however, some of the cells may lose the EBV genome and revert to a germinal center BL phenotype. Some BL cell lines, infected with EBV *in vitro* and maintained in culture for several months, remain EBV infected and continue in a latency III phenotype. Others convert to a latency 1 phenotype and express only EBNA-1, EBERs, and BARTs (see Fig. 3). Some BL cells retain the EBV genome as an episome, whereas in other cells, the EBV genome can be integrated into the cell genome (318,361,467,543). Some BL cells with integrated EBV DNA maintain a latency III

phenotype.

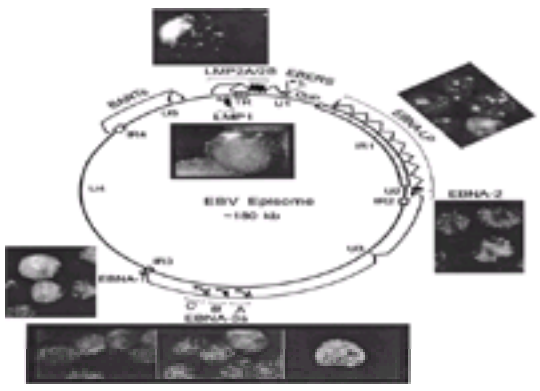

FIG. 3. EBV episome, transcripts, mRNAs, and proteins in type III latent B-lymphocyte infection. Largely unique (U1-U5) and repetitive internal (IR1-4) or terminal (TR) repeat DNA segments are indicated. The origin for latent infection EBV episome replication, oriP, is also indicated. Exons encoding EBV nuclear proteins (EBNA-1, -2, -3A, -3B, -3C, and -LP) and EBV integral membrane proteins (LMP1, -2A, or -2B) are indicated by *vertical lines* radiating from the circular episome map. EBNA transcription is shown as it is first initiated from the IR1 or Wp promoter. In many infected lymphocytes, after expression of EBNA-LP and EBNA-2, the Cp promoter in U1 dominates EBNA transcription. Alternative polyadenylation and splicing lead the various EBNA mRNAs. EBNA-LP is encoded by repeating exons from IR1 and two short unique exons from U2. The EBERs are two small, nonpolyadenylated RNAs transcribed in latent or productive infection. LMP1 is transcribed in the direction opposite to the EBNAs, LMP2A and -B, EBERs, and BARTs. The typical intracellular localizations of the proteins that are known to be expressed in type III latency are shown on the EBV DNA map on the *left.* The proteins are identified by immune fluorescence microscopy using specific antisera. The smaller episome drawing on the *right* shows the terminal exons of the differentially spliced Bam A fragment rightward transcripts that are likely to encode the proteins provisionally designated RPMS1 and BARF0 in all three types of latent infection (234,422,716,766). LMP2A also has an upstream EBNA-2 response element, whereas LMP1 and LMP2B share the same EBNA-2 response element.

As described in Chapter 75, most EBV-infected BL tumors have a latency I phenotype. When these cells are explanted to culture, they initially maintain latency I and express only EBNA-1, EBERs, and BARTs. Paradoxically, on continued culture, many of the *in vivo*–infected BL cells switch to a latency III phenotype and grow in clumps similar to LCLs. Most *in vivo*–infected BL cells never lose their EBV episomes when the cells are grown *in vitro*, whereas BL cells infected *in vitro* may lose their EBV genomes entirely or may have only integrated EBV DNA (361,527,871). The persistence of EBV episomes in most *in vivo*–infected BL cell lines that have been maintained for years in culture is compatible with the possibility that the episome is important for cell proliferation or survival. Cells of other B- or even T-lymphocyte malignancies that can be grown as continuous cells lines *in vitro*, and that express low levels of EBV receptors, usually express only EBNA-1, EBERs, and BARTs when infected with EBV *in vitro*.

With a frequency characteristic of each EBV-infected B-lymphocyte line, some progeny latently infected proliferating cells growing *in vitro* become spontaneously permissive for virus replication. Primary human B-lymphocyte-derived cell lines (LCLs) vary from zero to a few percent of cells permissive for EBV replication. *In vitro*–infected BL cell lines tend to be even less permissive for virus replication, whereas *in vivo*–infected BL cell lines are frequently substantially more permissive for virus replication than LCLs. The lack of permissivity of *in vitro*–infected BL cells for EBV replication is in part related to the poor persistence of EBV episomes in such cells, as lytic replication probably requires episomal viral DNA.

In all instances, permissively infected cells exhibit the characteristic cytopathic changes associated with herpesvirus replication, including formation of an intranuclear inclusion in the center of the nucleus at the site of lytic infection DNA replication, margination of nuclear chromatin, assembly of capsids within the nucleus near the nuclear membrane, budding of virus through the nuclear membrane, and formation of cytoplasmic vesicles containing enveloped virus (189,190,191,192 and 193,261,659). As with other herpesviruses, cell macromolecular synthesis is inhibited early in EBV replication (247).

The frequency with which latently infected lymphocytes become permissive for virus replication can sometimes be influenced by specific culture conditions. Transient exposure to drugs that inhibit host macromolecular synthesis, cell starvation, arginine-free media, inhibition of DNA methylation with azacytidine, exposure to butyric acid (which inhibits histone deacetylase), treatment with phorbol ester to stimulate protein kinase C (PKC), exposure to ionophores (which increases intracellular free calcium), or cross-linking of surface Ig can each increase the permissivity of some EBV-infected cells for lytic infection (45,152,350,464,717,802,804,805,896,898,899).

Analyses of cultures of a latently infected BL tumor–derived cell line that is particularly permissive for virus replication led to the identification of defective EBV genomes in these cultures (332,559,678). The defective genomes express an EBV immediate-early protein, BZLF1 or Z (381,383). The expression of Z following heterologous gene transfer is now frequently used to induce lytic EBV replication in latently infected cells (129,130,264,564). Not all cells in which Z is expressed go on to lytic infection (129).

The most sensitive method for recovering EBV from a latently infected cell line that is largely nonpermissive for virus replication is to lethally irradiate 10^4 induced cells and co-cultivate them with 10^5 primary B lymphocytes in 150 µL of complete medium in a microwell (566,567). This allows maximal contact between the rare cell that becomes permissive for lytic EBV infection and uninfected B lymphocytes. Under such conditions, the irradiated cells also provide feeder

effects and enhance the growth of the newly infected primary B lymphocytes. In the absence of autologous or heterologous feeder cells, EBV-transformed B lymphocytes do not usually regrow from suspensions of single cells in 100 µL of rich growth medium.

The induction of virus replication in latently infected B lymphocytes remains the principal way to study EBV replication. Fortunately, latently infected BL and marmoset cell lines have been identified in which a substantial fraction of the cells can be rendered permissive for lytic virus infection (137,138,333,566,567,802,804,805). These cell lines are essential for studying lytic infection *in vitro*, and they are the best source of EBV for studying virus structure or cell infection. After induction of lytic EBV infection in B lymphocytes in culture, 2 to 3 days are required for maximal late gene expression. Maximal titers of extracellular virus are reached at 4 to 5 days.

Since epithelial cells *in vivo* are fully permissive for lytic EBV infection (606,760), considerable effort has been made to adopt EBV to growth in epithelial organ cultures or transformed epithelial cell lines (763). Primary cultures or even some continuous cultures can be infected, particularly when incubated with cells that are producing virus, but the infection is inefficient and little virus results (759). The efficiency of infection has been slightly improved by expression of the B lymphocyte EBV receptor in an epithelial cell line (481). More cells are infected but the infection is largely abortive. Epithelial cell cultures, especially of HEK293 cells, have recently been useful for EBV genetic studies because of the relative ease of transfection of these adherent cell cultures with plasmid DNAs that include the entire EBV genome. The small amount of virus recovered from such cells can then be expanded in B lymphocytes. Surprisingly, the EBV receptor on some HEK293 cells appears to be the same as the normal B-cell receptor (213).

MOLECULAR BIOLOGY OF VIRAL INFECTION OF CELLS*IN VITRO*

Adsorption

The *in vitro* host range restriction of LCVs to B lymphocytes is partly the result of a restriction in high-level expression of a cell surface protein, CD21, which is an efficient receptor for EBV and for the C3d component of complement (214,456,878,879). Efficient B-lymphocyte infection correlates with the stages of B-lymphocyte development in which CD21 is expressed (364,390). Monoclonal antibodies to CD21 block virus infection (214). Furthermore, purified CD21 binds to EBV and can block infection (604,605). Moreover, CD21 expression on heterologous cells confers the ability to adsorb EBV (6,481). CD21 is an immunoglobulin superfamily glycoprotein, and it consists of 15 or 16 imperfect repeats of a 60-plus amino acid domain, a transmembrane domain, and a short carboxyl-terminal cytoplasmic domain (588,878). EBV binding activity maps to the two amino-terminal domains (537,582,587,604).

The most abundant EBV outer envelope glycoprotein, gp350/220, is the CD21 ligand (602,603,810,811,880). Gp350 and gp220 are translated from abundant late-replication-cycle nonspliced and spliced mRNAs that are transcribed from the same gene (50). CD21 is the only B-lymphocyte surface protein that binds to gp350/220 (810). The gp350/220–CD21 binding affinity is 1.2×10^{-8} M (811). Soluble gp350/220 can saturate B-lymphocyte receptors and block virus infection, confirming a key role for gp 350/220 in virus adsorption (604,811). A gp350/220 peptide sequence EDPGFFNVEI is similar to the peptide sequence EDPGKQLYNVEA through which the C3d component of complement binds to CD21. Peptides containing the LYNVEA C3d sequence block C3d binding to CD21 (456), and peptides containing the EDPGFFNVEA sequence block EBV infection (602), whereas mutant gp350/220 molecules that lack VE in the EDPGFFNVE peptide do not bind to CD21 (811). The EBV receptor on epithelial cells that lack CD21 has not been identified, in part because of the less efficient adsorption of EBV to primary or continuous epithelial cell lines than to B lymphocytes. Recently, the derivation of a virus that has an insertion into gp350/220 codon 79, which should functionally inactivate gp350/220, has resulted in a virus that can still infect B lymphocytes and epithelial cells, albeit with reduced efficiency. This indicates that gp350/220-mediated adsorption to CD21 is not absolutely required for lymphocyte or epithelial infection (375).

Penetration and Uncoating

Wild-type EBV infection of primary B lymphocytes is initiated by gp350/220 adsorption to CD21 on the B-lymphocyte plasma membrane, aggregation of CD21 in the plasma membrane, and internalization of EBV into cytoplasmic vesicles (91,601). CD21 is part of a complex that includes CD19 and associated intracellular tyrosine kinases, similar to the surface Ig (sIg)–associated signal transducing cell surface proteins. EBV aggregation of CD21 probably results in CD21-mediated tyrosine kinase signal transduction, and this may have an activating effect on the B lymphocyte (536,541). Infected cells begin to synthesize RNA, enlarge, express activation and adhesion molecules, clump, and secrete Ig soon after exposure to virus (12,24,363,810). CD21 ligation also increases NF-kB activation and may up-regulate the EBNA Wp promoter at the start of EBV infection (782). The precise role of these effects in initial infection is somewhat uncertain, because inhibitors of cell protein synthesis, of tyrosine kinases, or of PI3 kinase do not block initial EBNA RNA transcription (756).

The EBV gH homolog, gp85, is the second most abundant envelope glycoprotein (177,178,310,779). EBV gp85 is part of two virion glycoprotein complexes: a heterodimeric complex with the EBV gL homolog, gp25, a product of BKRF2, and a heterotrimeric of gp85, gp25, and gp42, the product of BZLF2. EBV gL is all that is necessary for gp85 processing (666,905). Studies with a monoclonal antibody to gp85 that does not affect virus adsorption to B lymphocytes but that blocks EBV envelope fusion with B lymphocyte membranes, provided an initial indication that gp85 is particularly important in envelope fusion with cellular membranes (289,480,568). This role of gp85 is similar to that of HSV-1 gH, which mediates envelope fusion with the cell membrane and thereby enables nucleocapsid exocytosis into the cytoplasm (260).

The heterotrimeric complexes of EBV gH/gL and gp42 (905) have a unique role in mediating a coreceptor interaction in B lymphocyte infection by gp42 engagement of human leukocyte antigen (HLA) class II, D_R, D_P, and a subset of D_Q alleles (286,287,479,581,776,875,876). Epithelial cells do not express HLA class II, and antibody to gp42 blocks B-lymphocyte infection but not epithelial infection (480). The lack of effect of gp42-specific antibody on epithelial infection suggested

the possibility that gp42 has an insignificant or different role in epithelial infection. Recent studies with an EBV recombinant that does not express gp42 confirm a key role for gp42 in efficient B-lymphocyte infection and a noncritical role in epithelial cell infection (581,875,876).

EBV gH and the gH/gL heterodimer have still another role in epithelial infection. An EBV recombinant that does not express gp85 adsorbs normally to B lymphocytes and is not only deficient in fusion with B-lymphocyte membranes but is unable to adsorb to epithelial cells (581,623). These latter studies confirm the importance of gp85 in fusion with B-lymphocyte membranes and indicate a unique role for gp85/gp25 dimeric complexes in interaction with a putative epithelial cell receptor or coreceptor.

Early Intracellular Events in Infection

Little is known about EBV capsid dissolution, genome transport to the cell nucleus, or DNA circularization. By analogy with other DNA viruses that replicate in the nucleus, the cytoskeleton is likely to mediate EBV capsid transport to the nucleus or to nuclear pores (140). A protein similar in size to the HSV virion tegumentary protein VMW 65, or VP16, has been detected in purified EBV preparations and remains associated with cells after infection (12). HSV VP16 is a key trans-inducer of immediate-early lytic virus gene expression (see Chapter 73). The EBV BPLF1 ORF is colinearly 30% homologous to the HSV VP16 ORF. EBV BPLF1 could therefore be a transactivator of lytic EBV replication in epithelial cells. The role of BPLF1 in lymphocyte infection is even less predictable. The initial latent infection promoter, Wp (12,721,773,855), has high constitutive activity in B lymphocytes (852).

The first evidence that herpesvirus genomes circularize in infected cells arose from the observation that almost all EBV-infected cells contain covalently closed circular EBV episomes (3,496). In primary B lymphocytes, EBV genome circularization precedes or coincides with earliest virus gene expression and may require activation from G0 to G1 (12,363). Whether the putative viral protein that recognizes EBV TR for cleavage and packaging (see later section, Late Gene Expression, Cleavage, Packaging, Envelopment, and Egress) facilitates the joining of the linear virion EBV TRs to produce genome circularization is not known. A cellular protein complex that includes Sp1 has also been identified that can recognize the ends of the DNA and could be involved in genome circularization (790,791). By 16 hours after infection, each infected cell contains one EBV episome. In some experiments, the addition of inhibitors of DNA, RNA, or protein synthesis to cells at the time of infection blocked genome circularization, indicating that active cell macromolecular synthesis is required for circularization. Inhibition of infected cell protein synthesis does not, however, prevent viral gene transcription (756).

Latent Infection in Primary B Lymphocytes and Growth Transformation

Viral Gene Expression in Latent Infection

EBV infection of primary human B lymphocytes *in vitro* results in type III latency (see Fig. 2) and transformation of the infected cell into a proliferating lymphoblast capable of long-term growth as an LCL. In defining the genes expressed in latent infection, it is important to recognize that most latently infected cell cultures have a small number of cells that are spontaneously permissive for virus replication. Since virus gene expression in lytic infection is at a much higher level than in latent infection, lytic-cycle RNAs or proteins are frequently detectable in predominantly latently infected B-cell lines. Proof that an EBV gene is expressed in latent infection requires the demonstration that the specific virus gene product is in most latently infected cells in a culture. This has usually been accomplished by defining an mRNA sequence whose abundance is not affected by the number of permissively infected cells (212,317,427,428,852,853), deriving monospecific antibody to the putative protein product using heterologous antigen expression systems (324,325,326,327,328 and 329,511,650,651 and 652,870) or peptide synthesis (169,170 and 171), and using the antibody to identify the protein in latently infected cells by immune microscopy (324,325,327,329,511,650,652,870).

The time course of events in *in vitro* primary B-lymphocyte infection varies somewhat, depending on the virus inoculum and the physiologic state of the lymphocytes. The EBV genome circularizes in the infected cell nucleus within 12 to 16 hours of infection (see Fig. 3). At about the same time, the Wp promoter in the 3-kbp, Bam or IR1, long internal direct repeat element initiates rightward transcription (12,16,362,594,595,702). The B-cell specificity of the W promoter derives at least in part from the presence of upstream BSAP/Pax5 sites (830). As is true of the other herpesviruses, EBV does not encode an RNA polymerase, and host cell RNA polymerase II transcribes viral mRNAs. By nuclear run-on or transient transfection analysis, the initial EBNA promoter, Wp, and the more upstream promoter, Cp, which is activated by EBNA-2, are the strongest EBV pol II promoters in latent EBV infection (719,720,852). The promoter in the leftmost repeat appears to dominate, as most of the EBNA cDNAs have multiple exons from downstream copies of the W repeat (62,63,64,65 and 66,719). The simplest model for the domination of the leftmost W repeat element is a positive transcriptional element in the upstream U1 region (see Fig. 2).

Wp promotes the transcription of the first EBV mRNAs, and these are differentially spliced to encode EBNA-LP and EBNA-2, two proteins that coordinately up-regulate transcription from viral and cellular promoters, including Wp and an activatible upstream surrogate, Cp (66,198,886,887 and 888). The initial mRNAs have a 40-base first exon, W0, which ends with an AT (12,721). The W0 exon is spliced to a 66-base W1 exon or to a 5' 5-base truncated W01 exon. The W01 exon begins with a G, creating a translational start site, whereas the W1 exon has no translational start site. The W1 exons are followed by a 132-base W2 exon, by repeating 66-base and 132-base W1W2 exons derived from successive reiterations of the long internal repeats, by two short exons, Y1 and Y2, and then by one long exon (YH) from the unique DNA (Bam Y and H) downstream of Bam W long internal repeats (see Fig. 3) (12,719,870). The resulting mRNAs translate either EBNA-LP from the W01 translational start site or EBNA-2 from a translational start site near the 5' end of the YH exons of those alternatively spliced RNAs that lack the W01 translational initiation site. EBNA-LP derives its name from the fact that it is a nuclear protein encoded by the potential 5' ORF in the leader of the EBNA-2 mRNA.

The efficient translation of EBNA-2 from only those mRNAs that lack the EBNA-LP translational start site and therefore have a long untranslated 5' leader is surprising, because 40s ribosomal subunits usually associate with mRNAs at the 5'

cap and then move along the untranslated leader without a stabilizing 60s subunit, until either disengaging or encountering a translational initiation codon (444). Translation of the 5' EBNA-LP ORF would be expected to stabilize mRNA interaction with the ribosome and yield more efficient translation of the 3' EBNA-2 ORF. Although expected, an independent ribosome entry sequence upstream of the EBNA-2 ORF has not been defined, and this enigma has not been resolved.

EBNA-LP and EBNA-2 reach the level that is maintained in transformed B lymphocytes (LCLs) by 24 to 32 hours after infection (12). EBNA-2 has a well-characterized role in up-regulating virus and cell gene expression, including expression of the virus-encoded EBNAs, LMP1 and LMP2, and the cell-encoded CD23, CD21, c-*fgr*, and c-*myc* proteins (Fig. 4) (1,12,127,199,200,437,844,865,867,868,870,871,925,930). Up-regulation of CD23, CD21, and c-*fgr* is observed following transient or stable expression of EBNA-2 in non-EBV-infected BL cells. C-*myc* expression is also up-regulated in primary B-lymphocyte infection at the time that EBNA-LP and EBNA-2 are expressed, and c-*myc* expression is continuously dependent on EBNA-2 expression (12,394). EBNA-2 also up-regulates various LMP1 (1,199,388,764,848,873), LMP2 (460,461,930,931), and Cp (322,386,498,499,793,895) promoter constructs following transient transfection with an EBNA-2 expression vector into non-EBV-infected B-lymphoma cells.

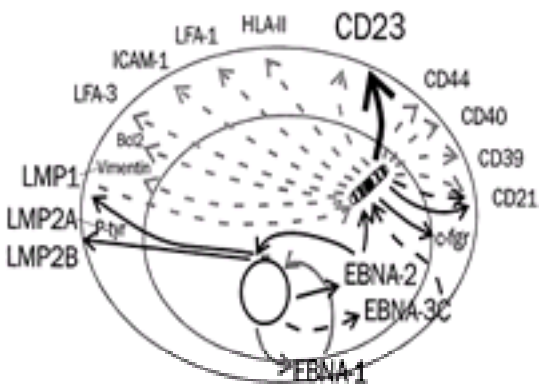

FIG. 4. Expression of EBNAs or LMPs in BL lymphoblasts provides indications of the biochemical mechanisms by which these proteins effect changes in lymphocyte growth or survival. EBNA-1 binds to oriP and to chromosomes and enables the EBV episome to partition to progeny cells. EBNA-2 specifically up-regulates cellular CD23, CD21, c-*myc*, and c-*fgr* expression and viral EBNA, LMP1, and LMP2 expression. EBNA-3C can also up-regulate CD23 expression, although the effects are much less than those of EBNA-2. LMP1 patches in the cell plasma membrane where it is associated with and induces higher level expression of vimentin. LMP1 has dramatic effects on BL cell growth; it functionally activates homotypic adhesion; it up-regulates ICAM 1, LFA 1, and LFA 3; it up-regulates bcl2; it raises the lymphocyte intracellular free calcium; it up-regulates activation markers including transferrin receptor, HLA-II, CD21, CD23, CD39, CD40, and CD44; and it down-regulates CD10 and bcl-6. LMP1 also alters lymphoblast TGF-beta responsiveness. Each of these effects is cell-line dependent, and most effects are not evident in all BL cell lines. LMP2A constitutively activates B-cell receptor tyrosine kinase signalling pathways at a low level and desensitizes B lymphoblasts to further B-cell receptor–type tyrosine kinase signal transduction.

EBNA-2 has three critical components to its transcriptional up-regulating effects (see Fig. 3) (125,296,842,894). First, the specificity of EBNA-2 effects on certain virus and cell promoters and not others is caused by an EBNA-2 domain that interacts with cell-sequence-specific DNA binding proteins (125,276,322,388,895). The repertoire of cellular transcription factors includes RBP-Jk, a transcription factor expressed in all cells (276,322,895), and PU.1, a hematopoietic transcription factor that is particularly important in B lymphocytes (388). Second, once it is near promoter sites, EBNA-2 has an acidic activating domain that recruits basal and activation-associated transcription factors, including transcription factor IIB (TFIIB), TAF40, TBP, transcription factor IIH (TFIIH), and CBP/p300 (123,124,839,840 and 841,874). Much of the EBNA-2 acidic domain is complexed with a cell nuclear protein, p100, that has coactivating effects with EBNA-2 (840). P100 is a scaffolding protein for the acidic domain, for TFIIE, for c-*myb*, and for PIM-1. Third, efficient assembly of multiple transcription factors at promoter sites appears to require multiple EBNA-2 acidic domains. EBNA-2 has two separate domains in its amino terminus that can mediate homotypic association, thereby enabling EBNA-2 to assemble multiple transcription factors near a promoter that has RBP-Jk or PU.1 sites (894). The ability of EBNA-2 to self-associate may account for the large size of EBNA-2 complexes in cell extracts.

Because EBNA-LP is transcribed along with EBNA-2 at the initiation of EBV infection in primary B lymphocytes and because it is a nuclear protein, it is a prime candidate for cooperation with EBNA-2 in the regulation of virus and cell gene expression (see Fig. 4). Indeed, EBNA-LP substantially enhances EBNA-2 up-regulation of virus and cell gene transcription (295,609). The effect is evident in transient expression assays with artificial LMP1 promoter constructs and with endogenous LMP1 expression in EBV-infected BL cells that are otherwise in latency I and fail to express LMP1 until EBNA-2 and EBNA-LP are coexpressed in these cells following gene transfer. EBNA-LP has no promoter-specific effects alone and stringently requires EBNA-2 for activation of specific promoters. Surprisingly, the EBNA-LP effect requires only the EBNA-2 acidic domain near a promoter site and expression of the repeating domains of EBNA-LP (295). Thus, EBNA-LP is likely to biochemically interact with the EBNA-2 acidic domain or with another factor that binds to the acidic domain.

Probably as a consequence of EBNA-2 effects on a response element in the unique DNA in the EBV Bam C fragment that is upstream of the long internal repeat, EBNA promoter usage in many EBV-infected primary B lymphocytes moves from Wp to the nearby Cp latency promoter (295,386,789,882,885,914). In those cells in which the Cp promoter is turned on and supplants Wp, two short exons downstream of the Cp promoter, C1 and C2, replace the short W0 exon in the EBNA mRNAs (66). As with the W0 exon, the C2 exon ends in an AT that is spliced to either the 66-base or the 61-base internal-repeat-derived exon, W1 or W01, resulting in an mRNA leader incapable or capable, respectively, of translating EBNA-LP. All resulting C- or W-initiated mRNAs have the same repeating 66- and 132-base exons in their leader

(62,63,64,65 and 66,387,653,699,721,773). A potential splice donor near the beginning of the EBNA-2-encoding YH exon but preceding the EBNA-2 initiation codon is now activated in some transcripts, and some RNA molecules are spliced to a far downstream acceptor in Bam U (62,65,66,653,721,773). The U exon is then spliced to any of four alternative acceptor sites of exons that begin the ORFs that encode for the amino terminus of EBNA-3A, EBNA-3B, or EBNA-3C, or for EBNA-1 (see Fig. 3). As a consequence of alternate 5' splicing of the Cp- or Wp-initiated RNAs, some mRNAs will still encode EBNA-LP. As a consequence of partial use of the alternative donor site between the beginning of the YH exon and the EBNA-2 initiation codon, some RNAs that do not encode for EBNA-LP or for EBNA-2 are spliced to the U exon and now encode for EBNA-3A, -3B, -3C, or -1 instead of EBNA-2. Alternative acceptor site usage after the U donor site determines the frequency with which transcripts encode EBNA-3A, -3B, -3C, or -1 (see Fig. 2).

The simplest model to explain the turn-on of EBNA-3A, -3B, -3C, and -1 expression is that EBNA-LP and EBNA-2 up-regulation of the EBNA-2 response element upstream of the Cp promoter leads to higher level transcription of the EBNA mRNAs by Cp or by Wp in those cells that do not switch to Cp. In a partial test of this hypothesis, cell lines were derived that were infected with an EBV recombinant that is deleted for the EBNA-2 response element upstream of the Cp promoter. As expected from the model, cells transformed with the response-element-deleted virus were biased toward initial Wp promoter usage relative to cell lines transformed with wild-type virus (915). Not surprisingly, given the need for EBNA-3A, -3C, and -1 for the establishment and maintenance of transformation (469,837), stable EBNA transcripts were not different in cell lines transformed by mutant and wild-type virus. Surprisingly, the mutant virus was not markedly impaired in transformation efficiency (914). A corollary of the model is that Cp dominates over Wp after EBNA-LP and -2 expression, because the EBNA-2 response element is upstream of the Cp promoter and the increased activity of the Cp promoter overrides and interferes with the 3-kb-downstream Wp promoter. In support of this aspect of the model, mutations that down-modulated Cp activity or reversed Cp direction resulted in up-regulation of Wp activity (664).

Whether the net effect of EBNA-LP and -2 is to up-regulate Cp or Wp, increased transcription by either or both promoters probably accounts for transcripts that extend past the polyadenylation site downstream of the EBNA-2 ORF and through the polyadenylation sites downstream of the EBNA-3A, -3B, -3C, or -1 ORFs. Presumably, the efficiency of polyadenylation at each site determines the relative amount of each of these downstream EBNA mRNAs. The subsequent processing of the transcripts is likely to be determined by the characteristics of their polyadenylation sites. The EBNA mRNAs are all at low abundance, with the EBNA-3 or EBNA-1 mRNAs estimated to be several copies per cell.

EBNA-1 expression probably further activates EBNA transcription by enabling EBNA-1 to bind to the EBNA-1-dependent enhancer component of oriP that is 3.5 kb upstream of Cp (241,665,683). The up-regulation of the Cp and Wp promoters first by EBNA-2 and EBNA-LP and then by EBNA-1 would be anticipated to result in unbridled up-regulation of EBNA mRNA transcription were it not for the repressive effect of EBNA-3A, -3B, and -3C expression on transcription mediated by EBNA-2 and EBNA-LP activation of the Cp enhancer (389,534,692,693,864,926). EBNA-3A, -3B, and -3C bind more strongly to RBP-Jk than EBNA-2 and associate with much of the RBP-Jk in the cell. Because the EBNA-3s have no demonstrable positive effects on the Cp enhancer, their net effect is to limit EBNA-2-mediated effects on this element. EBNA-3C has more complicated effects on the LMP1 promoter and can, under certain circumstances, up-regulate LMP1 expression (927).

Concomitant with up-regulation of the Cp and Wp promoters, EBNA-2 and EBNA-LP also up-regulate cell promoters, including c-*myc*, CD23, and the virus LMP1, -2A, and -2B promoters (12). LMP2 transcription is in the same direction as EBNA transcription, and the two LMP2 promoters bracket the LMP1 promoter, with the LMP2A promoter being 3.3 kbp 5' of the LMP2B promoter (see Fig. 3) (462,465,724). LMP2A and -2B transcription are regulated through EBNA-2 response elements upstream of their promoter (925,930). LMP1 transcription is in the opposite direction, and the LMP1 transcript is entirely within the first intron of, and antisense to, the LMP2A transcript (212). The LMP1 promoter upstream regulatory sequence is also the upstream regulatory sequence of the LMP2B promoter. The LMP1 and -2B promoters regulate transcription in opposite directions and are separated by only 266 bases.

LMP2A and -2B differ only in their first exons. The LMP2A first exon is 419 bases and the LMP2B first exon is 167 bases. The LMP2A exon encodes an amino-terminal 120-amino-acid cytoplasmic signaling domain of LMP2A, whereas the LMP2B first exon is noncoding. The remaining LMP2 exons are common to both LMP2A and -2B and are transcribed from U1. By 32 hours after infection of primary B lymphocytes, all EBNA and LMP mRNAs are expressed (12). Cell DNA synthesis follows the onset of LMP1 expression. By 48 hours after primary human B-lymphocyte infection *in vitro*, all of the EBNAs and LMP1 are near the levels that are maintained consistently through latent infection (12,16,362,594,595,700,702).

EBER expression lags by approximately 24 hours and does not reach substantial levels until 70 hours after infection (12). The EBER-1 and EBER-2 RNAs are mostly transcribed by cell RNA polymerase III, although polymerase II may also be involved (32,340,342,376,475,701). The EBERs have typical intragenic control regions common to pol III transcripts and upstream Sp1, ATF, and TATA box elements characteristic of pol II transcriptional sites (342). At steady-state levels in latently infected B lymphocytes, the EBERs are the most heavily transcribed and most abundant EBV RNAs. The EBERs are estimated to accumulate in cell nuclei at about 50,000 copies per cell (32,340,427,428,660,720,842).

The delineation of the highly spliced EBNA and LMP1 transcripts through Northern blot, S1 nuclease mapping, cDNA cloning and sequencing, and nuclear run-on studies explains the observations that latently infected cell nuclei have transcripts from most of the EBV genome, yet cytoplasmic polyadenylated polyribosomal mRNA is much less complex (146,303,306,427,428,628). Nuclear run-on studies indicate that almost the entire rightward or clockwise strand of the genome 3' to the Wp promoter is transcribed, although the rate of transcription drops off somewhat downstream of EBNA-2 and again downstream of EBNA 1 (see Fig. 3) (719). Transcription, per se, does not regulate EBV gene expression. As indicated previously, the differential use of latent infection polyadenylation sites probably determines upstream splicing and thereby regulates synthesis of the six EBNA mRNAs from the same promoter.

Each EBNA primary transcript has multiple copies of IR1 or Bam W–encoded RNA, and each copy has a 500-base segment that can form an extensively base-paired structure (104). This unusual sequence could have a cis-acting role in processing of EBNA transcripts, but such a role has not as yet been identified. Analysis of a defective EBV DNA indicates

that the corresponding DNA sequence can be a site for inversion within the EBV genome (381). This suggests that extensive base-pairing may occur within this nucleotide sequence under physiologic conditions.

Latent Infection Proteins

EBNA-LP

Because the number of copies of the IR1 repeat varies among EBV isolates, and because IR1-derived exons W1 and W2 encode repeating 22- and 44-amino-acid segments of EBNA-LP (Fig. 5), the size of EBNA-LP is frequently different in cells infected by different EBV isolates (169,215,872). The 44-amino-acid repeat domain encoded by W2 exons has two runs of basic amino acids, RRHR or RRVRRR, which are responsible for EBNA-LP nuclear localization (648). Aside from the N-terminal repeat domain, EBNA-LP has a unique 45-amino-acid carboxyl-terminal sequence. EBNA-LP is phosphorylated at multiple sites, probably at least once within each 44-amino-acid repeat, because the number of isoelectric forms varies with the W1W2 exon repeat number (651). The EBNA-LP 44-amino-acid repeat domain has a near consensus casein kinase II serine phosphorylation site. *In vitro*, p34cdc2 can phosphorylate this serine as well as a C-terminal unique serine. Casein kinase II can also phosphorylate only the unique C-terminal serine (433). EBNA-LP is highly phosphorylated in G2/M, consistent with a role for p34cdc2 in phosphorylation of EBNA-LP *in vivo* (433). At the present time, the effects of phosphorylations on EBNA-LP functionality are uncertain.

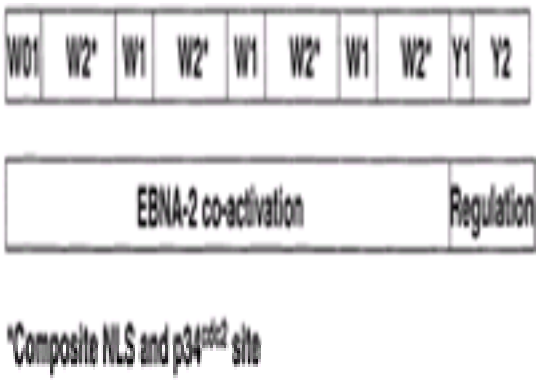

FIG. 5. Schematic diagram of the repeat and unique exon and domain structure of EBNA-LP. The EBNA-LP repeat domain can coactivate transcription mediated by the EBNA-2 acidic domain. The unique carboxyl terminus of EBNA-LP modulates EBNA-LP effects.

EBNA-LP is more associated with the nuclear matrix fraction than the other EBNAs (651). In immune microscopy of LCLs or of non-EBV-infected BL lymphoblasts in which EBNA-LP is expressed alone by gene transfer, EBNA-LP localizes to nuclear dots that correspond to sites of ND10 proteins (800,870). Some EBNA-LP is also diffusely spread through the nucleus. RNA *in situ* cytohybridizations with EBV IR1 DNA reveal similar intranuclear structures (466). These observations suggest the possibility that EBNA-LP could associate with EBNA transcripts and play a role in RNA processing.

EBV recombinant molecular genetic analyses of EBNA-LP have focused on the carboxyl-terminal two exons. Mutations in the repeating exons of EBNA-LP are more difficult to construct. Specific deletion of DNA encoding the carboxyl-terminal two exons, or placement of a nonsense codon at the beginning of the last two exons, has resulted in EBV recombinants that are deficient in primary lymphocyte transformation into LCLs (291,525). In two series of experiments that resulted in many wild-type EBV recombinant LCLs, only two LCLs were obtained that were infected with recombinants that are deleted for the carboxyl-terminal two exons, and these LCLs were deficient for growth. Transfection of one of these LCLs with an expression vector for wild-type EBNA-LP enabled the transfected LCLs expressing wild-type EBNA-LP to grow more rapidly than the LCLs that did not express wild-type EBNA-LP (13). Despite growth of infected primary B lymphocytes on fibroblast feeder layers, the frequency of derivation of nonsense recombinant transformed LCLs was less than 5% of wild-type, and infected cell growth was slower than with wild-type recombinants. One mutant recombinant infected LCL was obtained that had wild-type growth characteristics, and that LCL proved to be infected with a revertant (525). Passage of the deletion or nonsense EBNA-LP recombinants into other primary B lymphocytes further confirmed the reduced transformation phenotype (525). Infection of multiple primary B lymphocytes with higher-titer mutant recombinant virus enabled better outgrowth of LCLs infected with the mutant EBNA-LP EBV recombinants, presumably because of an enabling effect of cross-feeding among the multiple mutant EBV-infected cells (525). The mutant virus–infected LCLs were more highly differentiated toward immunoglobulin secretion, compatible with the possibility that wild-type EBNA-LP inhibits differentiation. In other experiments, transient expression of EBNA-LP and EBNA-2 in primary B lymphocytes co-stimulated with gp 350 resulted in induction of cyclin D2 (755). Thus, overall, these experiments favor the model that EBNA-LP has a key role in up-regulating cell gene expression critical for LCL outgrowth.

The effects of EBNA-LP on cell gene expression are likely to be similar to EBNA-LP effects in strongly coactivating viral promoters with EBNA-2. EBNA-LP coactivates EBNA-2-mediated transcription from the Cp and LMP1 promoters in transient transfection assays with reporter constructs, and it also coactivates EBNA-2 up-regulation of LMP1 expression in latency 1 EBV–infected BL cells (295,609). The EBNA-LP 22- and 44-amino-acid repeat domains have most of the activity of wild-type EBNA-LP, exerting very similar effects on EBNA-2 up-regulation of the Cp and LMP1 promoters or of a simple multimerized RBP-Jk site position near a basal promoter (295). Interactions with DNA sequence-specific transcription factors other than RBP-Jk are not critical for EBNA-LP coactivation with EBNA-2. EBNA-LP coactivation with EBNA-2 does not even require that EBNA-2 interact through RBP-Jk, because EBNA-LP robustly coactivates transcription mediated by the EBNA-2 acidic domain alone fused to the Gal-4 DNA binding domain when cells are

co-transfected with a minimal promoter/reporter plasmid that has multiple upstream Gal-4 binding sites (295).

The unique 3' exons of EBNA-LP encode 11- and 34-amino-acid carboxyl-terminal domains. Whereas the repeating exons are efficient coactivators, addition of 11 or even 35 of the carboxyl-terminal residues results in nearly complete loss of coactivating effects. Addition of the entire 45 carboxyl-terminal amino acids restores wild-type coactivation. These data indicate that the first 35 carboxyl-terminal amino acids have a strong negative regulatory effect on coactivation, and that the last 10 amino acids effectively silence the negative regulatory effect (295). The negative effect of the stop codon mutation that prevented expression of the last 45 amino acids on primary B-lymphocyte transformation (525) is evidence of the importance of this complex regulatory domain for efficient lymphocyte growth transformation. Differential phosphorylation of EBNA-LP by p34cdc2 or casein kinase II may be important in the natural regulatory effects of the carboxyl-terminal domain.

An effect of EBNA-LP on Rb and p53 has been suggested based on *in vitro* biochemical interactions and co-localization of EBNA-LP with Rb as detected with one monoclonal antibody but not with others (385,797). However, EBNA-LP is not associated with Rb family proteins or p53 in cell lysates, and expression of EBNA-LP in transgenic mice had no discernible effect on development or tumor incidence. The EBNA-LP transgenic mice died of heart failure, which was likely to be due to a toxic effect of EBNA-LP expression or to an insertion site effect (355). Immunoprecipitations of EBNA-LP from B lymphoblasts have resulted in the identification of the DNA-PK catalytic subunit, an AKAP 95 homolog HA95, HSP70, and HSP27 as EBNA-LP-associated proteins (434,526,799).

EBNA-2

Early studies identified a transformation-incompetent but replication-competent laboratory strain of EBV, P3HR-1 (565,598). The search for the biochemical basis of the nontransforming phenotype led to the discovery and characterization of EBNA-2 (Fig. 6). P3HR-1 is deleted for the DNA that encodes RNA and protein in latently infected cells, and the principal ORF in the DNA deleted from P3HR-1 encodes EBNA-2 (144,311,327,427,675).

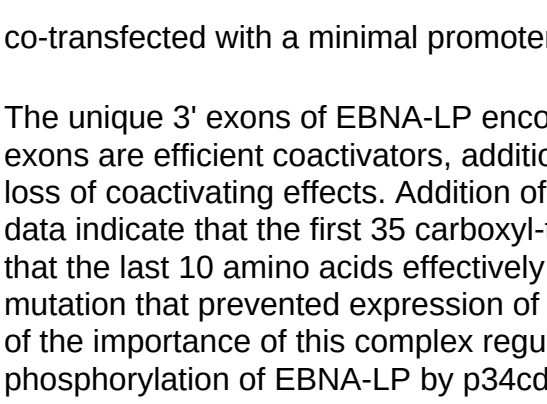

FIG. 6. Schematic depiction of the biochemical mechanisms by which EBNA-2 and EBNA-LP up-regulate transcription by the LMP1 promoter in B lymphocytes. EBNA-2 is an acidic transcriptional transactivator that biochemically interacts with the cellular sequence-specific DNA binding proteins RBP-Jk and PU.1 to bring it to specific promoters, including the LMP1 promoter. The EBNA-2 amino terminus has two domains that can mediate homotypic association with other EBNA-2 molecules. The EBNA-2 acidic domain interacts with TFIIB, TAF40, TFIIH, TBP, p100, P300/CBP, and EBNA-LP in stimulating transcription. The EBNA-2 acidic domain is extensively associated with p100, which is a scaffolding protein for c-*myb* and PIM-1.

Superinfection of latently infected cells with P3HR-1 induced replication of the endogenous viral genome, resulting in the production of virus that could transform primary B lymphocytes into latently infected LCLs. Restriction endonuclease analyses of the viral DNA in the resultant LCLs for polymorphisms that are characteristic of the P3HR-1 genome indicated that many of the genomes were partly from the P3HR-1 EBV. All of the viral DNAs were wild type at the site of the P3HR-1 deletion, supporting the hypothesis that the EBNA-2-encoding DNA is critical for LCL outgrowth (765).

More precise recombinant EBV molecular genetic experiments done by transfection of cells that are infected with the P3HR-1 EBV with molecularly cloned wild-type EBV DNA fragments that span the deletion resulted in homologous recombination and restoration of the deleted DNA segment in 1 in 10^5 progeny virus (126,290). The recombinant virus could be easily recovered because of its unique ability to transform primary B lymphocytes into LCLs. Transfection with cloned EBV DNA fragments deleted for part of the EBNA-2 ORF, or containing a stop codon one third of the way into the ORF, repeatedly failed to restore transforming ability, whereas wild-type DNA or DNA with a small marker deletion restored transforming ability. Recombinant EBVs with a nontransforming EBNA-2 mutation could also be recovered by infection of EBV-negative BL cells (527). Thus, several different genetic analyses proved that EBNA-2 is essential for primary B-lymphocyte growth transformation.

EBNA-2 also differs more extensively between EBV types 1 and 2 than any other latent infection–associated protein, and that difference results in a differential ability to cause LCL outgrowth (7,126,144,722,723,835). Infection of primary human B lymphocytes with EBV type 2 rarely gives rise to rapidly growing LCLs (689). Restoration of the P3HR-1 deletion with prototype type 1 or type 2 EBNA-2 genes indicated that EBNA-2 is the principal determinant that enables type 1 EBV to more efficiently transform primary B lymphocytes than type 2 EBV strains (126). Primary B lymphocytes infected with the type 2 P3HR-1 EBV that had its deletion cured with type 1 EBV DNA proliferated into LCLs as rapidly as lymphocytes transformed by type 1 EBV strains. In contrast, recombination of cloned type 2 EBNA-2 DNA into the site of the P3HR-1 deletion resulted in the deficient transformation phenotype characteristic of type 2 EBV strains (126).

Comparison of the nucleotide and predicted amino acid sequence of the EBV type 1 and 2 EBNA-2s, or the corresponding sequences of other LCVs, reveals conserved or divergent domains that in general correspond with sequences that are more or less critical in genetic and biochemical analyses (see Fig. 6) (123,124 and 125,144,276,296,322,498,500,647,840,842,894,895): (a) The amino-terminal 57 amino acids contain a motif like the immunoreceptor tyrosine-based activation motif (ITAM), have an overall negative charge, and are highly conserved between types 1 and 2. (b) The polyproline repeat of type 1 EBNA-2 is usually longer than that of type 2. (c) The 46 amino acids carboxyl-terminal to the polyproline repeat are well conserved between types 1 and 2, with 30 identical amino acids. (d) Only 52 of the next 149 amino acids are identical between types 1 and 2. (e) Carboxyl-terminal to this highly divergent region is a 46-amino-acid domain with 26 type-common amino acids. (f) A 26-amino-acid imperfect Arg-Gly repeat, of which 13 amino acids are Arg or Lys, is highly conserved. (g) In the 121-amino-acid carboxyl terminus, 84 amino acids are identical in types 1 and 2, and 16 are acidic. And (h) near the carboxyl terminus is a Lys-Arg-Pro-Arg sequence that can provide nuclear localization. In EBNA-2, the Arg-Gly repeat region near the carboxyl terminus can provide nuclear localization (125).

EBNA-2 is associated with nucleoplasmic, chromatin, and nuclear matrix fractions and localizes to large nuclear granules (327,651). It is phosphorylated on serine and threonine residues and may undergo significant posttranslational modification other than phosphorylation, as the size of the nascent protein is 10 kd smaller than stable intranuclear EBNA-2 (265,870). The basis for this modification is not known. EBNA-2 extracted from lymphoblasts or even from baculovirus-infected sf-9 cells is heterogeneous in velocity sedimentation and gel elusion chromatography. EBNA-2 can form homotypic complexes the size of tetramers or larger, and some of the EBNA-2 complexes in lymphoblasts are larger than 1 MDa (265,850,891,892). The size of EBNA-2 complexes is at least in part due to the ability of EBNA-2 to homotypically self-associate through two separate domains: the amino-terminal 57 amino acids before the polyproline domain and the 120 amino acids after the polyproline domain.

EBNA-2 is a specific transactivator of cell and viral gene expression, a property first described in delineation of the mechanism for up-regulated expression of CD23 (865), a B-lymphocyte-specific surface protein expressed in high abundance on EBV-transformed or antigen-activated primary B lymphocytes (362,429). EBNA-2 transactivates CD23 expression through an EBNA-2 responsive element upstream of the CD23 promoter (867,868). Subsequently, EBNA-2 has been shown to also up-regulate the cellular CD21 (25,127,868), c-*fgr* (437), and c-*myc* mRNAs (394), as well as the viral LMP1 (1,199,200,248,873), and LMP2A and -B (930) and Bam C promoter mRNAs (386,793). Curiously, EBNA-2 also transactivates the HIV LTR, and the transactivation is dependent on the NF-kB and PU.1 sites in the LTR, despite the absence of NF-kB sites in other EBNA-responsive cis-acting elements (730).

EBNA-2 response elements upstream of the CD23, LMP1, LMP2A, and Bam C promoters have been defined by deletional analyses and by positioning the response elements near a heterologous basal promoter (199,386,461,498,546,848,870,873,930). The LMP1 promoter, EBNA-2 response element, is largely restricted in EBNA-2 responsiveness to human B lymphocytes (200) and was not observed in epithelial cells, probably because of the role of the B-lymphocyte-specific factor, PU.1 in EBNA-2 activation of the LMP1 promoter (388,764).

Analysis of EBNA-2 using recombinant EBV molecular genetics with marker rescue of primary B-lymphocyte transforming activity in the EBNA-2-deleted, nontransforming, P3HR-1 EBV background has identified three essential EBNA-2 domains, and these domains are also critical for LMP1p or Cp promoter up-regulation. The essential domains correspond to a requirement for either of the amino-terminal domains that mediate homotypic association, the domain between 280 and 337 that mediates interaction with cellular DNA binding proteins, or the domain between amino acids 420 and 464 that is an acidic activation domain (123,124,125 and 126,296,840,842,894,895).

The EBNA-2 acidic domain is similar but not identical to the prototype VP16 acidic domain (123,124 and 125). Despite little colinear homology, both acidic domains include similarly placed critical hydrophobic residues, a phenylalanine in VP16 and a tryptophan in EBNA-2. A fusion of 28 amino acids of the EBNA-2 acidic domain to the Gal-4 DNA-binding domain is nearly as strong in activation of basal reporter constructs with multiple upstream Gal-4 binding sites as the core VP16 14 amino acids, whereas the corresponding EBNA-2 14 amino acids have only 25% of the VP16 activity. Despite their greater activity in transient assays, the VP16 14 amino acids can substitute for the corresponding EBNA-2 residues when expressed from an EBV recombinant (123). The EBNA-2 acidic domain is more active in BL cells than in Chinese hamster ovary (CHO) cells, and the VP16 acidic domain is more active in CHO cells than in BL cells, evidence of EBNA-2 selectivity for B lymphocytes (124). The EBNA-2 acidic domain shares with VP16 an affinity for TFIIB, TAF40, TFIIH, RPA70, and p300/CBP, but it has much less affinity for TBP (839,840 and 841,874). In contrast, the EBNA-2 acidic domain has greater affinity for p100 than does VP16, and the EBNA-2 acidic domain is highly complexed with p100 in LCLs (840). P100 is a scaffolding protein for c-*myb* and PIM-1 (150,476) and also can interact with TFIIE (840). Given the extent of association between the EBNA-2 acidic domain and p100, and the potential for p100 to recruit TFIIE, c-*myb*, and PIM-1, p100 is likely to have an important role in regulating EBNA-2-mediated transcription. Although p300 and CBP are less stably associated with EBNA-2, p300 and CBP are also likely to be critical for EBNA-2-mediated transactivation because of their intrinsic histone acetylase activities, because of their ability to recruit PCAF histone acetylase, and because of their interaction with other transcription factors. Much of the substantial histone acetylase activity that can bind to the EBNA-2 acidic domain is associated with p300/CBP (874). CBP has been specifically implicated in EBNA-2 activation of the c-*myc* promoter, whereas p300 appear to be repressive (377).

The second domain of EBNA-2 that is critical for transformation mediates an interaction and high-level association with a cellular sequence-specific DNA binding protein, RBP-Jk, also known as CBF1 (276,322,389,895). The EBNA-2 amino acid sequence that binds to RBP-Jk includes amino acids 290 to 337. Although PWWPP is the core sequence that interacts with RBP-Jk, and mutations of the WW to FF or SS are sufficient to ablate binding, deletion of amino acids 292 to 310 also significantly disrupts the ability of EBNA-2 to associate with RBP-Jk (276,296,497,895). The WWP sequence in EBNA-2 closely mimics the WFP sequence in the Notch-receptor intracellular domain that normally mediates tight association of the Notch intracellular domain with RBP-Jk for up-regulating HES1 in tissue development (808). The WW to SS mutation ablates EBNA-2 ability to up-regulate the Cp promoter, reduces the ability to activate the LMP-1 promoter by 50%, and ablates the ability of the specifically mutated EBV recombinant to transform primary B lymphocytes into

LCLs (895). These point mutation data are strong evidence for the key role of RBP-Jk association in promoter choice, promoter regulation, and LCL outgrowth; the data also support the hypothesis that RBP-Jk-mediated promoter regulation is linked to the transformation of resting B lymphocytes into LCLs.

RBP-Jk has intrinsic repressive activity that is at least in part mediated by interaction with SKIP, a component of the SMRT, Sin3A, and HDAC 2 corepressor complex (928,929). Notch and EBNA-2 may partly activate transcription from RBP-Jk-responsive promoters by interacting with SKIP and interfering with SMRT interaction with SKIP. The interaction with SKIP may also stabilize Notch and EBNA-2 interaction with RBP-Jk.

RBP-Jk recognizes the nucleotide sequence GTGGGAA (276,322,499). This sequence is part of the EBNA-2 responsive elements that have been implicated in Cp, LMP1, LMP2A, CD23, IL6, and c-*fgr* promoter regulation in LCLs (174,284,386,848,870,931). Although existing data favor the possibility that the PRF site in the c-*myc* promoter is critical in EBNA-2 promoter regulation (377), the first intron of c-*myc* has a GTGGGAA sequence that could also, or alternatively, mediate EBNA-2 up-regulation. The latter possibility might also explain the role of constitutively activated Notch receptors in human T-cell leukemia and in inducing mouse T-cell leukemia (185,640).

EBNA-2 enjoys a high-level continuous association with RBP-Jk in LCLs (389). Further, a multimerized Cp sequence that contains the RBP-Jk binding site or a multimerized minimal synthetic RBP-Jk binding site can convey EBNA-2 responsiveness to minimal promoters (295,499). However, analyses of EBNA-2-mediated activation of those EBNA-2-responsive enhancer elements that have been most extensively studied from the LMP1p and Cp promoters show that responsiveness requires at least one other cellular sequence-specific DNA binding protein, PU.1 for LMP1 (388) and AUF1 for Cp (238). Mutation of the sole RBP-Jk site in the LMP1 EBNA-2-responsive enhancer element, or point mutation of the EBNA-2 WW to SS so that EBNA-2 cannot interact with RBP-Jk, only reduces EBNA-2 responsiveness 50%. In contrast, mutation of the PU.1 binding site ablates EBNA-2 responsiveness (388). The EBNA-2 domain that interacts with PU.1 appears to include the site that interacts with RBP-Jk, and more-carboxyl EBNA-2 amino acids, because bacterial fusion proteins that include these EBNA-2 amino acid sequences can efficiently remove PU.1 from nuclear extracts (388). However, unlike RBP-Jk, which readily coimmunoprecipitates with EBNA-2 from LCL cell lysates, PU.1 does not coimmunoprecipitate with EBNA-2 (388). The targeting of PU.1 by EBNA-2 in transcriptional activation is an important aspect of EBV adaptation to lymphoid cells, because PU.1/Spi1 is a key Ets family regulator of the IgH enhancer (600). The role of AUF1 binding to CBF2 in complementing EBNA-2 interaction with CBF1 also seems to involve a AUF1 functional interaction with EBNA-2 that may be independent of EBNA-2 interaction with CBF1. AUF1 is a component of the cellular DNA binding protein complex that interacts with CBF2, and a highly multimerized CBF2 can be activated by EBNA-2 expression (238). Further, EBNA-2 activation through CBF2 is indirectly enhanced by protein kinase A (PKA) (238), as has been shown in regulation through an AUF1 site in the EBNA-2-responsive CD21 promoter (834). Although direct interaction or association of EBNA-2 with AUF1 has not been demonstrated, EBNA-2 activation of a minimal promoter through a mutimerized CBF2 element is coactivated by AUF1 overexpression and PKA activation (238).

The third EBNA-2 domain that is important for primary B-lymphocyte growth transformation appears to be either of the domains that are amino- or carboxyl-terminal to the polyproline repeat. Either domain, amino-terminal amino acids 1 to 57 or carboxyl-terminal amino acids 97 to 210, or almost all the prolines, can be deleted with only a moderate loss of primary B-lymphocyte growth transformation and Cp promoter activation, but deletion of *all* the prolines is incompatible with the mutant EBV initiating primary B-lymphocyte growth transformation (894). Biochemical studies indicate that either domain can mediate homotypic association. Homotypic association is likely to be critical to the ability of EBNA-2 to form large homotypic and larger heterotypic complexes (265,850,891,892) that can facilitate simultaneous recruitment of multiple transcription factors and enhance transcription. This probably explains the unusual effect of the deletion of both domains.

Although not essential per se for transformation or transcriptional activation, the domain that is carboxyl-terminal to the polyprolines has also been implicated in an interactions with human SNF5/Ini1 and the DEAD box protein DP103. Ini1 and DP103 interact with EBNA-2 amino acids 112 to 344 in yeast two-hybrid screens (281,891). DP103 is a DEAD box protein with imputed RNA helicase activity that appears to have transcription-repressive effects (629). *In vitro*, translated EBNA-2 amino acids 1 to 210 bind to Gst-Ini1, and a small fraction of phosphorylated EBNA-2 coimmunoprecipitates with Ini1 from 1.5- to 2-MDa fractions of cell lysates. Consistent with EBNA-2 recruitment of Ini1 to specific sites, immunoprecipitation of chromatin fragments with Ini1 antibody enriches for promoter DNA sequences downstream of LMP2A-derived enhancer construct or CD23 first-exon DNA in EBNA-2-positive cells (892). Thus, EBNA-2 interaction with Ini1 could be physiologically significant.

Deletion of the EBNA-2 DNA segment encoding the Arg-Gly repeat domain RGQSRGRGRGRGRGRGKG, amino acids 337 to 354, results in EBV recombinants that transform primary B lymphocytes with decreased activity. The transformed cells grow slowly and require maintenance at a high density. The Arg-Gly repeat has an intrinsic ability to bind to histone H1, to many other proteins (including EBNA-1), and to nucleic acids, especially poly(G). The strong interaction of the Arg-Gly domain with histone H1 is consistent with the observed effect of deletion of the Arg-Gly domain on release of a significant fraction of EBNA-2 that is in the 0.4 M salt–extractable chromatin fraction to the isotonic salt–extractable nucleoplasmic fraction in LCLs transformed by the mutant recombinant EBV. EBNA-2 deleted for the Arg-Gly domain is better than wild-type EBNA-2 at transactivating the LMP1 promoter and is as active as EBNA-2 in transactivating the *Bam*HI-C promoter. These data are most compatible with a model in which the Arg-Gly domain of region 3 is a modulator of EBNA-2 interactions with chromatin and activities in up-regulating gene expression.

EBNA-3A, -3B, -3C

The EBNA-3 genes are tandemly placed in the genome (see Fig. 3) and are transcribed from the far-upstream Cp or Wp EBNA promoters. The EBNA-3A, -3B, and -3C ORFs share colinear distant homology and are each encoded in the 3' terminal short and long exons of their mRNAs (36,62,64,65,325,329,387,395,418,651,653,721). Latently infected cells have only a few copies of each EBNA-3 mRNA. EBNA-3A, -3B, and -3C have repeating polypeptide domains near their carboxyl termini, representing unusual examples of domain amplifications within ORFs of genes that are themselves amplified from a common progenitor. Type 1 EBNA-3A, -3B, and -3C are 944, 938, and 992 amino acids, respectively.

The type 2 EBNA-3A, -3B, and -3C proteins are 925, 946, and 1,069 amino acids and are 84%, 80%, and 72% identical to their type 1 counterparts (725).

The EBNA-3 proteins (see Fig. 5) are remarkably hydrophilic, with up to 20% charged amino acids. Each has several localized concentrations of arginines or lysines, which could be responsible for nuclear localization; heptad repeats of leucine, isoleucine, or valine that could facilitate hydrophobic homo- or heterodimerization; and LXLXXL motifs that could enable interaction with nuclear hormone receptors. Despite the very low abundance of the three mRNAs in latently infected cells, EBNA-3A, -3B, and -3C are stable proteins. The EBNA-3s accumulate in intranuclear clumps, sparing the nucleolus (325,651,653). With differential salt extraction, EBNA-3A, -3B, and -3C partition to the nuclear matrix, chromatin, and nucleoplasmic fractions (651).

Although significantly divergent in nucleotide and amino acid sequence, type 1 and type 2 EBNA-3A, -3B, and -3C have similar effects in B-lymphocyte growth transformation (835). EBV recombinants made in a type 2 EBV P3HR-1 background with type 1 EBNA-LP and EBNA-2 have the robust primary B-lymphocyte transformation phenotype characteristic of type 1 EBV strains. Replacement of the P3HR-1 type 2 EBNA-3s with type 1 EBNA-3s does not alter infected B-cell outgrowth into LCLs, or the ability of the recombinant to replicate in response to induction of permissive infection. Thus, EBNA-3 type specificity does not affect latent or lytic virus infection of B lymphocytes *in vitro*.

EBNA-3B is not critical for latent infection of primary B lymphocytes, for LCL outgrowth, for cell survival, or for lytic virus replication (836). EBV recombinants with a nonsense codon after codon 109 of the 938 type 1 EBNA-3B codons are indistinguishable from wild-type recombinants in latent infection of primary B lymphocytes *in vitro*, in LCL outgrowth, and in lytic infection. The finding that EBNA-3B is not essential for any aspect of lymphocyte infection *in vitro* is surprising because EBNA-3B epitopes are frequently recognized by human immune cytotoxic T lymphocytes (see Chapter 75). Immune recognition would be expected to provide strong *in vivo* selection against a nonessential gene. Consistent with the lack of effect of the putative null EBNA-3B mutation on lymphocyte infection and LCL outgrowth *in vitro*, and the expectation that EBV strains with altered or absent EBNA-3B genes would be expected to emerge under immune selection, an EBV mutant with a truncated EBNA-3B ORF was recently discovered in a transplant patient with EBV-associated lymphoproliferative disease who was undergoing therapy with anti-EBNA-3B cytotoxic T lymphocytes. Nevertheless, the consistent presence of EBNA-3B in EBV isolates from normal people is evidence that EBNA-3B is important in natural infection, one aspect of which may be to contribute to immune recognition.

In contrast to the lack of phenotypic association with truncation of the EBNA-3B ORF, a nonsense codon after codon 302 of EBNA-3A or codon 365 of EBNA3C results in EBV recombinants that are unable to transform primary B lymphocytes (835). These experiments indicate that EBNA-3A and -3C are critical for B-lymphocyte growth transformation or survival, and that they differ significantly from EBNA-3B in their roles in EBV infection. Subsequent experiments with EBV recombinants that have a missense mutation beginning at EBNA-3A codon 304 confirm a critical role for EBNA-3A in LCL outgrowth and survival (412). However, two of more than 40 LCLs that were obtained in this latter study eventually grew in culture without wild-type EBNA-3A expression, indicating that EBNA-3A is not absolutely required for continued LCL proliferation or survival. Recombination of rhesus LCV EBNA-3A, -3B, and -3C, or -3B and -3C, into EBV results in recombinants that cannot transform human B lymphocytes into LCLs, consistent with the critical role of EBNA-3A and -3C in LCL outgrowth (384).

Surprisingly, EBNA-3A, -3B, and -3C are similar to EBNA-2 in being able to bind to and stably associate with RBP-Jk (389,446,534,692,693,864,926). In associating with RBP-Jk, the EBNA-3s effectively compete for RBP-Jk with EBNA-2 and Notch and limit EBNA-2 strong up-regulation through RBP-Jk (389,446,468,534,692,693,864,926). An RBP-Jk domain as small as amino acids 125 to 181 can bind to EBNA-3C, and amino acids 172 to 223 of EBNA-3C, which are relatively well conserved in all three EBNA-3 family members, can interact with RBP-Jk (926). EBNA-3A amino acids 224 to 556 also bind well to RBP-Jk, and amino acids 1 to 138 can bind at a low level (122,693).

Because of their role in LCL outgrowth, more attention has been given to the biochemical properties of EBNA-3A and -3C than to EBNA-3B. When expressed alone in B-lymphoma cells, EBNA-3s effect modest changes in cell gene expression. EBNA-3C up-regulates CD21 expression, but not that of CD23, CD10, CD30, CD39, CD40, CD44, or cellular adhesion molecules in BJAB cells (868), whereas EBNA-3B up-regulates vimentin, CD40, and Bcl-2 expression and down-regulates CD77 in DG75 cells (751,752).

EBNA-3C can increase the levels of LMP1 expression, which fall off normally in RAJI cells that arrest in G1 when they grow to saturation (17). EBNA-3C is unique among the EBNA-3s in its ability to coactivate the LMP1 promoter with EBNA-2 (534,927). This effect can occur independently of the RBP-Jk binding site in the LMP1 promoter and of the RBP-Jk site in EBNA-3C. The effect depends on the LMP1 promoter PU.1 site and appears to be mediated by an interaction of the bZIP domain of EBNA-3C with the Ets domain of PU.1 or Spi-B. When fused to the Gal-4 DNA binding domain, EBNA-3C glutamine- and proline-rich amino acids 724 to 826 can activate transcription from a Gal-4-responsive promoter (534). However, EBNA-3C also has repressive effects. Full-length EBNA-3C fused to the Gal-4 DNA binding domain represses transcription from a variety of promoters in a variety of cell types, and the effect is independent of the presence of RBP-Jk sites on the promoter plasmid (40,71). The repressive effects map to amino acids 280 to 525; the larger proline- and glutamine-rich regions corresponding to amino acids 580 to 992 also have repressive activity (40). EBNA-3C also represses transcription from the Cp promoter. In this instance, the effect depends on interaction with RBP-Jk and on the EBNA-3C repression domain. The repressive effect of EBNA-3C is in part attributable to an interaction and association with HDAC1, but that interaction maps to a region of EBNA-3C that includes the RBP-Jk binding domain (679). EBNA-3C has been reported to cooperate with oncogenic Ras in transforming rat embryo fibroblasts, and a low level of *in vitro* interaction with RB has been detected (633). In NIH3T3 fibroblasts or human U2OS cells compelled to arrest by serum withdrawal, EBNA-3C expression can inhibit the accumulation of p27(K1P1) and can cause bi- and multinucleated cells by abrogating the mitotic spindle checkpoint (634). EBNA-3C amino acids 365 to 509 avidly bind prothymosin-alpha, a 112-amino-acid nuclear protein that can interact with histone (128). Although only about 2% of EBNA-3C coimmunoprecipitated with ProT-a and much less than 1% of ProT-a coimmunoprecipitated with EBNA-3C, EBNA-3C appeared to co-localize with ProT-a in nuclei (128). These data indicate that EBNA-3C could be

involved in transcriptional effects through interaction with ProT-a.

EBNA-3A also represses the activity of the Cp promoter in B cells and in epithelial cells, and this activity largely depends on the domain through which EBNA-3A interacts with RBP-Jk (122). Using Gal-4 EBNA-3A fusion proteins and Gal-4-responsive promoters, the EBNA-3A-repressive domain has been mapped to 143 amino acids that do not interact with RBP-Jk and can mediate down-regulation of transcription (71,122). EBNA-3A also has a potential weak activation domain that is evident when EBNA-3A lacking the amino acid 100-to-364 repressive domain are fused to the Gal-4 DNA binding domain and expressed in B lymphoblasts along with a Gal-4-responsive promoter (122). The activation effects appear to be B-cell specific and are not evident in epithelial cells. EBNA-3A used as bait in a yeast two-hybrid search for interacting proteins curiously retrieved the carboxyl part of the epsilon subunit of the chaperonin T-complex protein 1, and the p38 subunit of the aryl hydrocarbon receptor complex (401,402). EBNA-3A binds to p38 and causes p38 to partially localize to the nucleus (401).

EBNA-1

EBNA-1 was initially identified as an EBV nuclear neoantigen that is present in all EBV-infected cells, regardless of the state of EBV infection (682). This was the first evidence that EBV encoded a nuclear protein in latently infected cells, perhaps similar to T antigen in simian virus 40 (SV40)-transformed cells. Soon thereafter, EBNA-1 was shown to associate diffusely with mitotic chromosomes (625). EBNA-1 is unique among the EBNAs in this regard (274,652). The significance of EBNA-1 association with chromosomes emerged later from the discovery that EBV has a cis-acting element, termed oriP, that enables the persistence of episomes in EBV-infected cells or in any human cells in which EBNA-1 is expressed (906,910). EBV and other oriP-containing episomes associate randomly with human chromosomes in cells that express EBNA-1 (159,299,753). The unique random association of EBNA-1 with chromosomes, the association of EBV or other oriP plasmid DNA with chromosomes in EBNA-1 expressing cells, and the need for EBNA-1 in oriP persistence, position EBNA-1 as the key mediator of EBV DNA binding to chromosomes and episome persistence. Indeed, EBNA-1 is essential for EBV episome maintenance (469).

OriP has at least two components: a family of 20 copies of a 30-bp repeat, FR, that can be an EBNA-1-dependent enhancer, and a dyad symmetry, DS, of four copies of the 30-bp repeat, two in tandem and two in a larger dyad symmetry, that are required for episome maintenance (683,684). A key component of the mechanism by which this system works is that EBNA-1 binds specifically to the 30-bp repeat (most strongly to the 20×30-bp repeat element) and then to the dyad symmetry element, and to another site within the EBNA transcript (681). An EBNA-1 expression vector and oriP can be combined with a cassette for positive selection to make a plasmid into which any gene can be cloned to enable its maintenance as an episome in human cells (784). The EBNA-1 and oriP system has been widely exploited to achieve heterologous gene expression. In one use, oriP enabled plasmids containing 150 to 200 kbp fragments of random human DNA to persist as multicopy episomes in EBNA-1-expressing cells. Two such plasmids could persist in the same cell (792). Although essential for oriP enablement of plasmid persistence, excess EBNA-1 expression does not increase oriP-replicated plasmid copy number. Cellular controls limit DNA replication to one initiation event per DNA molecule per S phase (2,909), and equal numbers of plasmids are distributed to cell progeny (787).

EBNA-1 is encoded by the 2-kb 3'-terminal exon of spliced mRNAs. In type 3 latency, the 3.5-kb EBNA-1 mRNA is initiated at the Cp or Wp promoter and is highly spliced, and the primary transcript is about 100 kb (see Fig. 3) (62,63,64,65 and 66,317,326,327,719,774,788). Transcription from the Wp promoter is initially regulated by cellular factors. Wp is up-regulated and Cp turned on by EBNA-2 and -LP. EBNA-1 then further up-regulates Wp and Cp. Eventually, high-level expression of EBNA-3s down-modulates the strong up-regulating effects of EBNA-2 and EBNA-LP and prevents runaway EBNA transcription (295,468,665,692,693,788,793,886). In latency type 1 or 2, the EBNA-1-specific 2.4-kb mRNA is primarily initiated at n62423, with secondary sites at 62392 and 62340 in the prototype B95 sequence (36,611,612,613 and 614,733). This latency type 1 and 2 Qp promoter lacks a recognizable TATAA element. Transcription appears to be positively regulated by an unknown factor, LBP-1 (611), by IRF1 and 2 (613,731), and by E2F (612,794), which bind to three distinct sites bracketing the n62423 initiation site. The two EBNA-1 binding sites just 3' to the transcriptional start site are the principal elements that self-regulate EBNA-1 transcription in latency type 1 and 2 (720,732,794). Similar regulatory sites are conserved in the baboon LCV (711).

EBNA-1 from the prototypical B95 EBV strain consists of 641 amino acids. The protein has a high proline content, is charged, and migrates on denaturing polyacrylamide gels with an apparent size of 76 kd. From amino to carboxyl terminus, EBNA-1 has four components: (a) an amino-terminal 89 amino acids, which include amino acids 32 to 83 and are Arg rich, (b) amino acids 90 to 327, which are an irregular copolymer of Gly and Ala, (c) amino acids 328 to 386, which are Arg rich and include a nuclear localization sequence at amino acids 379 to 386, and (d) carboxyl-terminal amino acids 387 to 641, which include amino acids 459 to 607 that bind DNA and dimerize. The two Arg-rich regions of EBNA-1 amino acids 1 to 379 can each bind to chromosomes and together reconstitute the chromosome association characteristic of EBNA-1 (360,532). Whereas EBNA-1 amino acids 379 to 641 appear to permit initial accumulation of oriP-containing plasmids in cells, the chromosome-associating domains are necessary for long-term plasmid maintenance, presumably because of their role in interacting with chromosomal proteins (349) and partitioning oriP episomes to progeny nuclei. Cellular chromosomal proteins, HMG-I amino acids 1 to 90, or histone H1 can functionally substitute for EBNA-1 amino acids 1 to 378 in enabling long-term episome persistence (360).

Identification of the biochemical interactions of the EBNA-1 carboxyl-terminal domain with oriP is facilitated by the high expression level of the EBNA-1 carboxyl terminus in bacteria- or baculovirus-infected sf9 cells (230,574). EBNA-1 amino acids 450 to 641 or 607 have similar DNA binding and dimerization activity to full-length EBNA-1 (26,27,391,573,681). The core amino acids for DNA interaction are amino acids 459 to 500, particularly 462 to 477, whereas the core residues for dimerization are amino acids 501 to 532 and 554 to 598. A dimer of an EBNA-1 oligopeptide corresponding to amino acids 458 to 478 can bind DNA, albeit nonspecifically (99,100). Surprisingly, amino acids 450 to 641 fused to the pyruvate kinase ORF and the EBNA-1 nuclear localization signal (NLS) are sufficient for wild-type EBNA-1 transcriptional activation through FR upstream of a minimal TK promoter in Vero cells, and the carboxyl-terminal acidic domain is critical for activation (26).

Each 30-bp EBNA-1 dimer-binding site is a partial dyad similar to TAGGATAGCATATGCTACCCAGATCCAG (27,391,681). Relative to the center of each half of the dyad, nucleotides 3 to 8 are most critical for EBNA-1 binding (27). EBNA-1 has a high affinity for its cognate sequence, and interactions with the cognate sequence can be demonstrated even after protein denaturation and renaturation on cellulose nitrate. EBNA-1 not only dimerizes on 30-bp elements but also forms higher-order oligomers. Oligomerization of EBNA-1 on templates that have EBNA-1 binding sites separated by intervening sequence induces looping-out of the intervening DNA (230,259,548,781). On oriP, EBNA-1 first saturates FR and then binds to DS, looping out the intervening DNA (230). EBNA-1 amino acids 322 to 377 are important for efficient looping of EBNA-1 bound to FR and DS, or for linking multiple oriP DNA molecules to each other in a larger complex (228,518,519 and 520). Only DNA-bound EBNA-1 can participate in the large, linked EBNA-1 DNA complexes.

The binding of EBNA-1 to oriP results in two thymine residues, 64 bp apart in the region of dyad symmetry, becoming reactive to potassium permanganate, indicative of a helical distortion. EBNA-1 binding to DS lengthens interstrand H-bonds for three base-pairs centered over the permanganate-sensitive thymine base and three potential intrastrand H-bonds are formed between adjacent bases. Dimethyl sulfate protection studies indicate that EBNA-1 binds on the opposite face of the helix from the reactive thymines (229,307). Analyses on oriP in EBV-infected cells indicate that similar permanganate- and dimethyl sulfate–reactive sites exist *in vivo* (344).

Crystal structures of the EBNA-1 carboxyl-terminal 255-amino-acid dimer have been resolved at 2.5 Å, and of the dimer of cognate DNA at 2.4 and 2.2 Å (58,59 and 60). The EBNA-1 DNA binding domain has two structural motifs: a core domain that mediates protein dimerization and is similar to the DNA binding domain of the papillomavirus E2 protein, and a flanking domain that mediates sequence-specific contacts. Genetic and biochemical studies of the EBNA-1 core domain residues, which are structural homologs of the E2 residues that mediate sequence-specific DNA binding, implicate the corresponding EBNA-1 residues in DNA binding. The EBNA-1 core domain, when expressed in the absence of the flanking domain, has sequence-specific DNA binding activity, and the flanking domain residues contribute to the DNA binding. Thus, both the core and the flanking domains of EBNA-1 play direct roles in DNA recognition (132).

Only seven to eight copies of the 30-bp repeats are required for full activity of FR in transcription or episomal DNA replication (893). EBNA-1 binding to FR may effect up-regulation of the Wp and Cp promoters and of the far-upstream LMP1 and LMP2B promoters (241,665). The requirement for FR to enhance transcription and for episomal DNA replication can be partially replaced by a tandem duplication of DS (893). Tandem duplication of DS decreases its ability to serve as an origin (655). FR also arrests and functionally terminates the replication of episomes containing oriP in cells expressing EBNA-1 (167,240).

FR increases the retention and enhances transcription of oriP plasmids in cells, whereas DS is the site of initiation of plasmid DNA replication (300). DS supports EBNA-1-dependent replication in the absence of the FR (908). DNA synthesis begins in DS and proceeds bi-directionally from DS (240). Plasmids containing two copies of DS are not amplified relative to wild-type oriP (431). Two EBNA-1 binding sites in DS appear to be adequate for initial DNA replication (300,908). The ease of unwinding the 65-bp dyad symmetry of two EBNA-1 binding sites in DS, or relative nucleosome sparing in DS (i.e., relative to other sites in oriP) may contribute to the preferential use of DS as an origin (744,882). DS is not stringently required for episome maintenance, and other sequences can substitute for DS in initiation of DNA synthesis (109), including another site in oriP, designated Rep* (432). DS is also a preferential but not exclusive site for EBV genome replication, and deletion of DS does not prevent EBV episome persistence (501,617).

At least one cellular cofactor that is not conserved in rodent cells is required for DS origin function and not for FR enhancer activity, as EBNA 1 enhances transcription in mouse or human cells, whereas oriP episomes do not replicate in rodent cells (893). Replication in rodent cells can be restored by replacing DS with a rodent DNA origin; such vectors are still dependent on the enhancer function of EBNA-1 and the family of repeats (447). Similarly, human cell DNA that contains a putative origin for DNA replication can functionally substitute for DS in oriP to allow persistence as an episome in human cells (448,542). A human cell cDNA has been identified that encodes a protein that interacts specifically with EBNA-1 cognate DNA, although the relevance of this protein to oriP function in DNA synthesis has not been established (924).

The ability of Rep*, human cell DNA origins, or rodent cell DNA origins to substitute for DS in the context of oriP in an EBNA-1-expressing cell, calls into question the fundamental role of EBNA-1 in DNA replication versus episome persistence (8). Indeed, oriP increases the conversion of transfected plasmid DNA to Dpn1 resistance about 10-fold in the absence of EBNA-1 at 48 hours after transfection and about 20-fold in the presence of EBNA-1. This DNA had gone through two cycles of DNA replication as evidenced by Dpn1 resistance and by bromodeoxyuridine incorporation. The major EBNA-1 effect occurred at 96 hours after transfection, at which point Dpn-resistant DNA disappeared from cells that lack EBNA-1. Further, DS was not specifically required for persistence; FR with a triplicate of Rep* DNA replicates and persists as well as wild-type oriP in cells that express EBNA-1.

EBNA-1 amino acids 90 to 327 are an irregular glycine–alanine repeat domain. The DNA encoding this domain is similar to repeat sequences in cell DNA, and similar polypeptides may be encoded from the cell genome (312). EBV isolates frequently differ in the length of this repeat. This difference has been useful in identifying the EBNA-1 ORF and typing EBV isolates (204,267,268 and 269,326). Deletion of the repeat does not affect EBNA-1 stability or function (907). EBNA-1 expressed in murine cells does not engender a specific cytotoxic T-cell response in mice (847). The failure to recognize EBNA-1 as foreign is due to the EBNA-1 Gly-Ala repeat, which inhibits EBNA-1 processing through proteosomes (477). Because proteosome-mediated degradation is necessary for antigen processing into major histocompatibility complex (MHC) class I molecules for presentation at the cell surface, epitopes in EBNA-1 are poor targets for attack by CD8 cytotoxic T cells. Fusion of the Gly-Ala domain to the EBNA-3B ORF down-regulates CD8 recognition of EBNA-3B-expressing cells. Other proteins are also protected from proteosome degradation by fusion to the glycine–alanine repeat (746). The length of the repeat and particularly the alanines are critical for this effect. Primate LCVs have shorter Gly-Ala repeats that do not have a similar effect on proteosome processing, leaving open the

possibility that the Gly-Ala repeat domain may have yet another role in EBV infection.

EBNA-1 is very stable and is phosphorylated on serine residues in at least two separable domains in the carboxyl half of the molecule (308,652,658). The role of these phosphorylations in EBNA-1 function has not as yet been established through genetic analyses. Further, EBV DNA in human cells that express EBNA-1 associates with the nuclear matrix. The fragment of EBV DNA that associates with the matrix includes oriP, potentially linking oriP to a site for DNA replication or transcription. EBNA-1 can also interact with diverse nucleic acid substrates *in vitro*, including EBER-1 and HIV-TAR (768).

EBNA-1 is the only EBNA that continues to be transcribed when cells are activated to lytic infection (317,706,873,877). Cp and Wp promoter activities cease in lytic infection, and the downstream Fp promoter is activated (614). The lytic mRNA initiates in an Fp promoter just upstream of the Qp promoter and otherwise has the same sequence as the latent infection RNA.

LMP1

Despite being a weak promoter for the LMP1 gene relative to the Cp and Wp EBNA promoters, as revealed by nuclear run-on assays, LMP1 mRNA is almost 10 times more abundant than the EBNA mRNAs in latently infected B lymphocytes (212,720). In epithelial cells, LMP1 transcription is mediated by an upstream promoter that initiates transcription from multiple TATA-less sites in the nearest copy of TR, resulting in a 3.5-kb transcript with a long, largely untranslated 5' exon (251,715). The LMP1 transcripts have two short introns (44,212). The EBNA proteins are remarkably stable, whereas a significant fraction of LMP1 has a short half-life. The primary amino acid sequence of LMP1 is that of an integral membrane protein and includes at least three domains: (a) a 20-amino-acid, arginine- and proline-rich, hydrophilic amino terminus lacking the characteristics of a signal peptide; (b) six markedly hydrophobic 20-amino-acid, alpha-helical, transmembrane segments, separated by five reverse turns, each eight to ten amino acids in length; and (c) a 200-amino-acid carboxyl terminus, rich in acidic residues (Fig. 8). LMP1, translated *in vitro*, posttranslationally inserts into cell membranes consistent with the expected membrane insertion properties of the three pairs of highly hydrophobic transmembrane segments joined by short reverse turns (490,492,724). Although LMP1 has little primary sequence homology to other proteins, aspects of its three-domain organization are similar to some other integral membrane proteins such as erythrocyte membrane band three or the *mas* oncogene.

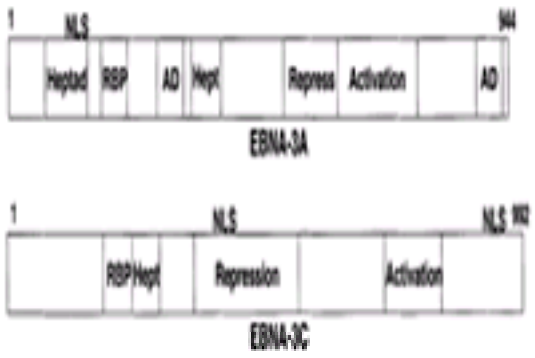

FIG. 7. Schematic diagram of the EBNA-3A and EBNA-3C open reading frames. Indicated are domains that associate with RBP-Jkappa as well as domains that have activating or repressive effects when fused to the Gal-4 DNA binding domains and assayed for transcriptional up- or down-regulating effects in transient transfection assays with a promoter that has multiple upstream Gal-4 binding sites.

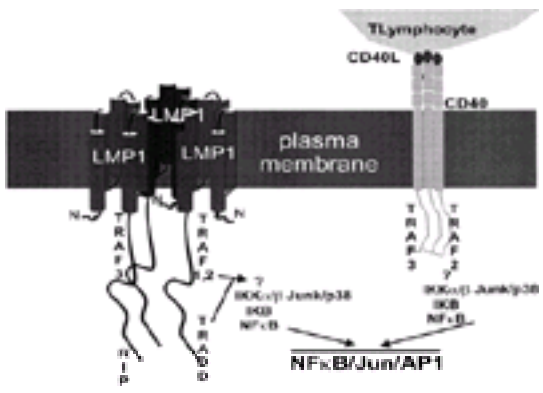

FIG. 8. Schematic diagram of biochemical mechanisms by which LMP1 effects cell growth and survival pathways by constitutively mimicking an activated tumor necrosis factor (TNF) receptor such as CD40. The six hydrophobic transmembrane domains of LMP1 enable LMP1 to aggregate in the plasma membrane. The amino-terminal cytoplasmic domain is fully dispensable for primary B-lymphocyte growth transformation, and its primary function is in tethering the amino terminus of the first transmembrane domain to the cytoplasmic side of the plasma membrane. The transmembrane domains and the carboxyl-terminal cytoplasmic domain are essential for primary B-lymphocyte growth transformation. The carboxyl-terminal cytoplasmic domain is composed of 200 amino acids and it has two essential components: One is the first 44 amino acids, which associate with TNF receptor-associated factors. The second is the carboxyl-terminal 30 amino acids, which associate with the TNFR-associated death domain proteins, TRADD and RIP, without propagating a death signal. Both domains activate the IkB kinases causing phosphorylation of IkB, IkB degradation, and NF-kB activation. Both domains also activate Junk and p38 kinases. The rest of the carboxyl-terminal cytoplasmic domain can be deleted without loss of B-lymphocyte transforming activity.

Immunofluorescence microscopy (324,492), membrane fractionation (523), and live-cell protease cleavage studies (492) indicate that about half of the cellular LMP1 is in the plasma membrane. LMP1 is less abundant in other cytoplasmic membranes. Live-cell protease cleavage studies also indicate that both the N- and C-termini are on the cytoplasmic side of the plasma membrane and only three short reverse-turn domains are on the extracellular side of the plasma membrane (492).

LMP1 is phosphorylated on serine and threonine residues, at a ratio of 6:1, and is not phosphorylated on tyrosines (38,490,524,589,591). Half or more of LMP1 is associated with the cytoplasmic cytoskeleton as defined by resistance to extraction with buffers supplemented with nonionic detergents (490,492,524,589,591). The half-life of LMP1 has been measured by determining the time to reach stable levels of ^{35}S-methionine label in LMP1 and by determining the rate of decay of LMP1 in the presence of protein synthesis inhibitors. The data do not precisely agree, possibly because of an effect of the protein synthesis inhibitors in increasing total LMP1 turnover, or differences in the cell lines studied (38,490,524,589,591). Clearly, nascent, nonionic, detergent-soluble LMP1 has a half-life of less than 2 hours and is converted to a more stable cytoskeleton-associated form. Cytoskeletal LMP1 is phosphorylated, and soluble LMP1 is not (490,524,589,591). LMP1 is ultimately cleaved near the beginning of the carboxyl-terminal cytoplasmic domain, resulting in a transiently stable soluble C-terminal domain of about 25 kd (589,591). The principal serine and threonine phosphorylation sites are near each other in the 25-kd cleavage product (591).

LMP1 constitutively forms discrete patches in the plasma membrane, which are often further organized into a single caplike structure, which localizes to the uropod (324,492). LMP1 aggregates in patches in LCLs or other cell plasma membranes in the absence of exogenous growth factors; the aggregation appears to be an intrinsic property of the multiple hydrophobic transmembrane domains (490,492). Vimentin co-localizes with the LMP1 cap in the latently infected B-lymphocyte plasma membranes (490). Vimentin is not ordinarily found in a plasma membrane patch and is drawn into this patch by LMP1. Vimentin relocalizes into perinuclear rings and coils when cells are treated with colcemid, and LMP1 then relocalizes to the vimentin rings (490). Thus, once LMP1 is associated with vimentin, vimentin can further direct LMP1's localization. LMP1 aggregates in patches and caps in the plasma membrane of cells that lack vimentin or other EBV proteins and does not require vimentin for its signal transducing effects (489,491,866). Thus LMP1 interacts with itself or with other cell membrane proteins to form large, noncovalently linked membrane complexes. LMP1 is partially associated with cholesterol-rich membrane microdomains (31).

In single gene transfer experiments under heterologous promoters, LMP1 has transforming effects in continuous rodent fibroblast cell lines (39,865,866,590). In Rat-1 or NIH3T3 cells, LMP1 alters cell morphology and enables cells to grow in medium supplemented with a low concentration of serum. In Rat-1 cells, LMP1 also causes loss of contact inhibition, so that cells heap up in monolayer culture (865). Rat-1 or BALB/c 3T3 cells lose anchorage dependence and grow in soft agar after LMP1 expression (39,866). Rat-1 cells expressing LMP1 are tumorigenic in nude mice, whereas control Rat-1 cells are nontumorigenic (865). The growth of BALB/c 3T3 cells in soft agar correlates quantitatively with the extent of LMP1 expression up to the levels ordinarily expressed in LCLs (866). Expression at higher levels results in toxicity. The hypothesis has been put forward that the toxic effects of LMP1 expressed at high levels may be a useful surrogate marker for LMP1 biologic activity in rodent fibroblasts; LMP1 mutants that have transforming activity when expressed at levels similar to LCLs, are usually toxic when expressed at higher levels (538). Comparison of the transforming properties of LMP1 with those of D1LMP1 indicates that D1LMP1 does not have these effects (37,866). D1LMP1 lacks the amino-terminal cytoplasmic domain and the first four transmembrane domains, inserts into cell membranes, and does not patch; these data indicate that the amino terminus and the first four transmembrane domains are essential for LMP1 transforming effects in BALB/c 3T3 cells. Addition of the 25-amino-acid N-terminal cytoplasmic domain to the amino terminus of D1LMP did not restore the ability to cause anchorage-independent growth of BALB/c 3T3 cells (37,538), indicating that abnormal transforming phenotype of D1LMP is not caused by an absence of the amino-terminal cytoplasmic domain. Carboxyl-terminal cytoplasmic domain truncations have been variable in rodent fibroblast effects but consistently unable to cause loss of contact inhibition in Rat-1 cells (590). These data suggest that the carboxyl-terminal cytoplasmic domain is important for loss of contact inhibition in Rat-1 cells.

LMP1 also dramatically alters the growth of EBV-negative BL lymphoblasts or even primary B lymphocytes when expressed stably or transiently at the appropriate level in such cells following gene transfer (57,321,489,645,646,649,709,867,868). LMP1 induces many of the changes usually associated with EBV infection of primary B lymphocytes or with antigen activation of primary B lymphocytes, including cell clumping; increased villous projections; increased vimentin expression; increased cell surface expression of CD23, CD39, CD40, CD44, and class II MHC; increased IL10 expression; decreased expression of CD10; and increased expression of the cell adhesion molecules LFA-1, ICAM-1, and LFA-3 (867). Not only does LMP1 increase plasma membrane expression of adhesion molecules, but it also functionally activates adhesion and induces higher levels of LFA-1 mRNA (866,867). D1LMP1 has none of these effects, confirming the importance of the amino terminus and multiple transmembranes for domains for phenotypic effects (491,867). LMP1 has also been shown to protect B lymphocytes from apoptosis (270,321,709). These effects are mediated in part through LMP1 induction of bcl-2 (321,539,707). LMP1 effects in BL cells or rodent fibroblasts vary with the particular cell background and particularly in B lymphoblasts with the basal level of activation molecule expression. LMP1 induction of B-lymphocyte adhesion molecules may be important, as homotypic B-lymphocyte adhesion or adhesion to other cells can facilitate cell growth through autocrine or paracrine growth factors and ligands expressed on other cell surfaces. Also, adhesion is important for the immune elimination of EBV-transformed B lymphocytes *in vivo*, and therefore for continued virus infection. Despite the robust and pleotropic effects of LMP1 expression in human B-lymphoma cells, the effects of deletion mutants that partially affect the membrane-patching properties of LMP1 on each of the phenotypes is intermediate without a clear loss of some effects and the retention of others (491).

LMP1 expression also alters cell growth and gene expression in multipotent hematopoietic stem cells and epithelial cells (156,201,202,346). The effects of LMP1 on epithelial cell growth are evident with transgenic expression of LMP1 in the skin of mice: LMP1 induces epidermal hyperplasia and alters keratin gene expression (885). In monolayer cultures, LMP1 alters keratinocyte morphology and cytokeratin expression (201). In stratified air–liquid interface raft cultures of

immortalized epithelial cell lines, LMP1 inhibits cell differentiation (156). In C33 cervical carcinoma cells, LMP1 expression induces matrix metalloproteinase 9 expression; matrix metalloproteinases are believed to be important in tissue invasion (807,917).

The ability of EBV recombinants specifically mutated in LMP1 to transform primary B lymphocytes into LCLs is a definitive assay for EBV transforming effects, because primary human B lymphocytes grow out as LCLs only in response to EBV infection. This assay has proven to be quite useful for defining the critical components of LMP1. As expected from the transforming effects of LMP1 expression in rodent fibroblasts and B-lymphoma cells, LMP1 is essential for primary B-lymphocyte growth transformation (409). EBV recombinants with mutations in LMP1 that result in amino-terminal truncation of the cytoplasmic and first transmembrane domain have a nontransforming phenotype (409). This form of LMP1 is expressed as a stable protein, localizes to the plasma membrane, but does not aggregate in the plasma membrane, indicating the importance of plasma membrane aggregation in LMP1 effects on primary B-lymphocyte transformation into LCLs (409,491). Similarly, expression of the last three transmembrane domains and the carboxyl-terminus resulted in a nontransforming phenotype; this form of LMP1 localizes to all cytoplasmic membrane without evidence of accumulation in the plasma membrane or aggregation (409,491). The effects of these mutations are not caused by specific interactions mediated by the amino-terminal cytoplasmic domain, because deletion of any part of the amino-terminal cytoplasmic domain results in at least 10% residual transforming efficiency, and the LCLs have a normal growth phenotype (368). The most severe effects of mutation in the amino-terminal cytoplasmic domain are associated with deletion of all of the arginines, which appears to interfere with membrane positioning effects of the transmembrane domains. In contrast, expression of the amino-terminal 187 amino acids of LMP1, which includes the amino-terminal cytoplasmic domain and all of the transmembrane domains but not the carboxyl-terminal cytoplasmic 200 amino acids, ablates primary B-lymphocytes transformation (411).

Specifically mutated EBV recombinants that allow expression of the amino-terminal 231 amino acids, which includes only the first 45 of the 200 amino acids of the carboxy-terminal cytoplasmic domain, results in LCL outgrowth that depends on fibroblast feeder layers (409). The LMP1 1 to 231 recombinant EBV is nearly wild type in the initiation of foci of LCL outgrowth, but most of these foci cannot be expanded to LCLs; their growth is unusually dependent on a high cell density (410). In contrast, an EBV recombinant deleted for DNA encoding only the first 15 amino acids of the cytoplasmic carboxyl terminus is unable to transform primary B lymphocytes (367). These data indicate that the first 15 amino acids of the carboxyl-terminal cytoplasmic domain include part of a site whose first 45 amino acids are essential for LCL outgrowth and even sufficient, in the context of the transmembrane domains, for initial B-cell transformation. Further, these data indicate that efficient LCL outgrowth requires the more carboxyl-terminal 155 amino acids. The first mutations of two of the three LMP1 carboxyl-terminal amino acids that were tested in an EBV recombinant defined a second site of up to 35 amino acids that is important for efficient transformation of primary B lymphocytes (370). Despite the fact that multiple sites between the first 45 and last 35 amino acids of the LMP1 carboxyl terminus have been implicated in various biologic or biochemical processes, specific deletion of all of the LMP1 codons for amino acids 232 to 351 results in an EBV recombinant that is indistinguishable from wild-type LMP1 in primary B-lymphocyte growth transformation, LCL outgrowth, LCL growth characteristics, or lytic EBV replication (371). Thus, the nontransforming phenotype resulting from the deletion of the first 15 codons of the cytoplasmic carboxyl terminus, the robust initial transformation phenotype of the LMP1 amino acids 1 to 231, the deficient LCL outgrowth phenotype of the recombinant with two of the last three carboxyl-terminal amino acids mutated, and the wild-type phenotype of the recombinant deleted for codons 232 to 351 indicate that LMP1 carboxyl-terminal residues 187 to 231 and 352 to 386 are the only residues that are critical for LMP1 cytoplasmic signalling effects in the conversion of primary B lymphocytes to LCLs. Therefore, these two domains have been given the acronym TES1 and 2, for transformation effector sites 1 and 2.

Investigations of the biochemical bases of LMP1 effects in up-regulating expression of B-lymphocyte activation markers, adhesion molecules, HIV, or A20 (an antiapoptosis factor) led to the identification of NF-kB activation as one basis for LMP1 signalling effects (292,453). The domains of LMP1 required for NF-kB activation are the multiple transmembrane domains and the carboxyl-terminal 55 amino acids or the carboxyl-terminal 36 amino acids and first 45 amino acids of the cytoplasmic carboxyl terminus; the amino-terminal cytoplasmic amino acids are not specifically required (356,578). The amino-terminal 45 and carboxyl-terminal 36 amino acids of the cytoplasmic carboxyl terminus are therefore designated C-terminal NF-kB activation regions 1 and 2, or CTAR1 and -2 (356). The need for the LMP1 transmembrane domains could be replaced in various ways, including expression of CD2-CTAR1 and -2, or CD2-CTAR2 chimeric fusions in cells, and adding anti-CD2 antibody to induce aggregation, confirming the important constitutive homoaggregating role of the LMP1 transmembrane domains (226,252).

The biochemical mechanisms that underly the transformation effector sites and NF-kB activating domains were initially united by the yeast two-hybrid-based discovery that LMP1 TES1/CTAR1 interacts with, and in the context of the LMP1 transmembrane domains constitutively associates with, human tumor necrosis factor (TNF)-associated cell cytoplasmic factors hTRAF3 and hTRAF1 (593); the mouse TRAF1 and -2 were described several months before by their interaction with the type 2 TNF-receptor cytoplasmic domains (703). LMP1 TES1 is structurally and functionally homologous to the TNF receptor (TNFR), CD40 (593), which, when activated, induces effects in B lymphocytes that are similar to LMP1 (42,101,585). The structural basis for LMP1 and CD40 engagement with TRAFs and many of the downstream effects are equivalent (74,164,166,180,181,182,183 and 184,225,227,302,408,424,572,667,726,798,854,911). LMP1 and CD40 share a PXQXT motif (164,227) that interacts with a shallow canyon on the surface of TRAF trimers (911,912). The biochemical effect is to stabilize TRAF1 and -2 and TRAF3 and -5 homo- and heterodimers on LMP1 TES1/CTAR1 and in the cytoplasm (164,166). TRAF trimers that incorporate TRAF2 and TRAF5 are particularly implicated in forward signalling from TNFRs. One aspect of LMP1 signalling through TRAFs is that the LMP1 PXQXT domain has a higher affinity for TRAF1 and -3 than for TRAF2 and -5 (164,166). TRAF1 is expressed at low levels in B lymphocytes and is then induced by LMP1 expression, whereas in epithelial cells or other cell types expression of TRAF1 may be minimal or not inducible, and this may affect the level of LMP1 signalling through TES1/CTAR1 in these cells.

TES2/CTAR2 also engages TNFR signalling pathways and ultimately signals through TRAFs (369,372). A yeast two-hybrid screen with TES2 bait retrieved the TNFR-I associated death domain protein, TRADD (369). The LMP1 carboxyl-terminal 11 amino acids interact with and constitutively associate with TRADD and RIP (369,372). LMP1 engages a small component of the death domain and does not propagate death domain complex recruitment or induce

cell death. Much of the signal that LMP1 transmits through TRADD and RIP appears to then be mediated by TRAFs, which are known to mediate nondeath signalling from TRADD and RIP. Dominant negative mutants of TRAFs block NF-kB activation from both TES1/CTAR1 and TES2/CTAR2 (408). Further, dominant negative mutants of the NF-kB-inducing kinase, NIK, or of the IKK inducing kinases, IKK a or b block TES1/CTAR1 and TES2/CTAR2-mediated NF-kB activation (Fig. 8) (798). However, NIK is probably only one component of the kinases that mediate signalling downstream of the TRAFs. NIK is probably not even the principal kinase that connects TRAFs to the IKKs. Furthermore, signalling downstream of the TRAFs activates not only IKKs and NF-kB, but also JUNK and *jun*/*fos*, p38 and AP-1, and CDC42 (180,182,184,302,423,667). Thus, while LMP1 signalling through TRAFs mediates most or all of LMP1's effects, aspects of these pathways are as yet incompletely delineated. One incompletely understood aspect of LMP1 signalling is the preferential role of TES1/CTAR1 over TES2/CTAR2 in the activation of EGF receptor expression in epithelial cells, or of TRAF1 expression in B lymphocytes (166,569,570,571 and 572). NF-kB activation is an important component of many of these transcriptional activations and is critical to LCL survival (82). Despite continued high level expression of Bcl-2 and Bcl-XI, inhibition of NF-kB activation results in apoptosis of LCLs.

LMP1 and EBNA-1 are the only latent infection–associated genes that are also transcribed in lytic EBV infection. In some latently infected BL cells such as Raji, LMP1 expression can be increased by treatment with activators of PKC, which increase early lytic cycle promoter activity (68,464,704). The promoter for full-length LMP1 expression in lytic infection has not been characterized. In late lytic infection, a promoter in the third LMP1 exon transcribes the part of the LMP1 ORF that encodes the last two transmembrane domains and the entire LMP1 cytoplasmic domain (353). This smaller integral membrane protein, referred to as D1LMP1, localizes to cytoplasmic membranes and does not have the transforming or cell activating properties of LMP1 and does not associate with vimentin or other cytoskeletal elements (490,491,523). The detection of LMP1 but not D1LMP1 in preparations of purified virus and newly infected cells indicates that LMP1 may be incorporated into virions (194,523). This raises the possibility that virion-associated LMP1 could have an effect on the growth of newly infected cells.

The expression of LMP1 in three lineages of transgenic mice under control of the immunoglobulin heavy-chain promoter and enhancer results in low-level expression in normal lymphoid tissue and an increase in B-cell hyperplasia and lymphomas (449). The incidence of lymphoma increased significantly with age with lymphomas developing in 42% of transgenic mice over 18 months of age. The lymphomas are monoclonal or oligoclonal by IgH rearrangement, and LMP1 is expressed at LCL levels in the lymphomas. These data indicate that LMP1 alone can be oncogenic in B lymphocytes *in vivo*. B cells of transgenic mice expressing LMP1 under the control of immunoglobulin promoter/enhancer–displayed enhanced expression of activation antigens, spontaneously proliferated and produced antibody. LMP1 expression in transgenic mice in CD40-deficient or normal backgrounds mimics CD40 signals to induce extrafollicular B-cell differentiation and blocks germinal center formation (854).

LMP2A and -2B

The cloning and sequencing of cDNAs (462,465,724) to 2.3- and 2.0-kb cytoplasmic polyadenylated RNAs (856) from latently infected cells provided the first evidence for two integral membrane proteins that were designated LMP2A and -2B, or TP1 and -2 (Fig. 9). (231,511). The first exons of LMP2A and -2B are the only unique exons; all other exons are shared by LMP2A and -2B. The first LMP2A exon is predicted to encode for a 119-amino-acid hydrophilic amino-terminal cytoplasmic domain. The first LMP2B exon is short and lacks a methionine codon. Translation of LMP2B initiates at a methionine codon at the beginning of the common second exon, before the first transmembrane sequence (724). The remaining LMP2A and -2B exons are predicted to encode 12 hydrophobic integral membrane sequences separated by short reverse turns and a 27-amino-acid hydrophilic carboxyl-terminal domain. Monospecific antisera generated against LMP2 fusion proteins localize LMP2A to a patch in the plasma membrane of latently infected B lymphocytes, where it co-localizes with LMP1 (510,511). LMP2A localizes to the same site in the plasma membrane of B-lymphoma cells whether or not LMP1 is expressed in the same cell.

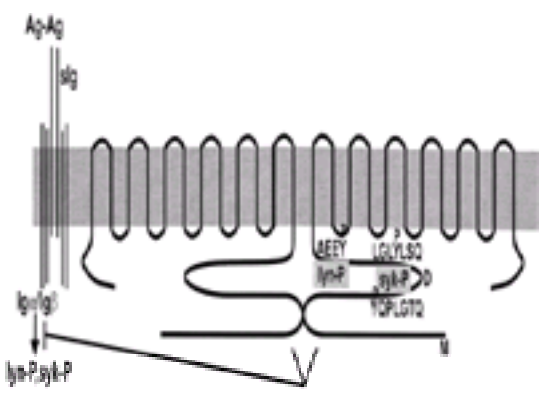

FIG. 9. Schematic diagram of the biochemical mechanisms by which LMP2 constitutively effects tyrosine kinase signalling pathways, inducing low-level activation and high-level global desensitization.

LMP2A is a substrate for and is associated with B-lymphocyte src family tyrosine kinases. Antiphosphotyrosine antibodies localize sites of constitutive tyrosine phosphorylation in the plasma membrane of cells that express LMP2A (510). The sites of tyrosine phosphorylation coincide with LMP2A, indicating that LMP2A is one of the few localized stable tyrosine phosphorylated proteins in BL cells or LCLs (510). LMP2A is stably associated with src family tyrosine kinases and with syk, unlike the sIg B-cell receptor complex, which markedly increases its association with these kinases when cross-linked by antigen (78,80,88,510). The first 167 amino acids of LMP2A, which include the amino-terminal cytoplasmic domain and the first two transmembrane domains, are able to associate with and be phosphorylated by these kinases (80,510). Among src family tyrosine kinases, LMP2A exhibits specificity for fyn and lyn in B lymphocytes

(80).

Despite the interaction of LMP2A with B-lymphocyte tyrosine kinases, LMP2A and -2B do not effect EBV transformation of primary B lymphocytes into LCLs or LCL survival. LMP2A and -2B have been extensively mutated in EBV recombinants (425,512,513 and 514,698,771). Except for one anomalous result (73), the specifically mutated recombinants transform primary B lymphocytes with wild-type efficiency. The resultant LCLs grow the same as wild-type EBV-transformed LCLs under standard culture conditions, in reduced serum, in soft agarose, and in mice with severe combined immunodeficiency disease (SCID) (425,512,513 and 514,698,771). Virus replication is also normal following treatment of latently infected lymphocytes with chemical inducers of lytic infection (425,512,513 and 514). The specific mutations include insertion of an amber nonsense linker after codon 19 of the LMP2A ORF, which results in ablation of expression of LMP2A and continued expression of LMP2B (512); insertion of an amber nonsense linker after DNA encoding the first five transmembrane domains, which results in ablation of expression in the last seven transmembrane domains and the carboxy-terminus of LMP2A and -2B (513); and deletion of DNA encoding the first five transmembrane domains of LMP2A and -2B, which results in truncation of LMP2A after the amino-terminal cytoplasmic domain and the addition of missense codons (514).

LMP2A expression in BL lymphoblasts constitutively blocks the signal transduction events that would follow the cross-linking of sIgM, CD19, or class II MHC on cells that do not express LMP2A (552,555). This blockade is similar to the desensitization that occurs after sIg signal transduction (78,88). LMP2A effects depend on the LMP2 transmembrane domains that mediate aggregation in the cell plasma membrane and on the LMP2A amino terminal cytoplasmic domain. The simplest model that would account for this activity is that LMP2 transmembrane domain–mediated aggregation of LMP2A results in phosphorylation of LMP2A, constitutive binding of src and syk, a constitutive low level of forward signaling, and turn-on of a down-regulatory kinase or phosphatase that globally blocks other src family–associated receptor tyrosine kinase–mediated signal transduction. Indeed, the basal tyrosine phosphorylation of many cellular proteins, including lyn, syk, and the p85 subunit of PI3 kinase, are higher in LCLs transformed by EBV recombinants that express wild-type LMP2A than in LCLs transformed by EBV recombinants that do not express LMP2A. Further, cross-linking of sIg on wild-type EBV–transformed LCLs results in abrogation of tyrosine kinase signalling at the first steps of src family and syk phosphorylation, whereas cross-linking of sIg on LMP2 null mutant recombinant–transformed LCLs results in normal sIg protein tyrosine kinase signal transduction, including transient phosphorylation of lyn, fyn, syk, p85, Vav, PLCgamma, SHC, and Grb2 (552). The amino terminus of LMP2A has a YXXL$(N)_7$YXXL sequence that in the B-cell receptor–associated molecules Ig alpha and Ig beta binds syk, and a YEEI sequence that binds lyn or other src family tyrosine kinases (88). When these LMP2A domains are fused to the CD8 surface and transmembrane domains and CD8 is cross-linked on cells that express the chimeric protein, the LMP2A domains transmit an increase in intracellular free calcium and are then refractory to further stimulation, as is characteristic of sIg cross-linking (49). The key roles for the LMP2 putative src family PTK binding site at Y112 and the putative syk binding site at the ITAM motif have been directly demonstrated by expression of the appropriate mutant proteins in BL cells and by examining sIg signal transduction in LCLs transformed by specifically mutated EBV recombinants (235,236 and 237). Both Y112 and the ITAM are stringently required for B-cell receptor desensitization.

The effect of LMP2A expression on LCLs is to block lytic infection that would occur in the absence of LMP2A following cross-linking of sIg on the surface of LCLs. Cross-linking of sIg on primary B lymphocytes transformed by LMP2 null mutant recombinants results in normal sIg-mediated signal transduction and activation of EBV replication (553,554). The LMP2A blockade to lytic activation can be bypassed by activating PKC and raising intracellular free calcium with phorbol ester (TPA) and calcium ionophore treatment. Treatment of wild-type or mutant transformed cells with TPA and calcium ionophore results in similar inductions of lytic infection (554). Because LMP2A is expressed in most latently infected B lymphocytes *in vivo*, one role may be to keep EBV infection latent in these cells when they encounter T lymphocytes or other potentially activating signals; a corollary of this hypothesis is that activation of lytic EBV infection in a latently infected lymphocyte could still be triggered by a cytokine released from an epithelial cell that might trigger a G protein–coupled receptor or JAK kinase signal transduction pathway (758).

A second role for LMP2 may be to provide survival and antidifferentiation signals to B cells that are not in type 3 latency. LMP2A expression in transgenic mice under control of IgH chain promoter and enhancer results sIg-negative B cells escaping from the bone marrow and colonizing peripheral lymphoid organs, bypassing normal B-lymphocyte developmental checkpoints (84). This indicates that LMP2A has sufficient constitutive forward signaling activity to affect the biology of normal B cells. The LMP2A effect is also evident in RAG 1(–/–) mice and is dependent on the LMP2A ITAM (83,547). Thus, LMP2A expression could have a role in latency type 2–infected lymphocytes in enhancing cell survival, in lymphoid organ persistence, or in blocking differentiation. As described in Chapter 75, LMP2A is also expressed in type 2 latency in Hodgkin's disease and nasopharyngeal carcinoma. Constitutive forward signalling effects of LMP2 could also be important in the pathogenesis of these malignancies. The effects of LMP2 are, however, subtle. No effect on epithelial differentiation or survival is evident with transgenic expression of LMP2A in normal mouse epithelium under control of the keratin 14 promoter (509). Effects on cell survival are evident with LMP2A expression in the human keratinocyte cell line, HaCaT. LMP2A-expressing cells are hyperproliferative in raft cultures, differentiation is inhibited, and cloning efficiency in soft agar is substantially increased (737). Cells that grew in soft agar formed aggressive, poorly differentiated tumors in nude mice. PI3 kinase and AKT were activated in the LMP2A-expressing cells and tumors. Thus, in the appropriate cell type, LMP2A can have survival-enhancing effects.

EBERs

The EBV-encoded, small, nonpolyadenylated RNAs are by far the most abundant EBV RNAs in latently infected cells. Estimates of abundance place the EBERs at 10^4–10^5 copies per cell (32,340,343). EBER-1 is transcribed by RNA polymerases II and III, whereas EBER-2 is solely transcribed by RNA polymerase III (340,341 and 342). The EBERs localize to the cell nucleus, where they are complexed with the cellular proteins La and EBER-associated protein (EAP) (475,832,833). The EBER RNAs have stable secondary structures that persist in RNA La protein complexes (256). La protein is associated with the 3' terminus of the EBER RNAs (256), whereas EAP is associated with the stem-loop 3 structure (832,833). Most of the EBER-1 is precipitable with antibody to EAP. EAP is L22 ribosomal and about half of the EAP in EBER-expressing cells is in EBER-1 ribonucleoprotein (RNP) particles in the nucleoplasm (831). The EBER

RNPs are predominantly in the nucleoplasm. L22 is associated with chromosomal translocation in leukemia, raising the possibility L22 association with EBERs could be of functional significance. EBER-1 and -2 have extensive primary sequence similarity to adenovirus VA1 and VA2 and cell U6 small RNAs, both of which also form similar secondary structures and complex with La protein (256).

EBER-1 or -2, adenovirus VA, and U6 cell RNAs may have similar primary sequences, secondary structures, and association with La protein in order to accomplish similar functions. Based on the known functions of VA and U6 RNAs, two alternative roles have been proposed for the EBERs. In adenovirus infection, VA1 RNA acts in the cytoplasm to directly inhibit activation of the interferon-induced protein kinase PKR, which would, in the absence of VAI RNA, phosphorylate protein synthesis initiation factor eIF-2 alpha and block translation (736). EBER-1 and -2, provided by transfection into cells or substituted in to the adenovirus genome, can partially complement the replication of adenovirus with null mutations in VA1 and -2 (53,54). EBER-1 can also inhibit PKR *in vitro*, at levels that are similar to VA1 RNA (116,117,118 and 119,747). Moreover, EBV-mediated growth transformation is sensitive to high levels of interferon, and the EBV Bam W latency 3 EBNA transcript can activate PKR, so a role for the EBERs in inhibiting PKR could be important (179). However, evidence that PKR is inhibited in latency 1, 2, or 3 infected cells has not been obtained.

Small nuclear RNAs have long been suspected to be involved in RNA splicing, partly because of base complementarity to splice sites. U6 RNA has been shown to be base-paired to U4 RNA in particles required for *in vitro* RNA splicing. Six of seven identical nucleotides to those through which U6 binds to U4 are in a single-strand loop in EBER-2 RNA (256).

EBV recombinants specifically deleted for the EBER genes have been compared with wild-type recombinants in primary B-lymphocyte infection (797). EBER-deleted virus was as able to initiate primary B-lymphocyte infection and growth transformation as wild-type virus. No difference could be found in the growth of LCLs infected with EBER-deleted or control virus or in the permissivity of these cells for lytic virus infection following induction.

To further evaluate the hypothesis that the EBERs could have an antiinterferon effect, the effect of the EBERs on the replication of an interferon-sensitive virus in EBV-transformed human B lymphocytes was determined (796). Replication of vesicular stomatitis virus (VSV) in human lymphocytes is sensitive to interferon. However, interferon had a similar inhibitory effect on VSV replication in LCLs infected with EBER-deleted or wild-type virus (796). Further, lytic wild-type EBV replication could not be inhibited by high levels of interferon, and replication in cells infected with EBER-deleted virus was not more sensitive to interferon. Moreover, EBER-deleted virus was not more sensitive to the antitransforming effects of interferon (796). Once established as LCLs, neither EBER-deleted nor wild-type EBV–infected LCLs were sensitive to potential antiproliferative effects of interferon. Thus, the role of the EBERs in EBV infection is not obvious from studies in B lymphocytes *in vitro* and may emerge from testing of the mutants in other cell types or in an *in vivo* model.

Recent data indicate that EBER expression may increase the tumorigenicity of BL cells or non-EBV-infected nasopharyngeal carcinoma cells, in which EBERs have been specifically expressed (440,441,818). Surprisingly, EBER expression in Akata BL cells resulted in increased Bcl-2 levels (440).

Other Viral Gene Products Expressed in Latent EBV Infection: BARF0, RPMS1, A73, and BHRF1

Complementary-strand Bam A rightward transcripts, also known as CSTs, BARTs, or BARF0 RNAs, are differentially spliced RNAs that were identified in the cloning of cDNAs from RNA of latently infected nasopharyngeal carcinoma cells grown in nude mice (98,251,334,399,716,766). CSTs have also been identified in latently infected BL cells (75,766), latently infected lymphocytes from human peripheral blood or marmoset tumors (97,922), and early primary infection of B cells *in vitro* (75) and LCLs (75,766). These RNAs initiate at n 150645 in the B95 sequence (36,716,766). Transfection of EBV DNA sequences corresponding to n 150199–151283 results in expression of the first exon in HeLa cells (766). Three ORFs in the differentially spliced CSTs may encode protein in latently infected cells, BARF0, RPMS1, and A73. BARF0 is potentially encoded in the most 3' ORF of the CSTs. Humans have antibody to the 173-amino-acid BARF0 polypeptide, consistent with its expression at some point in EBV infection (251). Two differentially spliced forms of BARF0 are described, BARF0 and the further spliced ORF, RK-BARF0 (234,421). Both are encoded by CST exon 7 (766). RK-BARF0 has a signal peptide sequence and interacts with the Notch4 ligand binding domain in yeast two-hybrid, coimmunoprecipitation, and confocal microscopy assays (452). RK-BARF0 expression can induce translocation of part of Notch4 to the nucleus and can turn on LMP1 expression in latency 1 infected BL cells.

RPMS1 is encoded in an ORF formed by the fourth exon and components of the fifth exon of some CSTs, includes a WWP motif similar to EBNA-2, interacts with RBP-Jk amino acids 310 to 500 in yeast two-hybrid assays, and blocks EBNA-2 transactivation of a promoter with a multimerized upstream RBP-Jk site (766). Expression of RPMS1 alone does not up- or down-regulate promoters. Thus, RK-BARF0 can potentially up-regulate promoters with upstream RBP-Jk sites, and RPMS1 would modulate that activity.

The third potential CST ORF, A73, is formed by components of exons 6 and 7 (766). A73 is expressed as a cytoplasmic protein that can interact with the cell RACK1 protein in yeast two-hybrid assays, and it can associate with a small fraction of RACK1 in 293 cells. A73 could potentially affect RACK1 modulation of PKC or src tyrosine kinase signaling.

Although the CSTs are likely to be important in latent EBV infections, infections of primary B lymphocytes with EBV recombinants that are deleted for the DNA that encodes the CSTs efficiently results in LCLs that can be readily expanded *in vitro* (412,691,694). Thus, at this first level of analysis, CSTs are not critical for EBV transformation of primary B lymphocytes *in vitro* or for LCL outgrowth or survival.

Some EBNA-type Bam W transcripts from various latently infected cells include BHRF1 at their 3' end (34,721). BHRF1 is expressed at high levels early in lytic infection, it is a bcl-2 homolog, and it has antiapoptotic effects (320,339,641). These antiapoptotic effects are likely to be quite important for efficient lytic infection in most cell types. Expression at even a low level in latent infection could be of significance. However, searches for the protein in latently infected cells using

polyclonal or monoclonal antibodies that readily detect the protein in lytically infected cells fail to detect BHRF1 in LCLs or type 3 latently infected BL cells (641). BHRF1 protein has been detected transiently after refeeding growth-arrested Raji cells but not in similarly treated LCLs (G. Pearson, personal communication).

Consistent with the failure to detect BHRF1 protein expression in latently infected LCLs and the abundant expression of antiapoptotic Bcl-2 family proteins in these cells (82,321,775), EBV recombinants with a nonsense mutation or deletion of the BHRF1 ORF are fully competent for the transformation of primary B lymphocytes into actively growing LCLs (471,530). Mutant recombinant virus replicated in LCLs could be recovered from these cells, and it transformed primary B lymphocytes with efficiencies similar to wild-type virus. BHRF1 is therefore not critical for outgrowth or survival of latency 3 infected LCLs or for EBV replication in such cells.

Role of Latency 3 Infection Proteins in LCL Outgrowth and Survival

EBV-transformed primary B lymphocytes are nearly indistinguishable from B lymphocytes proliferating in response to polyvalent antigen and T-cell help or IL4, IL10, and CD40 in their growth and display of molecular markers of adhesion, activation, and differentiation (23,24,42,85,263,337,363,585,635,661,688,824,825,829,913). The growth and survival of LCLs is highly dependent on autocrine and paracrine signalling mediated by IL5, IL6, IL10, TNF-beta, and transforming growth factor (TGF) (19,48,79,165,168,183,186,197,263,330,345,436,445,544,584,599,638,639,705,728,729,778,812,829,845,846,859). The major characteristics that distinguish LCLs from B lymphocytes proliferating in response to polyvalent antigen and T-cell help are the expression of EBV latency 3–associated genes, immortality, and autonomy. For heuristic purposes, two hypotheses are considered here and in Chapter 75. First, the unique set of genes that LCVs use to cause LCL outgrowth evolved to enable these viruses to rapidly expand the number of latently infected B lymphocytes in the course of primary infection and to periodically reexpand that pool to further the persistence of virus infection *in vivo*. Second, the principal constraint in evolution of these genes is that they use normal B-cell growth pathways and leave the cell susceptible to checkpoint controls, external regulatory signals, and immune surveillance, so as to minimally damage the host. LCVs encode EBNAs to constitutively activate and regulate transcription from Notch- and PU.1-responsive promoters in cell DNA, including the c-*myc*, c-*fgr*, CD21, and CD23 promoters. EBV regulation of c-*myc* is significantly more akin to c-*myc* regulation by B-cell growth stimulatory processes. Constitutive c-*myc* expression in an LCL radically alters the cell phenotype (135,508,657). Constitutive c-*myc* expression in LCLs negatively regulates endogenous c-*myc*, alters adhesion and activation molecule expression so that the cells have the characteristics of a BL cell, increases susceptibility to NK cell cytotoxicity, and increases tumorigenesis in nude mice.

EBV has evolved EBNA-2 responsive cis-acting transcriptional regulatory sequences that bind RBP-Jk and PU.1 to autoregulate EBNA and LMP transcription from the viral genome. LMP1 constitutively activates the TNFR/CD40 downstream signalling pathways to co-stimulate cell growth and survival through NF-kB, junk, and p38 map kinase activation. These two pathways are depicted in Figure 10. *In vivo*, EBV regulation of LCL growth can be overridden by the microenvironment of infected cells: simply resuspension of the dispersed cells in dilute culture medium stops growth for weeks until the medium is adequately conditioned. Some of the mechanism by which the normal cell and the EBV-transformed cell regulate progress through the cell cycle, maintain telomeres through multiple rounds of expansion, and escape programmed cell death are unclear and present substantial future challenges in this area of EBV investigation. A substantial body of genetic and biochemical data described in this chapter and in the references indicate that the EBV latency-associated genes do not inactivate normal cell checkpoint controls such as Rb or p53 (18,89,366). EBNAs and LMPs do have “transforming effects.” EBNA-2, expressed under control of the SV40 promoter and enhancer in transgenic mice, caused islands of kidney tubular hyperplasia at 20 weeks in all animals (843). At 50 weeks, multiple foci of microscopic renal tubular adenocarcinomas were evident; eventually, 90% of the transgenic mice has renal tubular adenocarcinomas. *In vitro*, EBNA-2 lowers the serum dependence of Rat-1 cells (148). EBNA-2 also exerts strong activating effects on genes that are regulated by Notch: Constitutive Notch activation in T cells induces leukemia (185,640). Moreover, EBNA-2 is involved in up-regulation of c-*myc* in LCLs (394). However, EBNA-2 has not been reported to have SV40 virus–like T antigen, or adenovirus-like E1A effects in collaborating with activated Ras in primary rodent cell immortalization. As described earlier, LMP1 has multiple activated Ras–like effects on immortalized rodent fibroblast cell lines, and transgenic LMP1 expression in mice results in increased incidence of lymphoma. LMP1 is not reported to substitute for activated Ras in complementing T or E1A in primary rodent fibroblast transformation. EBNA-1 has had a c-*myc*-like effect in inducing lymphomas in transgenic mice (884). However, the one lineage with this robust effect on lymphoma incidence did not express EBNA-1 in the transgenic normal lymphocytes. Only one study ascribed an E1A-like effect to one of the EBNAs in primary rat fibroblast immortalization experiments (633). The potential basis for the latter effect has not as yet emerged from intensive investigation of EBNA-3C.

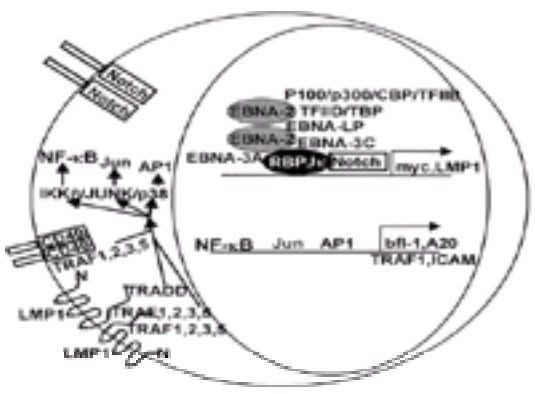

FIG. 10. Schematic diagram of the biochemical mechanisms by which EBNA-2, -LP, -3A, and -3C and LMP1 collaborate to induce primary B-lymphocyte growth transformation and survival. EBNA-2, -LP, -3A, and -3C use the nuclear anchor for Notch signaling and the B-cell Ets family protein PU.1 to constitutively up-regulate cellular and viral promoters including the c-*myc* promoter, the LMP1 promoter, and the EBNA promoter. LMP1 constitutively activates TNFR-associated factor signalling, inducing NF-kB, Jun/Fos, and AP-1.

Persistence of EBV DNA in Latently Infected Cells

The circularization of linear input EBV DNA in the nuclei of acutely infected lymphocytes requires 12 to 24 hours (12,362). Cells do not enter S phase until all of the EBNAs and LMPs are expressed. Stable latently infected proliferating lymphocytes characteristically contain multiple copies of EBV episomes (3,400,496,616,786,809). Most LCLs have about 10 episomes per cell. The range of episome copy number in BL cells is greater. Raji cells have 50 episomes per cell and the number has been stable over 30 years in culture (2,26). EBV episomes are replicated early in S phase by cell DNA polymerase (2,283,293). The initial amplification of circular EBV DNA is at the start of latent infection and requires early S phase DNA synthesis, as prior to S phase each infected cell has only one episome (12,786).

Although EBV DNA usually persists in cells as an episome, the EBV genome can also integrate into chromosomal DNA, and both integrated and episomal DNA coexist in some cells (159,282,318,361,393,467,543,889). In one EBV-infected human Burkitt tumor cell line, EBV DNA has persisted by integrating on chromosome one at IP35 (318,467). The entire EBV genome is integrated into A-T-rich cell DNA through the EBV TR (543). More than 15 kb of cell DNA were deleted by the integration of the 170-kb complete EBV genome. The entire block of cell DNA with the integrated EBV genome has then been duplicated as an inverted DNA domain (467). Another example is a latently infected fetal human LCL that contains an EBV genome integrated at chromosome 4q25 (318,543). In this instance, integration appears to be through a site within U1 (315,318), and there are several EBV genomes integrated in tandem (362). In the first instance, integration through TR favors the hypothesis that integration occurred prior to circularization; however, in the second instance, integration through U1 and the finding of tandem repeats of the EBV genome are more consistent with the hypothesis that integration occurred after initial circularization. Integration occurs frequently when BL cells are infected with EBV *in vitro* and extensively passaged (361). In contrast, infection of BL cells with EBV and selection for cells infected with virus almost always results in cell lines that contain episomal EBV DNA (527,528 and 529,869). The genome persists as an episome in such cell lines for at least 1 year. Clearly, integration is not a regular feature of EBV infection or EBV induced cell growth transformation. However, because LMP2 is the only EBV gene that spans the TR, and LMP2 is not required for cell transformation, EBV may be able to transform cells with the genome persisting solely as integrated DNA.

Episomal DNA is likely to be necessary for lytic cycle EBV DNA replication, because lytic herpesvirus DNA replication characteristically proceeds from a circular DNA intermediate (for review, see Chapter 72). Circular EBV DNA copy number increases in lytic infection (747a). Lytic EBV replication has not been observed in cells that contain only integrated EBV DNA, and virus has not been recovered from such cells in response to known inducers of virus replication.

In the establishment of latent infection, the EBV genome undergoes progressive methylation (203,347,374,429,458,459,478,540,577,615,650,695,718,801,813,814) and associates with chromosomal proteins so as to give a nucleosomal pattern after micrococcal nuclease digestion (176,654,744,747b). Regulatory domains involved in maintaining latent infection such as oriP tend to be undermethylated in latently infected cells relative to DNA that is expressed only in lytic infection (196,203,205,347,374,546,575,576,615,695). Extensive methylation of lytic genes and their regulatory elements probably helps to maintain latency by inhibiting lytic gene expression. Treatment of latently infected cells with drugs that reduce DNA methylation increases the frequency of spontaneous activation to lytic infection (51,540,696).

Induction of Lytic Infection

Lytic EBV infection is usually studied by inducing latently infected BL cells to become permissive for lytic virus replication (51,350,516,680,717,933). Various induction strategies give characteristic, although not precisely reproducible, levels of permissivity for each latently infected B cell line. Autocrine TGF-beta may participate in lytic reactivation, as antibody to TGF-beta reduces the responsiveness of cells to lytic induction (168). Phorbol esters are among the most reproducible and most broadly applicable inducers. The effect is probably mediated by PKC activation of *jun-fos* interaction with AP-1 sites upstream of the immediate-early virus genes (28,139,210,211,218,219,221,222,223 and 224,464,473,486,817). The rapidity of activation of immediate-early EBV genes by phorbol ester is most consistent with the activation of a preexisting transcriptional coactivator of lytic cycle gene expression, or with inactivation of an active repressor of lytic infection. PKC does activate BZLF1 itself, and the effect of PKC could be to increase background activity of the BZLF1 promoter through autostimulation (47). Among latently infected LCLs, marmoset LCLs tend to be more inducible than adult human lymphoblasts, and neonatal human lymphoblasts are least inducible for virus replication (558,561,562,566,567, and for review see ref. 556). A few cell lines can be consistently induced to permit lytic virus replication in 10% of the cells (333,567,802,803). One cell line, Akata, can be induced to 20% to 50% lytic infection by cross-linking sIg; it is currently the best source for large quantities of EBV (803). SIg cross-linking activates phospholipase-C-gamma. Phospholipase-C-gamma releases IP3 and diacylglycerol, which mobilize calcium from intracellular stores and activate PKC. Treatment of cells with calcium ionophore and phorbol ester induces a rise in intracellular free calcium and activates PKC but is only a partial surrogate for sIg cross-linking, compatible with the possibility that other pathways activated by sIg cross-linking may have a role in the induction of lytic infection in Akata cells (95,136,137,139,257,505,507,748,772). Several elements upstream of the BZLF1 promoter seem to mediate the sIg response: Sp1, Sp3, myocyte enhancer factor 2D, ATF-1, and ATF-2 (505). The ATF-1 and ATF-2 binding sites correspond to a site that is regulated in part by CAM kinase IV (95). The initial activation of Z may be dependent on two 7-bp dyad symmetry elements separated by 27 bp. These sequences are similar to a reversible YY1-dependent silencing element in adeno-associated virus and may contribute to the lack of Z expression during latency (583). Other negative regulatory elements are more upstream from the transcriptional initiation site (739). Changes in the BZLF1 promoter histone acetylation appear to be critical for BZLF1 activation (380).

The responsiveness of Akata cells to sIg cross-linking is due in part to stable latency 1 infection. The absence of LMP2A enables sIg cross-linking induced signal transduction and induction of lytic EBV infection. In latency 3–infected lymphocytes where LMP2A is expressed, calcium ionophore and TPA can be used to induce virus replication (554). An

alternative strategy is to use cells infected with EBV recombinants with specific null mutations in the LMP2A gene (551,554).

A second approach to studying virus replication is to induce lytic replication by superinfection of Raji cells with the P3HR-1 EBV (55,597,670). Raji is an EBV-infected Burkitt tumor–derived cell line that has an unusually high EBV episome copy number and is responsive to this type of induction. The endogenous Raji genome has at least two deletions and is defective for EBV DNA replication and late gene expression (301,656). Thus, EBV late genes are expressed in Raji cells only after superinfection. The P3HR-1 virus is efficient in inducing lytic infection in Raji because of defective virus genomes in most noncloned P3HR-1 cell cultures (129,311,559,564,701). An abundant class of defective virions from noncloned P3HR-1 cells has rearranged EBV DNA molecules in which the Z or R and Z immediate-early transactivator(s) are downstream of the latent infection cycle IR1 EBNA gene promoter and are, therefore, expressed in latently infected cell lines following superinfection (110,311,381,382 and 383,564,677,678). The induction of productive infection following high multiplicity superinfection is more rapid and synchronous than following chemical induction. Maximal late virus protein expression and enveloped virus release requires 48 to 96 hours.

Following induction, cells that have become permissive for virus replication undergo cytopathic changes characteristic of herpesviruses, including margination of nuclear chromatin (406), inhibition of host macromolecular synthesis, replication of viral DNA at the center of the nucleus, assembly of nucleocapsids at the nuclear periphery, nucleation of nucleocapsids, and envelopment of virus by budding through the inner nuclear membrane (158,247,261,262,631,727). Virus gene expression follows a temporal and sequential order (for review, see refs. 209 and 803). Some virus mRNAs are expressed early after induction despite the inhibition of new protein synthesis. These RNAs are classified as immediate-early (630). Most early lytic virus genes that are expressed before the onset of virus DNA replication are dependent on the immediate-early BZLF1 or BRLF1 protein transcription factors for their expression. Genes are formally classified as early if their expression is not affected by inhibition of viral DNA synthesis. Late proteins are expressed temporally later but are formally categorized as late based on the marked reduction in their mRNA abundance in the presence of viral DNA synthesis inhibitors.

Immediate-Early Genes and Their Targets

In typical herpesvirus infection, immediate-early genes are defined by their transcription following infection in the presence of inhibitors of protein synthesis (for review, see Chapter 72). Characteristically, a virion tegument protein contributes to the activation of immediate-early gene expression. *In vivo*, EBV replicates in epithelial cells of the oropharynx before infecting B lymphocytes. Infection of epithelial cells lines *in vitro* is not efficient, and studies of the biochemical events of synchronous lytic infection in permissive epithelial cell cultures has not been feasible. Only B lymphocytes can be efficiently infected by EBV, and the outcome of infection is nonpermissivity for virus replication and the expression of the EBNA-2 and EBNA-LP mRNAs. EBNA-2 and -LP are likely to be immediate-early gene products in primary B lymphocytes, given the constitutive activity of the Wp EBNA promoter and the indications that EBNA-LP and -2 are the first EBV mRNAs expressed in these cells, but independence of transcription from new protein synthesis has not been demonstrated. Similarly, the constitutive activity of the Bam Q EBNA-1 promoter in BL cells (718) and the early expression of EBNA-1 mRNA in infected BL cells may be in the mode of an immediate-early gene.

Because synchronous lytic EBV infection *in vitro* can be studied only by induction of permissivity in cells that are already latently infected, the definition of immediate-early lytic infection–associated gene expression must be modified to acknowledge the potential direct or indirect effects of EBV latent infection genes on transcription from the activated EBV genome or the potential effect of the induction strategy on the transcription of specific EBV genes. Moreover, chemical induction may fail to activate an immediate-early gene whose transcription in lymphocytes or primary epithelial cells depends on a virion trans-acting factor. Thus, our current definition of BZLF1 and BRLF1 as the principal immediate-early viral genes may be incomplete.

P3HR-1 superinfection of Raji cells and inhibition of protein synthesis with anisomycin results in accumulation of 1-kb BZLF1, 2.8-kb BRLF1, and 4.1-kb BI'LF4 mRNAs (55). Induction of lytic infection in Akata cells by sIg cross-linking and incubation of the cells in the presence of moderately high concentrations of cycloheximide (50 µg/mL) results in relatively abundant expression of the 1-kb BZLF1 and 2.8-kb BRLF1 mRNAs, confirming that these are immediate-early gene products (803). Cycloheximide resistant 1.6- and 4.1-kb mRNAs from Bam M and A, respectively, are also expressed in induced Akata cells, but these mRNAs are much less abundant in cycloheximide-treated cells than in nontreated cells. In the absence of cycloheximide, the Bam M and A mRNAs are most abundant from 4 to 12 hours after induction, whereas the BZLF1 and BRLF1 mRNAs are expressed earlier. Thus, the M and A mRNAs appear to be early but not immediate-early genes. The Bam A mRNA is encoded by BALF2, which is the EBV homolog of HSV-1 ICP8. ICP8 is also expressed very early in HSV infection and is less sensitive to viral protein synthesis inhibition than other early virus genes. Another immediate-early gene is encoded from the BI'LF4 ORF (533).

The first evidence that BZLF1- and BRLF1-encoded proteins are key transactivators of lytic EBV gene expression (Fig. 11) came from the discovery that highly defective P3HR-1 virus preparations that induce lytic infection in EBV-infected BL cells express BZLF1, or BZLF1 and BRLF1, under control of the Wp promoter (381,382 and 383,557,564). BZLF1 expression from heterologous vectors broadly activates lytic infection (272,381,382 and 383). BZLF1 and BRLF1 coordinately up-regulate expression from early EBV promoters (96,105,106). BI'LF4 also has transactivating effects, although these effects are restricted to specific types (533). Consistent with these *in vitro* observations, BZLF1 is expressed in advancing margins of lytic EBV infection in oropharyngeal epithelia (919).

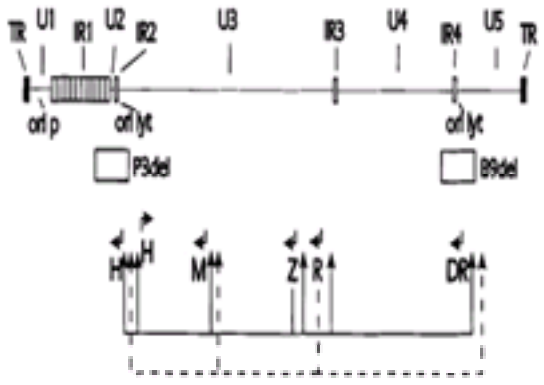

FIG. 11. Immediate-early lytic EBV infection. In latently infected B lymphocytes, the promoters for BZLF1 and BRLF1 can be activated by physiologic changes, by pharmacologic treatment, or by heterologous Z overexpression. In newly infected epithelial cells, the BZLF1 and BRLF1 promoters are presumed to be activated by virion-associated transactivators. BZLF1 and BRLF1 are transcribed, translated, and localized to the nucleus, where they coordinately further up-regulate their promoters and turn early genes, including BHLF1, BHRF1, D_R, BSMLF1, and BALF2 (not shown).

Two key early promoter regulatory elements within D_L and D_R (duplication, left and right) are coordinately up-regulated by the BZLF1- and BRLF1-encoded proteins. D_L and D_R encode abundant early mRNAs (149,232,351,357,620,621) and include the origins for lytic viral DNA replication within their promoter upstream regulatory domains (291). BZLF1 and BRLF1 synergistically up-regulate the bidirectional BHLF1 and BHRF1 D_L promoters in transient transfection assays (96,105,106,131). Promoter activation has a strong positive effect on DNA synthesis from the neighboring D_L origin. The cis-acting domains of D_R and D_L have been partially dissected and have many similarities including multiple BZLF1 binding sites (96,105,106,297,486,735). The promoter proximal domain (–79 to –221 bp relative to BHLF1) confers strong promoter activity in HeLa or Vero cells only when BZLF1 is provided in trans (736). ZBP-89 and Sp1 bind synergistically to a site near the promoter, stimulate transcription, and interact with the viral DNA polymerase and processivity factor (46). PKC phosphorylation of BZLF1 S186 increases BZLF1 transactivation and DNA replication effects (47). A DNA segment 639 bp upstream of the BHLF1 cap site is a position- and orientation-independent enhancer composed of one component with constitutive activity in fibroblasts or epithelial lines but not in B lymphocytes, and a second component, TTGTCCCGTGGACAATGTCC, which is responsive to the BRLF1 transactivator. Although BZLF1 interaction with this site has negligible effects on transcription from the BHRF1 promoter, BRLF1 activates transcription and BZLF1 strongly up-regulates transcription with BRLF1 (131). Regulation of the D_R element appears to be different, in that BZLF1 does not strongly up-regulate the BZRF1 effects on D_R (279).

The BSMLF1 and BMRF1 promoters are also coordinately regulated by BZLF1 and BRLF1 (336,672). Direct BRLF1 binding to the BMRF1 promoter upstream DNA is essential for BMRF1 coordinate up-regulation by the BZLF1 and BRLF1 transactivators (672). BRLF1 transactivation of the BSMLF1 early promoter is also mediated by activation of an upstream sequence CCGTGGAGAATGTC similar to the activation sequence in BHLF1 (277,413). *In vitro* translated R binds directly to this R response elements by interacting with two sequences catGTCCCtctatcatGGCGCagac within the element that are close to an optimal R binding site (277,278,280). The BZLF1 protein interacts with a TPA response element upstream of the BSMLF1 promoter (506).

The BZLF1 protein interacts with NF-kB, p53, and virion proteins (285,338,925). NF-kB interaction inhibits the transactivating effects of BZLF1. Similarly, the BZLF1 coiled-coil dimerization domain interacts with the carboxyl-terminal portion of p53, the two proteins associate *in vivo*, and both proteins are transcriptionally inactivated by the association. BZLF1-mediated inhibition of p53 could be important in preventing p53-induced apoptosis in response to lytic EBV DNA replication. Later in lytic infection, BZLF1 becomes associated with virion structural proteins; BZLF1 has not been detected in virus (404). The interaction of BZLF1 with NF-kB, p53, and virion structural proteins could down-modulate BZLF1 activity late in infection so as to minimize the toxic effects of high-level BZLF1 expression.

A minor immediate-early RNA encodes an unusual spliced product of the BRLF1 and BZLF1 bi-cistronic transcript that could also down-modulate BZLF1 activity (239,742). This RNA has the beginning of the BRLF1 ORF spliced in-frame to the DNA binding and dimerization domains of BZLF1. Because the BRLF1 activation domain is at the C-terminus and the BZLF1 activation domain is at the N-terminus, the spliced product lacks an activation domain and when dimerized with Z, it represses Z activity (239).

BZLF1 can down-regulate the EBNA Cp promoter, perhaps facilitating the transition from latent to lytic infection (415,754). The action of BZLF1 on Cp appears to be indirect, involving the up-regulation of *fos* by BZLF1 and the down-modulation of the positive effect of a glucocorticoid response element, which maps about 1 kbp upstream of Cp (450,754,757). Glucocorticoid withdrawal from culture media increases permissivity for replication, indicative of a mutual antagonism between Cp function and lytic reactivation. The Cp promoter may antagonize lytic infection, in part because Cp transcription is antisense to BZLF1 and BRLF2 transcription.

BZLF1 probably autoregulates its own promoter and the BRLF1 promoter (218). The Z promoter has several AP1-like upstream elements that mediate activation in the presence of low levels of Z and repression in the presence of high levels of Z. Differential Z binding to the various upstream sites could be mediated by changes in Z abundance during lytic infection.

BZLF1 mRNA is composed from three exons, each encoding a separate functional domain (215,485). The first exon encodes amino acids 1 to 167, which constitute a transactivating domain when fused to a Gal-4 DNA binding domain

(107,218,483,560). The activating domain can recruit TAFs and stabilize TFIID association with TATA elements through protein–protein interactions (483,484,488). Replacement of the BZLF1-activating domain with the VP16 acidic domain results in enhanced transactivation of early promoters (48). The second exon encodes amino acids 168 to 202, a sequence that includes a strongly basic domain with homology to a conserved region of the c-*fos* and c-*jun* family of transcriptional modulators (211). This domain confers the ability to interact with AP1-related sites in DNA (94,220,482,483,485,486) and also targets Z to the nucleus (550). A BZLF1 intron also has homology to the 3' untranslated c-*fos* sequences, suggesting that BZLF1 relatively recently evolved from c-*fos* (211). The third exon encodes for amino acids 203 to 245, a sequence that includes a near-perfect leucine and isoleucine heptad repeat capable of coiled-coil dimer formation (94,211,219,220,443,483). Like c-*fos*, BZLF1 is a dimerizing DNA binding protein that binds directly to AP1-related sequences (211,220,222,223 and 224,483,485,486). Dimerization may facilitate high affinity interaction with templates having two or more Z binding sites (92).

BZLF1 is multiply phosphorylated by casein kinase II, PKA, and PKC on serines 173, 186, and 336 (47,136,439). The phosphorylation regulates DNA binding activity and transcriptional activating effects. Phosphorylation of S186 in response to PKC activation stimulates transcription but decreases affinity for cognate DNA (47).

The R transactivator is also a DNA sequence-specific acidic transactivator and has distant homology to c-*myb* (280,521,522). C-*myb* can interact synergistically with Z in transactivating the BMRF1 promoter in lymphocytes (414). Two domains of R when fused to the Gal-4 DNA binding domain have transactivating activity for Gal-4 response elements upstream of basal promoters (297,298). Amino acids 416 to 519 are weakly activating and are required only for activation in B lymphocytes, whereas the carboxyl-terminal amino acids 520 to 605 are a potent acidic transactivating domain similar to VP16.

Early Lytic Infection

EBV early replicative cycle genes are operationally differentiated from late genes by their persistent transcription in the presence of inhibitors of viral DNA synthesis. By this criterion, at least 30 EBV mRNAs are early mRNAs, and almost 30 EBV mRNAs are late mRNAs (see Fig. 1) (36,43,55,56,209,210,249,250,301,352,353 and 354,358). Early and late mRNAs are intermingled through most of the EBV genome. Frequently, different promoters initiate nested transcripts, which begin with different ORFs and terminate at the same polyadenylation site, so that the longer mRNAs include all of the shorter mRNAs; the primary reading frames of the shorter mRNAs are 3' to the primary reading frame in the longer mRNAs and are likely to remain untranslated or inefficiently translated in this context. Some early and late genes are spliced, and others are not. Minor spliced mRNA species have frequently been discerned when genes have been studied in detail.

Because of the difficulty of doing genetic studies of EBV, proteins encoded by EBV early or late genes have usually been identified and assigned functions from predictions based on the ORF sequence, from the temporal class and abundance of the RNA or the size of its *in vitro* translation products, or from functional assays of *in vitro* translated or *in vivo* expressed proteins. The function of many EBV genes was first suggested from comparison of predicted primary amino acid sequences with those of other herpesvirus proteins of known function. Subsequent studies have generally confirmed these tentative functional assignments, and they frequently revealed unique as well as common attributes of the EBV proteins.

Aside from the two immediate-early proteins BZLF1 and BRLF1, the EBV early proteins BSMLF1 and BMRF1 may also transactivate expression of other early EBV genes. Both are moderately abundant early nuclear proteins (113,114). BMRF1 activity has been demonstrated only by co-transfection with SV40 promoter driven by chloramphenicol acetyl transferase reporter gene DNA into BHK cells (624). BSMLF1 is a promiscuous transactivator of gene expression that acts synergistically with BZLF1 or BRLF1 in inducing higher-level expression in transient expression assays (413,415,416,487,624,890). The level of CAT reporter gene mRNA does not increase in cells co-transfected with BSMLF1-expressing plasmids (417). BSMLF1 does not effect increased transcription in nuclear on assays (72,713). Instead, BSMLF1 increases cytoplasmic transport of unspliced mRNAs, and this accounts for the promiscuity of its effects in transactivation (72,713). Both cytoplasmic transport and promiscuous transactivation depend on BSMLF1 association with CRM1.

Two other EBV early proteins are quite abundant. One encodes the 135-kd BALF2 protein (357). This protein has primary amino acid sequence homology to the major HSV DNA binding protein ICP8, and it is important in DNA replication (217). A second RNA that is less abundant encodes BHRF1 (34,641). BHRF1 encodes an 18-kd protein that consists of a predicted hydrophobic signal peptide, a 135-amino-acid hydrophilic domain that contains two potential N-linked glycosylation sites, a hydrophobic potential transmembrane domain, and a short carboxyl-terminal cytoplasmic domain. BHRF1 has extensive colinear homology with *bcl-2*, a cell gene activated by the chromosome 14/18 translocation in human follicular B-cell lymphomas (120). Immunofluorescent microscopy with specific sera reveals nuclear membrane and cytoplasmic localization compatible with endoplasmic reticulum or mitochondrial residence (641). *Bcl-2* is important in lymphocyte survival because of its role in stabilizing mitochondrial membrane potential and preventing apoptotic death, and BHRF1 appears to have similar effects in preventing apoptotic cell death in lytic EBV infection (320). The effects of BHRF1 are evident with lytic replication of EBV in type 1 latency–infected BL cells, but they are not evident when lytic commences in type III latency–infected LCLs because of their high-level expression of other antiapoptotic proteins (82). EBV recombinants with a stop codon early in BHRF1, or with deletions of the BHRF1 ORF, are fully able to initiate or maintain cell growth transformation, enter lytic cycle, and produce virus even in media with low serum or low cell concentration (471,530). BHRF1 is expected to have a similar role in epithelial infection. EBV BALF1 also has significant homology to *bcl-2* and is likely to have similar antiapoptotic effects (535).

Among the EBV early genes identified by their homology to early genes of other herpesviruses are several that are linked to DNA replication. These include DNA polymerase (BALF5), major DNA binding protein (BALF2), ribonucleotide reductase (BORF2 and BARF1), thymidine kinase (BXLF1), and alkaline exonuclease (BGLF5). These genes are

distributed through the long EBV U_L domain (see Fig. 1).

The EBV DNA polymerase has been extensively purified and is 117 kd (396). Partially purified DNA polymerase is associated with several other EBV nuclear proteins, including the 50-kd protein encoded by BMRF1 (420,481). The catalytic subunit expressed in insect cells from a baculovirus vector has 3'-to-5' proofreading exonuclease activity in addition to DNA polymerase activity (851). Reconstitution of baculovirus-expressed polymerase with a 2:1 molar ratio of baculovirus-expressed BMRF1 enhances the double-strand 3'-to-5' exonuclease activity fourfold (849) and the DNA polymerase activity tenfold (848). BMRF1 also markedly enhances polymerase processivity and results in full-length products (848). Unlike cellular polymerases, the EBV polymerase is active in 100mM ammonium sulfate or in KCl and is sensitive to inhibition by ethyl maleimide, phosphonoacetic acid, phosphonoformic acid, arabinofuranosyl-thymine, and acycloguanosine triphosphate (14,102,108,121,143,144,145,146,147,148 and 149,151,152 and 153,275,344,345 and 346,348,625,626 and 627,786). The EBV DNA polymerase also differs from HSV DNA polymerase in its salt sensitivity and its relative resistance to amphidicolin. The EBV DNA polymerase only weakly distinguishes between 2-amino-purine nucleoside trip-hosphate and dATP, so that 2-amino-purine is preferentially incorporated into viral as opposed to cell DNA (273).

The EBV, VZV, and HSV ribonucleotide reductases are extensively colinearly homologous. The large HSV subunit is 140 kd, whereas the EBV subunit is 85 kd, and VZV is predicted to be 87 kd (250). The EBV, VZV, and HSV large and small subunits have domains that are common to ribonucleotide reductases from a wide variety of prokaryotic and eukaryotic species (90,606). The HSV-1 large subunit has an amino-terminal domain that is absent from other ribonucleotide reductases. Surprisingly, the EBV ribonucleotide reductase large subunit is confined to multiple discrete regions in the cytoplasm of productively infected cells (258). The large subunit is a delayed early protein that accumulates in cells approximately 4 hours after the MRF1 nuclear early protein (258,641). Acetone fixation of cells destroys the immunologic reactivity of the large subunit, suggesting that it may be a major component of the restricted early antigen complex originally identified by EBV immune human sera from African patients with BL (see Chapter 75).

The existence of an EBV-specific deoxypyrimidine kinase was inferred from the co-induction of EBV lytic replication and a new kinase activity in P3HR-1 cells (157,777). An EBV-induced dTK and dCK activity elutes as a single peak on DEAE-cellulose, away from the cellular dTK and dCK activities. Gene transfer of EBV DNA, or of the EBV DNA fragment with homology to HSV TK, into TK-mammalian cells or into TK-*E. coli* restores TK activity mapping the kinase activity to this DNA fragment (502,503 and 504). The EBV TK is similar to HSV TK in accepting a broad range of nucleosides or nucleoside analogs as substrates and has some antigenic cross-reactivity with the HSV TK (503).

The D_L and D_R EBV DNA segments (see Fig. 1) that have strong early promoter activity are also origins of lytic infection viral DNA replication (290,730,734). Using transient transfection to activate lytic EBV replication co-transfection of either of these EBV DNA segments on plasmids results in replication of the plasmid DNAs in the lytically infected cells. An essential 1.4-kb core element replicates with considerably reduced efficiency (290). The core 1.4-kb origin has numerous inverted repeat elements that could serve as the definitive origin. Even within the 1.4-kb segment, at least three domains contribute to the replicative activity. One domain can be functionally replaced in part by the CMV immediate-early promoter and enhancer, suggesting that this domain is important for lytic origin function because of transcriptional enhancement (163). Interestingly, when cells containing lytic origin plasmids are induced to lytic EBV infection, plasmid copy number increases slightly and linear concatemers are produced. With induction of lytic EBV replication, episome copy number increases, and labeled thymidine, initially incorporated into circular EBV DNA, chases into very large, presumably linear concatemeric EBV DNA (115,757,762). Other LCVs have D_L and D_R elements; these are anticipated to have similar roles in DNA replication (313,314,316,474). The herpesvirus Papio element has transcriptional activation and DNA replication sites that are similar to those in EBV (714).

Considerable progress has been made in constituting an *in vitro* minimal replication system similar to the Challberg HSV system (217). The components include BALF5, which encodes the core DNA polymerase; BALF2, the single-strand DNA binding protein; BMRF1, the processivity factor; BSLF1 and BBLF4, the primase and helicase complex; BBLF2/3, a spliced primase helicase complex component; and BKRF3, the uracil DNA glycosylase. A surprising aspect of the EBV DNA replication genes is the extent to which they are dependent on expression of the BZLF1, BRLF1, and BSMLF1 transactivators. EBV DNA replication also requires topoisomerase 1 and 2 activity (407). The redistribution of BZLF1 and BMRF1 gene products to the same nuclear site may identify the site at which viral DNA is replicated (806).

Late Gene Expression, Cleavage, Packaging, Envelopment, and Egress

The EBV TR has obvious similarities to the HSV “a” sequence (543,580,767,769,770). Both EBV TR and the HSV “a” sequence are directly repeated at both ends of the DNA. Both sequences are high in G+C composition, with runs of three to five Cs. In both HSV and EBV, there is a short extra oligonucleotide segment (D_R1) where the repeat joins the unique DNA. The EBV D_R1 oligonucleotide GCATGGGGGG brackets the multiple TR copies (543,580). In HSV-1, D_R1 is the site of cleavage of head full-length DNA for packaging into virions (767,769,770). There seems to be little sequence specificity for D_R1, because the nonhomologous oligonucleotides of HSV-1, HSV-2, and CMV are interchangeable (770). HSV or CMV cleavage and packaging appear to occur 33 bases 3' to a conserved sequence of $C(G)_{6–8}TGT(G/T)(T)_3NG(C/G)(G)_6(G/C)(T/C)$. A similar sequence $C(G)_5TGT(T)_2CCT(G)_5CC$ occurs 25 bases before the EBV D_R1 and is the key cleavage packaging recognition sequence for EBV. The EBV rightmost TR acquires a short unique sequence from the leftmost TR during cleavage and packaging, and that sequence becomes the left end of the DNA (932). Plasmids containing the EBV latent infection episome origin, the EBV lytic origin, and the EBV terminal repeat sequence are stably maintained as an episome in latently infected cells, are replicated into linear concatemers by EBV DNA polymerase when lytic infection is induced, and are cleaved and packaged into infectious virions (291,871). Cell lines have recently been derived that are infected with a TR-negative EBV that cannot itself be packaged, but they are suitable hosts to support the replication and packaging of plasmids that include oriLyt and EBV DNA termini.

The viral glycoprotein genes that have been identified so far are all late genes

(50,208,262,310,359,451,454,455,480,517,610,622,643,644,905). These have been more intensively studied than other late genes because of their potential importance in antibody-mediated immunity to virus infection (70,289,331,472,479,480,568,581,631,776,875,876). Current knowledge of nonglycoprotein late genes is quite limited. Among the nonglycoprotein late genes, the major nucleocapsid protein is almost certainly encoded by BcLF1 based on homology to the major HSV capsid-protein gene (545). Further, BcLF1 encodes a 4.5-kb late mRNA that, translated *in vitro*, yields a 150-kd protein, identical in size to the major EBV nucleocapsid protein (357). Similarly, BNRF1 probably encodes a major 140-kd virion nonglycoprotein. The NRF1 4.1-kb late mRNA, translated *in vitro*, produces a 140-kd protein, identical in size to the virion component (357). Because the BNRF1 predicted sequence has no major hydrophobic domains or glycosylation sites, it is more likely to encode a tegument protein than an integral membrane protein. Another late RNA includes an ORF BXRF1 homologous to the VZV basic virion core protein gene (154,232).

The known (gp25) EBV glycoprotein genes are BLLF1 (gp350/220), BALF4 (gp110), BXLF2 (gp85), BKRF2, BZLF2 (gp42), BILF2 (gp55/80), BDLF3 (gp150), BLRF1 (gp15), BBRF3 (gp84/113), and BILF1 (gp64) (50,245,262,273,310,359,517,621). Other glycoproteins may be encoded by BFRF1 and BMRF2. BILF2 expressed from a recombinant vaccinia virus is 55 to 80 kd. A 78-kd glycoprotein has been identified in EBV lytically infected cells and in virus using antiserum from recombinant vaccinia virus–infected rabbits or EBV-immunized mice. The BILF2 glycoprotein corresponds to an abundant glycoprotein in purified virus preparations. Antibody to BILF2, however, fails to neutralize virus infectivity (517).

BDLF3 cDNA cloning and sequencing confirm that BDLF3 mRNA is not spliced (245). The predicted amino acid sequence includes a hydrophobic amino terminus, consistent with a signal peptide, a hydrophilic external domain with nine potential N-linked glycosylation sites, and a single hydrophobic transmembrane domain. Translation of the 0.9-kb mRNA *in vitro* yields a 32-kd protein that is processed by dog pancreas microsomes to 60 kd, and the size of the fully processed glycoprotein in EBV infected cell is 150 kd. Disruption of gp150 expression for the context of a specifically mutated EBV indicates that gp150 is not critically important for lymphocyte infection.

Because HSV-1 gB is a major virion and infected cell surface glycoprotein, the homologous EBV BALF4 ORF is of interest (187,262,642). Both BALF4 and HSV-1 gB are predicted from their primary amino acid sequence to have amino-terminal cleavable signal peptides, external domains of 650 amino acids with four potential N-linked glycosylation sites, three potential membrane-spanning domains, and a 150-amino-acid cytoplasmic domain (642). BALF4 encodes two late mRNAs: an abundant 3-kb RNA that is not spliced and a scarce 1.8-kb RNA (262). The BALF4-encoded 3-kb mRNA translates a 93-kd protein that is glycosylated to 110 kd (261,262). Gp110 is one of the most abundant late EBV proteins (187,261,262). The glycosylation is probably both N- and O-linked, because N-glycanase, which cleaves N-linked oligosaccharides, only reduces gp110 to 105 kd (261,262). Endoglycosidase H has a similar effect on almost all of the gp110. Because endoglycosidase H cleaves only N-linked oligosaccharides that have not been modified in the Golgi, this suggests that most of the gp110 is not Golgi processed. A small fraction of gp110 is processed to a form compatible with a size of 120 kd. This 120-kd glycoprotein is not endo-H sensitive and is partially incorporated into virus (Alfieri and Kieff, manuscript in preparation). The intracellular distribution of gp110 closely parallels that of an endoplasmic reticulum resident protein (261,262). Immune light or electron microscopy localizes gp110 to the inner and outer nuclear membranes and to cytoplasmic membranes frequently surrounding enveloped virus, but not to the Golgi or plasma membrane. Further, despite the high abundance of gp110 in the inner nuclear membrane through which nucleocapsids bud to acquire their initial envelope, only small amounts of gp110 are in enveloped extracellular virus, as seen by immune electron microscopy (261,262). Protein and sugar stains of polyacrylamide gel–separated proteins from purified virus confirms that gp110 is not a major virion glycoprotein. Thus, EBV gp110 is a very abundant glycoprotein in the nuclear and endoplasmic reticular membranes and may have a critical role in initial envelopment, but only a small amount of gp110 is in the definitive virion envelope.

In contrast to gp110, gp85 and gp350/220 are processed much more efficiently through the Golgi and are found on the virus and in the plasma membrane of lytically infected cells (50,172,173,261,262,309,310,335,517,597,618,619,621,622,668,669 and 670,780,822,823,827).

Gp85 is encoded by XLF2, which has significant colinear homology to HSV-1 gH (310,622), whereas gp350/220 is encoded by LLF, which has only a small region of distant homology to HSV-1 gC (50). Gp85 is a relatively minor virus component, important in fusion of the virus and cell membranes (568), whereas gp350/220 is the dominant external virus glycoprotein that mediates virus binding to the B-lymphocyte receptor, CD21 (see preceding). Interestingly, gp85 expressed in NIH3T3 cells localizes to the internal cytoplasmic and nuclear membranes, whereas gp350/220 localizes to the Golgi and plasma membrane (262,881). In fact, gp85 requires another virus protein to bring it to the plasma membrane of lytically infected lymphocytes, where it is characteristically found, whereas gp350/220 possesses the necessary signals for efficient Golgi transport, processing, and plasma membrane insertion. Gp85 complexes with the BKRF2-encoded protein, which enables its transport to the plasma membrane (905). Two homologous glycoproteins, gH and gL, heterologomerize and have similar functions in HSV replication: EBV gp85 (gH) has a dual role both in fusion and in coreceptor recognition. A third glycoprotein, gp42 or BZLF2, is a component of gH–gL complexes. BZLF2 binds to several HLA class II complexes and is critical for B cell infection. Overexpression of gp42 results in saturation of gH/gL complexes with gp42, a virus that can infect only B lymphocytes and not epithelial cells. Thus, BZLF2 could have a critical role in directing the virus toward B lymphocytes versus epithelial cells. In B lymphocytes, gp42 may have still another role in down-modulatory class II expression.

Although gp350/220 is the most abundant viral protein in the lytically infected cell plasma membrane and in the virus envelope, only small amounts of gp350/220 accumulate in the lytically infected cell nuclear membrane (261). EBV gp350/220 is extensively N- and O-glycosylated (261,743,822,823,827,881). Gp350 nascent protein has an apparent size of 135 kd, and 37 potential N-linked glycosylation sites, whereas mature glycoprotein has an apparent size of 350 kd. Approximately half of the glycosylation is due to N linkage and half to O linkage. Virtually all of the N-linked oligosaccharides are complex, with tri- and tetra-antennary chains, whereas most O-linked chains are probably di- or tri-N-acetyl lactosamine, consistent with extensive Golgi processing (743).

Early electron microscopic observations of lymphocytes lytically infected with EBV revealed the presence of

nucleocapsids in the cytoplasm. Although this could occur as a consequence of nuclear disruption late in infection or as a consequence of reinfection of the infected cell by released virus, an alternative hypothesis is that virus acquires an initial envelope as it buds through the nuclear membrane, that de-envelopment occurs within cytoplasmic vesicles resulting in release of nucleocapsids into the cytoplasm, and that re-envelopment occurs at the plasma membrane, where the virus acquires a definitive envelope rich in gp350/220 and gH/gL. Consistent with this hypothesis, the plasma membrane and virus are both rich in gp350/220, whereas the nuclear membrane is relatively deficient (261). Even if this hypothesis is correct, late in infection, as the cell deteriorates, partially enveloped or initially enveloped virus may be released in substantial quantity. The relative importance of these various pathways in natural infection is difficult to evaluate. A second possible role for high-level plasma membrane gp350/220 expression is in saturation of lymphocyte CD21 and HLA class II, so that virus can be completely released from and not reabsorbed to the lytically infected cells. A price may be paid for such efficiency, however, because antibody to gp350/220 and gH/gL may fix complement and cause lysis of infected cells *in vivo*.

Gp350/220 is not only the most abundant viral protein in the lytically infected cell plasma membrane, it is also one of the most abundant late viral proteins and the most abundant protein on the outer surface of the virus. Surprisingly, disruption of the gp350/220 ORF is not lethal to the virus, and both lymphocytes and epithelial cells can be infected with reduced efficiency. Most EBV neutralizing antibody response is directed to gp350/220 (827). Gp350/220 is therefore an important component of any prospective EBV vaccine that would aim to engender neutralizing antibody (592,618). Significant parts or all of the protein have been expressed in *E. coli*, in *Saccharomyces cerevisiae*, and in mammalian cells, and a recombinant VZV that expresses Gp350/220 under control of the gpI promoter has been constructed (50,604,738,811,881,923). Gp350 is expressed in large amounts in recombinant VZV-infected cells, and it is incorporated into the infected cell plasma membrane and into the VZV outer envelope (515). Gp350/220 has also been inserted into vaccinia capable of under control of the p8.5 promoter (592). Injection with purified EBV gp350/220, or infection with vaccinia expressing gp350/220, protects cottontop tamarins against a lethal, lymphomagenic EBV challenge (592).

BCRF1 is a close colinear homolog to the human IL10 gene, with nearly 90% colinear identity in amino acid sequence (345,857). BCRF1 is expressed only late in EBV replication despite its location in the middle of the EBNA regulatory domain between oriP and the Cp promoter. IL10 has B-cell growth factor activity (586), and some data have suggested that BCRF1 could be important in latent EBV infection (579). However, nonsense or deletion mutations involving BCRF1 have no effect on the ability of the recombinants to initiate growth transformation, to maintain wild-type latent infection and transformed cell growth, or to lytically infect induced B lymphocytes *in vitro* (795). Thus, the role of BCRF1 is in lytic infection *in vivo*. The principal role of IL10 in mice and humans appears to be as a negative regulator of macrophage and NK cell functions that otherwise positively regulate TH1 cytotoxic T lymphocytes (586). BCRF1 has most of the activities of human IL10 *in vitro*.

Thus, BCRF1 is likely to act to blunt the initial NK and T-cell cytotoxic response to EBV infection in epithelial cells and B lymphocytes. One important aspect of that response is the release of gamma interferon. The initiation of cell growth transformation is quite sensitive to interferon (242,795). A mixture of lytically infected EBV recombinant transformed LCLs with normal peripheral blood mononuclear cells results in low interferon release and efficient transformation of primary B lymphocytes, whereas a mixture of lytically induced BCRF1 null mutant recombinant infected LCLs with peripheral blood mononuclear cells results in high-level gamma interferon release and inefficient transformation of the primary B lymphocytes (795). A second aspect of the NK and CD8 cytotoxic responses is the direct cytotoxic component. Blunting of that component is likely to be important in both primary EBV infection and in reactivation of lytic infection in B lymphocytes. To create an analogous murine model for this possible effect, infection of C57BL/6 mice with vaccinia virus expressing beta galactosidase was compared with infection of C57BL/6 mice with vaccinia virus expressing murine IL10. The NK- and vaccinia-specific CD8 cytotoxic responses were lower in the mice infected with vaccinia virus expressing IL10, although there was no difference in virulence or in antibody response (438). Thus, virally expressed IL10 appears to have an effect on the initial interferon and NK and CD8 cytotoxic responses and may have a local effect on these responses to reactivated virus infection.

Defective Virus

The complete EBV genome is usually maintained as an episome in latently infected lymphocytes, including BL lymphoblasts when there is restricted EBV gene expression. However, in several instances, incomplete genomes have been detected in latently infected BL cells growing in culture or in subclones of such cells. The three best-studied examples are the EBV genomes in the Raji, P3HR-1, and Daudi cell lines (69,110,111 and 112,162,301,311,378,381,382 and 383,392,426,675). The Raji cell has 50 EBV episomes, each of which is deleted for EBNA-3C and for BALF2, the 135-kd, major DNA binding protein. As a consequence of the deletion of the BALF2 gene, the EBV genome in Raji cells is not replicated by the Raji DNA polymerase when lytic infection is induced. Thus, no late genes are expressed and the infection is abortive. Expression of BALF2 in Raji cells allows lytic infection to proceed, and virus is produced.

P3HR-1 and Daudi have fewer EBV episomes and are deleted for a single EBV DNA fragment that includes some of the IR1 copies, all of U2 and IR2, and several hundred base pairs of U3. The P3HR-1 EBV deletion appears to have arisen on *in vitro* passage, because the parent cell lines from which P3HR-1 was cloned are not deleted (4,426,677). The EBV genome in P3HR-1 can be induced to full lytic infection and virus is produced. Thus, EBV genes deleted from P3HR-1, including EBNA-LP, EBNA-2, and HLF1, are not necessary for EBV replication in B-lymphoma cells *in vitro*. The resulting P3HR-1 or Daudi virus cannot transform normal B lymphocytes. These cell lines carrying minimally defective EBV genomes are useful for EBV recombinant genetic studies (see later). Interestingly, similar defectives arise during EBV infection in epithelial cells *in vivo* (637,762).

Aside from the minimally defective EBV DNA, some of the EBV DNA in P3HR-1 cells is more highly defective. There are several formats for the more highly defective DNAs and several biologic properties have been delineated (110,112,311,381,382 and 383,816). Analysis of P3HR-1 subclones reveals that most cells contain only the minimally defective EBV P3HR-1 genome (332). A rare cell contains both the minimally and the more defective P3HR-1 EBV genomes. The more defective genome is spread by cell-to-cell transmission following spontaneous reactivation of lytic EBV replication (559). Reactivation occurs in cells containing the defective genomes because the defective genomes

contain the ZLF1 immediate-early transactivator under control of the IR1 latent infection cycle promoter (381,382 and 383). One population of defective genomes appears to be centered about the IR1 palindrome (272,381,382 and 383). In the highly defective DNA, the left arm of the palindrome is a complete inverted copy of the right arm. The IR1 sequence to the right of the palindrome now also extends from the palindrome in the opposite direction into a new linkage with the right end of Bam Z. A second new linkage joins the left of Bam Z to Bam S and Bam M. A third new linkage joins Bam M to Bam B1, W1I1 and *Bam*HI A. *Bam*HI A is presumably linked to TR. The lytic ori in *Bam*HI B1 and the TR presumably provide the necessary cis-acting lytic EBV DNA replication origin and packaging signals, respectively, to ensure the perpetuation of the defective virus in the P3HR-1 cell cultures. The specific and selective inclusion of BZLF1, BSMLF1, and BI'LF1 probably arises because of the adjuvant effect of these transactivators on lytic EBV replication.

GENETICS

Attempts at constructing EBV recombinants have been hindered by the limitation in the EBV host range to human B lymphocytes and the nonpermissivity of these cells for EBV replication. The development of strategies for switching latently infected cells into lytic infection has partially alleviated this major experimental barrier. The first attempt at developing an EBV recombinant genetics system was to infect replication-defective Raji cells with P3HR-1 EBV stocks, and to plate the resultant virus onto primary B lymphocytes (111,233). Raji EBV cannot replicate its own genome in lytic infection because of deletion of the major single-strand DNA binding protein BALF2, but it has EBNA-LP and EBNA-2. Raji is also deleted for EBNA-3C, which in later experiments turned out to be a critical gene for B-lymphocyte growth transformation. The P3HR-1 EBV genome is lytic replication competent, but it is transformation incompetent because of the deletion of a DNA segment that encodes EBNA-LP and EBNA-2. Infection of Raji cells with P3HR-1 EBV induced partial permissivity for lytic infection, and replication of both genomes ensued. Because Raji cells contain 50 episome copies of EBV DNA, most of the transforming virus that came out of the infection should have been simply Raji EBV genomes. However, the few transforming viruses that were obtained in transformed primary B-lymphocyte-derived cell lines were in fact recombinants between Raji and P3HR-1 that had restored the deleted EBNA-LP and EBNA-2 encoding fragment, providing initial genetic evidence that EBNA-2 or EBNA-LP is essential for transformation (765). In retrospect, these results also provided an indication that the Raji EBV genome was itself transformation incompetent because of the EBNA-3C deletion. Recent attempts to exploit the EBNA-3C deletion in Raji to assay the ability of wild-type or specifically mutated LBNA-3C genes to marker-rescue a transforming EBV amma from Raji have met with very limited success because of the limited virus from Raji cells even when BALF2 is provided by a heterologous expression vector.

More recently, the entire EBV genome has become amenable to molecular genetic manipulation. In these experiments, specifically mutated recombinant EBV genomes have been obtained by transfecting latently infected lymphocytes with specifically mutated recombinant EBV DNA fragments that had been cloned and amplified in *E. coli.* When virus replication is then induced, the mutant EBV DNA fragment undergoes homologous recombination with replicating viral DNA (125,126,290,368,409,411,470,471,512,513,514,525,527,529,530,694,795,797,835,836,837 and 838,871). Parental and recombinant virus can be used to infect primary B lymphocytes or non-EBV-infected BL cells. Because primary B lymphocytes depend on EBV infection for their ability to grow *in vitro*, a mutation in an essential transforming gene will only be recoverable in primary B lymphocytes if the cells are co-infected with a defective EBV that is wild type for the mutated gene. The usual source for defective EBV is P3HR-1 cells, because 10 $^{7–8}$ P3HR-1 EBVs can be obtained from 10^7 P3HR-1 cells, and the virus is wild type except for the EBNA-LP and EBNA-2 deletion. BL cells are not dependent on EBV for their growth in culture and therefore are potentially useful for recovery of recombinants with mutations in essential transforming genes (527,528,529 and 530,871). BL cells or primary B lymphocytes can be made dependent on recombinant virus for their growth by including a positive selection marker such as SV40 promoter-driven hygromycin phosphotransferase in the transfected recombinant EBV DNA. Only cells infected with a recombinant virus will then grow out under selective conditions (871). Alternatively, cells infected with the replication-competent but transformation-defective P3HR-1 EBV can be used as the source of a parent virus strain. When these cells are transfected with a wild-type EBV DNA fragment spanning the EBNA-LP and EBNA-2 deletion, a small number of transformation-competent wild-type EBNA-LP and EBNA-2 P3HR-1 EBV recombinants result, and these can be specifically isolated in primary B-lymphocyte-derived cell lines, because only the recombinants will be able to cause LCL outgrowth (125,126,290).

Because transfection with a wild-type EBV cosmid DNA fragment that includes EBNA-LP and EBNA-2 into P3HR-1 EBV-infected cells and induction of lytic infection results in homologous recombination between the transfected DNA and the replicating P3HR-1 EBV with restoration of transforming ability to recombinant P3HR-1 genomes, the effect on transformation of specific EBNA-LP or EBNA-2 mutations or of EBNA-LP or EBNA-2 type-specific differences could be determined (125,126,290,525). Recombination with a wild-type EBV cosmid DNA fragment that spans the deletion uniformly resulted in transforming recombinants. The number of transforming recombinants was sufficiently consistent in a clonal transformation assay that differences in transformation efficiency could be detected. Some deletion mutations within the EBNA-2 ORF or a stop-codon mutation resulted in no transforming recombinants, demonstrating that EBNA-2 is essential for lymphocyte growth transformation. EBNA-2 was also shown to account for the differences between high-transforming type 1 EBV strains and low-transforming type 2 EBV strains (126). Analysis of the phenotype of 11 linker insertion and 15 deletion mutations within the EBNA-2 ORF revealed four separable domains that are essential for transformation of primary B lymphocytes (125). Subsequent experiments with EBV recombinants containing EBNA-LP deletion or stop-codon insertion mutants revealed a markedly reduced B-lymphocyte transformation efficiency.

The use of large cosmid DNA fragment for EBNA-2/EBNA-LP marker rescue of transformation in P3HR-1 cells enables specific mutations to be made in genes mapping near EBNA-LP and EBNA-2 and within the flanking EBV DNA that is common to both the P3HR-1 and transfected EBV DNA fragment. Deletion of the EBER-encoding DNA, or mutation of the BHLF1 or BHRF1 ORFs in the cosmid fragment, resulted in many of the transforming recombinants being also mutant in the adjacent gene (530,797). The resultant mutant EBV recombinants transform cells with wild-type efficiency and replicate following induction.

This led to the observation that almost as high a frequency of incorporation into recombinant EBV genomes occurs with a second, nonlinked, cosmid EBV DNA fragment transfected along with the EBNA-LP and EBNA-2 cosmid DNA into P3HR-1 cells (835,836 and 837). Using this strategy of second-site homologous recombination, mutations could be made

on any EBV DNA fragment, and, after transfection into P3HR-1 cells, harvest of the resultant virus, and clonal infection of primary B lymphocytes, a substantial fraction of the resultant LCLs are infected with mutant recombinants. The frequency of incorporation of nonlinked second EBV DNA fragments is directly related to transfected fragment size. Fragments of 4 to 5 kb are incorporated with about 20% to 30% of the efficiency of 40-kb fragments, the latter being incorporated into about 10% of the EBV DNAs that recombine with the EBNA-LP/2-positive selection marker.

An alternative strategy for constructing EBV recombinants, which is particularly useful for making deletions in the EBV genome, is to use the P3HR-1 cells as a lytic infection transcomplementing and packaging cell line for cosmid cloned EBV DNA fragments (694,837). Approximately 50% of all transforming recombinants from cells transfected with five overlapping EBV DNA fragments representative of the entire genome consist of the transfected cosmid DNAs without any evidence for recombination with the P3HR-1 EBV genome. For studying the transforming EBV genes, only two and a half cosmid-cloned EBV DNA fragments are necessary, because all of the genome between EBNA-1 and LMP1 is unnecessary and most of the noncoding exons and introns of the EBNA mRNAs can be deleted.

Although positive selection for transformation from the transformation-negative P3HR-1 parent strain is useful for making specifically mutated recombinants in most genes, there are limitations. First, nontransforming mutations in EBNA-LP or EBNA-2 cannot be recovered, and the effect of the mutation can be ascertained only by the failure to generate a transforming recombinant from P3HR-1. Second, nontransforming mutations in other essential or critical transforming genes such as EBNA-3A or -3C or LMP1 can be recovered only when the wild-type EBNA-3A, -3C, or LMP1 is provided to the infected primary B lymphocyte. In many instances, this can be conveniently provided by nonrecombinant P3HR-1 virus, as 10^{7-8} nonrecombinant P3HR-1 EBVs are in each preparation of 50 to 200 recombinant EBVs. Because the virus preparation is used to infect 10^{7} primary B lymphocytes, 50% of the primary B lymphocytes are initially infected with nonrecombinant P3HR-1. Any cell infected with a recombinant therefore has a 50% chance of being initially co-infected with a nonrecombinant. Both genomes can stably persist in cells and function, although the nonrecombinant P3HR-1 genome is usually lost over a few months in continuous culture of the resultant LCL if it is not required to maintain cell growth transformation. The characterization of the mutant recombinant genome in co-infected cells is more complicated than in cells infected with a single EBV genome. Furthermore, in some instances, the mutant recombinant can be lost, because the mutant recombinant with its mutated EBNA-3A, EBNA-3C, or LMP1 gene and its wild-type EBNA-2 and EBNA-LP genes undergoes secondary recombination with the co-infecting P3HR-1 EBV, which is wild type for EBNA-3A, EBNA-3C, or LMP1 but deleted for EBNA-2 and EBNA-LP. The secondary recombinant genome could be fully wild type. Third, the efficiency of second-site recombination is about 10%. Many recombinants are obtained that are not mutant at the second site, and these must be identified by polymerase chain reaction for the mutated DNA.

To circumvent some of these problems, non-EBV-infected BL cells or primary B lymphocytes can be used to isolate and recover mutant EBV recombinants carrying a selectable marker (470,471,527,528 and 529,871). BL cells can be infected with EBV *in vitro*. The efficiency of infection varies among BL cell lines and is frequently 10% of the efficiency of primary B-lymphocyte infection. Mutant recombinant virus can be recovered from such cells. Because the BL cells are not dependent on EBV for their ability to grow *in vitro*, mutant recombinants deleted for an essential transforming gene can be transferred to non-EBV-infected BL cells and marker-rescue experiments similar to those done in P3HR-1 cells can be carried out. A limitation of this strategy has been alleviated with the derivation of EBV-negative Akata BL cells, which retain EBV episomes and can be induced to become permissive for EBV replication (749).

Recently, several alternative strategies have been developed for making EBV recombinants. One strategy uses targeted homologous recombination to insert mutations, cassettes for expression of positive selection markers, or bacterial replicons into wild-type EBV episomes in cells that can be readily induced to lytic infection, such as Akata or B95 cells (750). The resultant virus can then be harvested and passaged into EBV-negative Akata cells, induced to replicate in these cells, and used for subsequent genetic studies (365,900). EBV recombinants with positive selection markers inserted using this strategy have been used to study the *in vitro* host range for EBV infection, and to show that EBV gp85 is essential for B lymphocyte and epithelial cell infection *in vitro*, that gp42 is critical for B-lymphocyte infection *in vitro*, and that gp150 deletion enhances the efficiency of epithelial cell infection (70,365,581,623,875,900).

A second strategy is a further modification, importing the entire EBV genome into *E. coli* using F plasmids and recombination-deficient cells. Targeted insertional mutations can then be made in cells that have recombination functions. F plasmids containing the entire EBV genome and a positive selection marker for mammalian cells have been recovered from *E. coli* and transferred to human epithelial 293 cells. These plasmids can be induced to replicate in the infected 293 cells and small amounts of virus can be obtained to study the effects of specific mutations on virus infection, replication, or cell growth transformation (160,161). This system should improve the efficiency of EBV genetic studies, assuming that the EBV genome proves to be stable in the recombination-deficient *E. coli.* Initial experiments that demonstrate the utility of the system for investigating the dependence of EBV on gp350 for B-lymphocyte or epithelial cell infection indicate that the system is useful (375).

INHIBITORS OF VIRUS REPLICATION

Lytic EBV infection in B lymphocytes *in vitro* and in EBV infection *in vivo* (see Chapter 75) are quite sensitive to acycloguanosine, which is a substrate for the EBV deoxynucleoside kinase (14,15,494,502) and an inhibitor of EBV DNA polymerase. Other inhibitors of herpesvirus DNA polymerases such as phosphonoacetic acid and phosphonoformic acid are also useful for *in vitro* inhibition of EBV DNA polymerase in B lymphocytes, so as to distinguish early from late gene expression (153,493,495,686). Because of the limited clinical benefit in inhibiting EBV replication with acycloguanosine in patients with acute primary EBV infection (see Chapter 75), there has been little effort to develop other specific inhibitors of lytic EBV infection.

BRIEF SUMMARY

In the first decade of EBV research, a great deal was learned about the biology of EBV infection *in vitro* and *in vivo*. The virus was found to cause infectious mononucleosis and to be latent in most adult humans. The tight linkage to BL and

NPC, the rare occurrence of lymphoproliferative disease in young children and renal transplant recipients, and the ability of the virus to efficiently immortalize lymphocytes *in vitro* and to induce lymphomas in marmosets provided a biologic framework indicating that EBV can be oncogenic under unusual circumstances. The discovery of cell lines that could be induced to replicate EBV led in the second decade to increasingly sophisticated biochemical analyses. The structure of the genome was determined, the genome cloned, the transcriptional program in latent and lytic infection worked out, and the entire genome sequenced. EBNA became a protein on an acrylamide gel, and then more than one protein. EBV mRNAs in latently infected and growth-transformed B lymphocytes were cloned, sequenced, and expressed in heterologous cells.

By the beginning of the third decade, the genes encoding the EBV latent-infection nuclear and membrane proteins and the proteins themselves were identified in rapid succession. Six EBNAs, two LMPs, and two EBERs were involved in latency III and cell growth transformation. Studies of the biologic activity of these genes following single-gene transfer revealed EBNA-1 and oriP to be sufficient for plasmid episome maintenance, and LMP1 to have significant transforming activity in rodent fibroblasts. Gene transfer into BL cells and recombinant EBV molecular genetics emerged as important experimental paradigms. Activities of the EBNAs and LMPs were more evident in human B lymphocytes, a natural target of EBV infection.

In the last 5 years, knowledge of the roles of the EBNAs and LMPs in maintaining latent infection and growth transformation and of the various types of latent infection has rapidly advanced. The interaction of EBNAs and LMPs with B-lymphocyte proteins is offering increasing understanding of the mechanisms of EBV-induced and normal B-lymphocyte activation, proliferation, and survival. Molecular targets for inhibition of EBV-mediated growth transformation and cell survival have been identified. Immediate-early and early regulation of lytic EBV infection are better understood. New strategies for manipulating the transition to lytic infection and for genetic analyses have facilitated EBV research. These discoveries and those described in Chapter 75 on the molecular pathogenesis of EBV infection *in vivo* open new possibilities for understanding, preventing, diagnosing, and treating EBV infection and its associated malignancies.

CHAPTER 75 Epstein-Barr Virus

Alan B. Rickinson and Elliott Kieff

HISTORY

The catalyst for the discovery of Epstein-Barr virus (EBV) was Denis Burkitt, a surgeon working in East Africa in the 1950s, who first draw attention to a novel childhood tumor, now known as Burkitt's lymphoma (BL), which he found to be unusually common throughout equatorial Africa. The apparent influence of climatic factors in determining those regions of Africa where BL was “endemic” led Burkitt to postulate that an infectious agent, possibly arthropod-borne, was involved in the tumor's etiology (60). This caught the attention of Tony Epstein who, with his Ph.D. student Yvonne Barr, succeeded in establishing a number of BL-derived cell lines in culture, of which the first to be examined in the electron microscope showed clear evidence of herpesvirus-like particles in a small proportion of the cells (124). The agent present in BL cells proved to be biologically and antigenically distinct from other members of the human herpesvirus

(HHV) family, thereby identifying EBV as the first candidate human tumor virus.

Contrary to expectations for an agent linked to an African tumor, seroepidemiologic studies showed that EBV was in fact widespread in all human populations with more than 90% of adults positive for serum antibodies to the virus (186). Furthermore, the virus could be rescued *in vitro* from the circulating lymphocytes and from the throat washings of seropositive individuals, indicating that EBV was able to persist in the serologically immune host (147,333). Most importantly, EBV was a B-lymphotropic agent that could transform its target cells *in vitro* into latently infected B-lymphoblastoid cell lines (LCLs) (188). Such behavior has since become the defining biologic characteristic of the lymphocryptoviruses (LCVs), a genus of the gamma herpesvirus subfamily whose other members are all homologs of EBV isolated from Old World, and more recently New World, primate hosts (88,484). The *in vitro* growth-transforming capacity of EBV provided strong circumstantial evidence that the association of the virus with BL, a tumor of B-cell origin, was more than just coincidental. Furthermore, experimental infection of certain species of New World primates led to the outgrowth of virus-positive B-cell lymphomas (125,421). These key observations did much to sustain interest in EBV over the ensuing years during which human tumor virology as a general field of investigation swung in and out of scientific fashion.

IN VITRO INFECTION

The extensive literature on EBV infection of target cells *in vitro,* much of it focusing on infections of human B cells, is reviewed in Chapter 74 (245). The essential points only are summarized here as a prelude to discussing what is known about EBV infection *in vivo*.

Growth-Transforming Latent Infection, Latency III

A wide range of human B cells, from pro-B to antigen-experienced memory cells (but excluding plasma cells), appear susceptible to EBV infection and transformation *in vitro* (227,333), broadly reflecting expression within the B-cell lineage of the principal EBV receptor CR2. The resultant LCLs all show a similar lymphoblastoid phenotype and a Latency III pattern of viral latent gene transcription, as illustrated in Figure 1. This involves expression of (a) the small nonpolyadenylated RNAs (or EBERs); (b) the BamHI A RNAs, a family of spliced polyadenylated transcripts whose protein products are still not well characterized; (c) six differentially spliced mRNAs expressed either from the BamHI W promoter (Wp) or more commonly from an adjacent BamHI C promoter (Cp) and encoding the viral nuclear antigens EBNAs 1, 2, 3A, 3B, 3C and -LP,; and (d) three spliced BamHI N RNAs encoding the latent membrane proteins LMP1, LMP2A, and LMP2B; note that LMP2B, which is expressed from the same bi-directional promoter as LMP1, represents an N-terminally truncated version of the independently expressed LMP2A protein. Most adult-origin, as opposed to fetal-origin, LCLs contain a small fraction of cells (less than 5%), which have switched from latency into virus productive (lytic) cycle, apparently coincident with differentiation toward a plasmacytoid phenotype (96). The inability to reproduce the Latency III form of infection in several other cell types (see later) implies that the growth-transforming program of EBV is indeed B-cell specific, one possible exception being CR2-positive follicular dendritic cells in which *in vitro* infection has been reported to induce the slow outgrowth of cells expressing the full range of EBV latent cycle proteins (281).

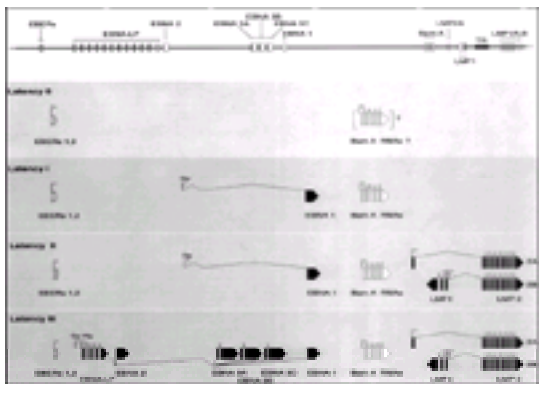

FIG. 1. Patterns of EBV latent gene transcription in four different forms of latency either postulated in the case of Latency 0 for an infection of noncycling cells or as observed in the cases of latency I, II, and III from *in vitro* model systems. Transcripts are drawn in correct orientation relative to one another, with promoters (*pennants*) and splicing patterns as shown; exons are illustrated for noncoding RNAs (*white*; including the BamHI A RNAs, whose coding capacity is still unresolved) and for mRNAs (*black*). The actual genomic positions of these exons are shown (*top*) on a linear map of the viral genome. Note that the genome is circularized in latently infected cells through fusion of the terminal repeats (TR), and the LMP2 transcripts are spliced across this fused TR region.

More Restricted Forms of *In Vitro* Latency, Latency II and I

The existence of more restricted forms of latent infection first became apparent from the study of EBV-positive malignancies but is best illustrated using experimentally generated *in vitro* models in which viral gene expression is homogeneous throughout the cell population and stably maintained with serial passage. It is important to note that Latency II and Latency I, defined using these *in vitro* models and presented as distinct entities in Figure 1, represent two ends of a spectrum with various intermediate possibilities depending on the relative activities of the LMP promoters.

Latency II can be established *in vitro* by fusing LCL cells with certain EBV-negative human epithelial, fibroblast, or hemopoietic cell lines (92,230). In the resultant cell hybrids where the cell phenotype resembles that of the EBV-negative parent rather than the LCL, there is a concomitant switch in the pattern of virus gene expression. This now involves (a) expression of the EBERs, (b) expression of the BamHI A RNAs, (c) silencing of the Cp/Wp promoters and selective

expression of a different EBNA1 mRNA from the BamHI Q promoter (Qp), and (d) expression of the LMP1, LMP2A, and LMP2B mRNAs, leading to a cell in which viral antigen expression is limited to EBNA1 and the LMPs (possibly plus BamHI A–encoded products).

Latency I can be established by fusing LCL cells with other human hemopoietic cell lines, such as HL60 (230). In this case, the resultant hybrids have again suppressed the LCL phenotype, and viral transcription is reduced to expression of (a) the EBER RNAs, (b) the BamHI A RNAs, and (c) the EBNA1 mRNA from Qp, with silencing of the Cp/Wp and LMP promoters. In this case, therefore, viral antigen expression is restricted to EBNA1 (possibly plus BamHI A–encoded products).

Various attempts have been made to establish these more restricted forms of latency by direct experimental infection of target cells rather than by manipulating the LCL phenotype. Infection of CR2-positive human B-cell lines (derived from EBV-negative lymphomas) leads to a transient Latency III pattern of gene expression but only rarely to stable conversion of cells to an EBV genome–positive state. In the absence of any selection system for EBV-positive converts other than enhanced survival under dense culture conditions, the rare converts detected tended to show a Latency III phenotype and pattern of viral gene expression (320), often carrying the EBV genome in an integrated rather than the expected episomal form (209). However, using a recombinant EBV with a drug selection marker has allowed the more efficient isolation of stable converts that carry the viral genome as an episome and display Latency I (483).

A number of studies have examined the infectability of human epithelial cells *in vitro,* prompted by the association of EBV with some nasopharyngeal and gastric carcinomas. Direct infection of primary skin or pharyngeal epithelium is detectable *in vitro* but very inefficient (429), whereas established skin keratinocyte lines, expressing CR2 from an introduced vector, are much more susceptible (279). By contrast, both primary gastric epithelium (334) and gastric carcinoma cell lines (512) can be infected by a CR2-independent route. In these susceptible epithelial systems, there is selective expression of Qp-initiated EBNA1 and of LMP2A transcripts, with little evidence of LMP1 expression either at the mRNA or protein level. This is one of several indications that forms of latency intermediate between Latency I and II can exist. A proportion of these epithelial cells, either in acutely infected cultures or in derived EBV-positive cell clones, are capable of entering a virus lytic cycle either spontaneously or after induction of terminal differentiation (254,279,334,429,512).

Somewhat similar findings have come from experimental infections of T-lymphoma cell lines, which EBV can infect by CR2-dependent (255) or CR2-independent (182) routes. These lines typically sustain latent infections characterized by EBNA1 and LMP2A expression with or without LMP1 (348). Conventional attempts to infect freshly isolated CD4+ or CD8+ T cells from peripheral blood have been unsuccessful. However, one study described the establishment of slow-growing EBV-positive T cells with a Latency I pattern of viral gene expression from cultures of virus-infected peripheral blood mononuclear cells (PBMCs) following electroporation with a drug resistance marker and drug selection (166). The mechanism underlying this rare T-cell outgrowth has yet to be identified.

Other Forms of Latency

All stable programs of latent gene transcription seen in EBV-infected cell lines *in vitro* or tumors *in vivo* must be consistent with maintenance of the viral genome in the proliferating cell population, that is, with continued expression of the virus genome maintenance protein EBNA1. This would not necessarily be the case were EBV to establish latency in a noncycling host cell. In this example, in principle, the virus might persist without expressing any viral antigens, as in latent alpha herpesvirus infections of neuronal cells *in vivo*. As illustrated in Figure 1, the analogous situation for EBV would therefore be a “Latency 0,” in which Cp/Wp, Qp, and the LMP promoters are silent and viral gene expression is limited to the noncoding EBERs, possibly accompanied by the BamHI A RNAs.

Lytic Infection

There are as yet no *in vitro* cell systems in which EBV infection leads directly into a fully productive lytic infection. Virus replication must always be studied by inducing latently infected cells into lytic cycle. Such induction is associated with a down-regulation of the latent cycle EBNA promoters (either Cp/Wp in Latency III or Qp in Latency I and II) and activation of a lytic promoter Fp immediately upstream of Qp. A minority of the Fp-initiated transcripts splice into the EBNA1 open reading frame (405) such that EBNA1 expression appears to be maintained in lytic cycle. Furthermore, in the Latency I BL cell line Akala, the LMP promoters are also activated after the induction of lytic cycle, such that the LMPs are expressed with the kinetics of early lytic cycle proteins (388).

There are, however, some *in vitro* systems in which EBV infection has been reported to enter an abortive lytic cycle without a detectable latent phase. These all involve atypical target cells, namely a CR2-positive subpopulation of immature fetal thymocytes (228), cultured syntiotrophoblasts again apparently expressing CR2 (469) and primary monocytes (401). The *in vivo* significance of such interactions is unknown, but at present none seems likely to provide a fully permissive *in vitro* system that is experimentally tractable.

INFECTION IN THE NATURAL HOST

Epidemiology of Primary Infection

Seroepidemiologic surveys of immunoglobulin G (IgG) antibodies to the viral capsid antigen (VCA) complex show that most children in the developing world become infected within the first 3 years of life and that antibody prevalence reaches 100% within the first decade (1,126). These early primary infections, which are almost always asymptomatic, probably reflect parent-to-child transmission by the oral route; indeed, there is now sound molecular evidence for the transmission of a single EBV strain between generations within families (158). By contrast, one consequence of lifestyle change in the more developed Western world is that up to half of children are still seronegative at the end of their first decade, many of whom subsequently become infected through intimate oral contact in adolescence or young adulthood. A serendipitous observation in the Henles' laboratory, that a young technician had seroconverted during the course of

infectious mononucleosis (IM) (187), prompted retrospective serologic studies that quickly confirmed EBV as the etiologic agent of this disease (127). Up to half of such delayed primary infections may be symptomatic, although only the more severe are likely to present clinically and be diagnosed as IM. About 5% of adults in Western societies remain EBV-uninfected, both by serologic criteria and by virus detection assays, and constitute a population from which rare cases of classic IM in older adults (200) and of iatrogenic “postperfusion” mononucleosis (148) are drawn.

Most of what is known about primary EBV infection comes from the study of IM patients, but it is not clear how closely the events occurring in IM reflect those occurring in an asymptomatic primary infection in childhood. It is worth remembering that, in evolutionary terms, IM is a novel disease that has arisen through a recent change in the epidemiology of virus transmission, as yet peculiar to the developed Western world.

Virus–Cell Interactions During Primary Infection

Lytic Infection at Oropharyngeal Sites

Little is known about the earliest events that follow oral transmission of EBV to the naive host because there is a 4- to 6-week incubation period before the clinical symptoms of IM appear. By this time, high titers of cell-free infectious virus are detectable in throat washings and saliva as measured by *in vitro* transformation using indicator cord blood B cells (147). Early evidence suggested that this virus was being produced from lytically infected oropharyngeal epithelium, with viral DNA or lytic cycle transcripts being detectable in desquamating epithelial cells by *in situ* hybridization (427). This issue is not fully resolved, however (225), particularly since histologic studies of IM tonsils could not identify any viral infection of tonsillar epithelium but did detect small numbers of lytically infected B-lymphoid cells, usually situated near crypt epithelium, expressing the immediate early BZLF1 protein and a component of early antigen (11,490). Interestingly, these cells had mostly lost expression of CD20 and had acquired an early plasmacytoid marker (328), consistent with an association first noted *in vitro* between lytic cycle entry and plasmacytoid differentiation (96).

One view is that epithelial cells, perhaps at a specialized oropharyngeal site, constitute the primary targets in which orally transmitted virus replicates and that progeny virions subsequently transfer into the B cell system. An alternative view is that, while there may be secondary spread of infectious virus to permissive epithelium, the virus primarily targets B cells infiltrating the oropharyngeal mucosa where the local milieu might favor lytic rather than latent infection. Circumstantial evidence for this latter view comes from X-linked agammaglobulinemia (XLA) patients, who lack circulating B cells and receive infusions of pooled Ig preparations; such patients do not harbor detectable EBV DNA either in throat washings or in peripheral blood and show no evidence of the virus-specific T-cell memory, which even a transient primary infection of oropharyngeal epithelium would have been expected to elicit (133).

Latent Infection: Colonization of the B-Cell System

In addition to virus replication in the oropharynx, acute IM patients also show a generalized infection of the circulating B-cell pool, apparent from the ease with which EBV-positive LCLs grow out spontaneously from cultures of PBMCs (358). Indeed, from studies of individuals fortuitously sampled in the incubation phase of IM, it is clear that virus colonization of the B-cell system is ongoing well before the onset of clinical symptoms (116,451). During the acute disease itself, immunofluorescence staining has shown that, in exceptional cases, 10% or more of the circulating B cells can be EBNA-positive (98,379); more usually, however, values lie in the 0.1% to 1% range (250). Similar frequencies are obtained when IM B-cell preparations are screened by *in situ* hybridization for cells expressing EBERs, a sensitive marker of latent infection (466). Even using the less sensitive assay of spontaneous LCL outgrowth, culture seedings of 10^4 to 10^5 PBMCs (equivalent to less than 10^3 to 10^4 B cells per well) are frequently sufficient to give growth (506). The inability to detect infectious virus in freeze-thawed extracts of freshly isolated IM B cells suggests that most of the EBV-positive cells are latently infected *in vivo*, although some lytic cycle gene transcription is detectable using highly sensitive nested reverse transcription–polymerase chain reaction (RT-PCR) assays (361). Interestingly, many of these latently infected cells appear to be rapidly triggered into lytic cycle when placed in culture. Spontaneous LCL outgrowth in fact largely depends on this process of virus replication, release, and infection and transformation of co-resident B cells rather than on the direct *in vitro* growth of *in vivo*–infected cells (375).

RT-PCR analysis of viral transcription in freshly isolated IM B cells (466) has detected many of the RNAs characteristic of a Latency III (LCL-like) infection, including the Cp/Wp-initiated EBNA mRNAs and the various LMP transcripts. This strongly suggests that at least some of the latently infected B cells generated during primary infection are growth-transformed and is consistent with the presence of rare EBNA-positive mitotic cells in IM blood (379). However, RT-PCR analysis also detected the presence of Qp-initiated (and not Fp-initiated) EBNA1 transcripts in the circulating B-cell pool (466), suggesting that cells sustaining alternative forms of latent infection may also be present.

The complexity of latent virus–cell interactions *in vivo* is graphically illustrated by screening IM tonsillar sections with a combination of RNA *in situ* hybridization for EBERs and monoclonal antibody staining for virus latent proteins or cell lineage markers. As illustrated in Figure 2, a substantial number of EBER-positive cells are present, mainly in the extrafollicular paracortical areas and only very rarely in the B-cell areas (follicles) or their constituent germinal centres (11,328,490). Most of the EBER+ cells are B lymphocytes, but some studies have also reported evidence of T-cell infection (11); this latter point remains controversial (328,474). The EBER-positive B-cell populations are heterogeneous both in morphology and viral antigen expression. They include (a) small cells expressing EBNA2 in the absence of LMP1, perhaps recently infected and progressing to the EBNA2-positive, LMP1-positive stage; (b) medium-sized lymphoblastoid cells expressing both EBNA2 and LMP1, consistent with a LCL-like Latency III infection and virus-driven B-cell growth; (c) large blast cells, morphologically similar to the malignant Hodgkin–Reed Sternberg (H-RS) cells of Hodgkin's disease (HD), which are EBNA2-negative, LMP1-positive; and (d) small cells, which are EBNA2-negative and LMP1-negative (260,328). How these different forms of infection interrelate in time is not known, but analysis of Ig-variable gene sequences in individual microdissected cells clearly shows that different cell phenotypes can be generated within the same EBV-infected B-cell clone (260). One possibility is that some cells leave the proliferating EBNA2-positive, LMP1-positive compartment and differentiate either to an EBNA2-negative, LMP1-positive, H-RS–like cell or to an

EBNA2-negative, LMP1-negative form of infection like that which characterizes EBV-infected B cells in the blood of virus carriers.

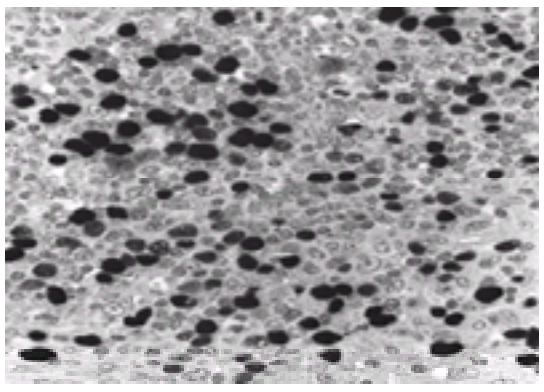

FIG. 2. *In situ* hybridization with digoxygenin-labeled probe demonstrating the high frequency of EBER-RNA–expressing lymphocytes (see dark nuclei) in tonsillar tissue taken from a patient with acute infectious mononucleosis. In separate experiments, double staining with a monoclonal antibody against the B-cell–associated membrane marker CD20 confirms the B-cell origin of most EBER-positive cells. (Courtesy of G. Niedobitek.)

An important lesson emerging from this work is that, although some individual EBV-positive cells in IM tonsils carry nonmutated *Ig* gene sequences characteristic of naive B cells, the expanding clones preferentially, if not exclusively, involve cells that already carry somatically mutated *Ig* genes (260). Such somatic mutations are diagnostic of an antigen-experienced (memory) B cell that has previously acquired these mutations during antigen-driven transit through a germinal centre (366). However, the EBV-driven expansion of such clones in IM tonsils occurs without further intraclonal hypermutation, consistent with the observation that these expansions are occurring outside germinal centers. Interestingly, the virus itself may determine the homing of these growth-transformed cells to extrafollicular sites. Thus, in a transgenic mouse model system, constitutive LMP1 expression in B cells prevents their involvement in germinal center reactions (471); furthermore, viral infection of human B cells induces expression of CCR7 (41), the receptor for a cytokine preferentially produced by dendritic cells in extrafollicular areas of lymphoid tissues (325). The preferential expansion or survival of EBV-infected memory, as opposed to naive, B cells in IM is as yet not understood; possibly, it reflects an increased ability of these more mature cells to differentiate from the proliferating EBNA2-positive LMP1-positive lymphoblastoid state to a resting EBNA2-negative, LMP1-negative resting state upon which their ability to persist in the immunocompetent host depends.

Virus–Cell Interactions During Persistent Infection

Lytic Infection at Mucosal Sites

As the acute symptoms of IM subside, virus replication in the oropharynx falls but is never completely eliminated. Even long-term virus carriers with no history of IM continue to secrete low levels of infectious virus, detectable in throat washings by the cord blood B-cell transformation assay (507). There is again debate over the source of this orally shed virus. EBV clearly can replicate in mucosal epithelium under some circumstances (163,478), but histologic screening of oropharyngeal and nasopharyngeal tissues suggests that lytic infection is restricted to small numbers of B cells, usually underlying mucosal surfaces, rather than to epithelium itself (330,460). Virus replication within sub-mucosal plasmacytoid B cells is again consistent with the recent finding that linear EBV DNA (diagnostic of lytic infection) is detectable only in a fraction of tonsillar lymphocytes that have lost the CD19 marker (23).

It is also clear that replication is not restricted to the oropharynx, having been detected also in the cervix (426) and in the lungs (118) of seropositive individuals. This supports the view that, once the virus has successfully colonized the B-lymphoid system, reactivation from latency can occur at any mucosal site with a B-cell infiltrate. Relevant in this context are iatrogenic primary infections in which the virus is acquired through latently infected B cells within a bone marrow graft (159) or blood transfusion (148). The fact that this virus can subsequently be isolated as infectious virions in a patient's throat washings clearly shows that a reservoir of latently infected cells can seed foci of virus replication at mucosal sites.

Latent Infection of the B-Cell System

EBV-infected B cells remain detectable in the peripheral blood and throughout all lymphoid tissues of asymptomatic carriers, albeit at much lower levels than seen in IM. This was again first recognized by spontaneous LCL outgrowth *in vitro* (333) and subsequently confirmed by direct PCR amplification of viral DNA (24,119,232,306). Most work has concentrated on the peripheral blood where seedings of 4×10^5 to 4×10^6 PBMCs (equivalent to less than 4×10^4 to 4×10^5 B cells) are usually sufficient to obtain LCL outgrowth, providing cyclosporine has been added to culture medium to prevent interference by immune T cells (505). The absolute frequency of circulating EBV-infected cells has been more accurately determined by PCR amplification on limiting PBMC numbers, giving a normal range of 1 to 50 per 10^6 B cells for healthy virus carriers (232,306). Both approaches have emphasized the stability of EBV-infected B-cell numbers in individual carriers when monitored over several years. In normal donors, there is no evidence of virus carriage in non-B leukocytes.

In contrast to the activated EBV-positive lymphoblasts seen during primary infection, infected cells in the blood of virus carriers all lie in the noncycling (G_0 phase) population, lacking activation markers such as CD23 or CD80 and the Ki-67 proliferation marker (305,306). Importantly, those infected cells all segregate within the memory subset of circulating B cells, a population defined by loss of surface IgD expression, and not within the naive IgD-positive, IgM-positive

population (24). Normally, exposure of a naive B cell to its cognate antigen induces clonal expansion of that cell within a germinal center; during this expansion, somatic hypermutation produces intraclonal diversification of antibody-coding (*Ig*) gene sequences, after which just a few progeny cells producing the highest-affinity antibody are positively selected into memory by virtue of their ability to compete for antigen binding (366). These events usually involve loss of IgD expression and are also frequently accompanied by Ig class switching; hence, the resultant IgD-negative memory pool contains some cells that have remained IgM-positive and others that have switched to become surface IgG-positive, IgA-positive, or IgE-positive. EBV-infected cells are detectable in all of these memory cell subsets (24,119), although apparently not (464) in another recently identified subset of memory B cells, which atypically remain IgD-positive and IgM-positive but are distinguished from the IgD-positive, IgM-positive naive population by their acquisition of the CD27 marker (252). The sequestration of EBV within the memory B-cell pool of virus carriers accords with the observation that during primary infection, clonal expansion of EBV-infected cells appears to favor those clones with a somatically mutated (i.e., memory) Ig genotype (260).

EBV latent gene expression in the circulating B cells of virus carriers is different from that seen in IM. Now only the EBERs (466), BamHI A RNAs (84), and LMP2A transcripts (305,363,466) are still detectable, in some cases accompanied by trace levels of Qp-initiated EBNA1 transcripts (305,466). This narrowing of viral gene expression between primary infection and the carrier state is consistent with the reversion of infected cells from an activated lymphoblast to a resting memory B-cell phenotype. Care must be taken in extrapolating from the results of RT-PCR assays on total cell populations to viral transcription in individual cells. Quantitative considerations suggest that most EBV-infected B cells in the blood are EBNA1 mRNA negative and that many could also be LMP2A mRNA negative; indeed where such transcripts are detectable, they may represent residual signals from cells that have recently left the lymphoid tissue environment (23). This implies the existence of a circulating pool of EBV-positive cells in which all viral antigen expression is suppressed and viral transcription is limited to the noncoding EBERs and possibly the BamHI A RNAs; this is equivalent to the Latency 0 form of infection postulated in Figure 1.

Analysis of lymphoid (mainly tonsillar) tissues from virus carriers suggests that the proportion of B cells that carry the virus here is again very low, similar to levels seen in the blood (11,24,330). *In situ* hybridization on tissue sections identifies occasional EBER-positive cells, again usually within extrafollicular areas, which have the appearance of small B lymphocytes and show no evidence of EBNA2 or LMP1 expression (17,330). A more complete histologic picture may be easier to discern, however, in the tonsils of virus carriers from areas where parasitic infection provides a chronic antigenic stimulus to the B-cell system. In such circumstances, recent work suggests that the extrafollicular load of EBER-positive small B cells is slightly elevated and that in some cases EBER-positive centroblasts, always EBNA2-negative but occasionally expressing LMP1, are detectable within germinal centres (17). Such findings would be consistent with a recent RT-PCR analysis of EBV gene transcription that has detected LMP1, LMP2A, and Qp-initiated EBNA1 mRNAs both in the germinal center B cell (CD19+, IgD–, CD77+) and in the memory B cell (CD19+, IgD–, CD77–) compartments of tonsillar lymphocytes (25,26). These appear to represent reactivations from the preexisting memory cell pool rather than *de novo* infections because such transcripts were consistently present in tonsils whether or not there was evidence of ongoing virus replication. Interestingly, Cp/Wp-initiated EBNA transcription, diagnostic of growth- transforming Latency III infection, was found only in tonsils in which virus replication was occurring to provide a source of progeny virus for *de novo* infections (25). Therefore, reactivations from the latently infected memory B-cell pool and *de novo* infections may be occurring simultaneously in the lymphoid tissues of virus carriers but are likely to involve different programs of virus gene expression and lead to different outcomes.

The spectrum of B-cell differentiation stages represented within lymphoid tissues is much broader than that represented in peripheral blood, and the resident forms of EBV infection are correspondingly more heterogeneous. EBV has evolved mechanisms to colonize, persist within, and reactivate from the human B-cell system that very probably exploit normal B-cell physiology, using differentiation-dependent cellular controls to activate or suppress different programs of viral gene expression at appropriate times in the life history of the infected cell. The full complexity of these viral strategies is only just being realized, and any current attempt to map the lineage, kinetic, and anatomic relationships between infected cells *in vivo* (see later overview section) must be regarded as preliminary.

ANTIBODY RESPONSES TO INFECTION

The seroepidemiology of EBV infection and of EBV-associated diseases relies heavily on a set of immunofluorescence assays developed in the laboratories of Werner Henle and George Klein within the first decade of EBV research (126). These measure antibody responses to the following serologically defined antigens: (a) the EBNA expressed in latently infected cells; (b) the early antigen (EA), divisible into diffuse (EA-D, methanol-resistant) and restricted (EA-R, methanol-sensitive) components and expressed within cells early in lytic cycle; (c) the virus capsid change (VCA) expressed within cells late in lytic cycle; and (d) the membrane antigen (MA) expressed on the surface of cells late in lytic cycle. As described in Chapter 74 (245), each of these “antigens” is a composite of several distinct viral proteins. Thus, EBNA is a complex of six distinct nuclear proteins, EBNA1, 2, 3A, 3B, 3C, and -LP, with antibodies to EBNA1 being the most frequent (but not the only) reactivity detected in the conventional anti-EBNA immunofluorescence test. EA is a plethora of immediate-early and early viral proteins, including the BZLF1 immediate early and the abundantly expressed BALF2, BHRF1, BMRF1, and BMLF1 early proteins. Much of what was termed VCA reactivity is diffuse cytoplasmic fluorescence and is directed against virus-encoded nucleocapsid components, including BcLF1, BFRF3, BLRF2, and the glycoprotein gp110, which are expressed in late lytically infected cells. On the other hand, most MA reactivity, detected by immunofluorescence staining of living cells, is directed against gp350, the most abundant viral protein present both on the surface of lytically-infected cells and on the viral envelope. Although less frequently assayed than anti-EA and anti-VCA, anti-MA levels in serum are of particular interest because they tend to correlate with virus neutralizing activity.

For clinical diagnostic work, attempts have been made to replace the above assays with enzyme-linked immunosorbent assay (ELISA)-based or other tests using as substrates either individual EBV proteins expressed in recombinant form or synthetic peptide mimics of immunodominant epitopes. Several such assays have been developed for the detection of primary EBV infection, based on IgM antibodies to the BALF2 and BMRF1 components of EA or to the low molecular weight VCA components BFRF3 and BLRF2. Screening on combinations of such antigens is still recommended for

diagnostic accuracy (57,450).

Responses in Primary Infection

IM patients again provide the bulk of information available on the primary antibody response to EBV; what little is known about asymptomatic primary infections in young children suggests that their pattern of response is broadly similar (353). By the onset of clinical symptoms, most IM patients already have substantial titers of IgM antibodies to VCA and rising IgG titers both to VCA and to EA (most frequently, to the D component). IgA responses to these antigens may also appear transiently at this time, but this has not been systematically studied. The IgM anti-VCA response subsequently disappears either during convalescence or over the next few months, whereas IgG anti-VCA titers rise to a peak then may fall slightly over the ensuing months to a stable steady-state level. The IgG anti-EA response usually falls slightly faster and further than IgG anti-VCA and either becomes undetectable or stabilizes at a very low level (185). Virus neutralizing antibodies in acute IM tend to be of low titer and complement-dependent, consistent with antibodies to the major neutralization target antigen gp350 being predominantly of IgM class at this time, with IgG titers rising relatively late in the disease. A transient IgA response to gp350 is also detectable (430). Another characteristic and interesting feature of IM serology is the pattern of anti-EBNA reactivities. Many, but not all, patients in the acute phase of the disease show an IgG response to the EBNA2 protein (and probably also to the EBNA3A, 3B, 3C family of proteins, although these are more difficult to assay), whereas an IgG response to EBNA1 is not usually detectable until convalescence (190). Antibodies capable of recognizing EBNA1 in immunoblots have been detected in the IgM fraction of acute IM serum, but these are thought to be part of the autoantibody response (see later), with cross-reactivity against the glycine-alanine repeat domain of EBNA1 (372). Antibody responses to the latent membrane proteins LMP1 or LMP2 have not been seen in IM patients and indeed are only detectable in a small proportion of healthy carriers even using the most sensitive assays (139,300).

What role the humoral response plays in the overall control of the primary infection remains uncertain. Clearly, the virus-neutralizing components of the response (predominantly anti-gp350 antibodies) have the capacity to prevent generalized spread of the virus as a cell-free viremia; even here, however, the possibility has been raised that the IgA anti-gp350 response may actually facilitate virus spread to epithelial compartments (430). The delayed antibody response to EBNA1 remains difficult to understand. The original view, that this reflected the delayed destruction of latently infected cells *in vivo* and hence delayed availability of the antigen, is hard to reconcile with the observation that responses to EBNA2, another latent protein, are detectable during the acute disease (190), although they may not persist in the longer term. Possibly, the change in anti-EBNA reactivities between primary and persistent infection may reflect the fact that different types of latently infected cells predominate at these different times.

In addition to the previously described EBV-specific antibody responses, the early phase of acute IM is associated with generally elevated levels of total serum IgM, IgG, and IgA, again consistent with a virus-driven polyclonal activation of the B-cell system (185). Concomitant with this general increase is the transient appearance of a range of heterophile and autoantibodies, mostly of IgM class, which may also be products of virus-infected B cells (145). Of these various reactivities, heterophile antibodies with the capacity to agglutinate sheep and horse erythrocytes form the basis of the Paul-Bunnell-Davidsohn test that, when positive, is diagnostic of EBV-associated IM. Not all primary EBV infections become heterophile antibody-positive, however, and thus distinguishing EBV-associated IM from the IM-like illnesses caused by other agents, such as cytomegalovirus or toxoplasma, requires EBV-specific serology (185). The overall patterns of antibody responses seen during the acute and convalescent phases of IM are illustrated diagrammatically in Figure 3 relative to the virologic events (virus shedding in the throat, virus-infected B cells in the blood) occurring over the same time frame.

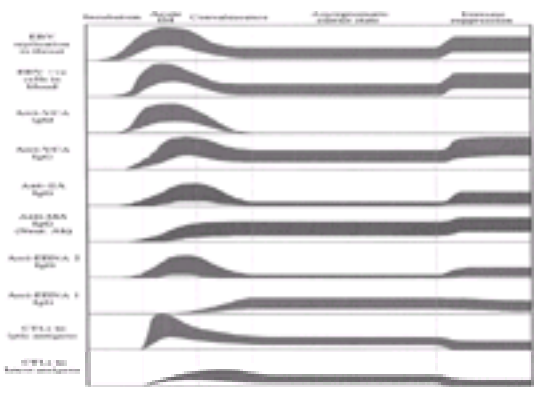

FIG. 3. Parameters of the EBV–host balance during the incubation, symptomatic and convalescent phases of acute infectious mononucleosis (i.e., primary EBV infection), during subsequent asymptomatic virus carriage and after the imposition of immunosuppressive therapy on an existing virus carrier state. For each parameter, the *shaded band* represents the broad range within which most infected individuals lie; where the band extends to the baseline, this indicates that the relevant responses are detectable in some, but not all, infected individuals.

Responses in Persistent Infection

Healthy virus carriers are consistently IgG anti-VCA positive, anti-gp350 neutralizing antibody positive, and anti-EBNA1 positive; the serologic picture in convalescent IM patients also gradually changes to assume this same profile (126,185). Titers can differ markedly among individuals, and such differences tend to be stable over time. A significant number of long-term virus carriers possess additional reactivities, for instance, to EA (most frequently to the R component) or to one or more of the other EBNA proteins, and these again are stably maintained. The basis for these individual differences is not known. Healthy individuals with anti-VCA, anti-EA titers at the top of the normal range are not necessarily those

showing the highest levels of virus replication, at least as measured by transforming virus titers in throat washings (507). Because antibodies to VCA, EA, and EBNA target intracellular antigen complexes, they seem unlikely to play a major effector role in recognizing and removing virus-infected cells *in vivo*. By contrast, anti-MA (anti-gp350) antibodies can bind to the surface of late lytically infected cells and also to virions, and they have the capacity to neutralize a broad spectrum of EBV strains. Such antibodies could therefore contribute to overall control of the established virus carrier state by preventing a recrudescence of viremia and, as discussed later, by helping to protect the immune host from superinfection with further strains of orally transmitted virus.

CELL-MEDIATED RESPONSES TO INFECTION

EBV has proved an important general model for studying the human cell-mediated response to virus infection. Key features in this regard are the ubiquity of the virus in human populations, its genetic stability within the infected host, its strong immunogenicity to the T-cell response, and the ability to follow both primary and memory phases of the response through prospective work on IM patients. Although many of the ground rules governing EBV-induced cellular responses were established in early work on healthy virus carriers (reviewed in 376), a more complete picture is now emerging that includes the events of primary infection (373).

Responses in Primary Infection

One of the key diagnostic features of IM is the presence of large numbers of “atypical mononuclear” cells in the blood. These are predominantly T lymphoblasts of the CD8+ subset but include some CD4+ T cells and also activated natural killer (NK)-like cells with the CD16 or CD56 markers.

The NK-like component, which displays broad-ranging killing of NK-sensitive targets in *ex vivo* cytotoxicity assays (441,468), may be the remnants of an innate immune response that is thought to act as a first line of defense against many types of virus infection. The paucity of studies of patients in the incubation period of IM means that little is known about the earliest cellular responses *in vivo*. However, challenging the PBMCs of uninfected individuals with large numbers of autologous LCL stimulators *in vitro* induces a potent activated NK-like response (477). Likewise, in experimentally infected PBMC cultures from nonimmune donors, a delay in the kinetics of B-cell outgrowth has been ascribed in some cases to a CD16+ NK cell–mediated response, and in others to the rapid induction of interferon-a (IFN-a) or IFN-g release (reviewed in 374). Only rarely, however, were such effects capable of preventing LCL outgrowth. Such findings imply that innate immune responses are of limited value, at least in the control of latent growth-transforming infections. The point is reinforced by observations on bone marrow transplant recipients following primary EBV infection when virus-associated lymphoproliferative lesions have appeared at times when NK cell function was intact but T-cell responses had not yet developed (13,289).

The nature of the highly expanded CD8+ T-cell response in IM has long been debated, with assays on LCL targets implying the presence of some latent antigen-specific cytotoxic T lymphocytes (CTLs) accompanied by other apparently irrelevant reactivities detectable on allogeneic LCL targets (441,468). A first indication of the possible magnitude of the virus-specific component was the markedly skewed Vb subset distribution seen within IM CD8+ T cells, with many of the preferentially expanded Vb subsets showing an oligoclonal pattern of T-cell receptor (TCR) usage (72). Such results were more consistent with an antigen-driven response than with “bystander” (441) or superantigen-driven (449) activations. Parallel studies focusing on the antigenic specificity of IM CD8+ T cells took advantage of the fact that several immunodominant EBV latent cycle epitopes (mostly drawn from the EBNA3A, 3B, 3C family of proteins; see Table 1, presented later) and their HLA class I restriction elements had already been identified from work with long-term virus carriers. Marked focusing of the EBV latent cycle-induced CTL response against the same limited number of viral epitopes was indeed apparent even at the height of primary infection (438). Studies of the CTL responses in young infants within months of primary infection led to a similar conclusion (456). However, when these EBV latent epitope-specific T cells in IM blood were visualized by the new technique of staining with HLA class I/peptide tetramers, responses to the most immunodominant EBNA3-derived latent cycle epitopes, such as B8/FLR, accounted for only 1% to 2% of the CD8+ T-cell pool (73); interestingly, limiting dilution assays with IM PBMC populations *in vitro* had given similar frequency estimates (438).

EBV antigen[a]	Epitope location	Epitope sequence[b]	HLA allele	EBV type specificity[c]
EBNA 1	407–417	HPVGEADYFEY	HLA-B35.01	1 + 2
EBNA 3A	458–466	RPPIFIRCH/QW	HLA-B35.01	1
	325–333	FLRGRAYGL	HLA-B8	1
	158–166	QAKWRLQTL	HLA-B8	1
EBNA 3B	416–424	IVTTSVIK	HLA-A11	1
	399–408	AVFDRKSDAK	HLA-A11	1
	244–254	RRARSLSAERY	HLA-B27.02	1
EBNA 3C	258–266	RRIYGLIEL	HLA-B27.02/45	1
	386–343	KEKVKQNAF	HLA-B44.02	1
	103–171	EEGVGSPQHW	HLA-B44.03	1 + 2
LMP2	426–434	CLGGLLTMV	HLA-A2.01	1 + 2
	419–427	TYGPVFMCL	HLA-A24.02	1 + 2
	200–208	IEDPPFNSL	HLA-B40.01	1 + 2
BZLF1	190–197	RAKFKQLL	HLA-B8	1 + 2
	256–217	SYNDRLRLL	HLA-B40.01	1 + 2
BRLF1	91–99	AENAGRDAC	HLA-B45	1 + 2
	109–117	YVLDHLIVV	HLA-A2.01	1 + 2
BMLF1	280–288	GLCTLVAML	HLA-A2.01	1 + 2
	397–405	DEVEFLGHY	HLA-B18	1 + 2

[a]Latent antigens are shown EBNAs 1, 3A, 3B, 3C, and LMP2; lytic antigens are BZLF1, BRLF1, and BMLF1.
[b]Epitopes are referred to in the text using the first three letters of the epitope sequence.
[c]For most of the lytic cycle antigens, conservation between type 1 and 2 strains is based on sequence data from limited numbers of virus isolates.

TABLE 1. *Examples of CD8+ T-cell epitopes in EBV latent and lytic antigens*

A different picture emerged when the analysis turned to include EBV lytic cycle antigens as potential targets. Memory T cells to a lytic cycle epitope (RAK from the immediate early protein BZLF1) had first been identified by peptide stimulation *in vitro* (45), but it was the study of IM T cells that revealed the presence of multiple CD8+ T-cell reactivities to epitopes from immediate early (BZLF1, BRLF1) and several early (BMLF1, BMRF1, BALF2) proteins of the lytic cycle. Examples of some of the best studied lytic cycle epitopes, their source antigens, and their HLA class I restriction elements are

shown in Table 1. Responses to such epitopes were clearly more abundant than latent epitope-specific responses whether detected in cytotoxicity assays using IM T-cell effectors *ex vivo* or by clonal outgrowth in *in vitro*–limiting dilution assays (437). When visualized by the appropriate HLA class I–peptide tetramers, the response in individual patients could show remarkable focusing on individual immunodominant epitopes. Thus, in HLA-B8–positive IM patients, regularly between 25% and 50% CD8+ T cells stain with the HLA-B8/RAK (BZLF1 epitope) tetramer (73). Likewise, in HLA-A2.01–positive patients, up to 25% CD8+ T cells are specific for one of two immunodominant A2.01 epitopes, YVL from the immediate early protein BRLF1 and GLC from the early protein BMLF1. Such findings strongly imply that EBV lytic antigen-specific reactivities make up the bulk of the highly expanded CD8+ T-cell pool in IM. Moreover, some of these immunodominant epitope-specific responses show highly restricted TCR usage (16) and clearly contribute to particular Vb expansions of the kind described earlier in IM blood (72). It is still too early to say whether immediate-early and early antigens of the virus lytic cycle are consistently immunodominant over late antigens as targets of the CD8+ CTL response because the analysis of potential late antigen targets has been mainly restricted to the viral glycoproteins; to date, only relatively weak reactivities to A2.01-restricted epitopes in gp350 and gp85 have been detected (242). The origin of the broad-ranging killing of LCL targets described in the earlier literature on IM T cells is now easier to explain. This lysis of HLA class I–mismatched targets proved to be through cross-reactive recognition of allo HLA–peptide complexes present on particular allogeneic LCLs and on EBV-negative lymphoblasts from the same donor (441). There are now several well-documented examples of such allo–cross-reactivity being mediated by EBV latent epitope-specific clones, including clonotypes that dominate responses *in vivo* (63,64,416), and a similar potential clearly exists for the even more highly expanded clonotypes recognizing immunodominant lytic epitopes (304).

In contrast to the wealth of information emerging on CD8+ T-cell responses in IM, still little is known about CD4+ responses. It is likely that such responses are present, although the only example to date of a defined HLA class II–restricted reactivity in IM involves an unusual CD4+, CD8+ T-cell clone specific for a BHRF1 epitope (493). From heteroduplex analysis of TCR usage in IM T cells, individual CD4+ reactivities are unlikely to show the massive expansion noted for dominant CD8+ clonotypes (295); however, a clearer picture should emerge as the identification of CD4+ T-cell epitopes proceeds and HLA class II–peptide tetramers are developed.

Resolution of the Primary Response

Most CD8+ T cells in IM blood, and indeed most cells within EBV-specific tetramer-positive populations, display a CD38+, HLA-DR+, CD45RO+ activated cell surface phenotype (73). These activated cells have low levels of bcl-2 and are highly susceptible to apoptotic cell death *in vitro* unless rescued by antigenic stimulation or cytokines of the interleukin-2 (IL-2), IL-7, IL-15 family (6,313). After acute IM, most of these CD8+ T cells die, presumably because antigen dose becomes limiting *in vivo*. The remaining tetramer-positive cells (operationally defined now as “memory”) mostly revert to a CD38–, HLA-DR– resting phenotype but show heterogeneous expression of CD45 isoforms, being found in both the RO+ and RA+ populations (73).

The controls that govern antigen-specific CD8+ T-cell selection into memory are poorly understood but, from prospective studies of IM patients, it is already clear that the composition of memory is not simply a scaled-down version of the primary response. Thus, the highly expanded EBV lytic cycle-specific populations in IM appear to be disproportionately reduced in number during memory selection compared with the less highly expanded latent cycle-specific populations (73). Indeed the percentage representation of some latent epitope-specific reactivities in the circulating $CD8^+$ Tcell pool may even go on rising during the first four months post-IM before stabilizing at a lower level; this is never the case for lytic epitope reactivities, which fail immediately post-IM. Interestingly, some of the TCR clonotypes that dominate the primary response to immunodominant lytic cycle epitopes such as A2.01/GLC or B8/RAK appear to be replaced by others in memory (16,422), whereas the clonotypic composition of the B8/FLR latent epitope-specific response appears not to change over time (71,423). These contrasts in the size and maturation kinetics of the lytic versus latent antigen-specific responses are illustrated in Figure 3 beneath the serologic profiles observed over the same time scale.

Responses in Persistent Infection

The existence of long-term T-cell memory to EBV latent cycle antigens was first apparent in experimentally infected PBMC cultures in which a complete regression of LCL outgrowth, mediated by *in vitro* reactivated CD8+ CTLs, occurred at 2 to 3 weeks but only in cultures from virus-immune (seropositive) donors (315). Subsequent analysis of LCL-stimulated bulk T-cell lines and derived clones showed that EBV latent antigen-specific memory is usually dominated by T cells reactive to epitopes derived from the EBNA3A, 3B, 3C family of proteins (236,319). Responses to LMP2-derived epitopes, although usually subdominant, are the next most frequent reactivity in such T-cell preparations, whereas responses to EBNA2, EBNA-LP, LMP1, and especially EBNA1 are rare. Very weak responses have also been detected to an epitope within one of the predicted BamHI A–encoded polypeptides BARF0 (246). This marked hierarchy of immunodominance among latent cycle proteins, seen in a wide range of donors with different HLA class I types (236,319), implies some form of differential access of the EBNA3 proteins to the proteasomal degradation through which most HLA class I epitope peptides are generated. Examples of some of the best characterized immunodominant latent cycle epitopes, their location within latent proteins, and their HLA restriction elements are shown in Table 1. Note that these epitopes were almost all identified through studies of European and North American donors infected with the type 1 virus strains that are prevalent in the Western world. Although such epitopes are conserved in most Western type 1 strains, sequence divergence between the EBNA3 family proteins of type 1 and type 2 viruses means that many of the immunodominant EBNA3-derived epitopes are not present in type 2 strains (314); still relatively little is known about the identity of type 2 virus epitopes (376).

What determines epitope immunodominance in the context of any one HLA class I allele is still not fully understood. In the case of the HLA-A11–restricted epitopes IVT and AVF, both of which are derived from EBNA3B, the consistent numeric dominance of IVT-reactive over AVF-reactive CTLs in A11-positive individuals appears to correlate with a higher representation of A11–IVT complexes at the LCL surface and with the induction of a clonotypically more diverse T-cell response to this more abundantly expressed epitope (106,276). However, not all immunodominant latent cycle epitopes are abundant at the cell surface (99) and not all induce clonotypically diverse responses (19). Indeed, the fact that T cells representing numerically dominant components of EBV-specific memory frequently kill LCL targets poorly in cytotoxicity

assays (197,416) implies that LCL-like cells may not be the antigen-presenting cell that primes these responses *in vivo*. Important in this context is the example of EBNA1, an antigen that was never recognized as a preferred target by LCL-restimulated CTL preparations. In its endogenously expressed form, EBNA1 is protected from presentation by the conventional HLA class I pathway by a large internal glycine-alanine repeat (GAr) domain (274). Recent work suggests that this protection, which can be transferred to any protein by GAr domain insertion, operates by preventing proteasomal degradation following the ubiquitination step that usually target proteins for breakdown (275,414). Although in chimeric proteins the strength of protection is influenced both by the nature of the recipient protein and the length of its GAr insert (101), the effect of the large native GAr domain in EBNA1 itself appears to be extremely robust and renders endogenously expressed EBNA1 immunologically silent as far as CD8+ T-cell responses are concerned. Yet CD8+ T cells specific for EBNA1 epitopes are nevertheless induced *in vivo* (43) and in some cases can be as abundant as responses to conventionally processed EBNA3 epitopes, both in primary infection and in memory (42). This strongly implies that antigen-presenting cells other than naturally infected B cells must prime the CD8+ T-cell response *in vivo*, possibly dendritic cells, which have the capacity to take up viral antigens (including EBNA1) released from infected cells and re-present their derived epitopes through the HLA class I pathway.

Latent epitope specificities appear to be stably maintained for life in the circulating T-cell pool of virus carriers. Staining with HLA class I–peptide tetramers indicates that T cells specific for the immunodominant B8/FLR or A11/IVT epitopes can account for 0.1% to 1% of CD8+ T cells in the blood. These values are on average fourfold higher than estimates of epitope-specific memory cell numbers obtained in ELISPOT assays of rapid peptide-induced IFN-g release, and 20-fold higher than apparent in limiting dilution assays requiring the *in vitro* outgrowth of clones with epitope-specific cytotoxic functions (458). Using similar approaches, one can show that virus carriers also maintain CTL memory to the immunodominant lytic cycle epitopes (16,45,73,437,458). Their frequencies often exceed those seen for latent epitope-specific memory and, by tetramer staining, can reach as high as 5% circulating CD8+ T cells in exceptional cases. Such a large commitment of the T-cell system to the control of a particular virus probably reflects the persistent nature of EBV infection and the fact that it is harbored within B lymphocytes. When responses to one of the more immunodominant EBV epitopes involves highly focused TCR usage (19), this can impact significantly on the TCR repertoire available within the circulating CD8+ T-cell pool (424); furthermore, when the epitope-specific receptor shows allo–cross-reactivity, as in the case of the dominant B8/FLR-specific TCR cross-reacting with HLA-B44.02, preexisting EBV-specific memory can profoundly influence the strength of allo-responsiveness to the HLA allele (63,64).

Information on CD4+ T-cell memory to EBV is still rudimentary by comparison, although such cells may well be important both for the maintenance of CD8+ T-cell memory and also as effectors in their own right. Until recently, reports of CD4+ responses to latent cycle antigens were limited to rare clones found within LCL-reactivated CTL preparations (376). A more systematic analysis stimulating CD8+ T-cell–depleted PBMCs with autologous dendritic cells expressing individual latent proteins from recombinant vaccinia vectors (318) or with peptide pools (269) is revealing a hierarchy of CD4+ memory T-cell responses with EBNA1, and to some extent EBNA3C (367), as rich sources of epitopes. Some of these reactivated cells have cytotoxic function in addition to their capacity for cytokine (IFN-g, tumor necrosis factor-a [TNF-a]) release. An important issue is the potential of such cells to recognize endogenously expressed (as opposed to exogenously acquired) latent cycle proteins (318) because this could offer a means of targeting EBV-positive tumors that is complementary to that begin pursued with CD8+ CTLs.

OVERVIEW OF THE VIRUS–HOST INTERACTION

Virus Infections and Their Immune Control

Figure 4 attempts to present the virus–cell interactions thought to be involved during primary infection, in the establishment of latency and in subsequent reactivation, alongside the cell-mediated immune responses to viral infection occurring at these different times.

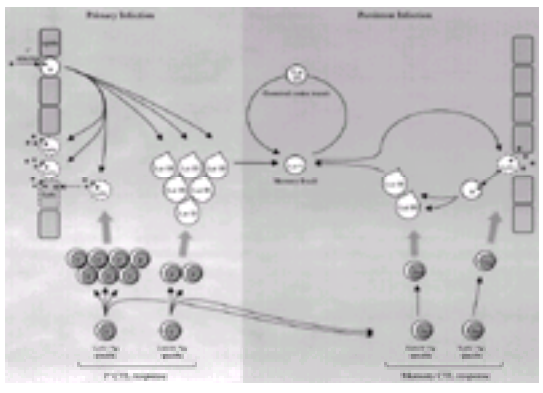

FIG. 4. A provisional model of EBV–cell interactions during primary infection and persistence. The model restricts itself to infections of the major target tissue, the B-lymphoid system and to potential infections of mucosal epithelium; lined arrows represent movements of cells, dotted arrows represent movements of infectious virions. Also shown is the cytotoxic T-lymphocytic arm of the immune response to lytic and latent cycle antigens; *broad shaded arrows* represent cytolytic effector function. Supporting data are cited in the text.

An initial focus of virus replication occurring at the site of transmission in the oropharynx may involve locally infiltrating B cells as the primary target. It is possible that virus-induced activation to a lymphoblastoid phenotype is a prerequisite for subsequent entry of these cells into lytic cycle within mucosa-associated lymphoid tissue. Certainly, proliferating LCL-like cells with a Latency III form of infection arise within tonsillar tissue during primary infection and are detectable in the

circulating B-cell pool.

Both lytic and latent infections induce CD8+ CTL responses, which, in the context of IM, are highly magnified and produce the exaggerated CD8+ T-cell lymphocytosis characteristic of this disease. The lytic cycle-induced response is an order of magnitude higher than that seen against latent antigens. This probably reflects the higher antigenic loads generated during virus replication and the ready accessibility of lytically infected B cells and their products for re-presentation to the CD8+ repertoire by dendritic cells; virus replicative events that are entirely restricted to mucosal epithelium (e.g., human papillomavirus infection) are unlikely to be so immunogenic. The relatively rapid reductions in oropharyngeal viral shedding and in the load of latently infected B cells in the blood seen in convalescent IM patients imply effective CTL-mediated lysis of the two previously mentioned target populations. As antigen load falls, activated CTL numbers are culled by apoptosis, especially those cells involved in the highly amplified lytic antigen response. The CD4+ T-cell response is probably also important at this time as a source either of effector cells or of cytokine help for the massive CD8+ T-cell expansion. A role for the antibody response during primary infection is less obvious because virus neutralizing antibodies, mainly directed against gp340, are slow to develop.

The establishment of a sustainable reservoir of latently infected B cells in the now immune host requires down-regulation of the growth-transforming Latency III program of viral gene expression, because a reservoir of LCL-like cells would almost certainly be cleared by CTL surveillance. The low numbers of infected cells detectable within the blood of virus carriers are in fact resting B cells in which viral latent antigen expression is largely, perhaps completely, extinguished; the fact that they carry the virus genome as a covalently closed episome (110) strongly suggests that such cells are the progeny of earlier viral transformation events. Evidence that cells can switch from the growth-transforming Latency III program to more restricted forms of viral gene expression, and that this coincides with a change in host cell phenotype, has come from *in situ* analysis of infected B cells in IM tonsils. However, the precise sequence of events remains to be determined. Interestingly, all EBV-infected cells in the blood of virus carriers lie within the memory (IgD–) B-cell subset, yet the initial viral infection in IM can presumably target both the naive and preexisting memory B-cell populations. Therefore, either transformants of memory B-cell origin are preferentially able to reenter the resting memory B-cell pool or viral transformation itself can impose a memory phenotype on any infected cell that subsequently enters the pool. The evidence strongly suggests that this pool of resting memory B cells is necessary and sufficient for virus persistence in the immune host. Thus, some bone marrow transplant recipients who undergo enough total body irradiation to destroy their lymphoid system (but leave other tissues such as mucosal epithelium relatively intact) are cleared of their resident EBV infection (161).

It must be remembered, however, that persistently infected individuals also show chronic virus replication at mucosal sites. The most likely source of this shed virus is through reactivation from the preexisting B-cell reservoir. The controls governing reactivation are not understood, but one clear possibility is that the virus exploits the natural events of the B-cell life cycle for this purpose. In this context, memory B cells, when reexposed to cognate antigen in lymphoid tissues, will take one of two routes (366). One option is to reenter a germinal center reaction and, through another round of somatic *Ig* gene mutation and selection, generate more memory cells. An EBV-infected cell taking this route has the potential to replenish the EBV-carrying memory B-cell pool if certain conditions are met; EBNA1 synthesis would be required if the virus genome is to be maintained during clonal expansion in the germinal center, whereas transient activation of LMP1 and LMP2 expression at the centroblast stage may be required to guarantee reselection of some infected cells back into memory. The second option for a memory B cell reexposed to cognate antigen is to differentiate to an antibody-producing plasma cell, some of which are known to locate at submucosal sites. An EBV-infected cell taking the pharmacyloid route of differentiation may activate lytic gene expression, thereby guaranteeing virus production at sites from which transmission of infectious virions to a new host can occur. These postulated events would be consistent with the observed patterns of viral gene transcription in different tonsillar cell subpopulations (25) and with the implication that chronic antigenic challenge to the B-cell system can influence the EBV–host balance in favor of the virus (17).

The relationship between this ongoing low-grade virus replication at lymphoepithelial sites and the circulating reservoir of latently infected resting B cells remains to be resolved. It is possible that new growth-transforming infections of host B cells, initiated at sites of virus replication, continually serve to replenish the memory cell pool in a recapitulation of the events of primary infection. Were that the case, long-term treatment with a drug such as acyclovir (ACV), which blocks virus replication, might be expected to lead to a slow reduction in the size of the latently infected cell reservoir. Experiments of this kind have so far not detected any such reduction over a 4-week period (505,506), but it will be necessary to follow patients receiving ACV for much longer times to examine the issue critically.

These multiple pathways of reactivation from latency are of course occurring in the immune host. It is likely that CTL surveillance continues to control reactivations into lytic cycle. Indeed, the strength of CTL memory to immediate-early and early lytic cycle antigens implies that many productive infections are contained before the cells can complete the cycle and release progeny virions. This could explain why RT-PCR assays of lytic gene transcription and immunofluorescence assays of lytic antigen expression on *ex vivo* samples so often only detect cells in the immediate-early and early stages of the cycle (330,361). *De novo* transformation events are also likely to be recognized by CTLs once the full spectrum of latent cycle proteins is expressed and the cells acquire a lymphoblastoid phenotype. In principle, cells in which a latency II form of infection (EBNA1, LMP1, LMP2+) has been activated would also be subject to T-cell control, but here it must be remembered that endogenously expressed EBNA1 is protected from recognition and that both LMP1 and LMP2 elicit at best only subdominant CD8+ responses. The capacity of such responses to recognize and kill target cells will be critically dependent on the level of expression of the target protein and the antigen-processing capacity of the infected cell.

Virus Evasion Strategies

Viruses have evolved multiple different strategies for evading host immune responses. For herpesviruses, which are persistent but genetically stable pathogens, these frequently involve an ability both to establish an antigenically silent form of latent infection and to impair the antigen-processing capacity of lytically infected cells (356). EBV has successfully achieved the former in that viral antigen expression is largely if not completely down-regulated in the

circulating B-cell pool. Whether EBV replication employs immune evasion mechanisms analogous to those shown by other herpesviruses in lytic cycle is still not known. There are, however, other strategies that appear unique to EBV.

The most obvious is the ability of the GAr domain to protect endogenously expressed EBNA1 from proteasomal processing and presentation to CD8+ T cells (101,274,275,414). This protection only operates in *cis* and has no effect on the presentation of coexpressed latent cycle proteins. It is in fact a moot point whether the acquisition of the GAr domain by EBNA1 is primarily an immune evasion strategy or a mechanism for ensuring the stability of a protein that is crucial for persistence of the viral genome in infected cells. The ability of EBNA1 to tether the viral episome to cell chromatin (see Chapter 74 [245]) may be important not just in proliferating cells but also arguably (using preformed EBNA1) in the long-lived resting memory B cell. Interestingly, the GAr-mediated protection from immune processing may be a recent evolutionary acquisition because the shorter (52 to 62 amino acid) glycine-serine-alanine repeats seen in the EBNA1 homologs of Old World primate LCVs apparently lack this function (44).

None of the other EBV latent cycle proteins have obvious immune evasion strategies; indeed, one of the many cellular changes induced by LMP1 in B cells, mirroring those induced in B cells by CD40 ligation (241), is to up-regulate expression of HLA class I molecules and of the TAP1/TAP2 transporter involved in furnishing these molecules with antigenic peptides (387). Such changes are to the evolutionary advantage of the virus. Thus, EBV's initial requirement for expansion of latently infected B cells in the naive host through growth transformation needs to be balanced against the threat of fatal lymphoproliferative disease were that expansion not to be recognized by the host's immune response.

The other novel routes whereby EBV might modulate immune responses all involve products of the lytic cycle. The first involves the gp42 glycoprotein, encoded late in the cycle by the BZLF2 gene and forming part of a tri-molecular complex with gp85 and gp25 on the surface of infected cells and on the viral envelope. Binding of gp42 to the b-chain of HLA-DR class II molecules appears to be involved in mediating viral entry into HLA class II–positive B cells after the initial gp350–CR2 attachment step (278). Recent work showed that gp42 complexes with nascent HLA-DR molecules in the endoplasmic reticulum of lytically infected B cells *in vitro* (46), raising the possibility of some interference with HLA class II maturation or epitope presentation to CD4+ T cells.

A second lytic cycle protein, BARF1, is naturally secreted from infected cells and functions as a soluble receptor for human colony stimulating factor-1 (CSF-1) (442). Both recombinant and naturally produced BARF1 are capable of interfering with at least one of the activities of CSF-1, namely the poly(I:C)-induced release of IFN-a from monocytes (91). Such interference could be important *in vivo* in view of the role that IFN-a may play in the early host response to EBV infection, either through its direct antiviral action or through activating NK cells.

Third, in common with certain other gamma herpesviruses, EBV encodes a viral homolog of cellular IL-10. This viral IL-10 (expressed by the late lytic gene *BCRF1*) retains the ability of the cellular cytokine to augment B-cell growth and differentiation and to inhibit antigen presentation by monocytes and dendritic cells, but apparently not its ability to directly impair T-cell function (282). At sites of virus replication and *de novo* infection, therefore, locally produced viral IL-10 could inhibit the priming of both lytic cycle-specific and latent cycle-specific T-cell responses, the latter effect having been seen experimentally in the *in vitro* regression assay (33). Other potential important effects of viral IL-10 may be mediated at the level of the *de novo*–infected B cell, both in transiently reducing the cell's antigen-processing capacity (516) and in enhancing the proliferative response to infection (443). Note that the *in vivo* relevance of all three potential immunomodulatory proteins is unknown and will become clear only when the appropriate gene knock-out viruses can be tested in an informative animal model.

Virus–Host Coevolution

EBV, like the LCVs of other primates, has a long history of coevolution with its host species. Evidence for such coevolution is apparent even within the 100,000 years since *Homo sapiens* radiated out of Africa. Thus, EBV isolates from modern-day European, Asian, and African populations are distinguishable at a number of polymorphic sites in the genome, reflecting the long period over which these host populations have been geographically isolated. Genetic comparisons between EBV and other LCVs (484), and to some extent between the geographically distinct EBV strains themselves (see later), indicate that the latent protein-coding sequences have evolved more rapidly than other regions of the genome; the reasons for this are not understood.

There are two broad types of EBV, types 1 and 2 (originally called A and B), distinguished by allelic polymorphism of their *EBNA2, 3A, 3B,* and *3C* genes (3,100,397). Interestingly, this may reflect an ancient subdivision within the LCV genus rather than a more recent branch of EBV evolution because rhesus LCV isolates also fall into two types based on polymorphism of their *EBNA2* homolog (87). The type 1 and type 2 versions of the EBNA2, 3A, 3B and 3C proteins, sharing 55%, 84%, 80% and 72% amino acid identity respectively, induce host antibody responses which for EBNA2 and 3A can be partially cross-reactive between types and which for EBNA3B and 3C are predominantly type-specific (391,411). As shown in Figure 5, immunoblotting of LCL extracts with the serum of a type 1 virus–infected individual (in this case with type 1–specific EBNA2, 3B, and 3C antibodies, weakly cross-reactive EBNA3A antibodies, and pan-EBNA1 antibodies) can clearly identify the type of the resident virus. Furthermore, individual type 1 strains can be distinguished through the different sizes of their EBNA1, 2, 3A, 3B, and 3C proteins, constituting a characteristic “EBNA print” for each individual strain (159,509). This size polymorphism largely reflects the facts that all the EBNA proteins contain repeat regions and that the precise number of repeats varies between virus strains (131). Less work has been done on the EBNA prints of type 2 virus isolates owing to the paucity of informative sera, but it appears that the type 2 EBNA2, 3A, 3B, and 3C proteins are less variable in size than their type 1 counterparts (391).

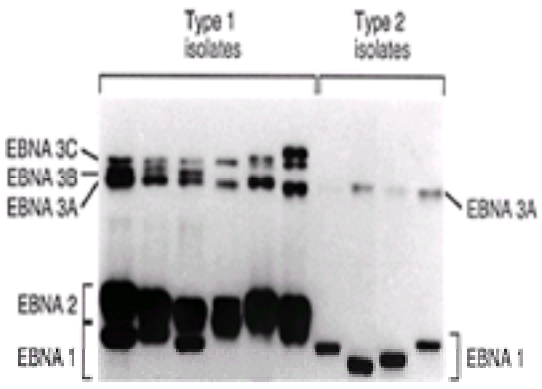

FIG. 5. EBNA printing of EBV isolates. Protein extracts of B-lymphoblastoid cell lines (LCLs) carrying individual (type 1 or 2) virus isolates were separated by gel electrophoresis and immunoblotted using a polyclonal human serum (from a type 1 virus–infected donor) with antibodies to EBNA 1, 2, 3A, 3B and 3C. Antibody cross-reactivity against the corresponding proteins in type 2 virus–carrying LCLs is restricted to EBNA1 and (weakly) to EBNA3A.

Based on virus isolates rescued as LCLs *in vitro*, about 90% of seropositive individuals in European populations carry type 1 and about 10% carry type 2 virus strains (157,160,509,518). Although the more potent *in vitro* growth-transforming activity of type 1 strains (377) could bias *in vitro* isolation in their favor, the balance of evidence from direct PCR amplification on *ex vivo* samples (428,472,475) still favors the greater prevalence of type 1 strains in most Western societies. In contrast, type 2 strains appear to have reached almost equal prevalence with type 1 in the general population in parts of equatorial Africa and in New Guinea (5,515,518). It may be that type 2 viruses, which appear slightly less efficient as B-cell–transforming agents, are better able to compete in circumstances in which high levels of parasitemia provide a preexisting chronic stimulus to the host B-cell system.

Several other polymorphic loci have now been identified in the EBV genome that are not necessarily linked to virus type. These lie within the *EBNA1* (39,171), *EBNA2* (5,408), *EBNA3* (243), *EBNA-LP* (135), *LMP1* (117,202,399), and *LMP2* (65,268) genes as well as at other sites (2,290). Many are markers of geographic origin, distinguishing for instance among European, Asian, and African strains, but in other cases, they can discriminate between strains from the same area (171,399,408). These polymorphisms are cited extensively in the context of two current debates in the EBV field. One concerns the possibility that particular virus strains have enhanced pathogenic and oncogenic activity; we shall return to this issue in the relevant disease sections of this chapter. The second concerns the possibility that immunologic pressure has influenced the long-term evolution of EBV within particular host populations. This idea was first raised by the observation that in Southeast Asian populations, in which the HLA-A11 allele is unusually common, the prevalent type 1 EBV strains show a variety of mutations in the *EBNA3B* gene that always destroy the immunodominant A11-restricted IVT epitope and frequently also destroy the subdominant AVF epitope (104,105). However, subsequent work has questioned the attribution of these changes to immune selection because similar mutations were also present among viruses from New Guinea Highland populations, which are entirely A11-negative, as well as in Lowland groups, in which A11 incidence is similar to that of other Southeast Asian populations (61,243). To date, no other potential examples of the population-driven selection of CTL epitope-loss variants have been found.

INFECTION IN THE T-CELL–IMMUNOCOMPROMISED HOST

Studies of transplant recipients and human immunodeficiency virus (HIV)-infected patients have helped to document the effects of T-cell impairment on the EBV–host interaction. In both cases, it is important to distinguish between the majority of patients (mainly adults) in whom iatrogenic or HIV-mediated immune impairment is imposed on a preexisting EBV carrier state, and the minority (mainly children) in whom T-cell competence is already impaired at the time of primary EBV infection. Effects on the virus–host interaction can be monitored using two parameters, described in the following sections.

Deregulation of the Virus–Host Balance

Early studies showed that the relatively low levels of immunosuppressive therapy used to maintain long-term renal allografts not only reduced EBV-specific CTL responses as measured in the *in vitro* regression assay but also increased viral shedding in the throat and the numbers of infected B cells in the blood (97,508). More recently, quantitative PCR assays have confirmed the increase in EBV genome load in the PBMCs of asymptomatic solid organ transplant recipients (27,29,248,386), with pediatric patients most likely to give values clearly above the normal range. Although such assays may prove useful in clinical monitoring, it is not clear to what extent higher virus genome loads reflect an increase in the frequency of latently infected cells in the blood and to what extent they reflect the detection of progeny genomes in lytically infected B cells. Recent work on adult patients soon after solid organ transplant reported frequencies of infected cells (1 to 1,670/10^6 B cells) that clearly extended beyond the normal range (1 to 50/10^6 B cells) but showed that, in some cases, although not necessarily those with the highest frequencies, both latently infected and lytically infected cells were present (23). Interestingly, the latently infected cells that accumulated in the blood after transplantation were not virus-transformed lymphoblasts with a Latency III form of infection, as might have been anticipated, but resting B cells that showed the same highly restricted form of latency as seen in healthy carriers (23). Arguably, the relaxation of T-cell control allows quantitative shifts in the virus–host balance in both blood and lymphoid tissues, but the resident forms of infection do not change.

Studies of HIV-infected patients with detectable T-cell impairment in the EBV-specific *in vitro* regression assay, but not yet with symptoms of acquired immunodeficiency syndrome (AIDS), have shown similar shifts in the EBV–host balance, although once again cohort values still overlap the normal range (115,231,504,511). Also, the analysis of lymphoid tissues from HIV-positive patients with persistent generalized lymphadenopathy has revealed only moderate increases in

the number of EBV-infected cells; these were again predominantly small EBER-positive B cells within extrafollicular areas, and only in a few cases could EBNA2-positive, LMP1-positive immunoblasts or evidence of virus-infected germinal center cells be detected (48,340). There is no obvious link, therefore, between EBV and the follicular hyperplasia characteristically seen early in HIV carriage.

The increased virus load seen in EBV carriers after iatrogenic or HIV-induced immune suppression is also reflected in serum antibody profiles. In both groups, existing IgG anti-VCA and anti-MA titers rise, and almost all patients become detectably anti-EA positive (508,511), presumably in response to the increased antigenic load, whereas anti-EBNA1 titers do not change. In more immunocompromised patients such as those with progressive HIV infection, antibodies to EBNA1 may fall and anti-EBNA2 antibodies increase, leading to an inversion of the usual anti-EBNA1–to–anti-EBNA2 ratio (190,498). These virologic and immunologic changes seen in asymptomatic virus carriers with onset of T-cell suppression are illustrated diagrammatically in Figure 3.

The effects of immune impairment are often more dramatic in bone marrow transplant recipients, where T-cell function is more strongly suppressed, and in seronegative transplant recipients (usually children), who often acquire their primary EBV infection iatrogenically either from the transplant itself or from blood transfusions (reviewed in 157). In bone marrow transplant recipients, EBV DNA loads in PBMCs assayed by PCR can reach very high values, especially in the first 3 to 6 months after transplantation (169,381,386) when there is a high risk for B-lymphoproliferative disease (see later). Primary EBV infection has been less well studied in HIV-positive children but appears to be more frequently symptomatic than in controls (353). It is also associated with higher rates of oral shedding, which is sustained in children who progress rapidly to AIDS (217), and in some cases, is characterized by an atypical antibody response. HIV-infected infants appear to be particularly susceptible to another EBV-associated B-lymphoproliferative condition, lymphocytic interstitial pneumonitis (15).

Multiplicity of Virus Strains

Isolations of EBV from bone marrow and cardiac transplant recipients and characterization of the derived LCLs by EBNA printing identified a significant proportion of patients carrying more than one viral strain (160), a situation seen only rarely among isolates from healthy immunocompetent individuals. It was not clear, however, whether this simply reflected the iatrogenic acquisition of new viral strains from donor B cells in the graft or in blood transfusions. Subsequently, studies of two other immunocompromised groups have suggested that T-cell impairment genuinely does sensitize the host to serial acquisition of EBV strains by the natural route. Thus, a group of young hemophilic patients, who had acquired HIV by contaminated factor VIII, and an HIV-positive male homosexual cohort both showed multiple co-resident EBV strains in 30% to 50% of individuals studied (504,511). Because these patients all had high serum antibody titers to EBV antigens (including neutralizing antibodies), the implication is that humoral immunity alone is insufficient to protect the host from additional serially acquired EBV infections. This is also the lesson drawn from clinical experience, where infusions of pooled human Ig were unable to prevent primary EBV infection (337).

In the above studies, all based in Western countries, both the transplant recipients and the HIV-positive hemophilia patients, whether singly or multiply infected, gave predominantly type 1 virus isolates; the overall incidence of detectable type 2 virus infection was no more than 10% (160,511), a figure broadly in line with that for the general population. By contrast, the HIV-positive homosexual cohort showed a more than 30% incidence of type 2 virus infection (504). This was consistent with earlier studies of HIV-positive patients, again mainly male homosexuals, which found an unexpectedly high frequency of type 2 virus-specific antibody responses (412), of type 2 virus isolations from the blood (410), and of type 2 viral DNA in oral lesions (479). Contrary to earlier suggestions, therefore, high type 2 virus prevalence is not associated with the immunocompromised state per se. Rather, type 2 strains have become unusually prevalent in homosexual communities in the West (472), from which most of the early HIV-positive study cohorts were drawn; this likely reflects the multiplicity of close contacts within these communities. One interesting consequence of the frequent co-infection of HIV-immunocompromised patients with type 1 and type 2 EBV strains is the greatly increased chance of intertypic recombination. Indeed, virus strains with a type 1 allele at the EBNA2 locus and type 2 alleles at the EBNA3A, 3B, 3C loci were isolated from 2 of 40 patients in an HIV-positive homosexual cohort (510). Such recombinants have never been seen in the general population in the West, although rare intertypic strains have been identified among isolates from New Guinea and China (62,301).

The frequency with which multiple infection occurs in immunocompetent EBV carriers remains to be resolved. It is clear that most individuals carry the same dominant strain over many years (509), in contrast to the changing patterns of dominance sometimes seen in prospective studies of HIV-positive patients (58). However, direct amplification of EBV DNA from *ex vivo* samples is a more sensitive assay than *in vitro* virus isolation and may yet reveal a higher incidence of co-resident strains in healthy carriers than is currently apparent (54,428).

DISEASES ASSOCIATED WITH EPSTEIN-BARR VIRUS

Infectious Mononucleosis

A proportion (in some studies up to 50%) of serologically confirmed primary infections in adolescence or early adult life manifest as IM. The virologic and immunologic events occurring in IM patients have already been discussed. Disease symptoms can range from mild transient fever to several weeks of pharyngitis, lymphadenopathy, and general malaise. The viral etiology of IM and the fact that EBV replication was detectable at high levels in the oropharynx of acute IM patients prompted clinical trials of ACV, a nucleoside analog that blocks lytic EBV infection *in vitro* through inhibition of the viral DNA polymerase. Although oral ACV clearly can block viral shedding in the oropharynx of IM patients, it did not reduce the load of latently infected B cells in the circulation as measured by *in vitro* outgrowth (506) and had little if any effect on the disease course (14). Disease symptoms are therefore unlikely to be the result of virus replication per se and indeed recent studies have indicated that subclinical primary infection in young adults may still involve high viral loads but are not accompanied by T cell expansion (424a). IM is therefore most likely to be an immunopathologic disease whose general symptoms are caused by proinflammatory cytokines, such as IL-1, IFN-g, and TNF-a, known to be

produced at high levels by the large numbers of reactive T cells seen infiltrating all tissues throughout the body (11,328,474). In addition, complications such as interstitial nephritis, hepatitis, and pneumonia have been linked to the combined effects of infiltration by EBV-infected B cells and reactive T cells.

It is not known why EBV causes IM in adolescence when primary infections in childhood are almost always asymptomatic. One possibility is that much higher doses of infectious virus are likely to be transmitted by an oral route to adolescents than to children. This may greatly increase the chances of the pool of infected B cells exceeding a threshold and driving the expansion of immune T cells to a point at which resultant cytokine levels are pathogenic. In this context, reported examples of postperfusion mononucleosis, a disease identical to classic IM but induced by the transfusion of seropositive donor blood to a seronegative recipient, frequently involve cases in which the donor happened to be in the incubation phase of IM, that is, in which an unusually large number of EBV-infected B cells are likely to have been transfused (148).

X-linked Lymphoproliferative Syndrome and Fatal Infectious Mononucleosis

Two papers appearing in the mid-1970s first drew attention to a rare familial condition, subsequently called the *X-linked lymphoproliferative syndrome* (XLP), affecting young boys and characterized by extreme sensitivity to EBV (30,362). The recent cloning of the *XLP* gene from the Xq24-25 locus (90,327,403) has given new impetus to unraveling the complex pathogenesis of this syndrome in its various clinical guises (reviewed in 448). Some 50% to 60% of cases present in childhood with hyperacute IM-like symptoms and a serologic profile consistent with primary EBV infection. Thereafter, the disease rapidly takes a fatal course, culminating in liver failure as a result of widespread lymphocytic infiltration and hepatic necrosis. Of the minority who survive the acute primary EBV infection, many subsequently develop marked immunodeficiency, hypogammaglobulinemia being the most common symptom; some 30% of XLP patients present in this way. A third aspect of the XLP phenotype, accounting for about 20% cases, is a high susceptibility to B-cell lymphoma. Perhaps surprisingly, these tumors, usually of Burkitt's or diffuse large cell type, are often EBV genome-negative and indeed have been seen to develop in boys who are still EBV-uninfected both by serologic criteria and by PCR screening for EBV DNA (52,440).

Early studies focusing on the fatal primary infection detected, as in IM itself, the coexistence of virus-infected B cells and reactive CD8+ CTLs in the circulation (448), although the virus specificity of the CD8 response has not yet been ascertained. From this point, the disease course follows one of two paths. In some cases, especially where immunosuppressive therapy has been attempted, EBV-transformed B lymphoblasts become dominant (130), and the patient dies of organ failure arising from lymphoblast infiltration. Similar B-cell proliferations have been observed in heavily immunosuppressed transplant recipients (see later) and also in very rare nonfamilial cases of fatal IM where, for unknown reasons, individuals fail to mount a CD8+ T-cell response to the virus (98,309,380). In many other cases of XLP, however, EBV-infected B cells are outnumbered by a massive proliferation of reactive T cells, culminating in widespread tissue necrosis and the repopulation of lymphoid tissues and bone marrow with phagocytic cells (histiocytes) (448); the result is a clinical and histologic picture essentially indistinguishable from virus-associated hemophagocytic syndrome (VAHS, see later). Furthermore, the lymphoid aplasia that characterizes the later stages of this process appears likely to underlie the hypogammaglobulinemia, which most survivors subsequently display.

It appears that the cell-mediated immune response to EBV is somehow deregulated or ineffective in XLP patients. The molecular mechanisms underlying these effects will no doubt soon emerge with the identification of the XLP gene product as a small SH2 domain-containing protein, currently called SH2D1A (90) or SAP (403), involved in lymphocyte signaling. This protein, which is preferentially if not exclusively expressed in T and NK cells, was first shown to bind to the intracytosolic domain of CD150 (SLAM), a cell surface molecule expressed on both B and T cells and mediating B-cell–T-cell co-stimulation through homotypic interactions (403). More recently, SH2D1A has also been shown to be involved in other lymphocyte-signaling pathways, in particular signaling through 2B4, a molecule expressed at the surface of NK cells and some CD8+ T cells. It appears that NK cell function, besides being controlled by the balance of activating and inhibitory receptors, in some circumstances also requires licensing through 2B4 signaling. In the absence of the SH2D1A regulator, ligation of 2B4 through its natural ligand CD48 on a target cell can inhibit rather than activate NK lysis (347). It seems possible that 2B4 and SH2D1A could also play a similar role in licensing CD8+ T-cell function and, if so, that the fatal IM syndrome stems from a functional impairment of both virus-specific CD8+ T cells and NK cell effectors responding to EBV infection. Importantly, the natural ligand for 2B4 is CD48, a molecule preferentially expressed on activated B cells and indeed induced on resting B cells after EBV infection (136). The apparently specific sensitivity of XLP patients to EBV and not to other common viruses may therefore reflect the fact that EBV preferentially infects and activates B cells, whereas the sensitivity to B-cell lymphoma may be a consequence of some more fundamental deregulation of B-cell–T-cell communication or B-cell–NK cell recognition.

Virus-Associated Hemophagocytic Syndrome

Hemophagocyte syndromes, grouped together on histologic grounds through their common features of prominent histiocytic proliferation in tissues and phagocytosis of blood cells, have multiple etiologies of which viral infection is only one. However, many childhood cases of VAHS are now firmly linked to EBV, with the patients showing serologic profiles (anti-VCA IgM, and IgG-positive, anti-EBNA1–negative) diagnostic of a primary infection (454). The disease, most commonly seen in Japanese and Chinese populations, is characterized by fever, lymphadenopathy, hepatosplenamegaly, hemophagocytosis in various tissues, and a tendency to pancytopenia, often leading to a fatal outcome. A similar condition, reported as Kawasaki-like disease, was shown to be associated with a rare EBV-infection of T cells (247). This prompted several studies, all of which confirmed the presence of oligoclonal or even monoclonal populations of EBV-infected T cells in the blood or tissues of VAHS patients (reviewed in 338 and 444). Both major T-cell subsets could be involved, and culturing the cells in IL-2–conditioned medium in some cases allowed the establishment of EBV-positive T-cell lines with a Latency II pattern of viral gene expression (212).

EBV-associated hemophagocytic syndrome is therefore a rare condition in which virus-driven T-cell proliferation arising in the setting of primary infection replaces the usual virus-driven B-cell and reactive T-cell proliferations seen in classic IM. The clinical symptoms again result either from the lymphocytic infiltrate per se or from the effects of proinflammatory

cytokine release. The latter is particularly relevant in the context of hemophagocytosis given the macrophage-activating capacity of cytokines such as TNF-a. Serum levels of TFN-a are markedly elevated in VAHS patients (214) and expression of the cytokine in T cell lines *in vitro* can be up-regulated by EBV infection (264). Two EBV-associated conditions, VAHS and XLP, can therefore lead to a common end point, hemophagocytosis, by different routes but with the inability to control T-cell proliferation as a common theme. Interestingly, some cases of familial hemophagocytic syndrome are now known to be caused by mutation of the perforin gene, again resulting in an inability to down-regulate CD8+ T-cell responses (436).

Chronic Active Epstein-Barr Virus Infection

Classic IM in young adults almost always resolves to an asymptomatic carrier state. Exceptions to this rule are extremely rare (409), and most young adult patients presenting with chronic fatigue-like symptoms show no authentic link to EBV infection. This contrasts with an increasing number of case reports of young children who suffer from recurrent fever, lymphadenopathy, and hepatosplenomegaly over several years dating from a proven or a presumed primary EBV infection (7,190,338). These all share a highly unusual serologic profile with extremely high titers of IgG anti-VCA (more than 1:5,120) and anti-EA (more than 1:640) antibodies, often with persistent IgM anti-VCA, low or undetectable IgG anti-EBNA1, and, where examined, high IgG anti-EBNA2 titers. This profile resembles that of an unresolved primary infection, and more recent analyses using semiquantitative PCR assays have confirmed the presence of very high genome loads in the PBMCs of these patients, greater than those seen in classic cases of acute IM (293,409).

A variety of immunologic investigations have so far failed to reveal any consistent abnormality in patients with such chronic active infection (338), although in most cases the possibility of an EBV infection of T cells has not yet been examined. Another potentially interesting observation comes from a subset of such patients in whom, despite high virus loads, it was either very difficult or impossible to isolate the resident strain by LCL establishment *in vitro* (7,216,409). These individuals all proved to carry a virus that, although replication-competent, was either impaired or completely defective in transforming ability, with clear evidence of genomic rearrangements in regard to standard EBV strains. To what extent such transformation-defective strains circulate in the wild and contribute to disease pathogenesis is not known.

Clinically Apparent Virus Replicative Lesions

The clearest example of an EBV replicative focus *in vivo* is oral hairy leukoplakia (OHL), a wartlike lesion on the lateral borders of the tongue. This was first recognized in immunocompromised HIV carriers (163) but now also reported in various transplantation settings and even occasionally in healthy individuals (478). Figure 6 shows a cross-section through an OHL lesion to illustrate the general thickening of the epithelium, consistent with a delayed or disturbed progress of cells through the normal squamous differentiation program. Cell replicating viral DNA (detectable by *in situ* hybridization, as illustrated) and expressing a range of lytic cycle antigens such as BZLF1 (detectable by monoclonal antibody staining) are reproducibly present in these lesions but restricted to the outer more differentiated half of the epithelium; late lytic cycle antigens are detectable once viral DNA replication has initiated. The delayed differentiation of epithelial cells within OHL lesions may reflect the influence of BHRF1, the viral Bcl-2 homolog, which is expressed as an early lytic cycle antigen and which has the capacity to prolong the lifetime of lytically infected cells either through anti-apoptotic effects (183) or through disturbance of the epithelial differentiation program (102). A second early lytic cycle protein, BALF1, may also mediate anti-apoptotic effects (296a). Clinically, OHL lesions respond well to high-dose oral ACV, with apparent clearance of virus replication and a restoration of normal epithelial architecture within 2 to 4 weeks (162). However, withdrawal of treatment usually leads to a recurrence of lesions within 1 to 4 months; it is not clear whether this reflects viral reactivation from an epithelial reservoir or reseeding of the infection from the lymphoid system.

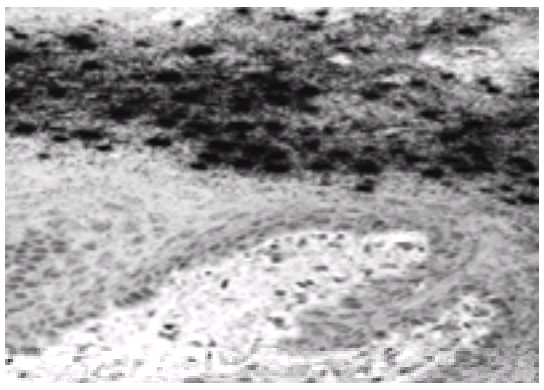

FIG. 6. EBV–epithelial cell interactions in oral hairy leukoplakia (OHL). A tissue section through an OHL lesion that was probed by *in situ* hybridization using a ^{35}S-labeled probe specific for the BamHI W repeat sequence of EBV DNA shows EBV genome–positive cells localized to the thickened outer layers of differentiating squamous epithelium; the less differentiated basal and parabasal layers show no significant labeling above background. (Courtesy of G. Niedobitek.)

Interestingly, OHL lesions show no evidence of either viral DNA or latent cycle markers (EBER RNAs or latent antigens) in cells of the basal and parabasal epithelial layers underlying the sites of virus replication (332,462). Surprisingly, however, a number of latent cycle antigens are expressed within the lytically infected upper layers, with EBNA1-positive cells consistently detectable by immunofluorescent staining (462) and, in some cases, smaller foci of EBNA2 or LMP1 staining (332,462). The corresponding latent cycle mRNAs are also detectable by RT-PCR analysis (480,487), whereas EBER expression is down-regulated (150). Although OHL lesions do produce transformation-competent virions (343), they also contain several defective forms of the EBV genome generated by illegitimate recombination or rearrangement.

These include various deletions or bizarre rearrangements of the *EBNA2* gene (479,480 and 481) and also rearrangements generating an aberrant BamHI W/Z junction fragment (351), which may itself promote BZLF1 expression and hence lytic virus replication. These OHL lesions also frequently harbor multiple virus strains, with evidence of interstrain and intrastrain recombination (478,479).

There is a more controversial literature describing EBV replication in lung epithelium and its possible association with a lung disease, idiopathic pulmonary fibrosis (IPF). Expression of VCA and gp350 has been reported in pulmonary epithelial cells in 70% of cases of IPF but only occasionally in control lung biopsies (118). However, the specificity of the staining and its correlation with the presence of PCR-amplifiable EBV DNA in biopsy specimens remains to be resolved (439,485). It is nevertheless clear that EBV-infected B cells do traffic to the lung, as witnessed by the instances of lymphocytic interstitial pneumonitis that occur in HIV-positive children after primary EBV infection (15). Such cells could well serve as a source of viral transmission to lung epithelium.

ASSOCIATED MALIGNANCIES OF THE IMMUNOCOMPROMISED HOST

The clearest evidence for the oncogenic potential of EBV in its natural host comes from the fatal B-cell lymphoproliferations, which are seen in three different groups of immunologically compromised patients.

Lymphomas in Congenitally Immunodeficient Patients

As described earlier, in some XLP patients, fatal IM presents as an EBV-positive B-lymphoproliferative disease arising within weeks of primary infection (448). These acute lesions generally appear to be oligoclonal by Ig markers or by size heterogeneity of the fused terminal repeat region of the EBV genome. In most cases, the proliferating cells display a lymphoblastoid phenotype and express several viral antigens, in particular EBNA1, EBNA2, and LMP1, consistent with a Latency III (LCL-like) form of infection (130,463). Children with other immune defects, such as common variable immunodeficiency or Wiskott-Aldrich syndrome, are also at risk for EBV-driven lymphoproliferative disease through an inability to mount effective T-cell control over the virus infection (reviewed in 120). Interestingly, Wiskott-Aldrich patients remain relatively susceptible to the disease even after total-body irradiation and transplantation with HLA-matched bone marrow (342), implying that the priming or maintenance of virus-specific T-cell responses *in vivo* may require a radio-resistant cell with antigen-presenting or helper function.

Posttransplantation Lymphomas

The link between sustained immunosuppression of transplant recipients and increased incidence of lymphoma, probably post-transplant lymphoproliferative disease (PTLD), has long been apparent and the association with EBV is now widely recognized (reviewed in 323). One major factor influencing PTLD risk, the intensity of T-cell suppression, underlies most of the differences seen in PTLD incidence in different transplantation settings. Thus, renal and liver transplantation programs have overall incidence rates of 1% to 2%, versus 3% to 8% for heart and lung transplantations where higher levels of immunosuppression are often given. Overall, rates of PTLD in allogeneic bone marrow transplantation programs are less than 1% but can rise dramatically to 12% to 24% among patients in whom donor T cells are depleted from the marrow graft. Because bone marrow transplantation frequently involves total ablation of host lymphoid cells (and can indeed clear a resident EBV infection [161]), the PTLDs that develop after transplantation often derive from EBV-infected donor B cells present within the bone marrow graft itself (159). Protocols that deplete the graft of both B and T lymphocytes, therefore, significantly reduce the risk for PTLD by reducing the incidence or effective dose of iatrogenic EBV infection (172).

A second major influence on PTLD risk is the patient's EBV status at the time of transplantation. A survey of PTLD cases arising in all solid organ transplant recipients cohorts at one major center showed a 20-fold higher incidence of the disease in EBV–seronegative recipients (198), explaining why young children are at particular risk. Subsequent studies of solid organ transplant recipients as a whole (476) and of recipients of renal (40,122), heart-lung (452), and liver (296) grafts have confirmed the age-independent predisposition to PTLD among patients who were EBV-seronegative at the time of transplantation. One of these studies also identified a history of cytomegalovirus-induced disease after transplantation as possibly a third independent variable predisposing to later PTLD development (296), and it will therefore be interesting to see how such an episode might affect the long-term position of the EBV–host balance.

Given the high EBV genome levels that develop in the PBMCs of immunosuppressed patients, it becomes important to know whether increasing loads might be used as a prognostic indicator of PTLD risk. Initial studies showing unusually high frequencies of EBV-infected cells in the blood of early-onset PTLD patients (402) have largely been confirmed by PCR assays of virus genome load, although most studies report some overlap with the wide range of virus loads shown by tumor-free transplant recipients (27,29,248,288,381,386). A recent prospective study of asymptomatic solid organ transplant recipients identified a small number with progressively increasing loads, one of whom became symptomatic (29). Virus load monitoring has also been used to identify bone marrow transplant recipients at high risk for PTLD for whom adoptive T-cell therapy is an option (249,381). To what extent ongoing virus replication might increase the risk for PTLD development through continual recruitment of new transformation events is another important but unresolved issue. Trials of prophylactic ACV in various transplantation settings have reported potential benefit in reducing PTLD incidence in some studies but not in others (reviewed in 352).

As interest in PTLD has grown, so has the variety of lymphomas reported to arise in transplant recipients (reviewed in 178). Nevertheless, most posttransplantation tumors still resemble the classic lymphoproliferative lesions first described in the literature (324). In this review, we use PTLD to refer specifically to these classic lesions, mostly arising within the first 1 to 2 years after transplantation. This disease is etiologically and histologically distinct from the range of other lymphomas (B-cell lymphomas of various kinds, and certain T-cell lymphomas), which are seen occasionally in transplant recipients, usually many years after transplantation. Although rare cases of BL are included among these late-onset malignancies, they are by no means all EBV genome positive, implying that PTLD and posttransplantation BL have

separate etiologies.

The classic PTLDs are themselves graded histologically into (a) early lesions involving plasmacytic hyperplasia and reactive elements similar to those seen in acute IM tissues, (b) polymorphic lesions described as B-cell hyperplasia or B-cell lymphoma, and (c) monomorphic lesions described as immunoblastic lymphoma. At least 90% of such lesions are EBV-associated (the exceptions being a recently identified subset of tumors of unknown etiology) and are either oligoclonal or monoclonal based on EBV terminal repeat and *Ig* gene analysis. Clonality does not necessarily correlate with polymorphic or monomorphic appearance and indeed there can be heterogeneity of histologic appearance both within a lesion and between different lesions arising in the same patient (reviewed in 178 and 323).

Most of these EBV-positive PTLDs arising in transplant programs in the Western world carry type 1 EBV strains typical of those prevalent in the general population (137,406). By immunostaining, the lesions are usually dominated by EBNA1-positive, EBNA2-positive, LMP1-positive cells (280,463,513), consistent with their being EBV-transformed LCL-like foci growing opportunistically in the absence of CTL surveillance. When the lesions show a T-cell infiltrate, this is mainly composed of nonactivated CD4+ T cells with little evidence of any ongoing CD8+ response (354). However, a minority of these tumors are EBNA1-positive, with low or undetectable levels of EBNA2 and LMP1 (76,111a,370), possibly reflecting the subsequent acquisition of cellular genetic changes, which have rendered some EBV-transforming functions redundant. In that context, a small proportion of PTLDs, usually among those with monomorphic histology, have acquired *p53* gene mutations (253), *c-myc* rearrangements detectable by DNA analysis (286), or identifiable cytogenetic changes (113,280). Some PTLDs with changes at the *c-myc* or *bcl-6* loci appear to remain both EBNA2 positive and LMP1 positive (280), whereas others, presenting with more complex chromosomal aberrations, display more restricted forms of latency (113). One of the earliest and most important clinical observations in this field was that many PTLDs, especially the early-onset lesions, regressed when immunosuppressive therapy was reduced (435). Indeed, a planned reduction of immunosuppression is now the first treatment option in many cases of PTLD (352), and its frequent success is thought to reflect reemergence of the patient's endogenous EBV-specific CD8+ CTL response (244).

Acquired Immunodeficiency Syndrome Lymphomas

HIV-infected individuals are at particularly high risk for developing B-cell lymphomas, with cumulative incidence rates estimated at up to 10% during the first decade of the AIDS epidemic (35). Not only is this higher than seen in most transplant recipients, but also the spectrum of tumor types is more diverse. Overall, about half of these AIDS lymphomas are EBV-associated, but the strength of the association differs between tumor types (reviewed in 143). Up to one third of the EBV-positive lymphomas of AIDS were found to carry a type 2 EBV strain in early surveys (49), reflecting the high prevalence of type 2 strains in the HIV-positive homosexual population that dominated AIDS cohorts at that time (511). In this same context, several studies (36,249) have reported that a high proportion of EBV-positive AIDS lymphomas carry virus strains with a small in-frame deletion at a mutational hot-spot in the *LMP1* gene. The argument that this is a marker of enhanced lymphomagenic potential remains controversial, however, because about 30% of type 1 and almost all of type 2 isolates from healthy individuals in Western countries also carry the same deletion (233).

One major category of AIDS lymphomas is essentially analogous to PTLD lesions and appears only in end-stage AIDS when patients are profoundly immunocompromised. These tumors present at a variety of extranodal sites as polymorphic B-cell hyperplasia or monomorphic immunoblastic lymphomas with varying degrees of plasmacytic differentiation; most of the AIDS lymphomas presenting in the central nervous system are of this type (292). Such PTLD-like lesions are again EBV-positive in at least 80% cases, the reported strength of the association varying between different studies because the histiologic boundary between these lesions and certain other AIDS lymphomas can be difficult to draw. When EBV positive, the tumors are largely composed of EBNA2-positive, LMP1-positive B lymphoblasts typical of an EBV-driven B-cell proliferation (143,174,175) and appear from *Ig* gene sequencing to be derived mostly from postgerminal center (memory) B cells (111). Outgrowth of these EBV-positive PTLD-like lesions is almost certainly linked to a failure of virus-specific T-cell surveillance. Thus, prospective studies of individual patients have shown a loss in EBV latent antigen-specific CTL function, and a concomitant rise in EBV-infected cell numbers in the blood, in patients who go on to develop lymphoma (231).

At least three other categories of AIDS non-Hodgkin's lymphomas appear to be etiologically distinct from the PTLD-like disease. Firstly, a small (noncleaved) B-cell lymphoma of Burkitt's lymphoma type (AIDS-BL) is unusually common and arises earlier than the PTLD-like lesions, in patients whose EBV-specific T-cell immunity is still intact (231). Such tumors show the characteristic *c-myc* translocations and a Bcl6–positive germinal center phenotype of classic BL but are EBV-positive in only 30% to 40% of cases; when positive, they lack EBNA2 and LMP1 expression completely or sometimes express LMP1 in a small percentage of cells (74,174,175). Secondly, some AIDS patients develop a large (noncleaved) B-cell lymphoma which may be difficult to distinguish histologically from PTLD-like disease (174) but differs from it in expressing the Bcl6 marker (74). As with AIDS-BL, these tumors are EBV positive in 30% to 40% cases and, when positive, tend to display an EBNA2-negative, LMP1-negative viral phenotype (74,143,175); this accords with *in vitro* studies of EBV-positive cell lines in which Bcl6 and LMP1 expression appear to be mutually exclusive (75). Thirdly, primary effusion lymphoma (originally called *body-cavity–based lymphoma*) is a rare tumor that arises in highly immunocompromised AIDS with HHV-8 infection. Such tumors are consistently HHV-8 genome positive and are thought to be pathogenetically linked to this virus (77); interestingly, most tumors analyzed to date also carry the EBV genome, with antigen expression restricted to EBNA1 and possibly trace levels of LMP1 (70,453). The contribution that EBV makes to the pathogenesis of these various AIDS lymphomas of non-PTLD type remains unknown.

Finally, there is evidence for a small but significant increase in the incidence of classic Hodgkin's disease (HD) in HIV-infected individuals (392). These tend to appear in more immunocompromised patients and in a more aggressive form. The histologic classification of AIDS-HD appears to be skewed toward those subtypes (mixed cellularity, lymphocyte-depleted) more frequently linked to EBV in classic HD (see later), and the tumors are EBV-positive in more than 90% cases, with a characteristic EBNA2-negative, LMP1-positive viral phenotype (22,34).

Smooth Muscle Cell Tumors

Leiomyosarcomas, an unexpected addition to the list of EBV-associated tumors of the immunocompromised (265,299,473), are especially seen in HIV-positive children, in whom they constitute the next most common malignancy after lymphomas. Similar EBV-positive tumors have also been seen in young transplant recipients (265) and, most recently, in a child with immunodeficiency (470). Like PTLDs, these tumors can be monoclonal or oligoclonal by EBV terminal repeat analysis, with examples of different clones at different sites within the same patient (299,473).

The consistency of the EBV association with such tumors and their unusually increased incidence in immunocompromised patients (compared with the general population, in whom smooth muscle tumors are very rare and EBV-negative [299]) strongly suggests an etiologic role for the virus in tumor development. It is interesting that these tumors frequently arise in sites (lung, gastrointestinal tract, liver) where EBV-infected B cells are known to accumulate in T-cell–compromised patients. However, the mechanism of viral entry into smooth muscle cells and the status of these cells with respect to CR2 expression are unresolved. Likewise, the form of latency established by EBV in the tumor cells has not been rigorously analyzed.

BURKITT'S LYMPHOMA

Endemic, Sporadic, and AIDS-Associated Forms

The endemic form of BL, first described by Denis Burkitt in Africa, had two remarkable epidemiologic features: (a) an unusually high incidence of 5 to 10 cases/10^5 per year over the first 15 years of life, making it the most common cancer of childhood in equatorial Africa, and (b) a marked geographic distribution, apparently determined by climatic factors and coincident with areas of holoendemic malarial infection (60,294). The same high-incidence tumor was subsequently identified in coastal New Guinea (359), the only other area of the world with such intense *Plasmodium falciparum* malaria. Endemic BL is classically a childhood malignancy (male-to-female ratio, 3:1) with an unusual pattern of presentation at extranodal sites, most frequently in the jaw in association with molar tooth development or otherwise in the orbit, in the central nervous system, or as an abdominal mass often involving the ovaries. All such tumors show the same homogeneous population of malignant cells, morphologically similar to germinal center B cells, interspersed with occasional macrophages which give the tumor its characteristic “starry sky” histology. The tumors are monoclonal and, more importantly, display one of three reciprocal translocations between chromosome 8 at or near the site of the *c-myc* locus at 8q24 and either the *Ig* heavy-chain locus on chromosome 14 (the common translocation seen in up to 80% tumors) or one of the light-chain loci on chromosomes 2 or 22 (the variant translocations). The coincidence of these clinical, histologic, and karyotypic markers firmly established endemic BL as a distinct pathogenetic entity (reviewed in 294).

Rare childhood lymphomas with the histologic appearance of BL and the same characteristic cytogenetic changes are now known to occur worldwide and are classified as *sporadic* BL. This tumor is best characterized in Europe and the United States, where its incidence is 50- to 100-fold lower than that of the endemic disease. Here, the tumor has a slightly later age peak and a different pattern of presentation, appearing much more frequently as an abdominal mass and occasionally in leukemic form (294). Studies of sporadic BL in other regions of the world are still at a relatively early stage. Nevertheless, it is already clear that incidence rates for histologically and cytogenetically confirmed BL may be higher in parts of South America and North Africa than in Europe and the United States (170,271).

As described earlier, there is a third form of BL, which appears in HIV-infected individuals often as one of the first symptoms of AIDS (74,143). Again, these tumors resemble classic BL on cytogenetic and histologic grounds, with sites of presentation following the sporadic rather than the endemic pattern. Because up to 10% of AIDS patients in Western societies develop B-cell malignancies of one form or another, the incidence of BL in this particular group is very much higher than either the endemic or sporadic BL of childhood. To what extent this susceptibility to lymphoma, and to BL in particular, is reproduced in HIV carriers in an African setting remains an important but unresolved question (93).

Association with Epstein-Barr Virus

The endemic form of BL shows the strongest and most consistent association with EBV. In virtually every endemic tumor analyzed to date, all the malignant cells are EBV genome–positive, and each tumor carries a monoclonal EBV episome (1,294). Interestingly, anti-VCA and anti-EA(R) antibody titers in the serum of endemic BL patients are considerably higher than in age-matched controls (186), and a large prospective survey of children in an endemic area showed that individuals who subsequently developed BL had significantly raised anti-VCA titers months or years before the clinical onset of the tumor (107,149).

The association between EBV and sporadic BL is less consistent but nevertheless still significant. In Europe and the United States, where sporadic BL occurs at very low incidence, only 15% to 25% of the tumors are EBV genome positive (1,271,294), although it is claimed that some EBV-negative tumors in fact harbor integrated viral sequences indicative of earlier virus involvement (369). In several other parts of the world, including the intermediate incidence areas of North Africa and equatorial South America, the proportion of EBV-positive cases reaches 50% to 85% (80,398). Such findings strengthen the view that wherever childhood BL exceeds the very low incidence rates seen in Western societies, most of the increase is EBV-associated (271). Set against this background, AIDS-BL again appears to be rather a special case. The incidence of this tumor among AIDS patients is unusually high, yet only a minority, some 30% to 40%, of AIDS-BL cases are EBV genome–positive (74,174). It is nevertheless important that, as with the endemic disease, in all EBV-positive cases of AIDS-BL and of sporadic BL so far analyzed, the EBV genome is detectable in every tumor cell; hence, the virus must have been present in the tumor progenitor cell before its expansion as a malignant clone.

There is to date no clear evidence that particular strains of EBV are preferentially linked with BL. Both type 1 and type 2 EBV strains have been found in association with the endemic tumor in Africa and New Guinea, whereas type 1 strains

are dominant among EBV-positive sporadic tumors in Europe (171,459,515,518), reflecting the relative prevalence of these two virus types within the general population in these different areas. A recent report that BL tumors tend to carry viruses with particular allelic polymorphisms in the *EBNA1* gene sequence (39) again seems more likely to reflect differences in geographic distribution than differences in pathogenicity between viral strains (171).

Cellular and Viral Aspects of the Burkitt's Lymphoma Phenotype

The B-lymphoid origin of Burkitt cells is clear from the regular expression of pan–B-cell antigens such as CD19 and CD20. Individual tumors are monoclonal in terms of *Ig* gene rearrangement and isotype expression; whereas most display surface IgM (μk or μl, usually without IgD), a minority appear to be derived from cells that have already switched to IgG or IgA production, again with appropriate light-chain restriction (294). In other respects, however, Burkitt's tumors display a remarkably consistent cell surface profile characterized (a) by the coexpression of two diagnostic markers, CD10 (CALLA) and the glycolipid moiety CD77 (BLA); (b) by the complete absence of B-cell activation antigens such as CD23, CD30, CD39, and CD70; and (c) by the absence or very low expression of molecules such as CD54 (ICAM1) and CD58 (LFA3), which normally play a role in cell adhesion to T lymphocytes, and CD80 (B7), which is a critical co-stimulatory molecule for T-cell activation (165,389). Cells with an essentially similar surface profile exist within the germinal centers of secondary lymphoid follicles (164); indeed, the similarity between the two cell types is reinforced by the consistent presence of the germinal center-associated protein Bcl-6 (75) and absence of the B-cell survival protein Bcl-2 (184,355) in BL cells.

Cell lines established from BL biopsies *in vitro* at first display the original biopsy cell phenotype and grow as a single cell suspension with no intercellular adhesions. On serial passage, some BL lines retain this group I (biopsy cell) phenotype, whereas other lines show marked phenotypic shift with the appearance in the culture of clumps of lymphoblastoid cells. These cells are clearly derived from the group I tumor cell population because they retain the relevant cytogenetic and Ig isotype markers but now express the full spectrum of B-cell activation antigens and adhesion molecules. As such cells come to dominate the culture, they frequently lose expression of the original CD10 and CD77 BL markers and thereby complete the move to a group III phenotype essentially indistinguishable from that of *in vitro*-transformed LCLs (390); other LCL-associated markers, such as cellular Bcl-2, have also been up-regulated (184). As illustrated in Figure 7, those cellular changes are associated with a change in the form of viral latency. Comparing isogenic but phenotypically distinct subclones of the BL line Mutu, group I cells express only the viral genome maintenance protein EBNA1, whereas group III cells express the full spectrum of viral antigens that are found in LCLs. Accordingly, group I cells, representative of BL *in vivo*, follow the Latency I pattern and express a uniquely spliced EBNA1 mRNA selectively transcribed from the Qp promoter region. By contrast, group III cells have moved to the Latency III pattern, involving a switch from Qp to Cp/Wp promoter usage, which leads to expression of all six EBNA species and hence to an EBNA2-mediated activation of the LMP promoters. Most of the cellular changes associated with the group I to group III transition can in fact be traced to activations of cellular genes induced by EBNA2 or LMP1 (184,482).

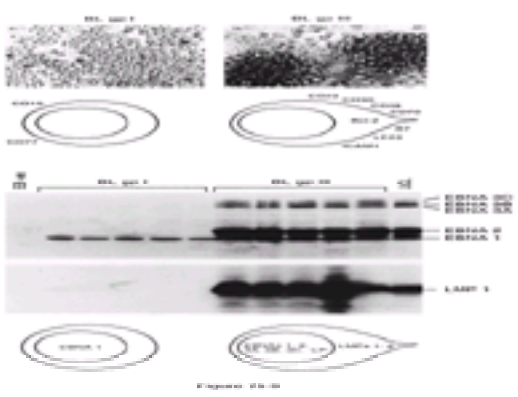

FIG. 7. Relationship between cellular phenotype and viral phenotype in EBV-positive Burkitt's lymphoma (BL) cells. Data are based on the analysis of phenotypically distinct subclones of the endemic BL cell line, Mutu. **Top:** Contrasting growth characteristics and cellular phenotypes of group I and group III subclones. **Bottom:** Different patterns of viral antigen expression in these same subclones. Protein extracts are probed with a polyclonal human serum reactive against EBNA1, 2, 3A, 3B, and 3C proteins (*upper gel*) or with the LMP1-specific monoclonal antibodies CS1–4 (*lower gel*). The negative-control track is loaded with protein from an EBV-negative sporadic BL line, the B-lymphoblastoid cell line control track with protein from a cord blood B-cell line transformed *in vitro* by virus rescued from Mutu cells.

It is not known why some EBV-positive BL lines stably retain the group I phenotype *in vitro* whereas others progress to group III. It may reflect differences in the degree to which extraneous viral gene expression is extinguished within the original tumor itself. Assays on biopsy cell preparations show that in some tumors, a small number of cells have spontaneously activated the expression of additional latent or lytic cycle genes (329,459).

The Burkitt's Lymphoma Phenotype and Immune T-Cell Recognition

EBV-positive group I BL cell lines appear to be “immunologically silent” in that they are not recognized by virus-specific CTL preparations with appropriate HLA class I restriction (382) and are extremely poor inducers not just of virus-specific but also of allo-specific CTL responses *in vitro* (297). Multiple features of the BL phenotype are now thought to contribute to this immunologic silencing.

First, the proteasome-dependent antigen-processing pathway that degrades endogenously synthesized proteins and delivers the resultant peptide fragments for cell surface presentation on HLA class I molecules is very much less active in BL cells than in LCLs. In fact, there appears to be a general impairment of proteasome function in the tumor cells, with

some of the proteasome's essential (nonimmunologic) functions being carried out by an alternative proteolytic system involving tripeptidyl peptidase II (146). Clear differences between BL and LCL cells are apparent in proteasome composition, with BL cells lacking the IFN-g–induced subunits found in immunoproteasomes of efficient antigen-presenting cells (32), and in the efficiency of peptide transport, with BL cells showing low-level expression of the TAP1/TAP2 transporter complex (387). In addition, group I BL cells show a general down-regulation of HLA class I antigen synthesis when compared with LCLs, with certain alleles particularly affected, leading to correspondingly lower steady-state levels of class I antigens at the cell surface (297,387). As a result of these multiple changes, group I BL cells are unable to present endogenously expressed target antigens to CTLs even when the target antigen is overexpressed in the cells from a recombinant vaccinia viral vector (235). These effects are reversed in BL lines that have switched to a group III LCL-like phenotype *in vitro*. In fact, antigen-processing function can be restored in group I BL lines by vector-mediated expression of LMP1 (387) or by ligation of CD40 (241); in both situations, there is a coordinate up-regulation of TAP1/TAP2 and of HLA class I antigen expression. Interestingly, despite deficiencies in the HLA class I pathway, group I BL cells retain the ability to process exogenous antigen through the HLA class II pathway for presentation to CD4+ T cells (239).

As a second feature of the immunologically silent BL phenotype, many of the ancillary molecules required for the efficient induction of T-cell responses are expressed weakly if at all at the cell surface. In particular, the very low level of CD80 expression is liable to be critical because CD80-mediated ligation of CD28 on the T-cell surface delivers an essential co-stimulatory signal for immune activation. In addition, BL cells lack adhesion molecules such as ICAM1 and LFA3, whose interaction with LFA1 and CD2, respectively, on the T-cell surface is thought normally to enhance the efficiency of immune stimulation (165). However, none of these ancillary pathways appears to be essential for recognition of the tumor by preactivated T cells because BL cells preincubated with an appropriate epitope peptide are killed by epitope-specific CTLs (238).

Third, and most obviously, the viral phenotype of BL cells is likely to be an important factor in reducing tumor susceptibility to EBV-specific CTL surveillance. Thus endogenous viral antigen expression is limited to EBNA1 (390), which is protected from CD8+ T-cell recognition, and possibly some BamHI A–encoded polypeptides that (even if expressed) appear to constitute very weak targets for the T-cell response (246).

It is tempting to conclude from the above that escape from virus-specific CTL surveillance has been a key selective step in the evolution of EBV-positive BL. However, EBV-negative BL also shows many of these same cellular features (165,235). Although it is possible that the presence of a different (as yet unidentified) virus in the EBV-negative tumor might likewise necessitate the selection of an immunologically silent tumor phenotype, a more plausible interpretation is that such a phenotype is either a characteristic of the normal cell from which BL is derived (164) or, as *in vitro* studies now suggest (146,357), has been imposed on the tumor progenitor cell by events that are essential for its malignant transformation but are unrelated to immune T-cell selection.

Pathogenesis, Chromosomal Translocation, and the Role of Epstein-Barr Virus

BL has a complex multistep pathogenesis with deregulation of *c-myc* expression and EBV infection being the best documented, but almost certainly not the only, factors involved. The relative contribution of these factors and their order of involvement remain to be determined.

The detailed structure of the *c-myc* gene translocations in BL has been extensively reviewed (294), the end result being to release the gene from its usual regulatory controls and to bring it under the control of long-range enhancer sequences within *Ig* loci. The common t(8:14) translocation tends to place the *c-myc* gene in one of two positions upstream of the IgH locus. In one case, a breakpoint within the body of the *c-myc* gene removes the 5'-regulatory exon and places the coding exons directly adjacent to IgH sequences; this is the pattern most often seen in (North American) sporadic and AIDS-associated BLs irrespective of their EBV genome status. In the other case, *c-myc* is some distance away from the breakpoint and so is translocated intact up to several hundred kilobases upstream of IgH sequences; this is the pattern seen in most endemic BLs. Variant t(2:8) and t(8:22) translocations, whether in endemic or sporadic tumors, produce an analogous situation in which *c-myc* is always positioned some distance upstream of the kappa or lambda light-chain loci. In addition, the translocated c-myc allele is frequently mutated both in and around the regulatory exon 1 (78) and in the protein-coding exons leading to key changes in the protein's N-terminal transcriptional activation domain (38). Both sets of mutations could have pathogenetic significance in addition to the effect of the translocation per se.

The position of the reciprocal breakpoints within the *Ig* gene loci is of particular interest because it could help to identify at what stage of B-cell differentiation the translocation occurred. Most work has focused on t(8:14) translocation where there are two main patterns of *IgH* gene breakage, again loosely correlating with tumor type. One group of (mostly sporadic) BLs show breakage within the Ig switch (S) region, usually involving Sμ but occasionally Sg or Sa; this suggests that translocation has occurred as an accident of the recombination events that normally occur in germinal center B cells during Ig class switching. Another group of (mostly endemic) BLs show breakage in the joining (J) region. However, the breakpoints do not target recombination signal sequences, as would have been expected if breakage had occurred as an accident of V-D-J joining in bone marrow pro-B cells during initial *IgH* gene rearrangement; instead, breakpoints are located within J region introns or rearranged V(D)J sequences (294). Recent work has shown that these areas are susceptible to breakage (leading to deletions and duplications) as a result of the process of somatic hypermutation occurring in germinal center B cells (154). This strengthens the possibility that all *c-myc/Ig* translocations in BL may originate as mistakes of physiologic processes occurring during the maturation of antibody responses in germinal centers. In this context, a germinal center origin for BL is supported not just by the tumor's phenotypic similarity to germinal centre B cells (164) but also by the fact that tumor-derived lines show evidence of ongoing hypermutation of their productively rearranged *Ig* genes (82,251,457).

It is also interesting that holoendemic malarial infection (12) and chronic HIV infection with its associated persistent generalized lymphadenopathy (213) both act as potent stimulators of lymphoid hyperplasia and produce greatly expanded germinal centers. These infectious agents may therefore be risk factors for BL development by virtue of their ability to act as chronic stimuli of germinal center cell proliferation rather than their frequently postulated role as

mediators of T-cell suppression. In this context, the immunosuppressive effects of malaria are generally restricted to short periods of acute disease (494), whereas those mediated by HIV do not become profound until late-stage AIDS, by which time the incidence of AIDS-BL is decreasing concomitant with a marked reduction in germinal center cell activity (213).

The mechanisms whereby EBV contributes to BL pathogenesis are still not fully understood. The potent growth-transforming ability of the virus suggests that it could act early in the lymphomagenic process by expanding the population of cells at risk for translocation or by increasing the survival and/or proliferation of a translocation-positive but still not fully malignant clone. These scenarios all envisage an important role for the Latency III growth transforming infection at some early or intermediate state of the lymphomagenic process, followed by a switch to Latency I as accumulated cellular changes render cell growth independent of viral-transforming proteins such as EBNA2 and LMP1. An important *in vitro* reconstruction of such a scenario has been achieved using as a starting point a recombinant EBV-transformed LCL in which EBNA2 is expressed as fusion protein with the estrogen receptor such that EBNA2 function, and consequently LMP1 expression and cell growth, is estrogen- dependent. When these cells were transfected with a *c-myc* expression construct cloned from a BL *c-myc/Ig* fusion locus, the constitutively active *c-myc* gene rendered cell growth estrogen-independent. Furthermore, the cells that grew out in the absence of estrogen had switched from an LCL-like to a group I BL-like phenotype and growth pattern (357). Enforcing high *c-myc* expression in an EBV-transformed B cell can therefore substitute for the growth-promoting effects of EBNA2 and LMP1 and can impose a BL-like phenotype on the resulting EBNA2-negative, LMP1-negative cell.

While EBV may play an initiating role in BL pathogenesis, it is also possible that the virus continues to contribute to the growth phenotype of the malignant clone. The evidence, however, is still circumstantial. Spontaneous loss of the viral genome has been noted in subclones of the Akata BL cell line (originally derived from an EBV-positive sporadic tumor) and was accompanied by a significant reduction in the cells' tolerance of suboptimal culture conditions, capacity for growth in soft agar and tumorigenicity in nude mice (419). Reinfection with virus reestablished the original latency I form of infection and restored the original growth phenotype. However, EBNA1, the anticipated mediator of this effect because of its reported lymphomagenic potential when expressed in the B cells of transgenic mice (495), was inactive in the Akata assay (257,393) whereas some restoration of the growth phenotype appeared to be mediated by *EBER* gene transfection (256). Further work is required to identify the viral contribution to the Akata cell phenotype and to determine how representative these results are of other BL cell backgrounds.

Whatever the mechanisms whereby EBV infection and chromosome translocation complement one another, it is unlikely that these are the only elements required for full malignant conversion. Thus, about 30% of BL biopsies, and an even higher proportion of BL cell lines, contain a mutated *p53* gene and frequently show loss of the second *p53* allele (132,142,497). The presence in a number of BL lines of karyotypic changes involving chromosome 1 (37) suggest that other relevant cellular genes remain to be discovered. The complex multistep nature of lymphomagenesis is further emphasized by the fact that BL, although expressing a germinal center-like phenotype, does not usually develop within lymphoid tissues. The tumor's unique pattern of presentation at extranodal sites, particularly in the jaw in association with molar tooth development, could therefore reflect additional clonal selection *in vivo* on the basis of migratory capacity or responsiveness to a locally available growth factor (294).

HODGKIN'S DISEASE

Epidemiology and Association with Epstein-Barr Virus

HD is an unusual lymphoma with a malignant population of mononuclear Hodgkin and multinuclear Reed-Sternberg (H-RS) cells within a reactive infiltrate of nonmalignant cells, which typically make up more than 98% of the tumor mass. Based on the H-RS–to–reactive cell ratio and the composition of the infiltrate, HD can be classified into four histologic subtypes, nodular sclerosing (ns), mixed cellularity (mc), lymphocyte depleted (ld), and lymphocyte predominant (lp) (179). Of these, ns, mc, and the (relatively rare) ld disease are now referred to as *classic HD,* whereas lp-HD is considered a separate clinical entity. Classic HD is seen worldwide and, although total incidence rates appear not to vary substantially with geography, there are interesting differences between countries in age incidence and subtype distribution (reviewed in 152). In Europe and the United States, HD incidence is low in childhood, shows a marked young adult peak dominated by ns disease, then appears to plateau through later life with equal contributions from both ns and mc subtypes. Patterns vary in other parts of the world, but generally, in less developed countries, childhood HD is more common, and the disease then shows a steady age-related increase with no young adult peak; the overall contribution of mc disease is therefore higher.

These differences suggested that the young adult disease seen in the West resulted from delayed exposure to a common infectious agent (291). The obvious epidemiologic parallel with IM raised the possibility of a link between EBV and HD; indeed, several studies have found that individuals with a history of IM have a roughly threefold subsequent increased risk for HD, the risk being greatest within the first 3 years after EBV infection (reviewed in 152). Furthermore, a retrospective analysis of banked serum samples showed significantly raised anti-VCA antibody titers in HD patients at least 3 years before development of the tumor, suggesting that deregulation of the EBV–host balance had preceded emergence of the malignant clone (317). However, the key findings that irrevocably linked EBV with HD were the detection of monoclonal viral genomes in some tumor biopsies by Southern blotting and terminal repeat analysis (492) and the localization of EBV DNA to the malignant H-RS cells of such biopsy specimens by *in situ* hybridization (9,491). In virus-positive cases, every malignant cell carries the viral genome, and in patients with multiple lesions, the same unique viral episome is present at every site (28).

The association between EBV and HD has subsequently been extensively investigated using archival HD material and the more sensitive screening methods of *in situ* hybridization for EBER RNAs (503) or immunohistochemical staining for LMP1 (192,344) in H-RS cells. Worldwide, some 60% to 80% of mc and ld subtype tumors are EBV genome-positive, compared with 20% to 40% of cases of nc subtype and very few of lp subtype (reviewed in 153). Thus, in the Western world, about half the cases of HD arising in children or in old age are EBV- positive, whereas the figure falls below 30%

for the young adult peak of disease; overall, some 35% of patients with classic HD carry the viral genome. Ironically, therefore, the young adult peak of predominantly ns-HD shows the weakest association with EBV. Even among young adult cases arising in patients with a proven history of IM, recent work indicates that many have EBV genome–negative tumors (431). By contrast, in other parts of the world (Africa, Asia, Latin America), more than 60% to 70% of all HD cases are EBV genome-positive, some of this increase being explained by the absence of the young adult peak. It is worth recalling that EBV infection occurs very early in life in these areas, and several reports now indicate that essentially every case of childhood HD from the above populations is EBV genome-positive (8,181,489).

As in several other tumor contexts, there is no clear evidence that particular strains of EBV might be linked with HD. Whether analyzed for virus type or for potentially interesting polymorphisms in EBV latent cycle genes, the spectrum of virus strains found in EBV-positive HD appears to reflect that seen in the general population as a whole (181,233). The extent to which HD incidence increases, if at all, in immunocompromised patients remains controversial. However, those cases of HD that do arise in transplant recipients (144), congenitally immunodeficient patients (467) and particularly AIDS patients (21) appear to be invariably EBV genome-positive.

Cellular and Viral Aspects of the Hodgkin's Disease Phenotype

The origin of the malignant cells in classic HD for many years remained unknown. Most H-RS populations (whether EBV genome-positive or -negative) do not express conventional B- or T-cell markers, although they are frequently positive for lymphocyte activation antigens such as CD25, CD30, and CD70, for a novel intermediate filament-associated protein restin, and for a carbohydrate antigen CD15 originally thought to be a myeloid-specific marker (reviewed in 345). However, PCR amplification of *Ig* gene loci from single micromanipulated H-RS cells has shown that, in all but very rare cases (321), classic HD is of monoclonal B-cell origin with all H-RS cells within a single tumor showing the same Ig heavy- and light-chain gene rearrangements (51,223,258,259). Furthermore, sequence analysis revealed that the cells carried heavily mutated *Ig* genes, often with stop codons in the reading frame or replacement mutations in the usually conserved framework regions (259,335). Such “crippling” mutations, which are normally inconsistent with B-cell survival *in vivo*, appear to be byproducts of somatic hypermutation in germinal centers (154). Their presence in H-RS cells, unaccompanied by any evidence of ongoing *Ig* gene mutation, therefore identified classic HD as a tumor of postgerminal center B-cell origin (258).

Whenever EBV is present in the H-RS cells of classic HD, the same pattern of viral gene expression is observed, described earlier as Latency II. This is characterized by expression of the EBER RNAs, the BamHI A transcripts, a Qp-driven EBNA1 mRNA, and the LMP1, LMP2A, and LMP2B transcripts (109). At the single-cell level, monoclonal antibody staining has confirmed the presence of EBNA1 (156), and unusually high levels of both LMP1 (192,344) (Fig. 8) and LMP2A (331) in the tumor cells. Only a few HD biopsy specimens showed any sign of lytic cycle antigen expression, and, when present, this appeared to be limited to the immediate early antigen BZLF1 seen in a small fraction of the tumor cells (345).

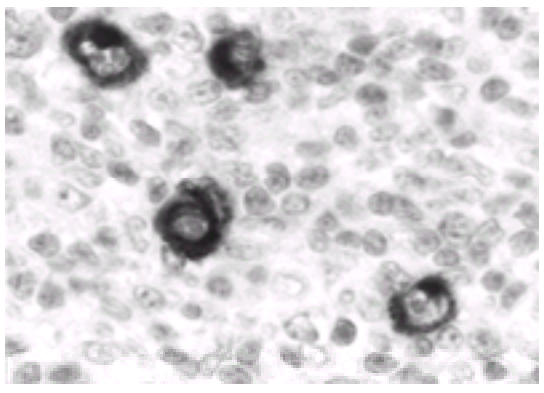

FIG. 8. Expression of LMP1 in the malignant cells of EBV-positive Hodgkin's disease (HD). A tissue section through an HD biopsy was stained with the LMP1-specific monoclonal antibodies CS1–4 and developed using APAAP immunohistochemistry shows strong cytoplasmic and membrane staining restricted to the malignant Hodgkin–Reed-Sternberg (H-RS) cell population. (Courtesy of G. Niedobitek).

The Hodgkin's Disease Phenotype and Immune T-Cell Recognition

The broader range of viral antigen expression in HD compared with that seen in BL raises the question of how these cells escape immune recognition by the EBV-specific T-cell response. Immunohistochemical staining has shown that in most EBV-positive tumors, the H-RS cells express both the TAP1/TAP2 peptide transporter and surface HLA class I and class II molecules; paradoxically, HLA class I expression is frequently down-regulated in EBV-negative cases of the disease (267,341). The implication is that antigen-processing function through the HLA class I pathway is intact in EBV-positive H-RS cells, as it is in small number of HD-derived cell lines available *in vitro* that, although from EBV-negative cases of the disease, have retained HLA class I expression (267,425).

A report that EBV-specific CTLs could be expanded from the T-cell infiltrate of virus-negative but not virus-positive HD (140) implied some local suppression of virus-specific responses by the tumor itself. Although subsequent work has in fact detected EBV-specific CD8+ T cells within EBV-positive HD samples, the range and frequency of these reactivities resembled those seen in the blood, and there was no selective recruitment of cells specific for viral antigens expressed in the tumor (81). Local evasion of T-cell control by the tumor, therefore, remains a possibility. In this context, H-RS cells appear to produce a range of cytokines, for example, transforming growth factor-b, IL-10, IL-13, and the thymus and activation-related chemokine (TARC) (reviewed in 360), which have the potential to suppress or divert cell-mediated

responses away from CTL induction. Of these, IL-10 has received most attention, being more commonly secreted by EBV-positive than by EBV-negative tumor cells (193); from *in vitro* studies, any effects of this cytokine on CTL responses appear more likely to be mediated at the induction rather than the effector stage (33,486).

Pathogenesis and the Role of Epstein-Barr Virus

In situ hybridization analysis has shown that individual tumors carry clonal chromosomal abnormalities but has not detected a common chromosomal marker that might provide a clue to tumor pathogenesis (reviewed in 258). A number of potentially interesting features of the H-RS cell phenotype have been reported, notably Bcl-2 expression, elevated levels of p53, and up-regulation of the IL-6 pathway of autocrine growth stimulation, but none of these is consistently present in all tumors or specifically linked to either EBV-positive or EBV-negative forms of the disease; furthermore, there is no evidence for *bcl-2* gene translocation or *p53* gene mutation in HD. By contrast, HRS cells do consistently stain strongly for components of the activated NF-Kb transcription factor complex, and in some HD-derived cell lines, the high NF-Kb activity appeared to be important both for continued cell growth and for the cells' resistance to apoptosis (31). Interestingly, such lines (all EBV-negative) frequently lacked the natural regulator of NF-Kb activity, IKba (501), and in some cases carried mutations in the *IK*ba gene (68,123). Recent extension of this work to fresh HD biopsies suggests that a significant fraction of EBV-negative tumors likewise carry mutant *IK*ba alleles (68,123,221).

The evidence that EBV, when present, plays a causative role in the development of HD is strong but circumstantial. Just as with BL, the most compelling argument for causality is the frequency with which the tumor cells in HD are EBV genome-positive. In the case of HD, however, a mechanism for the etiologic involvement of the virus is easier to conceive. As described previously, H-RS cells carry the genotype of a cell that has inappropriately escaped the apoptotic death to which most germinal center B cells succumb during the affinity maturation of antibody responses. Positive selection into the postgerminal center (memory) B-cell repertoire usually depends on the receipt of at least two cell surface signals, both of which may be mimicked by EBV. The first is normally delivered by the somatically mutated Ig molecule and requires high-affinity binding to cognate antigen. In this context, the intracytosolic N-terminus of LMP2 is capable of sequestering Src-family tyrosine kinases in a manner similar to that occurring at the cytosolic face of the surface Ig complex after antigen binding (245). LMP2 can therefore potentially substitute for a surface Ig-mediated signal, as it appears to do in a transgenic mouse system in which LMP2 expression in immature B cells allows such cells to populate the periphery even in the absence of *Ig* gene rearrangement and surface Ig expression (69). The second requirement for positive selection in germinal centers is normally delivered by the CD40 pathway and requires a cognate interaction between the B-cell and a CD40 ligand-expressing T cell. In this context, LMP1 is known to activate the CD40 pathway by constitutively binding members of the same TNF-receptor–associated factor (TRAF) family of signaling molecules as does CD40 following its ligand-induced aggregation in the membrane, leading to the activation of several transcription factors, including AP1 and NF-Kb (reviewed in 245).

A key aspect of the role of EBV in HD pathogenesis may therefore be to induce the inappropriate survival and possibly the proliferation of an otherwise sterile postgerminal center B cell through expression of the LMPs. When and where EBV acts relative to the cellular genetic events underlying tumor development can only be speculated on. However, cells with an H-RS–like appearance and a Latency II pattern of gene expression are generated within extrafollicular areas of lymphoid tissues during the course of primary infection. The fate of these cells is unknown, but they may form a persistent population from which HD might subsequently evolve by accumulated cellular changes; indeed, a proliferating clone of EBV-positive H-RS–like cells has been detected *in vivo* within 2 years of IM (224; see also next section). Whatever the role of the virus, the fact that all three histologic subtypes of classic HD can present in EBV genome–negative form indicates that the same end point can be reached by a different pathogenetic route. There are rare examples of EBV-negative HD that might have arisen from a preexisting virus-positive lesion (112), but generally tumors that are negative for the EBER and LMP1 markers lack any sign of integrated EBV genomic fragments (434), such as have been reported in some cases of EBER-negative sporadic BL (369). Indeed, there are well-documented cases of EBV genome–negative HD arising in patients with no serologic markers of prior EBV infection (273). It remains to be seen whether exposure to some other infectious agent is a factor in EBV-negative HD, particularly those cases of predominantly ns-HD arising in young adults in the Western world (152). However, the recent data on *IK*ba gene mutation in EBV-negative cases of the disease indicate that at least one aspect of EBV's likely pathogenetic role, the constitutive activation of NF-Kb, can be independently achieved by cellular genetic change.

OTHER B-CELL LYMPHOMAS

One of the findings that adds significance to the association of EBV with PTLD, BL, and classic HD is the rarity with which the virus is detected in other tumors of B-cell origin. Only a small percentage of non-Hodgkin's lymphomas arising in immunocompetent individuals show evidence of EBER expression—and then usually only in a small fraction of the tumor cells, suggestive of a passenger infection occurring after the malignant clone was established (reviewed in 173). There are, however, some rare B-cell lymphomas that do frequently carry the virus and that are potentially instructive in understanding some of EBV's better known lymphoma associations.

One is a B-cell lymphoma arising at certain sites of long-term inflammation, notably the pyothorax-associated lymphomas seen in patients sometimes 20 years or more after introduction of an artificial pneumothorax. These tumors are consistently EBV genome-positive (141,400), as are very rare examples of lymphomas arising from sites of chronic inflammation in bone and skin (94). Such tumors present as diffuse large cell lymphomas, sometimes with an immunoblastic appearance similar to PTLD and reportedly can display either full latent gene expression or more restricted forms of latency. It is thought that chronic inflammation might provide a local cytokine environment favoring EBV-induced B-cell proliferation at the expense of CTL control, predisposing over time to the evolution of lymphoma.

A second, unexpected association involves rare cases of chronic lymphocytic leukemia, a B-cell tumor not normally linked with EBV, which appear to transform to malignant cells with a H-RS–like phenotype. These H-RS–like cells, sometimes clonally related to the original leukemic population, are often EBV-positive and express LMP1 (224,308). There are indeed cases in which these lesions have progressed to classic EBV-positive HD (308), indicating the potential

value of such cases as a model for HD pathogenesis.

T-CELL LYMPHOMAS

The detection of EBV DNA in the circulating T cells of an infant with VAHS-like disease (247) and in three T-cell lymphomas arising in a setting of chronic active EBV infection (219) provided the first indication that EBV, long considered a strictly B-lymphotropic agent, could access the T-cell compartment. Recently, a wide range of T and NK cell tumors have been screened for EBV status by EBER *in situ* hybridization, and the following groups of virus-associated lymphomas have been identified (reviewed in 345 and 444).

Virus-Associated Hemophagocytic Syndrome T-Cell Lymphomas

The VAHS tumors are of mature CD4+ or CD8+ T-cell origin and are seen most frequently in Southeast Asian children either after acute primary EBV infection manifest as VAHS or in the setting of chronic active EBV infection with VAHS-like symptoms (219,445). The tumors are monoclonal by *TCR* gene rearrangement and EBV genomic analysis but often develop from a premalignant pool of EBV-infected T cells detectable in peripheral blood (222). When analyzed, they are reported to display a Latency II form of infection by EBV latent gene transcription but often with very low LMP1 transcription and only trace levels of LMP1 protein detectable by staining (83,222); such a pattern is better clarified as Latency I/II to distinguish from the classic Latency II seen in HD. The release of cytokines, particularly TNF-a, from the EBV-positive T lymphoma cells may induce macrophage activation and consequent histiocytic infiltration of the tumor (264), leading to its frequent reporting as malignant histiocytosis (445).

Nasal NK/T-Cell Lymphoma

This is a specific extranodal lymphoma of angiocentric type, again most common in Southeast Asia, which presents in the nasal cavity. The tumor causes progressive erosion of bone tissue, again probably cytokine-mediated; hence, its alternative description as lethal midline granuloma. A study of five cases in Japan first drew attention to the consistent presence of EBV in all tumor cells (177), and the strength of the association has been amply confirmed on similar tumors in Chinese and European patients (345). Some of these tumors display a CD3+, CD56+/– surface phenotype and carry TCR-b or -g chain rearrangements consistent with a T-cell origin, but most are CD3– and CD56+, have no TCR rearrangements, and appear to be derived from NK cells. They have, therefore, been jointly classified as *nasal NK/T-cell lymphomas* (215). EBV gene transcription again follows a Latency I/II pattern, with low LMP1 expression restricted to a minority of tumor cells (303).

Other T or NK Cell Tumors

A number of other uniformly EBER-positive T or NK cell tumors have been reported that do not fit easily into either of the above categories but that may share similar pathogenetic features with them (444). These include rare lymphomas presenting in the skin or gastrointestinal tract with either an NK/T-cell or distinct T-cell phenotype, other lymphomas of gd T-cell origin (20), and some NK cell tumors presenting as frank leukemias (180). Less consistent is the association between EBV and angioimmunoblastic lymphadenopathy (AILD)-like T-cell lymphomas (10,345), a heterogeneous group of node-based tumors that form a continuum with benign AILD lesions themselves. Often, the malignant T cells in these lesions are entirely EBER-negative, and EBV infection is restricted to small foci of B immunoblasts within the tumor mass. In contrast, EBER-positive T cells are detectable in about 40% of these tumors but, when present, constitute only a fraction (less than 5% to more than 50%) of the malignant population. When analyzed, such tumors are EBNA2-negative, LMP1-positive, but again, LMP1 expression is restricted to just a subset of the EBER-positive cells. Such situations, when EBV colonizes only a fraction of the malignant population, are most easily interpreted as a “passenger” infection, although in some cases, the infection might still confer a growth and survival advantage on the tumor cells *in vivo* (281,345).

EBV, therefore, appears etiologically linked to certain specialized groups of T-cell or NK cell lymphoma, of which the VAHS-associated T-cell lymphomas are potentially the most instructive in terms of tumor pathogenesis because of the speed of their development. Appearance of a malignant clone, often with defined chromosomal aberrations, can occur within 1 to 2 years of primary EBV infection and is frequently preceded by an EBV-positive T-cell lymphocytosis in peripheral blood (222,444). Because most surveys (see earlier) suggest that EBV rarely if ever accesses the T-cell system during the usual course of infection, the evidence from VAHS patients implies that EBV infection of T cells, if achieved, carries a high lymphomagenic risk. This could reflect the fact that EBV's latent genes have evolved for use in the B-cell system and that some of these genes, notably *EBNA1, LMP1,* and *LMP2,* could become inappropriately activated in a T-cell environment.

NASOPHARYNGEAL CARCINOMA

Carcinomas of nasopharyngeal epithelium are seen in all parts of the world but vary in incidence and histologic subtype among population groups (reviewed in 1). These tumors are now broadly classified into keratinizing carcinomas with clear evidence of squamous differentiation (originally designated World Health Organization [WHO] I), and nonkeratinizing carcinomas of poorly differentiated or undifferentiated epithelial cells (incorporating the original WHO II and III categories). The latter often show marked lymphocytic infiltration, hence their frequent description as *lymphoepitheliomas* of the nasopharynx. In many areas of the world, including Europe and North America, nasopharyngeal carcinoma (NPC) is a rare disease with an age-adjusted incidence below $0.5/10^5$ per year; both forms of the tumor are observed. By contrast, NPC is much more common among Southeast Asian populations, especially in Southern Chinese people, in whom incidence rates reach $25/10^5$ per year, as well as among Inuit people and in some North and East African populations. In all these high-incidence areas, most tumors are of the nonkeratinizing type and preferentially affect males (male-to-female ratio, 2:1 to 3:1), mostly in middle age.

Association with Epstein-Barr Virus

A link between EBV and NPC was first suggested on the basis of seroepidemiologic studies showing elevated antiviral antibody titers in NPC patients (339). Thereafter, DNA–DNA reassociation and *in situ* hybridization studies indicated the regular presence of the viral genome in NPC tumor cells, the first evidence for EBV infecting any epithelial target (499,519). Furthermore, analysis of the viral episome's terminal repeats showed that the tumor arose from a single EBV-positive progenitor cell (364). Essentially all cases of nonkeratinizing NPC analyzed worldwide are EBV genome-positive, and in most studies, this tumor type has been the sole focus of attention. However, EBV is now also linked to most cases of the rarer keratinizing form of NPC in Southeast Asia and to about 30% of such tumors seen in European populations (326,349).

The unexpected association of EBV with an epithelial tumor prompted speculation that particular viral strains might be preferentially epitheliotropic or have growth-transforming activity for epithelial cells. As described earlier, many of the unique polymorphic markers first identified in Chinese NPC-derived strains turned out to be characteristic of viruses prevalent in the general Chinese population. Nevertheless, the question of some form of preferential association of particular virus strains with this tumor remains open (290). Two recent studies, one based in Taiwan (502) and the other in North Africa (47), analyzed local EBV polymorphisms in the BamHI F and H regions, respectively, and found that the allelic distribution among NPC-derived virus strains is skewed compared with that seen in the general population and in EBV-positive lymphoid tumors from the same area.

An important development arising from EBV's association with NPC is the use of anti-EBV antibody responses as diagnostic and prognostic tools in disease monitoring. A key observation in this context was that most NPC patients have not only elevated IgG but also detectable IgA responses to VCA and EA(D) (189). The fact that IgA antibodies to EBV are only rarely present in healthy virus carriers prompted large-scale screening of Chinese populations in selected high NPC incidence areas. This identified 1% to 2% of the population who were persistently IgA anti-VCA positive, and many of the NPC cases arising over the next 3 years in the tested populations were drawn from this particular subset, indicating the value of IgA anti-VCA as a marker of elevated tumor risk (517). These approaches are not applicable to all populations, however, particularly in North Africa where a significant fraction of NPC arises in young adult males in the absence of a marked IgA response (108). Hence, work continues in an effort to identify individual EBV lytic cycle antigens, such as BZLF1, BRLF1, the viral thymidine kinase (BXLF1), or alkaline DNAase (BGLF), which when used as substrates in serologic assays, may offer greater specificity in identifying incipient NPC (1). An alternative and potentially more useful indicator of tumor status came with the finding that EBV DNA, presumably released from tumor cells, could be PCR amplified from the serum of NPC patients (322). This has led to the development of a real-time quantitative PCR assay for EBV DNA load in plasma and serum, which correlates with tumor burden and which can be used as a sensitive monitor of tumor recurrence (284,285).

Cellular and Viral Phenotype of Nasopharyngeal Carcinoma

Most work in this area has involved the direct analysis of biopsy material because the tumor has proved very difficult to grow both *in vitro* and in nude mice (66); indeed, the only NPC-derived *in vitro* line to retain the viral genome was established from tumor cells that had been first passaged in nude mice (86). Generally, the NPC cell phenotype resembles that induced in epithelial cells by cytokines such as IFN-g or TNF-a. Thus, the tumor cells express both HLA class I and class II antigens and have good antigen-processing function, at least in terms of presenting endogenously expressed proteins to CD8+ T cells by the HLA class I pathway (240,266). NPC cells also express cell surface molecules normally involved in epithelial–lymphoid interactions, namely CD40, CD54, CD70, CD80, CD86, and CD95 (4,404). It is not known to what extent this phenotype is imposed by EBV gene expression in the NPC cells themselves or is induced by cytokines derived from the largely CD4+ T-cell infiltrate. The concept of co-stimulation between the malignant and nonmalignant elements in NPC is frequently advanced, although which of the many candidate cytokine or co-stimulatory pathways might be important remains to be determined (4,207).

The pattern of viral gene transcription in NPC (55,67,226,432) is ostensibly similar to that seen in EBV genome–positive HD, but there are actually important quantitative differences that are also reflected at the level of antigen expression (129,514). Thus, the epithelial tumor cells are EBER-positive and appear to express unusually high levels of BamHI A transcripts; whether the latter encode any protein products in the tumor cells remains a controversial issue (246). The Qp-initiated BamHI Q/U/K–spliced EBNA1 transcript is readily amplifiable from tumor RNA, and this correlates with expression of the EBNA1 protein in the absence of other EBNAs. In contrast, LMP1 mRNA is frequently difficult to detect using the standard RT-PCR assay, in line with the absence of detectable LMP1 protein in up to 65% tumors. Although LMP2A and 2B transcripts are readily amplifiable, LMP2 protein expression has still not been unequivocally demonstrated in NPC using current reagents, although it is interesting that NPC patients are the only group who reproducibly show serum antibody responses to this protein (139,270). Given these results, NPC is best classified as displaying a Latency I/II form of infection, intermediate between those displayed by BL (Latency I) and HD (Latency II). Additionally, recent work has detected regular transcription of what was thought to be an exclusively lytic cycle gene, *BARF1,* in NPC, but not in other EBV-associated tumors such as HD (53). This could be pathogenetically significant since BARF1, if expressed at the protein level, has structural and functional homology with the cellular granulocyte CSF receptor (442) and has growth-transforming activity in some *in vitro* assays (488).

Finally, another puzzling aspect of the viral phenotype in NPC cells is the apparent absence by staining of lytically infected cells within the tumor population. The fact that antibody titers to lytic cycle antigens such as VCA and EA rise in proportion to tumor burden in NPC patients (191) suggests either that the antigenic stimulus comes from the tumor itself or that virus replication at some other site correlates with tumor evolution and progression. In this context, the analysis of viral DNA from NPC biopsy specimens showed that only episomal circular (latent) and not linear (lytic) forms were detectable (364). Likewise, screening tumor sections has in most cases either failed to find evidence of lytic antigen-positive cells or detected very occasional expression of the immediate early antigen BZLF1 only (89,168); sensitive RT-PCR assays have detected other lytic transcripts in NPC biopsy specimens, but it is difficult to know

whether these stem from tumor cells or from infiltrating B lymphocytes.

Nonviral Risk Factors

The high incidence of NPC in several Southeast Asian populations and in the anthropologically related Inuit people raise the possibility of genetic factors influencing NPC risk (reviewed in 1). Access to familial cases of NPC, reported in both high- and low-risk populations, should provide an important in-road into this question in the future. To date, most studies have focused on polymorphisms at the HLA locus, sibling pair data having suggested that a gene (or genes) closely linked to this locus is associated with a 20-fold increased risk for NPC (287). Although the susceptibility gene is unlikely to be an HLA allele itself, in Singapore Chinese, the HLA-A2, Bw46 and A19, B17 class I haplotypes and the DRB10803 class II allele are each associated with a more than twofold increased risk for NPC, whereas two other common class I alleles, HLA-A11 and B13, are each associated with a significant reduction in risk (1).

Environmental or dietary factors also appear to be important. Thus, in the immigrant Chinese population in North America, the NPC incidence is decreasing with time and is lower in the second generation, although still well above typical rates in whites (272). Most theories of dietary and environmental influence on NPC risk invoke as a mechanism chronic exposure of the nasopharyngeal mucosa to chemical carcinogens or physical irritants. Dietary exposure to salted fish (a source of volatile nitrosamines) in infancy has been implicated as a significant risk factor in Southern Chinese populations, whereas in some other Southeast Asian populations, occupational exposure to smoke or dust may be important (1). A number of environmental factors, dictated by diet or lifestyle, may therefore contribute to tumor risk. Furthermore, environmental and genetic influences may interact, as illustrated by the recent finding that individuals homozygous for a particular allele of cytochrome P450 2E1, an enzyme involved in nitrosamine activation, appear to be at increased risk for NPC (196).

Pathogenesis and the Role of Epstein-Barr Virus

Despite a current resurgence of interest, little is known at the molecular level about cellular genetic changes in the pathogenesis of NPC. Obvious candidate genes, such as *c-myc, ras, Rb,* and *p53,* are not detectably altered, although interestingly, some tumor cells do express high levels of the wild-type p53 protein (168). However, more recent work has detected frequent loss of heterozygosity at chromosomes 3p24, 9p21 (leading to deletion of the *p16* gene), 11q, 14q12-13, and 14q32 (203,204,208,283,433); such findings imply that a number of tumor suppressor genes may be targeted during NPC development.

The point at which EBV infection affects the process remains to be determined. However, several studies of tumor-free individuals in high NPC risk areas have been unable to find EBV-positive epithelial cells in nasopharyngeal biopsy specimens (85,396,461). NPC is therefore unlikely to evolve from a cell that naturally harbors EBV; rather, it must be a consequence of the rare entry of the virus into the target epithelium. How such entry is achieved is not known, but possibilities include direct CR2-independent transmission by B cell–epithelial cell contact, as has been observed *in vitro* (211,334,512), or entry of the virus as a virion–IgA complex by the polymeric IgA receptor (430). The initiating events of NPC pathogenesis may well be independent of EBV because the tumor usually presents in the fourth decade or later, yet the epidemiologic evidence suggests that exposure to environmental carcinogens early in life is an important factor. Inhaled particles of a particular size lodge in the fossa of Rosenmuller, the anatomic site from which NPC arises, and preneoplastic changes induced by such chronic exposure may even render cells more susceptible to latent EBV infection. Identifying preneoplastic lesions in the nasopharynx has been difficult, even in populations at high risk for NPC. One study of archival material identified two rare cases of EBER-positive NPC *in situ* (85), whereas another found six dysplastic and five carcinoma *in situ* lesions, all of which were EBV positive with a Latency II pattern of viral gene expression and uniformly expressing LMP1 by immunohistochemical staining (350). Most cases in the latter study developed frank NPC within 12 months of the original biopsy, indicating that the neoplastic process was well advanced at the time active EBV infection was detected. Whether EBV is involved at an earlier stage is not known, but other studies in Southern Chinese have detected low-grade dysplastic lesions in the nasopharynx with characteristic loss of heterozygosity at chromosomes 3p in the absence of detectable EBV infection; only higher-grade dysplastic lesions had acquired the virus (79).

The circumstantial evidence argues strongly for a role for EBV in NPC pathogenesis. Certainly, many of the tumor cell surface markers (CD40, CD54, CD70, CD80/86) are directly inducible in cultured epithelial cells by LMP1 expression (103,121), as are a number of other potentially interesting changes seen in LMP1 transfectants, notably up-regulation of the epidermal growth factor receptor (302) and of the matrix metalloproteinase MMP9 (455) as well as down-regulation of E-cadherin, leading to acquisition of a more invasive cell phenotype (128). Despite the pleiotropic nature of its effects *in vitro*, transgenic mouse studies indicate that LMP1 alone cannot push epithelial cells to full malignancy (496). Although not as well studied as yet, LMP2A could also have potentially important effects when expressed in epithelial cells, for example, through interaction with tyrosine kinase signaling pathways linked to cell adhesion molecules (407). Contributions from the other EBV proteins actually or putatively expressed in NPC cells, namely EBNA1, the BamHI A–encoded polypeptides (260a,432a), and BARF1 (488), remain possible but are as yet unsubstantiated.

OTHER LYMPHOEPITHELIOMAS AND GASTRIC CARCINOMA

Rare lymphoepitheliomas histologically similar to nonkeratinizing NPC (*undifferentiated carcinomas of nasopharyngeal type* [UCNT]) are seen at various anatomic sites. Very interestingly, when the target epithelium resembles the nasopharynx in being a foregut-derived tissue, the corresponding tumors are frequently EBER-positive. These include salivary gland carcinomas that are most common in Southern Chinese and Inuit people (205,394) as well as thymic (277), lung (500) and especially gastric (59,417) UCNT-type carcinomas. Surprisingly, in addition to these rare UCNT tumors of the stomach, about 5% to 15% of conventional gastric adenocarcinomas in human populations worldwide also carry the virus (418,454), whereas adenocarcinomas at other sites are consistently EBV-negative. Serologic assays have indicated a higher incidence of IgA anti-VCA antibodies among patients with EBV genome–positive disease than among healthy

controls or those with EBV-negative tumors, but the differences are much less marked than in the case of NPC (420).

The gastric tumors, whether of UCNT type or not, are uniformly EBER-positive throughout the malignant population and are slightly more restricted than NPC in their pattern of viral transcription; they express the Qp-initiated EBNA1 mRNA, the BamHI A RNAs, and usually also the LMP2A transcript but not LMP1 (210,447). A similar form of latency is established when EBV carrying a selectable marker is stably introduced into established virus-negative gastric carcinoma cell lines *in vitro* (512) or into primary gastric epithelial cell cultures (334). More importantly, EBV enhanced the doubling potential of these primary epithelial cells and in one case allowed the selection of clones that appear to be immortalized (334). Although the mechanism of this epithelial cell growth deregulation remains to be determined, these findings are again suggestive of an effector role for the virus in gastric carcinogenesis.

Interestingly, the EBV-positive gastric carcinomas as a group express both HLA class I and class II and show more consistent expression of CD54 and CD95 than their EBV-negative counterparts (395). EBV-positive tumors of UCNT type also show a greater infiltration of CD8+ T cells than is apparent in NPC (395), but the antigenic specificity of this infiltrate is as yet undefined (261).

TUMORS OF OTHER LINEAGES

A large range of other tumors and proliferative conditions have been examined for EBV association, usually by EBER *in situ* hybridization, with negative results in most cases. There are, however, rare exceptions worthy of mention. Apart from B cells, the only report of conventional EBV-induced cell transformation *in vitro*, albeit characterized by very slow growth, involves CR2-positive follicular dendritic cells (281). It is therefore interesting to note rare reports of EBV-positive follicular dendritic cell tumors (415) and of inflammatory “pseudotumors” composed of EBV-positive spindle-shaped cells that had markers of either follicular dendritic (413) or smooth muscle (18) origin. The latter lesions may represent earlier stages of a process that, in immunocompromised patients, culminates in EBV-positive leiomyosarcomas (265,299,473).

A second example of a situation in which EBV can be found in tumor cells involves hepatocellular carcinoma. Although hepatitis B and C viruses are much more likely to play an etiologic role in this context, a significant number of liver tumors in a recent study carried EBV DNA and expressed EBNA1 in a minority (7% to 13%) of cells in the tumor population (446). Surprisingly, these latently infected tumor cells were EBER negative, calling into question the validity of EBERs as a ubiquitous marker of latent EBV infection. As a result, the controversial question of an association between EBV and a subset of breast carcinomas, in which EBER *in situ* hybridization has given contrasting results in different laboratories (151,262), will need to be readdressed using alternative screening assays.

OVERVIEW OF MALIGNANCIES ASSOCIATED WITH EPSTEIN-BARR VIRUS

EBV is therefore now strongly linked to seven types of human malignancy, all of which satisfy two basic criteria: (a) that the viral genome is detectable as a monoclonal episome in a significant proportion of tumors of the relevant histologic subtype, and (b) that in virus-positive cases, the viral genome is present in every tumor cell. Table 2 summarizes the essential information regarding these seven tumor types, the length of the latency period between primary EBV infection (or initiation of immune suppression) and tumor development, the strength of the viral association, and the extent of viral antigen expression in tumor cells.

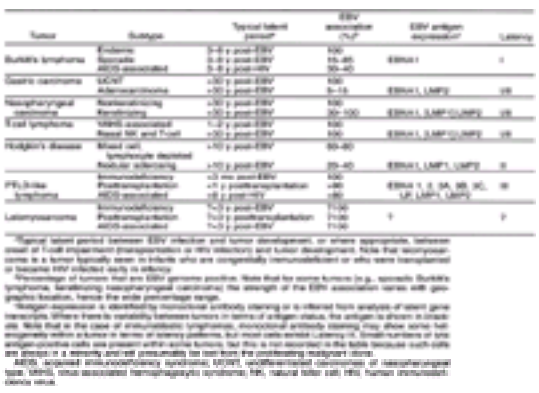

TABLE 2. *Overview of EBV-associated malignancies*

Note that the two tumor types arising in an immunocompromised setting, namely the PTLD-like lymphomas and the leiomyosarcomas, have relatively short latency periods. The lymphomas can arise in an immunodeficient patient within weeks to months of primary EBV infection and in a transplant recipient within the first year after transplantation when T-cell impairment is most marked. This reflects the fact that, in the special case of these PTLD-like lymphomas, EBV is both necessary and sufficient to induce tumor growth; the tumors are predominantly composed of EBV-transformed cells of the kind that appear transiently during all primary EBV infections but whose growth is usually curtailed by T-cell surveillance. The potential parallels between this situation and the pathogenesis of the EBV-positive leiomyosarcomas need to be explored; in that context, identification of the pattern of viral gene expression in the smooth muscle tumor cells is an important priority.

The only other virus-associated malignancy with a similarly rapid pathogenesis is the rare T-cell lymphoma that appears in young children either with an immediate history of VAHS linked to primary EBV infection or with chronic active EBV infection associated with VAHS-like symptoms. These children are not obviously immunodeficient before their EBV infection but arguably may become so as a result of the very event that underlies both VAHS and tumor development, namely an unusual level of virus entry into the T-cell system. The chronicity of VAHS-like symptoms in many patients
