The xenotropic MuLVs are viruses present as proviruses in the mouse germline but unable to infect inbred mouse cells. These viruses can infect some wild mice and mice of other species, as well as other mammals. The polytropic MuLVs are also endogenous viruses with a wide host range that includes many mammalian species. These viruses are often detected by the appearance of portions of the envelope sequences in recombinant polytropic viruses called mink cell focus-forming (MCF) viruses that arise during the replication of ecotropic viruses in mice. These MCF viruses can infect a wider range of cells than the parental viruses and can accelerate the course of leukemogenesis induced in mice by the ecotropic viruses. Xenotropic and polytropic MuLVs cross-interfere to various extents in nonmurine species and in wild Asian mice, suggesting that they might use a common receptor for infection. The mouse receptor for the polytropic viruses was cloned by gene transfer and was identified with the *Rmc1* gene (783). The human xenotropic receptor was cloned similarly (51,693). The human xenotropic receptor mediates infection by both the xenotropic and the polytropic

viruses, whereas the homologous protein of inbred mice mediates only polytropic MuLV infections. The gene encodes a membrane protein related to the yeast Syg1p protein (suppressor of yeast G alpha deletion). Its function is unknown, but its multiple membrane-spanning segments and its sequence suggest that it may act as a G-coupled receptor.

Very recently, the isolation of a distinct receptor utilized by the subgroup C FeLVs (FeLV-C) for entry into heterologous cells (590). The cDNA recovered was predicted to encode a protein with 12 membrane-spanning domains with significant sequence similarity to the D-glucarate transporters of bacteria and nematodes. The binding of virus to this receptor may be responsible for the pathogenicity, a block in erythroid differentiation.

Additional receptors for other gammaretroviruses are known to exist. Three newly characterized porcine endogenous retroviruses (PERV-A, -B, and -C) have been tested in interference assays with each other and with murine viruses using the known receptors, and all three apparently utilize distinct and novel receptors (697). The identity of these molecules is presently unknown.

Deltaretrovirus Receptors

The receptors for the delta-retroviruses are not well characterized yet. A candidate gene has been identified as a possible receptor for BLV (526,579). A determinant of the HTLV-1 receptor has been mapped to human chromosome 17 (671).

Lentivirus Receptors

The first receptor identified for any retrovirus was the CD4 molecule, established as essential for infection by HIV-1 (153,385,451). Soluble forms of CD4 can bind to virions and inhibit infection; in some strains of virus, CD4 induces release or shedding of the SU subunit from the virion. However, other strains are quite resistant to inhibition by soluble CD4. CD4 is an important surface protein on T cells, and with few exceptions it serves to define the helper subset of T cells. CD4 is also expressed at significant levels on dendritic cells, on macrophages, and on certain cells in the brain, which may be related astrocytes rather than cells of neural origin. The limited distribution of expression of CD4 accounts well for the tropism of HIV-1, largely restricted to helper T cells and macrophages. There may be other routes of entry utilized at lower efficiency: Antibody to virus, for example, can promote virus entry into cells by the Fc receptor (696).

Early work established, however, that although CD4 was sufficient to mediate virus binding to a cell surface, it was not sufficient to mediate virus infection and entry. For example, rodent cells and other cells of nonprimate origin could not be successfully infected by HIV-1 even if they were engineered to express human CD4. Searches for genes that would render such cells sensitive to virus infection ultimately led to the identification of various members of the chemokine receptor family, notably CCR5 and CXCR4, as coreceptors that were needed to mediate the postbinding step of membrane fusion and virus entry (194,233,268,660). The regions of the human coreceptors that are needed for virus entry have been identified (186,268,593,659), although, surprisingly, some HIV-1 isolates can utilize the murine CXCR4 (551). Antibodies to the coreceptor as well as the natural ligand for these molecules, the chemokines themselves, can block virus entry. Variants of simian immunodeficiency virus (SIV) and HIV-1 have been identified that are CD4-independent, needing only a chemokine receptor for infection; these viruses suggest that a chemokine receptor might have been the primary receptor for a primordial virus. A further proof of the importance of the chemokine receptor is the existence of a mutant allele of the gene encoding CCR5 in the human population, a 32-bp deletion, that confers dramatic virus resistance to homozygous individuals. More discussion of the roles of CD4 and the coreceptors in virus entry will be presented in the following chapters on HIV-1.

PENETRATION AND UNCOATING

Once virus particles have bound to the receptor, the virion and host membranes fuse together, and the virion core is delivered into the cytoplasm of the infected cell. For most retroviruses, the processes of fusion and entry are thought to be pH independent; that is, they are not dependent on an endosomal acidification step to induce a pH-dependent change in the conformation of the envelope (see, e.g., refs. 467,476, and 677). Thus, fusion can occur at the cell surface. However, there may be exceptions; early tests suggested that the ecotropic MuLVs could be inhibited from infection of some cells by drugs that block the acidification (476). This property has been mapped to the TM portion of the envelope protein (515).

It is not known whether specific uncoating steps are required before reverse transcription can begin. It is clear that the processing of the Gag precursor to the mature Gag proteins is required; immature virions are uninfectious and cannot initiate reverse transcription, and mutants that prevent particular cleavages of the Gag protein are similarly blocked. A large number of mutant viruses with other alterations in the *gag* gene have been shown to be defective in early steps of infection, before reverse transcription, but the functions of Gag proteins at this stage remain uncertain. Some of these mutations affect CA, suggesting that a mutant core may not properly open or allow the initiation of reverse transcription. Other mutations lie in NC (280), suggesting that the nucleic acid itself is bound inappropriately by the mutant protein, or again, is not properly unfolded for reverse transcription. There are also indications that host factors are important in these early stages (263). In the case of HIV-1, the host protein cyclophilin is required for the efficient initiation of reverse transcription, and Gag mutants that do not package cyclophilin cannot initiate reverse transcription (90). A plausible role for this protein is to facilitate virion disassembly. Recently, inhibitors have been used to demonstrate a role of the cytoskeleton in virus entry, and furthermore to suggest that viruses may utilize different entry pathways in different cell lines (384). Biochemical analyses of these early events are made difficult by the presence of large numbers of defective particles that are probably not on the infectious pathway and that tend to obscure the properties of the rare particles that are on this pathway.

REVERSE TRANSCRIPTION

The reverse transcription of the viral RNA genome into a double-stranded DNA form is the defining hallmark of the

retroviruses and the step from which these viruses derive their name. The course of reverse transcription is complex and highly ordered, involving the initiation of DNA synthesis at precise positions, and translocations of DNA intermediates that result in duplication of sequence blocks in the final product (reviewed in refs. 271 and 708). The major steps in the reaction are relatively well established, largely through the analysis of reactions carried out *in vitro* in purified virion particles (the so-called endogenous reaction).

Reverse transcription normally begins soon after entry of the virion core into the cytoplasm of the infected cell. The reaction takes place in a large complex, roughly resembling the virion core, and containing Gag proteins including NC, RT, IN, and the viral RNA (87). The signal that triggers the onset of DNA synthesis is not known, although it may be as simple as the exposure of the viral core to the relatively high levels of deoxyribonucleotides present in the cytoplasm. This notion is consistent with the observation that simply stripping or permeabilizing the virion membrane with detergents in the presence of deoxyribonucleotides is sufficient to induce DNA synthesis. This may also be at least part of the explanation for the difficulty HIV has in completing reverse transcription and infection in quiescent cells (794). In some cells, notably cells arrested by starvation, triphosphate levels may be low and limiting for RT, so that addition of exogenous nucleosides can stimulate viral DNA synthesis (286).

It has been recently appreciated that DNA synthesis can be initiated “prematurely” during virion assembly and release, such that virion preparations can be shown to contain small amounts of the early DNA intermediates, such as minus-strand strong-stop DNA (437,718,795,804). In most cases, the levels of these DNAs are very low, indicating that only a very small minority of the virion particles have carried out any significant synthesis. However, some circumstances affecting the rate of production and release of virions may enhance this synthesis (183). In addition, in some particular retroviruses, notably the spumaviruses, substantial DNA synthesis may occur during assembly, such that the major form of the genome found in mature virions is a partially or even completely reverse transcribed DNA molecule (493,790). These viruses thus resemble the hepadnaviruses more closely than the conventional retroviruses in the relative timing of assembly and reverse transcription.

Steps in Reverse Transcription of the Retroviral Genome

The course of reverse transcription is complex. The reaction can be broken down into a series of discrete steps (271), as presented in Figure 7.

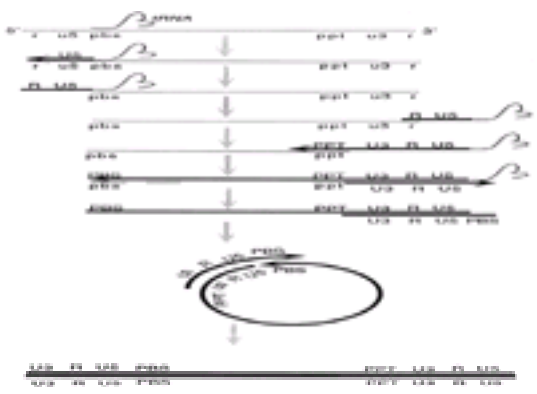

FIG. 7. The reverse transcription of the retroviral genome. *Thin lines* represent RNA; *thick lines* represent DNA. See text for details. Drawing courtesy of A. Telesnitsky.

Formation of Minus-Strand Strong-Stop DNA

The process of reverse transcription is initiated from the paired 3' OH of a primer tRNA annealed to the viral RNA genome at a complementary sequence termed the pbs. DNA is first synthesized from this primer, using the plus-strand RNA genome as template, to form minus-strand DNA sequences. Synthesis occurs toward the 5' end of the RNA to generate U5 and R sequences. The intermediate formed in this step is termed minus-strand strong-stop DNA. The primer tRNA remains attached to its 5' end.

First Translocation

The next step involves the translocation, or “jump,” of the strong-stop DNA from the 5' to the 3' end of the genome. This translocation requires the degradation of those 5' RNA sequences that were placed in RNA:DNA hybrid form by the formation of strong-stop DNA. The degradation is mediated by the RNase H activity of RT; mutants with altered RNase H activity do not mediate the translocation (71,702). This step exposes the single-stranded DNA and facilitates its annealing to the R sequences at the 3' end of the genome. Normally, a full-length strong-stop DNA, synthesized by copying to the 5' cap of the RNA, performs the translocation (404), although incomplete molecules can jump at low efficiency. Specific sequences or structures in or near the R region are required for efficient jumping (14,716). The NC protein may facilitate the transfer step. Although there have been reports that jumping is always in *trans,* from one RNA template to the other RNA in the virion, the best evidence is that minus-strand strong-stop jumping goes randomly to either RNA (788).

Long Minus-Strand DNA Synthesis

The annealing of minus-strand strong-stop DNA recreates a suitable primer-template structure for DNA synthesis, and RT can now continue to elongate the minus-strand strong-stop DNA to form long minus-strand products. Synthesis ends in the vicinity of the pbs. As the genome enters RNA:DNA hybrid form, the RNA becomes susceptible to RNase H action

and is degraded.

Initiation of Plus-Strand DNA Synthesis

The primer for plus-strand synthesis is created by the digestion of the genomic RNA by RNase H. A particular short, purine-rich sequence near the 3' end of the genome, the ppt, is relatively resistant to the activity of RNase H. The oligonucleotide remains hybridized to the minus-strand DNA and serves as the primer for synthesis of the plus-strand DNA, using the minus-strand DNA as template. Sequences upstream of the ppt, an AT-rich region called the T-box, are also important for proper priming (333,621). The primer, once it has served to initiate DNA synthesis, is quickly removed from the DNA, presumably by RNase H action. Synthesis proceeds toward the 5' end of the minus strand, first copying the U3, R, and U5 sequences, and then extending to copy a portion of the primer tRNA still present at its 5' end. Elongation stops at a modified base normally found at position 19 of the tRNA. The resulting intermediate is termed plus-strand strong-stop DNA.

In some viruses, secondary plus-strand initiation sites are used. There may be multiple RNA primers generated from the RNA genome by the nuclease action of RNase H that can initiate DNA synthesis at dispersed heterogeneous sites. In the case of the lentiviruses and spumaviruses, a second copy of the ppt sequence near the center of the genome is used at high efficiency and is important for proper completion of reverse transcription (112).

Removal of tRNA

In the next step, the primer tRNA at the 5' end of the minus-strand DNA is removed by RNase H. Its removal may occur in two stages, with an initial cleavage near the RNA–DNA junction and a second one within the tRNA. The cleavage need not occur exactly at the RNA–DNA junction, and a single ribonucleotide base (A) is normally left on the 5' terminus of the minus strand (588,646,664,758) without affecting subsequent processes. The sequence of bases near the junction can significantly modulate the cleavage by RNase H (663). Recent experiments indicate that the posttranscriptional modifications present in the natural tRNA may be important for proper recognition by RT and for plus-strand strong-stop translocation (37).

The Second Translocation

The removal of the tRNA exposes the 3' end of the plus-strand strong-stop DNA to permit its pairing with the 3' end of the minus-strand DNA. The sequences anneal via the shared pbs sequences. This annealing forms a circular intermediate, with both 3' termini in a suitable structure for elongation.

Completion of Both Strands

Both strands are now elongated. The final extension of the minus-strand DNA is coupled to displacement of the plus-strand strong-stop DNA from the 5' end of the minus strand; as minus-strand elongation occurs, the plus-strand strong stop is peeled away and transferred to the 3' end of the minus strand. At the end of this elongation, the circle is opened up into a linear DNA. The plus strands are all extended, and displacement synthesis may occur to remove short DNAs and make longer plus-strand DNAs (372). Any internally primed plus-strand DNAs may be prevented from participating in strong-stop translocation simply by kinetics; the normal plus-strand strong-stop DNA may simply form first, and elongation to transfer it to the minus strand may occur before it could be displaced by any plus-strand elongation (88). Finally, the plus-strand strong-stop DNA is extended to complete the plus strand.

When multiple plus-strand initiation events occur, the completed plus strand will consist of adjacent fragments and so contain nicks or discontinuities. Displacement synthesis by an upstream fragment can slowly displace downstream RNAs and DNAs, leading to longer plus strands (372). However, some nicks or gaps may persist in the final double-stranded product. These breaks may be at heterogeneous positions, although strong sites of plus-strand initiation, such as the one at the central ppt of lentiviruses, can lead to specific sites for such discontinuities. Sequences near the central ppt of the lentiviruses cause termination of synthesis during elongation from upstream primers, thus ensuring the maintenance of a discontinuity at this site (113). This site retains a partially displaced sequence or overlap of a few nucleotides—99 nt in the case of HIV-1. The structure has been shown to persist even to the time of integration of the DNA into the cell. Host DNA repair processes ultimately correct all such discontinuities.

Although most of the viral DNA is made in the cytoplasm, it may not always be completed in the cytoplasm. For some viruses, completion of the two DNA strands may occur only after entry into the nucleus (415). Specific mutants with alterations in the Cys-His residues of the NC protein show an interesting phenotype: the formation of linear DNA with heterogeneous and truncated ends (282). These experiments suggest that NC plays a role in the completion, or the stabilization of the ends, of the viral DNA.

A key consequence of the two translocation events that occur during reverse transcription is the duplication of sequences—duplication of U5 during minus-strand strong-stop DNA translocation, and of U3 during plus-strand strong-stop DNA translocation. The resulting DNA contains two LTRs that are assembled during reverse transcription. Each LTR consists of the sequence blocks U3-R-U5. The positions of the LTR edges—the left edge of U3 and the right edge of U5—are determined by the sites of initiation of DNA synthesis for the two DNA strands. Thus, the terminal sequences of the complete DNA molecule are also determined by these sites of initiation. These sequences for most viruses are perfect or imperfect inverted repeats, and they serve an important role during integration of the DNA (see later).

Biochemistry and Structure of Reverse Transcriptase

The enzyme that mediates the complex series of events outlined above is RT, one of the most famous of the viral polymerases (44, and reviewed in ref. 661). All RTs contain two separate activities present in two separate domains: a

DNA polymerase able to incorporate deoxyribonucleotides on either an RNA or a DNA template, and an RNase H activity able to degrade RNA only in duplex form. These two activities are responsible for the various steps of reverse transcription. Two distinct domains of the enzyme contain these two activities: an aminoterminal domain contains the DNA polymerase, and a carboxyterminal domain contains the RNase H activity (700). Whereas isolated domains can be shown to exhibit either one of the two activities separately, an intact enzyme is required for full activity and specificity. However, the two functions can be provided by two mutant RT molecules so long as they are co-incorporated into a single virion (707).

DNA Polymerase

The DNA polymerase activity is similar to that of all host and viral DNA polymerases in requiring a primer, which can be either RNA or DNA, and a template, which can also be either RNA or DNA. RTs incorporate dXTPs to a growing 3' OH end with release of inorganic pyrophosphate (PPi), and they require divalent cations, usually Mg^{2+}. The primer must contain a 3' OH end that is paired with the template. RTs cannot perform nick-translation reactions, but they can efficiently perform strand displacement synthesis. The only fundamental way in which RTs are unusual among the DNA polymerases is that they exhibit comparable specific activity on either DNA or RNA templates.

RTs are readily obtained from purified virion particles, and they can be even more easily prepared as recombinant proteins expressed in bacteria. RTs are relatively slow DNA polymerases, under standard conditions incorporating only 1 to 100 nucleotides per second, depending on the template. Further, they exhibit poor processivity, and tend to release primer-template frequently *in vitro*. The enzyme must then rebind to the substrate to continue synthesis. Secondary structures in RNA templates can strongly enhance the pausing of RT and its tendency to release from the template (298). The enzyme also exhibits low fidelity, and although the values of the error rate vary widely with the primer (533), template (374,378), and type of assay, the misincorporation rate of most RTs under physiologic conditions is on the order of 10^{-4} errors per base incorporated. This rate suggests that during replication there would be approximately one mutation per genome per reverse transcription cycle. Indeed, the mutation rate observed *in vivo* is roughly consistent with this high error rate (101,184,380,496,654), although fidelity *in vivo* may be somewhat better than *in vitro* (461). Drug-resistant variants that do not incorporate chain-terminating analogs are often found to exhibit higher fidelity, perhaps because they require a more precise fit for the correct incoming triphosphate to allow for discrimination against the analog. A wide range of types of mutations are created by RT errors, and both the type and the frequency of appearance of each type of mutation exhibit a complex dependence on sequences and structures in the template (54,553,554).

RTs do not generally exhibit a proofreading nuclease activity (52), and misincorporated bases are not removed efficiently by most RTs as they are by host DNA polymerases. Very recently, however, mutants of the HIV-1 RT resistant to azidothymidine (AZT) have been shown to exhibit an enhanced ability to remove the incorporated AZT moiety at the 3' end through a pyrophosphorolysis reaction (486). Thus, it is possible for RT to remove some such analogs and rescue a terminated chain for continued elongation.

RNase H

The RNase H of RT is an endonuclease that releases oligonucleotides with a 3' OH and a 5' PO_4. This property allows the products of RNase H action to serve as primers for initiation of DNA synthesis by the DNA polymerase function of RT. There is an obligate requirement that the RNA be in duplex form, normally an RNA–DNA hybrid. However, retroviral RTs are also able to degrade RNA–RNA duplexes (57,70), an activity termed RNaseH* (318). The RNase H enzyme is capable of acting on the RNA of a template in concert with the polymerase as it moves along a nucleic acid, and as it does so its active site is located about 17 to 18 bp behind the growing 3' end (279). RNase H can also act independently of polymerization. All RNase H activity requires a divalent cation.

Subunit Structures

RT is incorporated into the virion particle during assembly in the form of a large Gag-Pol precursor (see later), and it is released by proteolytic processing of the precursor during virion maturation. Different viruses make somewhat different cleavages in the precursor, and thus the RTs exhibit several different subunit structures (see later). In the gammaretroviruses, RT is a simple monomer in solution, corresponding only to the aminoterminal DNA polymerase and the carboxyterminal RNase H domains. These two domains can be expressed separately, and the isolated proteins exhibit their respective activities (700), although the specificity of the RNase H is affected by this separation. There is some evidence, however, that while bound to the substrate and carrying out DNA synthesis, this RT may act as a dimer (706). In the avian viruses, the RT is present as an ab heterodimer, composed of a smaller a subunit containing the DNA polymerase and RNase H domains, and a larger b subunit containing these two domains but also retaining the IN domain. In the lentiviruses, RT is again a heterodimer with a larger subunit (p66) containing the DNA polymerase and RNase H domains, and a smaller subunit (p51) lacking RNase H. The properties of the different enzymes as DNA polymerases are very similar in spite of these different subunit structures, and so the significance of these various compositions for RT function is unclear.

Crystal Structures

The three-dimensional structures of a number of RTs have been determined by x-ray crystallographic studies. Structures of the unliganded HIV-1 RT (320,622), RT bound to nonnucleoside RT inhibitors (160,174,391,605), RT bound to an RNA pseudoknot inhibitor (343), and RT bound to a duplex oligonucleotide (28,324,341,342), as well as the isolated RNase H domain (163), have all been reported. The two subunits are folded quite differently, so the overall structure is highly asymmetric. The structure of the p66 is similar to that of a right hand, with fingers, palm, and thumb domains all named on the basis of their position in the structure (Fig. 8). The nucleic acid lies in the grip of the hand, held by the fingers and thumb. The YXDD motif present at the active site for the DNA polymerase lies at the base of the palm. The RNase H domain is attached to the hand at the wrist. The p51 subunit, while made up of the same domains as the aminoterminal part of p66, is folded differently and lies under the hand, not making direct contact with the nucleic acid and so not

thought to participate in the chemistry. The structure of p66 with and without a liganded nucleic acid is quite different, with the thumb domain flexing to allow substrate binding. Theoretical considerations suggest the thumb may move during elongation (41). A structure of the fingers and palm subdomain of the MMLV RT at very high resolution (269) has also been determined.

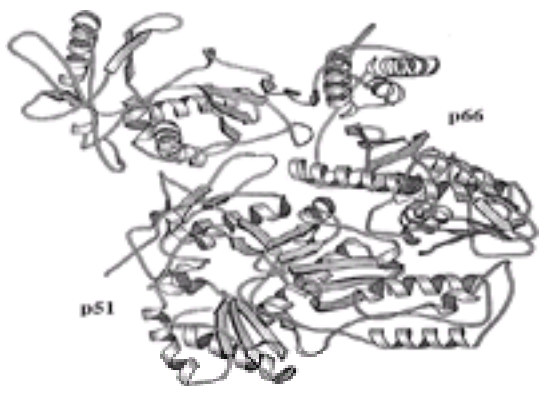

FIG. 8. A ribbon diagram of the heterodimeric reverse transcriptase of HIV-1, showing the p66 (*top*) and p51 (*bottom*) subunits. The molecule is arranged in the conventional orientation to show its similarity to the human right hand, palm up. The image was generated by Hans-Erik G. Aronson (Department of Biochemistry and Molecular Biophysics, Columbia University) using MOLSCRIPT (396). The HIV RT coordinates used to draw the image were retrieved as file 1VRT.pdb from the Research Collaboratory for Structural Bioinformatics (RCSB) Protein Data Bank (PDB) (http://www.rcsb.org/pdb). HIV RT secondary structural elements were defined according to the header (HELIX and SHEET records) of the coordinate file. The structure as solved was originally a complex of RT and the inhibitor nevirapine (604).

Inhibitors

RT is a major target of antiviral drugs useful in the treatment of retroviral diseases such as AIDS. All such drugs used to date are inhibitors of the DNA polymerase activity of RT, and they fall into two classes: nucleoside analog inhibitors (chain terminators) and nonnucleoside RT inhibitors (NNRTIs). The nucleoside analogs are typically precursors and need to be activated by phosphorylation to the triphosphate form. These are then incorporated by RT into the growing chain, and they serve to block further elongation. Examples include AZT, ddC, ddI, d4T, and 3TC. The NNRTIs are a group of compounds that are structurally diverse but nevertheless interact with a common binding pocket in RT to prevent its normal activity (724). There are indications that the binding may inhibit the enzyme's flexibility. For both classes of inhibitors, monotherapy with a single drug selects for drug-resistant variants that quickly predominate in the virus population, and for each drug, a pattern of mutations has been identified that serves to indicate the appearance of drug resistance (411). In many cases, these mutations alter the binding site for the nucleoside or NNRTI such that the drug cannot bind and so cannot inhibit the enzyme. In the case of AZT, however, the mutations do not prevent the binding and incorporation of AZT-triphosphate into the growing chain but rather seem to activate a reverse reaction in which the AZT nucleotide is removed from the chain, subsequently permitting normal elongation (486). Combination therapy, typically involving the simultaneous treatment with three different drugs, can suppress virus replication to such an extent that variants resistant to all the drugs do not appear, at least for months or years.

RECOMBINATION

The process of reverse transcription could in principle take place using a single template RNA molecule. In fact, however, retrovirions contain two copies of the RNA genome copackaged into one particle, and the course of reverse transcription typically makes use of both RNAs (322,686). Recombination occurs between homologous sequences in the two RNAs (170,562), and it happens normally at a surprisingly high frequency, perhaps once per replication event per genome on average (799). Normally the two RNAs in a virion are identical, so that homologous recombination events are invisible and without consequence. When the two RNAs are distinct, however, as when they derive from two viruses or viral strains, the result is a very high frequency of recombination between them among the resulting proviral DNAs. Thus, physical markers and genetic markers recombine rapidly whenever the two genomes are copackaged into one virion and so are coextant during a single round of reverse transcription. The frequency is highly dependent on the sequence and structure of the RNA in the region undergoing recombination (19). Similar recombination does not occur at high frequency when cells are co-infected simultaneously with two separate virus preparations, suggesting that each virus particle performs its own reverse transcription reaction in the cytoplasm in *cis*, and does not freely exchange RNAs with other reactions happening in the same cell.

Models for Recombination

Two mechanisms can provide for recombination between two genomes. In one, the copy choice model, recombination occurs during minus-strand synthesis. As RT proceeds along an RNA, it has the potential to carry out a template switch in which an incomplete DNA copied from one template serves to prime further elongation on the other RNA molecule (447,561). Pausing may enhance this transfer, and structural features in the RNA may act as hot spots for such recombination. A break in an RNA genome, which may be encountered often, would cause a “forced copy choice”; transfer to the other RNA would rescue an otherwise dead virus, and this may represent the major evolutionary basis for high-frequency recombination in the viruses. The RNase H activity of RT may help release an incomplete DNA and so promote its serving as primer on the new template, and NC may also facilitate the reaction (510).

In the other model, the strand-displacement assimilation model, recombination may occur during plus-strand synthesis.

When multiple plus-strand fragments are elongating on the minus-strand template, strand displacement can expose the 5' end of such fragments. If a second minus-strand DNA has been synthesized, these can then pair with this other minus-strand DNA to form a bridged “H” structure as intermediates; further synthesis and repair would lead to the transfer of sequences to the new DNA (353). These H structures are visible in electron micrographs of the nucleic acids from reverse transcription reactions. However, it is not clear how often this mechanism is used. The general inefficiency of reverse transcription dictates that two minus-strand DNAs may not always be available in one virion to permit this latter process, so it may be infrequent.

When a recombination event occurs, there is a nonrandom increase in the probability that another recombination will occur nearby—a phenomenon called negative interference (20,323). This suggests that RT or the genomes may become recombination prone at specific times. When multiple recombination events occur, the resulting DNA is a patchwork of the sequences derived from the two input RNAs.

The translocation of the strong-stop DNAs provides a special opportunity for recombination between the two viral genomes. When the minus-strand strong-stop DNA is formed, it has the potential to translocate from the 5' end of its template to the 3' end of either RNA molecule; although this event has been reported to occur strictly in *cis*, or strictly in *trans*, it most likely occurs randomly. Similarly, when plus-strand strong-stop DNA is formed, it too could in principle translocate to the 3' of either minus strand. However, this translocation seems most often to occur in *cis*, perhaps simply because the frequency with which two long minus-strand DNAs are formed, and so are available to serve as acceptors, is low.

Recombination between two RNAs during reverse transcription can also occur between nonhomologous sites at lower frequency. Reconstructions suggest that these events are perhaps 100 to 1,000 times less frequent than homologous recombination. These events can result in duplications or deletions in the DNA product of the reaction. Furthermore, if nonviral RNAs or chimeric RNAs containing viral and nonviral sequences are packaged into virions, such nonhomologous recombination events can create new joints and link a viral sequence to the nonviral sequences. These events are thought to play a central role in the process of transduction of cellular genes, and most importantly during the formation of acute oncogenic retroviral genomes (see later).

INTEGRATION OF THE PROVIRAL DNA

The integration of the linear retroviral DNA, like reverse transcription, is a crucial feature of the retroviral life cycle. Integration is required for efficient replication of most retroviruses; mutants that are unable to integrate do not establish a spreading infection. The orderly and efficient integration of viral DNA is also unique to the retroviruses. Although infection by some DNA viruses can result in the integration of viral DNA fragments into the host genome at low efficiency, these events are not the result of specific viral functions. Further, the establishment of the integrated provirus is responsible for much of retroviral biology. It accounts for the ability of the viruses to persist in the infected cell, for their ability to permanently enter the germline, and for the mutagenic and oncogenic activities of the leukemia viruses.

Once the provirus is established, the DNA is permanently incorporated into the genome of the infected cell. There is no mechanism by which it can be efficiently eliminated. At very low frequencies, homologous recombination between the two LTRs can delete most of the provirus, but even here a single (“solo”) LTR remains (736). As the host cell divides, the provirus is transmitted to daughter cells as a new Mendelian locus. Thus, it is likely to persist in the cell for its normal life span, and to convert the cell permanently to a chronic producer of progeny virus.

Unintegrated DNA Forms

The product of the reverse transcription reaction, as outlined earlier, is a full-length double-stranded linear DNA version of the genome, flanked at each end by copies of the LTR. The next step is the movement of the DNA into the nucleus, and the appearance two new DNA forms: closed circular molecules containing either one or two tandem copies of the LTR (Fig. 9). A small amount of the one-LTR circle may be formed during reverse transcription (see preceding), but the bulk is thought to be formed by homologous recombination between the two LTRs of the linear DNA. Little is known about the requirements for the formation of circles, although recently, mutants with alterations in portions of the MuLV Gag p12 protein have been shown to be blocked after synthesis of the linear DNA and before formation of circles (793). The tandem two-LTR circles are apparently formed by the blunt-end ligation of the termini of the linear DNA. This event creates a unique sequence, termed the LTR–LTR junction, that is often used as a hallmark of nuclear entry of the viral DNA. The joints are often imperfect, with loss of nucleotides from one or both termini at the joint (664,758). There are also some circles that arise by autointegration of the ends of the linear DNA into internal sites, forming DNAs with deletions or inversions (658); these circles are generally nonfunctional in terms of generating progeny virus.

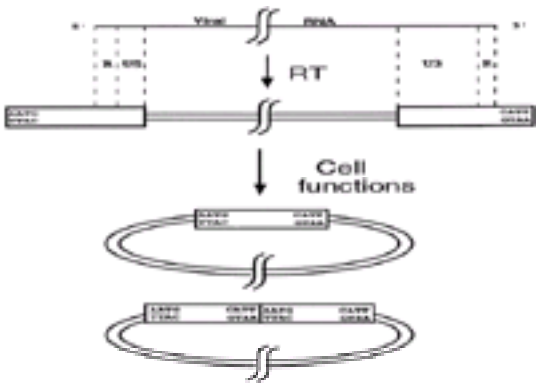

FIG. 9. Unintegrated DNA structures formed after retroviral infection. The incoming RNA genome (*top*) is converted by RT to a double-stranded linear DNA containing two LTRs (*boxes*) in the cytoplasm. The termini of the DNA consist of short inverted repeats and always contain a conserved CA dinucleotide near the 3' ends; the 3' terminal sequences of the

MLVs (CATT) are shown. The linear DNA is then localized to the nucleus, and two circular double-stranded DNAs are formed: a circle containing one LTR, and a circle containing two tandem LTRs. The LTR–LTR junction contains a unique inverted repeat sequence.

Because three distinct unintegrated DNA forms coexist in the nucleus, it was uncertain for many years which form might serve as the precursor for establishment of the integrated provirus. In spite of prejudices based on such precedents as phage lambda, it is now clear that circles are not efficient substrates in the integration reaction (206,427), and that the immediate precursor for the integration reaction is the linear duplex DNA. The circles are apparently dead-end products of a side reaction, formed by host enzymes acting on linear DNAs that have failed to integrate. There are settings and cell types in which unintegrated viral DNAs are observed to accumulate to high levels; various tissues in human HIV disease show considerable circular DNAs. While this DNA may reflect some unusual processing of the DNA, much of it is probably formed simply by massive infection occurring shortly before the DNA is harvested (620).

The unintegrated DNA is not a good substrate for forward transcription (636), perhaps because it is still retained in a complex that is poorly accessible to RNA polymerase. Mutant viruses that cannot integrate are unable to establish an efficient spreading infection, although low levels of virus can be produced (649). A very small subset of cells infected with such integration-defective mutants do integrate viral sequences through nonviral means, creating oligomeric tandem repeats similar to those formed after naked DNA-mediated transformation (294).

Entry into the Nucleus

A key step that must take place before integration can occur is the entry of the viral DNA into the nucleus. The mechanisms of nuclear entry are largely unknown, but there are probably at least two distinct routes used by different retroviruses. The simple retroviruses show a profound requirement for passage through mitosis for successful establishment of the integrated provirus (420,489,624,735), and the block in nondividing cells is at or close to the step of nuclear entry. Tests of the state of the viral DNA in nondividing cells are consistent with the notion that the preintegration complex must await the breakdown of the nuclear membrane to have access to the cellular DNA. Infection of nondividing cells results in the accumulation of linear double-stranded DNA in the cytoplasm, and no further signs of infection. The viral DNA will persist in the cell for some time, and if the cell is stimulated to undergo division, the viral DNA will integrate and infection will proceed. However, the DNA loses its capacity to become activated in this way fairly rapidly (23,489). The restriction is quantitatively very significant, and it profoundly limits the utility of simple retroviral vectors for gene therapy.

In contrast, the lentiviruses and spumaviruses are able to successfully infect nondividing cells, and thus there must be an active transport of the viral DNA through an intact nuclear membrane (100,419,635,752). This capability has made lentiviruses very attractive as gene delivery vectors for gene therapy applications. The molecular basis for this capability is a subject of great controversy. The lentiviral MA and Vpr proteins have been argued as essential for the infection of nondividing cells (257,507,513,743), and the phosphorylation of MA has been argued as necessary to promote dissociation from the membrane and allow nuclear import (99,106,258,259). These findings have not been universally confirmed (247,248,392), however, and the role of MA in these steps is uncertain. Similarly, it has been shown that the Vpr protein is present in the preintegration complex and can bind to nucleoporin components that may mediate nuclear import. However, here too universal support for this model has not been forthcoming. DNA structures present at the second internal copy of the ppt have also been suggested as important for infection of nondividing cells (798). Another attractive model is that the IN protein might be involved in the nuclear import of the complex. IN itself contains nuclear localization signals (257,401), and these can function to target ectopically expressed IN to the nucleus, but it is not clear whether this is related to preintegration complex (PIC) nuclear import or nuclear retention. The foamy viruses may have a distinctive route of nuclear entry involving microtubular transport and centrosomal association, but the mechanism is not well understood (635).

Structure of the Provirus

An important aspect of retroviral integration that distinguishes the process from nonviral or other viral mechanisms of DNA integration is the fact that the insertions create a consistent provirus structure. The integrated provirus is collinear with the product of reverse transcription, and it consists of a 5' LTR, the intervening viral sequences, and a 3' LTR, inserted cleanly into host sequences. The joints between host and viral DNA are always at the same sites, very near the edges of the viral LTRs. Compared to the unintegrated linear DNA, there is a loss of a small number of bps, usually two, from each terminus of the viral DNA; and there is a duplication of a small number of bps of host DNA initially present once at the site of insertion that flank the provirus (Fig. 10). The number of bps duplicated is characteristic of each virus and ranges from four to six.

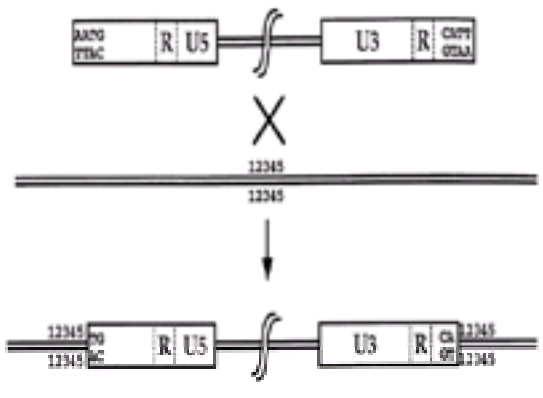

FIG. 10. Integration of the viral DNA to form the provirus. The precursor for the formation of the provirus is a linear double-stranded DNA containing two LTRs (boxes) and with inverted repeat sequences at the termini. The target site in the host DNA is indicated by the arbitrary sequence block denoted 12345. Integration occurs by joining the 38 CA dinucleotides near the termini to the target DNA. The reaction is associated with loss of two bps at the termini of the viral DNA, and with duplication of a small number of bps (five shown here) initially present only once in the target DNA.

Biochemistry of Integration

The actual integration of the viral DNA into a target is mediated *in vivo* by the viral IN protein (540,591,649), which is brought into the cell inside the virion and acts to insert the linear DNA into the host chromosome. Some IN functions have been studied by analysis of viral DNA formed *in vivo* (630). Most of our understanding of IN function, however, has been obtained through analysis of *in vitro* integration reactions, first using complexes extracted from infected cells (96,256), and later using recombinant IN protein. The reaction proceeds in two steps: 3' end processing and strand transfer. A schematic view of these reactions is shown in Figure 11.

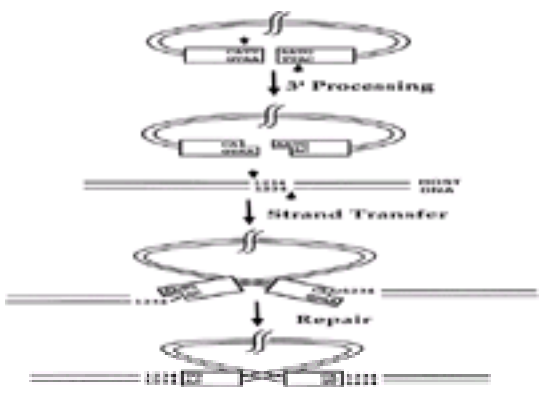

FIG. 11. Steps in the integration of the viral DNA. The full-length linear DNA (*top*) is processed by the viral integrase by the endonucleolytic removal of dinucleotides at the 3' termini. The resulting DNA is then used in a strand transfer reaction in which the 3' OH ends make staggered breaks in the two strands of the target site DNA. The resulting gapped intermediate is presumably repaired by host enzymes.

3'-End Processing

In the first step, the two terminal nucleotides at the 3' ends of the blunt-ended linear DNA are removed by the IN to produce recessed 3' ends and correspondingly protruding 5' ends. This cleavage occurs endonucleolytically at a highly conserved CA sequence, and it releases a dinucleotide. For most viruses, the terminal sequence is such that a TT dinucleotide is released, although this rule has exceptions. The ends do not remain covalently bound to protein, and the energy of the hydrolyzed phosphodiester bond is not retained.

Strand Transfer

In the second step, the 3' OH ends created by processing are used in a strand transfer reaction to attack the phosphodiester bonds of the target DNA (256). The attack occurs by an Sn2-type reaction, with inversion of the phosphorus center as detected with chiral labeling of the phosphate (213). The formation of the new phosphodiester bond between the viral end and the host DNA displaces one of the phosphodiester bonds in the host DNA, leaving a nick. The protruding 5' end of the viral DNA is not joined to the host DNA by IN. The reaction is a direct transesterification, and so no ATP or other energy source is required. Mutational studies strongly suggest that the two activities—processing and joining—utilize the same active site residues. In fact the two steps involve similar chemistry: 3'-end processing is an attack on DNA by a hydroxyl residue of water, while joining is an attack on DNA by a 3' hydroxyl residue of another DNA. It should be noted that other hydroxyl residues can participate; alcohols such as glycerol can be utilized (740), and the 3' OH of a DNA can even attack a phosphodiester bond on the same DNA, forming a cyclic product (213).

Disintegration

The IN protein exhibits a third enzymatic activity *in vitro*: a reversal of the integration reaction known as disintegration (118). This activity releases DNA from a branched structure and seals the nick at the site of the branch. The significance of the activity *in vivo* is uncertain.

Target Site Duplication

In a wild-type virus, when the two ends are joined to the two strands of the target DNA, the two sites of attack are staggered by a few bps. After the joining, the resulting structure contains short gaps in the host DNA and unpaired bases from each 5' end of the viral DNA. The 5' ends of the viral DNA are not joined to host DNA by any known activities of IN. However, the 5' ends are very quickly repaired *in vivo*, almost as quickly as the initial integration reaction (623). These discontinuities are presumed to be repaired by the host repair enzymes, although it is possible that the viral RT or IN

could participate. Indeed, the IN protein has been suggested to manifest a DNA polymerase activity that might fill in the gaps. The processing and filling in the gaps creates a short duplication of sequence that was present only once at the target site; these duplications flank the integrated provirus. The number of bases duplicated is characteristic of each virus. Thus, the murine and feline viruses cause a four-bp duplication; HIV-1 causes a five-bp duplication; and the avian viruses cause a six-bp duplication.

Viral *att* Sites

The sequences at the termini of the viral DNA, the *att* sites, are recognized by the viral IN protein and are important for end processing and joining (103,125,131,739). These terminal sequences are imperfect inverted repeats. The most conserved residues are a CA dinucleotide pair that lies near the 3' terminus and determines the site of 3' processing. Although these bases are absolutely conserved among all the retroviruses, and among many transposable elements, small changes can be tolerated, and mutants can utilize TA or CG relatively well (134). Sequences upstream from the CA for perhaps 10 to 12 bp are needed for efficient integration, but these sequences are different for different viruses, with no indication of broadly conserved sequence motifs. Since the two termini of any given virus are somewhat different, they usually show differential efficiency of utilization in various assays (472). The fact that two distinct ends are bound together in a complex may be important for the concerted integration of these ends into the target (744).

The sequence-specific binding to the *att* site is probably performed by the core domain of IN (367). The nonspecific DNA binding activity of IN has made it difficult to detect sequence-specific binding to these regions, although under some conditions preferential binding to the authentic sequences can be demonstrated (217). A demonstration that an IN mutation can compensate for a mutation in the DNA termini provides nice evidence for the delicate interaction between IN and the DNA termini (188).

Both 3'-processing and strand-transfer reactions are concerted reactions *in vivo*. The processing step occurs simultaneously at both termini of the viral DNA and requires the correct sequences at both termini. Thus, a mutation altering the sequence at one end of the viral DNA blocks the processing reaction at both ends (504). This result suggests strongly that the reaction requires both termini to be loaded into a complex before hydrolysis proceeds. Similarly, the strand transfer reaction normally occurs so that both ends are joined to the target DNA, and at a fixed spacing between the two sites along the DNA helix. The 3'-processing and strand-transfer reactions can both be carried out *in vitro* using native PICs, extracted from recently infected cells, and these reactions reconstruct the concerted nature of the *in vivo* reactions. Alternatively, integration can be performed using artificial DNA constructs and recombinant IN protein. However, these systems typically mediate only a half-reaction—that is, the uncoupled processing of one viral terminus and its joining into a single target DNA. Recent efforts have led to the identification of conditions and factors that can mediate formation of a complex and enhance concerted joining (8,240,745). Once such a protein–nucleic acid complex is formed, it is quite stable.

Structure of the Integrase

The IN protein consists of three distinct domains: an N-terminal region containing an HHCC zinc-finger motif; a central catalytic core containing the so-called D,D-35-E motif; and a less well conserved C-terminal region. The IN protein is a multimer: It readily dimerizes, and at high concentration it forms tetramers as well. All three regions may be involved in the multimerization of IN (21) and in DNA binding (448,503). Many of the residues important for enzymatic activities have been identified by mutagenesis. The most crucial residues for catalysis are the acidic amino acids in the D,D-35-E motif, a highly conserved array of three residues in the core region of many INs and transposases (403). Mutants indicate that both the N-and the C-terminus are also important for function. Surprisingly, pairs of IN mutants with alterations in different regions of the molecule can complement to restore normal function (212,732). The separate N-terminal domain can even complement a nonoverlapping fragment, suggesting that these domains can still coassemble into a functional oligomeric complex (780).

The structures of the HIV-1 and avian virus IN cores have been determined by x-ray crystallography (98,192,275,452), revealing a compact dimer with similarity to prokaryotic recombination enzymes and RNase H (781). The structures of the N- and C-terminal domains have been determined by nuclear magnetic resonance (NMR) (105,199,200,433). The structures can be partially merged into a complete molecule (22), but the models do not yet provide a clear picture of the binding sites for viral or host DNAs or the mechanism of the reaction. Indeed, the likely active sites are not located at positions in the dimeric molecule that could mediate concerted integration of two termini into a single target DNA. Cross-linking studies have helped the development of some models for the interaction of IN with DNA (309). We note that the avian IN is phosphorylated at a carboxyterminal serine (316), but the significance of this modification is not clear.

Preintegration Complex

IN does not normally act alone, and a large complex of proteins and nucleic acid is responsible for mediating the formation of the provirus *in vivo* (87,115,224). The nature and components of the PIC, or intasome, are not known in any detail for either the simple or the complex viruses. The PIC of the simple viruses seems to contain CA, RT, and IN, but other viral proteins may be present (87). Many of these proteins probably stay with the DNA even after entry into the nucleus (617). The PICs of the complex viruses do not contain detectable CA but instead contain MA, NC, Vpr, RT, and IN (492). Thus, the PICs of these viruses may be very different, consistent with their very distinctive ability to infect nondividing cells. Normal PICs apparently contain a large structure covering the two ends of the DNA, and perhaps holding them in proximity. The formation of this structure, detected as a footprint in a modified nuclease sensitivity assay (750), requires both IN and the correct sequences at the termini of the DNA (751).

Host Proteins and Integration

A number of host proteins have been recently identified as potentially involved in the establishment of the provirus. One such protein, Ini1, was recovered in a yeast two-hybrid screen as interacting with the HIV-1 IN protein (356). This protein

binds to IN and can enhance its activity *in vitro*. Ini1 is the human homolog of the yeast Snf5 protein, a component of the SNF/SWI complex involved in chromatin remodeling, and the interaction of IN with this complex raises the possibility of several contributions it may make to the course of integration. Ini1 is not present in the virion but associates with the PIC in the early phase of the life cycle. Another such protein is BAF-1, a low-molecular-weight protein recovered from the MuLV PIC for its ability to inhibit autointegration of the LTR edges into internal sites in the viral DNA (413,414). By inhibiting this reaction, BAF-1 can enhance normal integration into target DNAs in trans. The structure of BAF-1 has been recently determined by NMR, leading to models for its ability to bind and condense DNA (104). Other proteins include the high mobility group (HMG) proteins, important in transcriptional regulation at many promoters and found to dramatically stimulate concerted integration of the two LTRs into a target DNA *in vitro* (311); and HMG I(Y), similarly important in forming protein complexes on promoters, and stimulating both overall and concerted integration *in vitro* (223,421). The viral NC protein also exhibits similar activity (109). The relative importance of these and other proteins in modifying the integration reaction remains uncertain.

Recently, the integration of retroviral DNA has been shown to activate an apoptotic program in cells deficient in the DNA-stimulated protein kinase (DNA-PK), an enzyme implicated in the DNA damage response and required for the proper rearrangement of immunoglobulin gene and T-cell receptor gene segments in lymphocyte precursors (156). Although it is not clear whether DNA-PK plays any direct role in integration, the enzyme must be involved in sensing the products of active IN and responding to the damage. Its absence leads to substantial cell death in cells exposed to an active IN.

Distribution of Integration Sites

An important issue affecting the ability of the retroviruses to create mutations is the distribution of integration sites in the host genome. Proviruses are probably inserted at nearly random locations in the genome, with no or little sequence specificity, and thus have the opportunity to create mutations in any gene. Various studies, however, have suggested some deviations from a completely random distribution. Some potential targets for insertional mutagenesis seem to be less often disrupted after infection than predicted for truly random distribution of integration sites (383), suggesting that there may be “cold spots.” There may be some modest preference for transcriptionally active genes (498,643), for DNase I hypersensitive sites (625,738), or for open or accessible chromatin, but other studies have not detected such biases. Similarly, there have been reports of highly preferred integration sites or hot spots (655), but these observations have not been reproducibly confirmed (770). DNA in chromatin, such as simian virus 40 (SV40) DNA covered with nucleosomes, is a good substrate for integration *in vitro* (584), so nucleosomes probably do not need to be removed to allow efficient targeting; the presence of nucleosomes can, however, induce a 10-bp periodicity onto the pattern of integration, presumably reflecting the accessibility of the outside of the DNA helix to the PIC. DNA bound by other more sequence-specific binding proteins can be protected from integration (586). Heterochromatic satellite repeat DNAs seem to be disfavored sites of integration (110). The sites that are selected can have profound position effects on the ability of the provirus to be expressed, with some sites silent and some expressed at high levels, but on average the transcription of proviruses arising by natural infection is more efficient than when the same DNA is introduced artificially by transfection (331).

EXPRESSION OF VIRAL RNAs

The integration of the provirus signals a dramatic change in the life style of the retroviruses: It marks the end of the early phase of the life cycle and the beginning of the late phase. The early phase is driven by viral enzymes performing abnormal events such as reverse transcription and DNA integration, whereas the late phase is mediated by host enzymes performing such relatively normal processes as transcription and translation. This late phase of gene expression may begin immediately with the synthesis of viral RNAs and proteins, and the assembly of progeny virions (see Fig. 12 for an overview). For many viruses, the transcriptional promoters that drive this expression are constitutively active and cause the production of virions in a relatively unregulated way. In other viruses, the activity of the promoter may be regulated, either by viral or host factors. This section will review the basic phenomena of proviral gene expression and mention briefly the regulation exhibited by the complex retroviruses.

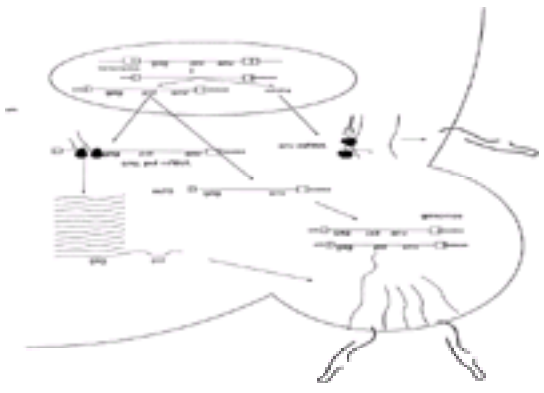

FIG. 12. The late stages of the retroviral life cycle. The integrated provirus is used as the template (*top*) for the expression of viral RNAs. A subset of the transcripts are spliced, and the unspliced and spliced mRNAs are exported to the cytoplasm. The unspliced RNA is used to make Gag and Gag-Pol proteins and also serves as the genome; spliced mRNA is used to make Env proteins. The proteins and RNA associate under the membrane to form the budding progeny virion.

Overview of Viral RNA Synthesis

The synthesis of viral RNA from the viral DNA leads to the formation of a long primary transcript, which is then processed and may be spliced to form a small number of stable transcripts. The U3 region of the LTR contains a promoter recognized by the RNA polymerase II system, and these sequences direct the initiation of transcription starting at the U3-R border. Cellular machinery then caps the 5' end of the RNA with $_{m7}$G5'ppp5'G$_{m}$p. The first G residue after the cap is a templated base in the provirus. Transcription proceeds through the genome, and continues through the 3' LTR and into the downstream flanking host DNA. Finally, the RNA is cleaved and polyadenylated at the R-U5 border of the 3' LTR, generating a complete, unspliced viral genomic RNA suitable for incorporation into the virion particle. Most genomes contain an AAUAAA sequence acting as the signal for this 3' processing. The sequence normally lies in the R region (159), but the complete sequence needed for recognition can be complex, lying upstream or downstream (78,171,730), and it may even be discontinuous, brought together by RNA folding to create the functional signal (6,46). The exact site of polyadenylation is not critical for virus replication; mutants in which the polyadenylation signal is inactivated generate longer RNAs that extend into downstream flanking sequences (800), and these RNAs are quite efficiently able to mediate normal replication (689). A subset of the RNA is spliced to give rise to one or more subgenomic RNAs. The patterns of spliced mRNAs can be simple or exceedingly complex. Both the unspliced and the spliced RNAs are then exported from the nucleus for translation.

Initiation of Transcription

The efficiency of initiation of transcription at the 5' LTR is the major determinant of the levels of viral RNA formed in the cell. The promoter in the LTR is typically a very potent one, and the levels of viral RNA are often constitutively high. However, the cell type, the physiologic state, and the integration site (10,229) can all result in substantial variation in the efficiency of transcription. In some viruses, the promoter is not constitutively active but depends on the activity of specific transcription factors such as the glucocorticoid receptors.

Positive Regulatory Elements in U3

The transcriptional elements in the U3 region of the simple viruses contain both core promoter sequences and enhancers. The core promoters contain a TATA box, bound by TFIIB; a CCAAT box, bound by CEBP (633); and sometimes an initiator sequence near the U3-R border. The U3 regions of even closely related retroviruses are very diverse and can evolve rapidly during viral replication. The enhancers are similar to those found in many host promoters, in that they contain multiple short sequence motifs, arranged in very close packing; often there are tandemly repeated copies of some of these motifs. These short sequences are the binding sites for a large number of host factors that regulate transcription (e.g., see ref. 674). Different cells and cell types will make use of distinct arrays of these factors to mediate transcription from a given viral LTR (284,287,505,606). The factors are not simply additive but may interact in complex ways on particular viral sequences.

Examples of the identity and distribution of known binding motifs in a few LTRs are shown in Figure 13. A partial list of these factors used by various retrovirus LTRs includes Sp1; USF-1; the Ets family of factors, which includes more than 20 members in vertebrates; the core-binding factor (CBF), consisting of an a-b heterodimer; nuclear factor 1 (NF1); and a mammalian type C retrovirus enhancer factor (MCREF-1). Specific viruses often contain recognition sites for other, more specific positive regulatory factors. Major examples of such factors include the glucocorticoid receptors, driving expression of the MMTV genome (25,140), and to a much lesser extent, other MuLVs; NF-kB, important for expression from the HIV-1 LTR in certain cell types (122,628); the GATA factors for Cas-BR-E and other viruses (47); and the myb protein (161). Evidence has recently been obtained that the STAT factors, DNA binding proteins normally activated the Janus kinases (Jaks) may also be important for MMTV transcription (589).

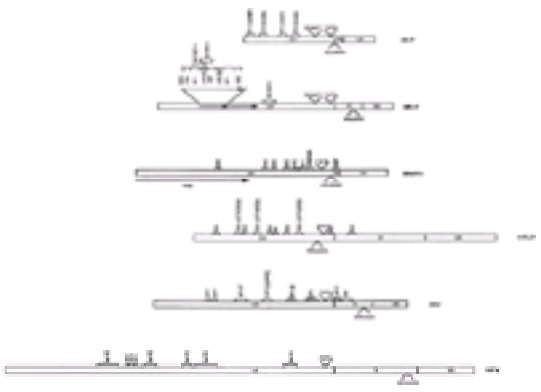

FIG. 13. Structures of the LTR regions of various representative retroviruses. The U3, R, and U5 sequence blocks are indicated for each virus. The binding sites for several of the most important transcription factors are indicated above the LTRs, and the signals for polyadenylation are indicated below. The imperfect direct repeats in the MLV LTR are indicated by the *arrows.* The open reading frame (ORF) for the *sag* gene of MMTV is indicated by the *bold arrow*.

Negative Regulatory Elements

A number of negative regulatory factors that reduce viral expression have been identified. Embryonic carcinoma cells, and true embryonic cells, are the best-characterized examples of cell types that strongly represses LTR-mediated transcription through expression of negative regulatory proteins (237,373,737). These factors include a cellular embryonal LTR-binding protein (ELP) (721,722); and a stem-cell specific repressor that binds, curiously, to the tRNA pbs (373,435,436,567,778). Viruses that lack the recognition sites for these proteins can escape the repression (310). Other

negative factors include one known variously as UCRBP, NF-E1, or YY1 (241); and others less well characterized (111).

Trans-acting Viral Regulatory Factors

The complex retroviruses encode an array of small regulatory proteins that can activate transcription from the viral LTR in trans. Examples of these transactivators include the HTLV-1 Tax protein (168) and the HIV-1 Tat protein (149). The Tax protein acts in concert with a complex of host proteins, the activating transcription factor/CRE-binding protein (ATF/CREB), and binds to three cAMP response elements in the viral LTR. Tax thus sets up a positive feedback loop that results in high levels of viral transcripts. The Tat protein is unusual among transcriptional activators in that it binds to a structure in the 5' end of nascent viral RNA (175, 652), rather than to DNA. Tat binds to a bulged hairpin structure, the TAR element, and recruits a pair of host proteins, cyclinT/cdk9, to the RNA. These proteins enhance the ability of RNA polymerase to elongate beyond the LTR and down the genome with high processivity, probably by phosphorylation of the C-terminal repeat domain (CTD) of the polymerase. Again, the result is a strong positive feedback loop that results in high levels of viral RNA. (For more detailed discussion of *tat* function, see Chapter 59 and refs. 149 and 150).

Beginning and Ending the RNA

Because there are two identical LTRs in the provirus, it is possible that transcription can be initiated at both the 5' LTR and the 3' LTR. However, the 5' LTR is generally much more efficiently utilized than the 3' LTR (306). One possible mechanism is promoter interference, in which the upstream promoter being active suppresses the utilization of the downstream promoter (151). It is possible that elements near the 3' LTR may restrict use of the downstream LTR, so that generally transcripts initiating at the 5' LTR predominate. These restraints may be lost in tumors, in which transcription from the 3' LTR can be significantly enhanced (76). Similarly, since there are two LTRs, transcripts might be subject to 3'-end processing at either the 5' LTR or the 3' LTR. For those viruses with a long R region, there are signals for RNA cleavage and polyadenylation at both ends of the RNA, and so these events could occur at both 5' and 3' sites. However, it is likely that sequences near the 5' end of the RNA (or the lack of sequences) restrict processing at the 5' LTR. The RNA that begins at the 5' LTR is so short when the site for cleavage is reached (the length of the R region) that structural constraints may limit its recognition by the processing enzymes (337). Finally, there may be signals promoting this recognition that are present only at the 3' sequences. Thus, most of the RNAs formed extend from the 5' LTR to the 3' LTR (306). There is at least one exception to this rule: The foamy viruses include a second internal promoter required for the formation of the Tas and Bet regulatory proteins (429, 430, 482). The separate promoter for formation of these proteins presumably reflects a need for their temporally ordered and regulated synthesis.

RNA Processing

The full-length transcript of the retroviral genome is directed into several pathways. A portion of the transcripts is exported directly from the nucleus and serves as the genome to be packaged into the progeny virion particle, assembling either at the plasma membrane or in the cytoplasm. Another portion with identical structure is also exported and used for translation to form the Gag and Gag-Pol polyproteins. It is not yet clear if these two subsets are truly distinct, whether there can be interchange between the pools, or whether there is a single pool of such molecules used for both purposes. It has been proposed that the translated mRNAs are selectively packaged in *cis* (370). A third portion is spliced to yield subgenomic mRNAs. For the simple retroviruses, there is a single spliced mRNA encoding the Env glycoprotein. For the complex viruses, there can be multiple alternatively spliced mRNAs, encoding both Env and an array of auxiliary proteins (150, 619). Examples of the complicated array of mRNAs that are formed for both simple and complex viruses are shown in Figure 14. The protein products of these multiply spliced mRNAs will be discussed in the following chapters.

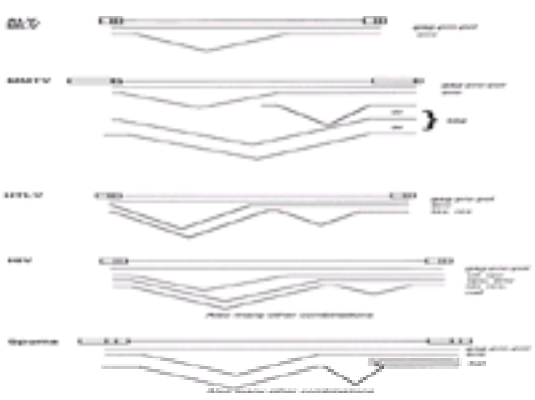

FIG. 14. Splicing patterns of representative retroviral RNAs. All retroviruses direct the synthesis of an unspliced RNA transcript, as well as a variable array of subgenomic mRNAs. Examples of the splicing patterns of the mRNAs of various retroviruses are show. The complex viruses such as HIV-1 also encode a larger array of mRNAs containing various combinations of exons.

The splicing and subsequent export from the nucleus of only a portion of an initially transcribed RNA is an extraordinary process; normally, splicing goes to completion, and only then is the mRNA exported. The export of a precursor mRNA is prevented until splicing is complete. At least three aspects of the retroviral genome may promote the export of unspliced mRNAs. First, the splice sites of the viral RNA may have quite poor overall efficiency of utilization by the splicing machinery in the cell (365). Indeed, the sequences at the splice donor and acceptor regions are often poor matches to the consensus sequences for splice sites, and mutations that make the sites better matches increase splicing and are actually deleterious to virus replication (31, 364). These mutations can be suppressed by secondary mutations that reduce splicing efficiency. The overall folding of the RNA may affect the efficiency of splicing, and thus sequences at

some distance, as in the *gag* gene, may modulate splicing (32,680).

Second, studies of ASLV have identified specific sequences that act as negative regulators of splicing (NRS) through their interaction with host factors (17,137,480,481). These elements can be important for the expression of transduced genes in some viruses (666). Similar signals may exist in other viruses; mutations in the Gag region of MuLV can affect RNA processing in complex ways (27).

In addition, unspliced mRNAs contain *cis*-acting elements that promote the export of the RNA out of the nucleus, the so-called constitutive export elements (CTEs) (92). These sequences are located near the 3' end of the genomic RNA of MPMV (216), between *env* and the LTR, and possibly in similar regions of ASLV (520). CTE function of the MuLVs may be present in the Gag region (382), or possibly in the R region of the LTR (719). The CTE is recognized by one or more host proteins that assemble a complex onto the RNA to mediate its export, although which proteins are most important is controversial (293,552,703). In the complex viruses, RNA export is regulated through complex interactions of both *trans*-acting proteins, the Rex or Rev gene products, and *cis*-acting sites, the Rev-responsive elements (RREs) that promote RNA export and the *cis*-acting repressive sequences (CRS) elements that prevent it (127,152,154,173,208,230,313,455,456 and 457). A key aspect of this process is the recruitment of Crm1, a cellular nuclear export factor, to the RNA (see Chapter 59 for detailed discussion of the mechanism of Rev action). The Rev/RRE pathways of export are probably distinct from those used by the CTEs, because the two are differentially sensitive to a competitive block acting through Crm1 (77,634).

Viral RNAs are subject to other modifications common to cellular mRNAs. Like cellular mRNAs, the N6 position on specific A residues can be methylated (357), and other sites can be modified by double-stranded RNA adenosine deaminase (295). The significance of these modifications is uncertain.

TRANSLATION AND PROTEIN PROCESSING

All retroviral genomes, at a minimum, contain ORFs designated the *gag*, *pro*, *pol*, and *env* genes. These genes are expressed by complex mechanisms to form precursor proteins, which are then processed during and after virion assembly to form the mature, infectious virus particle. The expression of the various proteins as large precursors that are subsequently cleaved provides several advantages: It allows for many proteins to be made from one ORF, it ensures that the proteins are made at proper ratios, and it allows many proteins to be targeted to the virion during assembly as a single entity. The *gag*, *pro*, and *pol* genes are expressed in a complex way from the full-length unspliced mRNA. The arrangement of these genes, and especially the way *pro* is expressed, are different in different viruses. A summary of the arrangement of the ORFs of various viruses is shown in Figure 15.

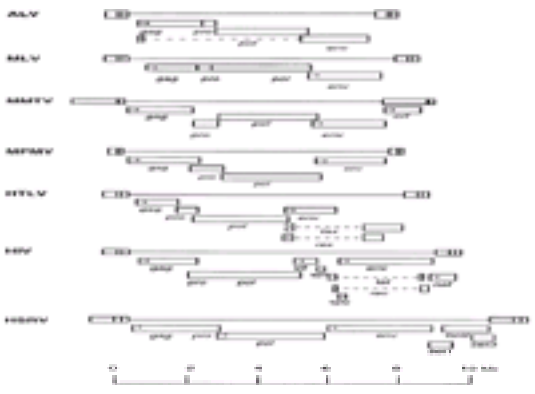

FIG. 15. Arrangements of the ORFs encoded by various retroviruses. The major ORFs of each virus are indicated by the *open boxes.* ORFs in the same reading frame are in the same line, and ORFs in different frames are on different lines. Translational starts are indicated by the *small arrows.* Spliced introns are indicated by the *dashed lines*.

Gag Gene Expression

The *gag* gene is present at the 5' proximal position on all retroviral genomes. A full-length mRNA, identical in sequence to the genomic RNA, is translated in the cytoplasm to form a Gag precursor protein, in the 50- to 80-kd range. Translation begins with an AUG initiator codon and proceeds to a terminator codon at the 3' end of the ORF. The viral RNA typically contains a relatively long 5' untranslated region (UTR), and it has been uncertain whether ribosomes could scan from the 5' cap to the start codon for Gag translation. These 5' RNA sequences are predicted to contain stable secondary structures that would inhibit scanning. Furthermore, the long 5' UTRs often contain AUG codons in contexts that are favorable for translation, that are not in frame with the *gag* ORF, and that presumably would inhibit successful translation of Gag (178). Recent experiments suggest that for the MuLVs, an internal ribosome entry site (IRES) is present near the start of the *gag* ORF and is used to initiate translation in a cap-independent mechanism (63,729). Thus, at least in these viruses, ribosomes can bind directly near the *gag* gene and do not need to scan the mRNA. However, other viruses, such as HIV-1, may not use such sequences (487).

Some retroviruses encode an additional Gag protein besides the major product. This Gag protein is longer than the major product and derives from translational initiation at a nonconventional CUG codon upstream from the initiating AUG codon. Translation beginning at this codon first forms an N-terminal leader sequence and then proceeds in the same reading frame through the normal AUG and the rest of the Gag protein. Thus, where the proteins overlap, their sequences are identical. The leader sequence contains a functional signal peptide directing the translation machinery to the ER, and specifying that the Gag protein be cotranslationally inserted into the secretory pathway. The Gag become glycosylated at several sites, is transported via the Golgi to the cell surface, and persists for some time as a

membrane-bound glycoprotein, with the carboxyl-terminal domain exposed on the cell surface (570). The protein is processed into several fragments and has a relatively short half-life. The function of the protein is uncertain. It is not required for virus replication, and mutant viruses lacking the protein show no gross defects (648). The glycosylated Gag is a prominent immunogen in infected animals, however, and it may thereby or in some other way modulate the replication and the leukemogenicity of the viruses (139). The neuropathogenesis associated with some of the MuLVs may depend on sequences in glycosylated Gag (255,580).

The major Gag product is often modified by the addition of myristic acid, a relatively rare 14-carbon fatty acid, to the penultimate aminoterminal residue, a glycine (304). The addition is mediated by a myristyl CoA transferase that cotranslationally transfers myristate from a myristyl CoA donor to the amino group of the glycine residue, forming an amide bond. The fatty acid is important for the membrane localization and binding of the Gag precursor, increasing the hydrophobicity of the aminoterminal domain. Mutant Gags in which the glycine is altered are not modified, and these Gags do not associate with membrane properly and do not aggregate to form virions (97,285,599). It should be noted that although myristate is important, it is not sufficient for membrane targeting; hydrophobic residues in the MA domain are also required. Furthermore, basic residues further downstream in the MA of some viruses form a patch of positive charge that may interact with negatively charged phospholipids in the membrane.

An aminoterminal myristate is not found on the Gags of bovine immunodeficiency-like virus (BIV), equine infectious anemia virus (EIAV), visna, or ASLV. For the avian retroviruses, the aminoterminus is not myristylated but rather acetylated. The Gag protein of these viruses is apparently sufficiently hydrophobic to be targeted to the membrane without the fatty acid in avian cells, although, curiously, not in mammalian cells. Alteration of the avian Gag to allow its myristylation permits virion assembly in mammalian cells (765) and does not block its function in avian cells (215).

Pro Gene Expression

The relative position of the *pro* gene on retroviral genomes is always similar—in between *gag* and *pol*. However, the *pro* gene is expressed in very different ways in different viruses. Sometimes it is fused in frame onto the 3' end of *gag*, sometimes it is fused to the 5' end of *pol*, and sometimes it is present as a separate reading frame. These various patterns have led to considerable confusion in the literature; sometimes *pro* is considered a portion of *gag*, or sometimes of *pol*. Because of these different patterns of expression, it is best to consider this ORF as a separate gene.

The various arrangements of the *pro* gene and its mode of expression are as follows. For the alpharetroviruses, *gag* and *pro* are fused and expressed as a single protein; *pol* is in a different reading frame, and a frameshift is used to express the Gag-Pro-Pol polyprotein. For the beta- and deltaretroviruses, *gag*, *pro*, and *pol* are all in different frames, and successive frameshifts are used to express Gag-Pro and Gag-Pro-Pol polyproteins. For the gamma- and epsilonretroviruses, *gag* and a *pro-pol* fusion are in the same reading frame and separated by a stop codon, and translational readthrough is used to make Gag-Pro-Pol. For the lentiviruses, *gag* and a *pro-pol* fusion are in different reading frames, and frameshifting is used to make Gag-Pro-Pol. Finally, for the spumaviruses, *pro* is fused to *pol*, and the Pro-Pol protein is expressed without Gag, from a spliced mRNA. More will be said about these varied mechanisms of expression in the following section.

Pol Gene Expression

The *pol* gene encodes several proteins needed at lower levels for the replication of the virus, including the RT and IN enzymes. The *pol* ORF is not expressed as a separate protein in most retroviruses, but rather is expressed as a part of a larger Gag-Pro-Pol fusion protein. The Gag-Pro-Pol protein must be made at the correct abundance, in proportion to the amount of Gag protein, for efficient assembly of infectious virus; expression of only Gag-Pro-Pol does not result in virion assembly (231,548). The formation of this protein is mediated by either one of two mechanisms, depending on the virus.

Translational Readthrough

In the gamma- and epsilonretroviruses, the Gag and Pro-Pol ORFs are in the same reading frame and are separated by a single UAG stop codon at the boundary between Gag and Pro-Pol. The translation of Gag-Pro-Pol in these viruses occurs by translational readthrough—that is, by suppression of termination—at the UAG stop codon (786). Most of the time, translation of the RNA results simply in the formation of the Gag protein. But approximately 5% to 10% of the time, ribosomes translating the RNA do not terminate at the UAG codon but instead utilize a normal aminoacyl tRNA, usually a glutamine tRNA, to insert an amino acid at the position of the stop codon. Translation then continues, in frame, through the entire long *pro-pol* ORF, resulting in the formation of a long Gag-Pro-Pol precursor protein. The high-level suppression of termination is specified by a specific structure in the RNA immediately downstream of the UAG stop codon (314,539). The precise features of this structure that are required for suppression are not completely known, but they include a purine-rich sequence immediately downstream of the stop codon, and a pseudoknot formed from the next 60 or so nucleotides (11,232,236,273,766,767). The structure may slow translation, and it may also in some other way alter the balance between termination, which requires binding of termination factors eRF-1 and eRF-3 by the ribosome, as opposed to incorporation of an amino acid, which requires misreading of the codon by an aminoacyl tRNA. No changes in the tRNA pool occur during infection (234). The signals in the RNA can operate to mediate suppression of both UAA and UGA termination codons as well (235).

Translational Frameshifting

In the alpharetroviruses and lentiviruses, the *gag* and *pol* ORFs lie in different reading frames, and the formation of the Gag-Pro-Pol fusion is mediated by a translational frameshift mechanism (340). Most of the time, translation again results in the simple formation of the Gag protein. But approximately 10% of the time, as the translation approaches a specific site near the end of the *gag* ORF, the ribosome slips back one nucleotide (a –1 frameshift) and proceeds onward in the new reading frame. The ribosome passes through the stop codon out of frame and so continues to synthesize protein using the codons of the *pol* ORF. As for readthrough, the determinants of frameshifting lie in the RNA sequence and

structure near the site of the event (338,462,550,769). The requirements for frameshifting include a “slippery site,” a string of homopolymeric bases where the frameshift occurs; these are oligo-U or oligo-A in different viruses. In addition, the frameshifting requires either a very large and near-perfect hairpin or stem-loop structure; or a large pseudoknot structure, similar to those used in readthrough, although apparently containing a distinctive bend at the junction of the two paired sequences (117,187,358,653). As for readthrough, the proper frame-shifting efficiency is crucial for normal virus replication.

In the betaretroviruses (e.g., MMTV) and deltaretroviruses (e.g., BLV, HTLV-1), the *pro* gene is present as a separate ORF, in a different reading frame from that of *gag* or *pol*. Two successive frameshifts are utilized to make the long Gag-Pro-Pol fusion protein (339,497,508). Near the 3' end of the *gag* ORF, ribosomes carry out a first (–1) frameshift and continue into the pro ORF; near the 3' end of the pro ORF, they perform a second (–1) frameshift and continue on into the *pol* ORF. These two frameshifts occur at extremely high frequencies—as much as 30% of the time that the ribosome transits through each site—so that the overall frequency of formation of the Gag-Pro-Pol protein is perhaps 10% that of formation of ag.

Separate Pol Expression

The spumaviruses are unique among the retroviruses in that the synthesis of the Pol protein is not mediated by the formation of a Gag-Pol fusion protein. Instead, a separate subgenomic spliced mRNA (352) is translated directly to form a separate Pro-Pol protein (214,428). This protein must be directed to the assembling virion by distinct domains rather than by the Gag portion of a Gag-Pol fusion.

Env Gene Expression

In all retroviruses, the *env* gene is expressed from a distinct subgenomic mRNA. The *env* message is a singly spliced mRNA, in which a 5' leader is joined to the coding region of *env*. Thus, the bulk of the *gag* and *pol* genes are removed as an intron from the mRNA. The resulting message is exported to the cytoplasm and translated from a conventional AUG initiator codon. In the alpharetroviruses, the AUG is actually the same one used for Gag translation; it lies in the leader, and the splicing brings this AUG and the first six codons into frame with the *env* coding region. The first translated amino acids constitute a hydrophobic signal peptide, and they direct the nascent protein to the rough ER. The leader is removed by a cellular protease (the signal protease) in the ER, and the protein is heavily glycosylated by transfer of oligosaccharide from a dolichol carrier to asparagine residues on Env. These residues lie in the conventional Asn-X-Ser/Thr motifs recognized by the modification enzymes. Near the end of the cotranslational insertion of Env into the ER, a highly hydrophobic sequence acts as a stop transfer signal to anchor the protein in the membrane. The remaining C-terminal portion of the protein stays on the cytoplasmic side of the membrane.

Before the Env proteins are transported to the cell surface, they are folded and oligomerized in the ER. The formation of oligomers is required for stable expression of the protein, and it is sensitive to overall conformation; many mutants of Env show defects in oligomerization (723). There is considerable controversy about the oligomeric state of the Env protein in different viruses and at different times during their transport (193,201,202,573,753). The most-studied envelope proteins (ASLV and HIV-1) may pass through dimeric or tetrameric intermediates, but the nature of these intermediates is not clear. Although some laboratories disagree (see e.g., refs. 193,479,642, and 713), ultimately these envelopes probably form trimers in the mature virus (202,441). The folding of the protein is presumably catalyzed by chaperone proteins in the ER, and the formation of disulfide bonds between various pairs of cysteine residues is similarly catalyzed by disulfide interchange enzymes.

The Env protein is then exported to the Golgi, and it is cleaved by furin proteases to form the separate SU and TM subunits. This cleavage is essential for the normal function of the Env protein. The cleavage occurs at a dibasic pair of amino acids (177), and it produces a hydrophobic N-terminus for the TM protein that is required to mediate fusion of the viral and host membranes during virus entry. In the Golgi, the sugar residues are modified by the sequential removal of mannose residues and addition of N-acetyl glucosamine and other sugars to many of the oligosaccharide. O-linked glycosylation and sulfation of Env glycoproteins have also been documented (572,656). The pathway by which Env is transported to the cell surface is not fully understood, but presumably host vesicular transport systems are utilized. There is evidence that clathrin adaptor complexes interact with the cytoplasmic tail of Env and direct its movement to the plasma membrane (64). The protein typically becomes a prominent cell surface protein on the infected cell.

In polarized epithelial cells, Env proteins are often restricted to the basolateral surface of the cell (534). This localization is mediated by a tyrosine-based motif, Yxxp, present in the cytoplasmic tail of Env (x, any amino acid; p, hydrophobic residue) (432,535). Remarkably, this targeting of Env can redirect the budding of Gag proteins to this surface.

Other Viral Gene Products

The complex retroviruses express a number of small proteins with a range of functions. The proteins are translated from subgenomic mRNAs, usually resulting from multiple splicing events that join a 5' LTR to a number of small exons encoding the protein. These gene products will be discussed in greater detail in later chapters, but a short summary follows (see refs. 149,150,290,485, and 577 for reviews).

Deltaretroviruses

Tax

The Tax gene product is a positive regulator of transcription from the viral LTR. Tax functions in association with the ATF/CREB by binding to three cAMP response elements in the viral LTR. Tax also plays a role in transformation, perhaps through E2F-1 activation or through effects on the cell cycle.

Rex

The Rex gene product facilitates the export of unspliced and singly spliced viral mRNAs from the nucleus. Its action is probably similar to that of the lentiviral Rev protein.

Epsilonretroviruses

ORF A

The ORF A product of the piscine retroviruses is a cyclin D homolog that functions as a cyclin in yeast (410). The function of the protein in virus replication or tumor formation is uncertain.

ORFs b and c

The function of these ORFs is unknown.

Lentiviruses

Tat

The Tat protein is a potent transactivator of transcription from the viral LTR. The protein acts by binding to a hairpin structure, the TAR element, encoded in the R region of nascent viral RNA, and recruiting host factors cyclinT and Cdk9 to the RNA. Tat does not increase the rate of RNA polymerase II initiation but seems to enhance its processivity or elongation, perhaps by phosphorylation of the CTD of pol II.

Rev

The Rev protein mediates the export of the unspliced and singly spliced viral RNAs from the nucleus, thus permitting the expression of the Gag, Pol, and Env gene products. Rev binds to the RRE present in the HIV-1 *env* gene, and by interacting with the importin Crm1, it acts to export the viral RNAs through the nuclear pore.

Nef

The Nef protein is a multifunctional protein not essential for replication in some cells in culture, but important for replication *in vivo*. Nef-defective viruses do not induce high-level viremia in infected animals, and progression to disease is delayed or prevented (376). Nef down-regulates the CD4 receptor from the cell surface, facilitating virus release, probably by bridging CD4 to adapter proteins (APs) (569). Nef also down-regulates MHC class I levels, thereby inhibiting the cytotoxic T-lymphocyte–mediated lysis of HIV-1–infected cells. Finally, Nef may enhance virion assembly and release through unknown mechanisms.

Vpr

The Vpr protein, as noted later, is packaged at high levels into virion particles through an interaction with the p6 domain of Gag (39,651). Vpr may facilitate the import of the PIC into the nucleus in nondividing cells. Vpr also causes a strong cell cycle arrest in the G2 stage of the cell cycle, perhaps through an indirect inhibition of Cdc25 phosphatase activity.

Vif

The Vif protein is expressed at high levels in the cytoplasm, and it is packaged into virion particles of both homologous and heterologous viruses. Vif enhances infectivity of virus produced in certain nonpermissive cells, perhaps by blocking the action of a cell-specific inhibitor.

Vpu

The Vpu gene product, found only in HIV-1, is a membrane protein that enhances virion production and also mediates the degradation of CD4 by the ubiquitin-conjugating pathway (644,762).

Spumaviruses

Tas

The Tas (or Bel1) protein is a transactivator of transcription from the viral LTR, acting at sequences near the 5' end of the genome. Its mechanism of action may be similar to that of the lentiviral Tat protein.

Bet, Bel2, and Bel3

The functions of the *bet* (and the overlapping *bel2*) and the *bel3* genes are unknown, although there is some evidence that the Bel3 protein may be a negative regulator of replication.

VIRION ASSEMBLY

As the Gag, Gag-Pro-Pol, and Env proteins are synthesized, they come together to form progeny virions (reviewed in

refs. 246,330,637,691, and 764). The assembly of the retrovirus particle is driven primarily by the Gag precursor protein. Gag is required for the formation of a virion, and indeed it is sufficient to mediate the assembly and release of a “bald” particle—lacking infectivity and the “hair” of the Env protein. The Gag protein that is responsible for assembly is the uncleaved Gag precursor. This form of the protein is thus targeted for assembly and export—the “way out” of the cell. Once the Gag proteins are processed, changes in virion structure can occur to promote entry—the “way in” to the next cell.

There are two major routes by which the various retroviruses assemble their virions.

Assembly of C-type Virions

For most of the retroviruses, those with the C-type morphology, assembly occurs at the plasma membrane; in these cases, the Gag precursor protein is targeted to the cytoplasmic face of the plasma membrane by hydrophobic sequences, by basic residues, and sometimes by a myristic acid moiety (304) present at the aminoterminus. It is not clear if monomeric or dimeric or higher-order structures of Gag are transported to the membrane to begin assembly. The Gag proteins then aggregate, presumably by side-to-side contacts, and create a patch under the membrane. As the patch of protein grows, curvature is induced in the membrane, causing the nascent virus to bud outward. The bud eventually grows to a complete sphere, attached to the cell by a narrow stalk. The stalk is then pinched off, the virion is released, and the host membrane is sealed. The various steps are depicted in Figure 16.

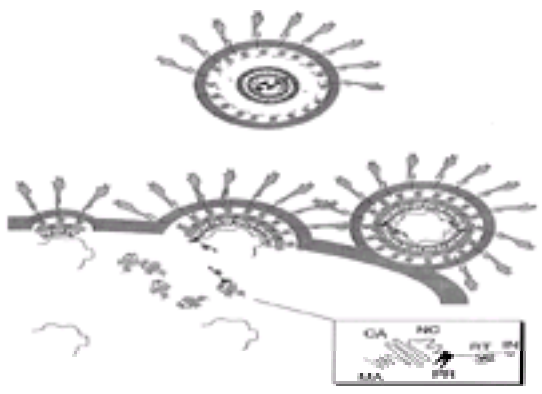

FIG. 16. A schematic diagram of the process of virion assembly. The Gag precursor, containing the MA, CA, and NC domains, and the Gag-Pol precursor, containing the MA, CA, NC, PR, RT, and IN domains (see *blowup*), are transported to the inner leaflet of the plasma membrane. The proteins bind the viral genomic RNA (*thin line*). Curvature is induced in the membrane as the virion grows, and the roughly spherical particle is finally pinched off and released from the cell. The virion proteins are reorganized upon processing by the viral protease to form the mature, infectious virus (*top*).

Assembly of B- and D-type Virions

In the alternative lifestyle of the viruses with B- and D-type morphology, the betaretroviruses and the spumaviruses assemble in the cytoplasm and are subsequently transported to the plasma membrane for envelopment and release (610). These two pathways would seem relatively distinct, and one might suppose that the two groups of viruses would have evolved very different requirements for assembly, and that the details of the Gag-Gag interactions would be different. But these two mechanisms are not so far apart. Indeed, a single amino acid substitution in the MA protein of MPMV can change the morphogenetic pathway of the virus from a cytoplasmic site of assembly to a membrane site of assembly (612). Thus, the main difference may be the timing of exposure of determinants for membrane transport: In the C-types, such a determinant might be constitutively available, whereas for the B- and D-types, the determinant may not be exposed until assembly occurs. For both mechanisms, the nascent virions consist of a spherical particle surrounded by a lipid bilayer, which is pinched off from the cell and then released into the extracellular space.

Assembly of Intracisternal A-type Particles

There is a third route by which retroviral-like particles can assemble, although it is not known to be important for any infectious agent. The endogenous retroviral elements known as IAPs direct the synthesis of virus-like particles with an immature morphology in the cytoplasm of cells expressing these elements. The particles are budded into the lumen of the ER and are not released efficiently outside the cell. These steps may be most closely related to the formation of hepatitis B virions.

Gag and Virion Assembly

For most retroviruses, the expression of the Gag precursor is sufficient to mediate virion assembly and release, earning the protein the name, the particle-making machine. [An exception to this rule is the foamy viruses, which also require the presence of the Env glycoprotein for efficient budding (568).] Because of its central role in virion assembly, the Gag proteins have been subjected to intense mutational analyses to define the domains required for various steps in the process (296,764). Surprisingly, small portions of Gag, containing only a few critical regions, can still assemble virions (746). Three domains seem to be crucial: a membrane-binding (M) domain; an interaction (I) domain; and a late assembly (L) domain. It is important to remember that the form of the Gag protein that is mediating assembly is the precursor; thus, the assembly domains need not lie neatly within any of the cleavage products that form later, and they can span cleavage sites.

The M Domain

The M domain, or membrane-binding domain, ranging from 30 to 90 residues in length, is located at the aminoterminus of Gag, in MA. Mutations affecting this domain abolish assembly, but M mutants retain their ability to interact with other Gags and can be rescued into particles by the coexpression of a wild-type protein. The region seems to contain both hydrophobic and basic residues that are needed for proper interaction with lipid and with the acidic moieties of phospholipids. Structural information for the isolated M domain is consistent with this role (478).

For many retroviruses, myristylation of Gag, along with specific residues in MA, is required for membrane binding. This interaction with membrane, in turn, is important for virion assembly of the C-type viruses, and for their proper subsequent Gag processing (645). Mutational studies have led to the notion of a “myristyl switch,” in which the myristic acid is exposed to mediate plasma membrane binding during virion assembly, but then can be sequestered in the compact globular core of MA after Gag processing (524,536,672,803). Although this region is generally considered important for virion assembly, surprisingly, much of the Rous sarcoma virus (RSV) MA (511), and the entire HIV-1 MA domain (597) can be deleted from Gag without preventing assembly, so long as a functional membrane binding signal is retained. In the latter case, there are some effects on assembly: Virions are budded indiscriminately into both intracellular membranes as well as at the cell surface. The aminoterminal sequences of Gag can be replaced with a heterologous membrane binding signal, such as that present at the aminoterminus of the Src kinase. It should be noted that the interaction of Gag with membrane is not required for assembly of the B- or D-type viruses per se. For these viruses, mutations in the myristate addition signals do not affect the cytoplasmic assembly of the virions, but rather block the transport of the assembled particles to the plasma membrane (611).

The I Domain

The I, or interaction, domain is defined as a major region of Gag-Gag interaction, largely contained in the NC region. Although the major I domain has been suggested to lie in NC, some analyses have suggested that the C-terminal half of CA and NC are equally important for normal assembly (1,85). Mutations in the I domain block or reduce assembly, and those particles produced by these mutants have aberrantly low density, indicating fewer and poorly packed Gag proteins. The key feature of the I domains is not the zinc-binding residues of the Cys-His box, but rather basic residues flanking the boxes (89). The assembly function could involve the binding of RNA—either the genomic RNA or other RNAs—but it is not completely clear that RNA is necessary. The assembly functions of NC can be replaced by foreign proteins, and the key activity seems to be the formation of protein–protein contacts (801). Mutations in this region can also affect particle size and yield (397). Recently, the I domain of HIV-1 has been proposed to be involved in the membrane association of the Gag precursor (640), but other studies suggest that NC is not required (523).

The L Domain

The third domain is the L, or late assembly, domain (763,776). Mutants affected in this function fail to produce and release particles efficiently, and although the mutant Gag proteins form spherical structures, they accumulate under the membrane and do not progress normally. The buds remain tethered to the cell surface by a membrane stalk, suggesting that the function of the L domain is to mediate virus–cell separation. Recently, the domain has been shown to also be important in determining the size of the virion: The structures formed by L domain mutants are often large and heterogeneous in diameter (264). L domains lie at different locations in the Gag proteins of different viruses. In ASLV, MPMV, and the MuLVs, the L domain lies in the aminoterminal third of the protein and its critical residues are the PPPY motif. In HIV-1, the domain lies in p6, at the C terminus, and instead contains the motif PTAP. Remarkably, many of these L domain motifs are interchangeable among the various retroviruses and show a substantial position independence for their function (544). It is likely that these motifs represent the binding site for some protein important for the late stages of budding, and indeed the PPPY motif has been identified as the recognition sequence for the WW-domain family of proteins, including the Yes-associated protein YAP, NEDD45, and many others (265). Recently, the L domain of the EIAV Gag has been shown to associate with a cellular adapter protein, AP-2, which could mediate transport or localization steps (587). Which of these (or other proteins that may interact with the L domain) are most crucial for virion release remains uncertain. A curious additional link between two of these proteins is provided by the observation that both HIV-1 p6 and the MuLV p12 proteins are modified by the addition of ubiquitin at low levels (529). It is possible that a PPPY-binding host protein is responsible for this modification.

Virion Assembly *In Vitro*

Recently, Gag proteins and fragments of Gag have been shown competent to assemble *in vitro* to form various structures that more or less closely resemble virion cores (196,386,638,673). The CA-NC portions of ASLV and HIV-1 expressed as recombinant proteins can assemble to form particles or long hollow tubes; the formation of these structures is dramatically enhanced by the addition of RNA, and the length of the tubes is determined by the length of the RNA (108). Larger Gag fragments that include more aminoterminal regions can assemble into spherical particles (292), and this assembly is stimulated by RNA and host cell extracts (107). Although HIV-1 Gag interacts with cyclophilin A *in vitro* and *in vivo*, addition of cyclophilin A to assembly reactions has only little effect (288). HIV-1 Gag CA-NC fragments can assemble into conical structures (262), with a pitch that falls into discrete values. Image reconstruction of these cones has allowed the formation of a model for the packing of the protein into hexagonal arrays. Virus-like particles have also been formed with the Gag proteins of MPMV in cell-free protein synthesis systems.

Virion Assembly *In Vitro*

Recently, Gag proteins and fragments of Gag have been shown competent to assemble *in vitro* to form various structures that more or less closely resemble virion cores (196,386,638,673). The CA-NC portions of ASLV and HIV-1 expressed as recombinant proteins can assemble to form particles or long hollow tubes; the formation of these structures is dramatically enhanced by the addition of RNA, and the length of the tubes is determined by the length of the RNA (108).

Larger Gag fragments that include more aminoterminal regions can assemble into spherical particles (292), and this assembly is stimulated by RNA and host cell extracts (107). Although HIV-1 Gag interacts with cyclophilin A *in vitro* and *in vivo*, addition of cyclophilin A to assembly reactions has only little effect (288). HIV-1 Gag CA-NC fragments can assemble into conical structures (262), with a pitch that falls into discrete values. Image reconstruction of these cones has allowed the formation of a model for the packing of the protein into hexagonal arrays. Virus-like particles have also been formed with the Gag proteins of MPMV in cell-free protein synthesis systems.

Virion Size

The number of Gag proteins per virion particle is estimated to be in the range of 1,200 to 1,800, although this number may vary somewhat from virus to virus. The number of Gag-Pol proteins is roughly 10 to 20 times lower, approximately 100 to 200 per virion. It is unlikely that these proteins form a completely homogeneous, ordered crystalline array, but rather they may form a “protein micelle” that is somewhat fluid like a lipid micelle. The diameter of even wild-type virus preparations is not tightly homogeneous but shows a distribution that suggests some flexibility in the structures during assembly. However, the average size of the particle is determined by the Gag protein, and mutants with alterations in Gag often show abnormal or excessively heterogeneous diameters (397). Mutations in the CA domain commonly show this phenotype. Thus, CA-CA contact may play a role in determining the angle between Gags during their packing into a spherical shape. The heterogeneity of virions has frustrated efforts to determine the detailed structure, although chemical cross-linking has provided some clues (297).

Gag proteins of one virus are sometimes able to interact with the Gags of another virus to coassemble and form mixed virion particles. Various mutants with alterations in the Gag proteins of the MuLVs can coassemble into particles that show phenotypes of both parental Gags (361,598). Viruses of very different genera can even form mixed particles in some cases (59). The physical interactions between Gags can be monitored in other assay systems as well (243,442).

Incorporation of Other Proteins into Assembling Virions

During assembly, other proteins are incorporated into the particle by contacts to Gag; these include Gag-Pol, Env, and auxiliary proteins encoded by the complex viruses. The Gag-Pol precursor is thought to be incorporated into the assembling bud by virtue of the Gag protein present at the aminoterminus. Gag to Gag-Pol contacts can in some cases lead to the incorporation of mutants of Gag-Pol that do not retain the myristate modification to the aminoterminus (549), suggesting that the interaction is quite strong. Gag fusions to foreign proteins can be similarly incorporated into particles formed by Gag (351); this process can even be used to target antiviral proteins into virions. Consistent with this notion, many mutations that block assembly of Gag, when tested in the context of Gag-Pol, are found have similar effects on the incorporation of Gag-Pol (146,650). However, some mutations in HIV-1 Gag have also been identified that specifically affect the incorporation of Gag-Pol, suggesting that Gag-Pol utilizes some distinctive contacts not important for Gag-Gag interactions (662). Further, in the spumaviruses, Pol is incorporated without an appended Gag region, suggesting that distinct interactions must be utilized for its incorporation (214).

The Env protein is thought to be concentrated at the sites of budding and incorporated into the virions by virtue of contacts between the cytoplasmic tail of Env and the aminoterminal portion of Gag. These interactions have been difficult to document directly, although there is some biochemical evidence (143) and cross-linking studies (267) in support of these contacts. Genetics has provided good evidence for this interaction. Selected mutants of MA show defects in Env incorporation (181,250,791), and some mutants of the cytoplasmic tail of TM are not efficiently incorporated (792). In addition, Env proteins that are specifically directed to the basolateral surface of polarized epithelial cells can redirect the sites of budding of Gag from a nonspecific assembly on both membranes to the exclusive assembly at basolateral membranes (432,535), and they can similarly redirect Gag in neurons (749). Finally, mutants and revertants of these mutants with second-site suppressors in the binding partner have provided strong evidence for these interactions (249,250). However, it should be noted that the envelope proteins of viruses very distant from retroviruses, including vesicular stomatitis virus (VSV) and influenza, can be functionally incorporated into retrovirus particles without any obvious sequence similarity in their cytoplasmic tails. Furthermore, truncating the tail of ASLV Env does not prevent its incorporation or function (563). Thus, there may be mechanisms to direct Env proteins to assembling virions without these specific contacts to Gag—a default pathway, or a pathway using other interactions. Indeed, other distinct parts of Gag, including the p6 region of HIV-1 Gag, have been implicated in Env incorporation (528).

The HIV-1 protein Vpr is efficiently incorporated into assembling virions at very high levels, approaching equimolarity with Gag. This incorporation requires the presence of the p6 domain of Gag (651) and may be mediated by a direct interaction (39). The binding can be used to direct foreign proteins into the particle; a fusion between Vpr and a foreign protein will be targeted to virions. Furthermore, Vpr can be used to direct separately expressed versions of RT or IN to particles in a functional form, to complement mutations in the RT or IN domains of the Gag-Pol fusion (402).

Host Proteins in the Virion

A number of host proteins have been shown to be present inside the virion particle; in most cases, the significance of the protein is unknown. Prominent among the virion-associated factors are a number of cytoskeletal proteins. These include actin (33,512,530,760) and various members of the Ezrin-Radixin-Moesin (ERM) family, specifically ezrin, moesin, and cofilin (530). The Gag, and especially the nucleocapsid protein of HIV-1 have been shown to directly bind to actin (426,609,760), perhaps offering a mechanism for its incorporation into the particle. A complication in analyzing virion-associated proteins is that virion preparations tend to be contaminated with substantial amounts of microvesicles, entities released by cells that exhibit a density and size very similar to that of virions, and containing an array of host proteins (66).

The virions of HIV-1 contain substantial levels of cyclophilin A, a proline isomerase of uncertain function but implicated in protein folding and signal transduction (244,443,712). The incorporation of cyclophilin A is not required for assembly, but it is important for efficient entry of HIV-1 into newly infected cells, before the process of reverse transcription is initiated

(90). Its exact role is uncertain. Several other proteins have also been found in virions: a translational elongation factor, eIF-1a (121), and a protein known as H03 (408), with similarity to histidyl tRNA synthetase, are additional examples.

Host proteins may also be attracted into virion cores by mechanisms other than Gag. Recently, the host uracil DNA glycosidase, responsible for removing uracil bases from DNA, was shown to be incorporated into virions by contacts to IN (761). Another protein, the RNA transporter staufen, was shown to be incorporated into virions, probably through contact to viral RNA (502).

There are also substantial levels of host proteins in the virion envelope. The mechanism of incorporation of these proteins into the virion is not clear, and in most cases again the significance is uncertain. However, one such molecule, major histocompatability complex (MHC) class I, is present at levels approaching those of the Env protein and can be functionally significant, in that xenogeneic antibodies targeted to MHC can neutralize the infectivity of viruses such as HIV-1 (33,34).

RNA PACKAGING

The RNA genome is incorporated by virtue of interactions between specific RNA sequences near the 5' end of the genome, termed the packaging or Psi sequences, and specific residues in the NC domain of Gag (see refs. 30 and 61). Both partners in this interaction have been intensively studied.

Gag Sequences Important for Packaging

The Gag precursor is probably the form of the protein that is responsible for packaging the RNA (519), and the NC portion of the precursor plays the largest role. Mutations affecting the NC protein often reduce the incorporation of the genomic RNA into the virion particle (see ref. 61 for review). The most crucial sequences are the Cys-His boxes, short sequence blocks resembling zinc fingers and containing the motif Cys-X2-Cys-X4-His-X4-Cys, but basic residues elsewhere in the NC molecule are also important (319,578). The NC protein of various viruses contains either one or two copies of the Cys-His box. When two copies are present, they are not equivalent or interchangeable, suggesting that they mediate distinct interactions with RNA (281). Some viral cores can cross-package heterologous viral RNAs, suggesting good binding to the heterologous Psi region, and sometimes there is a strong preference for the homologous RNA. Exchanging the NC domains between viruses can sometimes transfer the preferential selectivity of a Gag protein for its cognate RNA, although the specificity of these hybrid Gags is often poor, and in some cases other sequences in Gag can determine the preference for RNA packaging by chimeric Gags.

RNA Sequences Important for Packaging

The packaging or Psi regions on the viral RNA genome that are recognized for incorporation are quite distinct in nucleic acid sequence among the various viruses. The key Psi regions lie near the 5' end of the RNA, generally between the LTR and Gag. However, other regions of the genome can affect RNA packaging, including sequences upstream in R and in U5, downstream in Gag coding regions, and even near the 3' end of the genome. In the case of ALSV, a region of 270 nt is necessary and sufficient to mediate the packaging of a foreign RNA (29,45,366). In the case of the MuLVs, sequences that are at least partially sufficient to mediate packaging have been similarly identified (3). These Psi regions are relatively autonomous; Psi can be moved to ectopic positions in the genome with at least some retention of function (459).

The various Psi sequences have been predicted or shown to form a number of stem-loops, often containing GACG in the loops. Reversion analysis of mutants with alterations in these loops confirms the importance of the stem-loop structure (182). Mutational studies show that several such loops may incrementally contribute to the efficiency of packaging of the RNA, although one or two are often found to be most important (238,501). Recently, one of the stem-loop structures of the HIV-1 Psi was replaced by a completely foreign sequence that was selected on the basis of its binding activity with NC; the resulting RNA was efficiently packaged and utilized for replication, strongly suggesting that the binding to Gag is the key function of Psi (124). A structure of the HIV-1 NC bound to one such stem-loop has been resolved by NMR, revealing specific contacts between both hydrophobic and basic residues of NC and nucleotides in the stem-loop of the RNA (165).

Dimerization of the Viral Genome

Mature virions contain a dimeric RNA that is highly condensed into a stable, compactly folded structure referred to as the 70S dimer on the basis of its sedimentation rate. Packaging of RNA is associated with the dimerization of the RNA, but it is not completely clear whether the genome is present as a dimer before it is incorporated into virions or is incorporated as a monomer and then dimerized after its incorporation. However, some ASLV mutants suggest that monomeric RNA can be packaged under some circumstances (527), implying that dimerization may follow packaging. There are specific sequences in the RNA, termed dimerization or dimer linkage structures (DLS), that are required for RNA dimerization *in vitro*, and for the formation of the dimeric virion RNA *in vivo*. These DLS elements are in close proximity or even intermingled with sequences required for packaging of the RNA, often making it difficult to determine their separate contributions to these processes. The dimerization of viral RNAs can be induced *in vitro*, and it is stimulated by the addition of NC or the Gag precursor. However, it is uncertain to what extent these reactions reflect dimerization *in vivo*.

The viral RNA in newly budded virions is present as an unstable dimer, dissociated by heat at relatively low temperatures, and it becomes condensed to a more stable dimer during virion maturation (254). This condensation requires the proteolytic processing of Gag (252) and may be mediated by the free NC upon its release from the precursor. A model for the process of dimerization, the “kissing loop” model, suggests that duplex formation between two RNAs is initiated between loops on the two RNAs and propagates outward through the stems to form a more stable duplex. It is possible, but by no means certain, that such changes in the duplex regions could account for the change in

thermal stability upon maturation.

Many cells contain vast arrays of endogenous proviruses and retrovirus-like elements, a subset of which can be expressed constitutively or under various conditions of stress to produce large amounts of genomic RNA. If such a cell is infected by an exogenous virus or has been engineered by expression constructs to produce virions, the particles will incorporate the endogenous RNAs along with the viral RNA (65,556). The endogenous retroviral RNAs, notably the VL30 RNAs of rodents, contain highly efficient Psi sequences (484,717), presumably because they were selected to compete with the homologous genomes of exogenous viruses for packaging.

Virions also contain a number of host RNAs of uncertain significance. There are substantial levels of 7S RNA, a low-molecular-weight RNA thought to function in host RNA splicing (116). In addition, there are low levels of host mRNA. Particles released without efficient packaging of the viral genome (as are produced by Psi-mutant genomes) may carry enhanced levels of host RNAs, and various mutants with alterations in NC can show selective enhancement of both endogenous viral and host RNAs (484). A variant avian leukosis virus (ALV), SE21Q1b, packages unusually high levels of host RNA (260,425) and is capable of transducing these host sequences into new cells by reverse transcription (445). This phenotype of high-efficiency transduction is associated with an unusually high level of proviral expression and particle production rather than any specific alteration in a viral protein (18).

Incorporation of tRNA Primer

A key aspect of RNA packaging is the incorporation of a host tRNA along with the genome to serve as the initiating primer for minus-strand DNA synthesis (for review, see ref. 453). Virions contain a substantial pool of free tRNA, perhaps 50 to 100 copies per particle. The bulk of these tRNAs are not associated with the genomic RNA and are present in virions that lack the genome. In some viruses, these tRNAs are largely representative of the pool of tRNAs in the cell, whereas in others they are highly enriched for the tRNAs needed for priming DNA synthesis, although even here many other tRNAs are present. Viruses prepared without the Pol proteins do not show this enrichment, suggesting that Pol, and most probably the RT protein, are responsible for bringing these tRNAs into the virion (566). In accord with this notion, the RT of ASLV has been shown to preferentially bind tRNATrp from a mixture of tRNAs, accounting for its enrichment in the virion (538). Similarly, HIV-1 RT preferentially binds tRNALys3, and the interaction domain has been shown to at least include the anticodon loop of the tRNA. However, no similar preference for the natural primer tRNAPro has been detected for the MuLV RT. It may be significant that the MuLVs have been shown to be able to utilize a range of different primer tRNAs when only the complementary sequence in the genome (the pbs) is altered to promote their use.

tRNA Primer Placement

A very small subset of the incorporated tRNAs—two per virion—are annealed to the pbs, an 18-nt sequence near the 5' end of the genome with perfect complementarity to the 3' sequences of a specific primer tRNA. The pbs sequences are, as one would expect, essential for normal reverse transcription of the virus (613). The sequence of the pbs can determine the primer tRNA that is utilized (789), but changes in the pbs tend to revert back to the wild type (759), suggesting that alternate tRNAs do not function well. An interesting aspect of reverse transcription provides an efficient mechanism for this reversion: The use of the original tRNA even once during replication will convert the pbs back to the original sequence, because the tRNA itself is the template for the DNA copy of the pbs. Other sequence blocks of the tRNA are also paired with complementary sequences in R and U5 to form a large, complex structure required for proper tRNA primer placement and utilization (7,126,205,328,334). These other sequences are presumably responsible for the selectivity for the natural tRNA primer. In the alpharetroviruses, *pol* gene products are required to mediate the placement of the tRNA on the genome, but in the gammaretroviruses, *pol* is not required (253). The Gag precursor, and especially the NC domain, are thought to play a major role in promoting the annealing of the tRNA to the genome. Although NC can promote annealing of complementary RNAs and DNAs *in vitro*, its role and the mechanism by which it may act *in vivo* remain uncertain.

PROTEIN PROCESSING AND VIRION MATURATION

As retrovirions are budded from the cell surface, the Gag and Gag-Pro-Pol precursor proteins are proteolytically cleaved to release the smaller proteins present in the infectious virions (for review, see ref. 741). The cleavage of Gag and Gag-Pro-Pol is mediated by the viral protease PR, which is expressed either in Gag, Gag-Pol, or Gag-Pro-Pol fusion proteins. Thus, PR is responsible for cleaving itself out of a precursor protein and then making a number of other cleavages in these proteins.

Activation of the Protease

The processing of Gag and Gag-Pro-Pol precursors is intimately linked to assembly and budding, and it is controlled so that the precursors are not cleaved until they are assembled. It is not certain how PR is regulated during assembly to begin cleaving its substrates. The structure of PR has revealed that the active enzyme is a homodimer (see later), and thus its activation could be promoted by dimerization of the Gag or Gag-Pro-Pol precursor associated with assembly. As the virions form, one could imagine the high concentrations of the protein generating an active PR that would begin to cleave Gag and Gag-Pro-Pol, and that would release the mature PR dimer as well. However, for the betaretroviruses such as MPMV, this mechanism cannot explain the delay in processing. For these viruses, assembly occurs in the cytoplasm and should result in the establishment of a high concentration of Gag-Pro-Pol at that time. Yet cleavage does not begin in the cytoplasm, but rather is restrained until budding and export of the preformed virion particle. Thus, other unknown mechanisms, perhaps coupled to membrane association, must be responsible. Similar conclusions were reached from analysis of IAP virions, in which assembly in various intracellular locations did not result in processing—membrane association was required (755).

Various domains of Gag have been suggested to inhibit PR (266), and conformational changes could relieve this inhibition. In the alpharetroviruses, a cleavage at the NC-PR boundary is required to release active PR, so activating this

cleavage could serve as a trigger (102). Similar cleavages at the p6*-PR boundary are important for full activation of the HIV-1 PR (711). Another possibility is the activation of the PR by a drop in the pH associated with virion release. It should be noted that the overexpression of PR in many artificial settings, both in bacteria and in animal cells, as a Gag-PR fusion or alone, can result in formation of highly active enzyme (24). The high-level expression of PR is often toxic for cells, presumably because of its inappropriate action on many host proteins.

Protease Structure and Function

The retroviral proteases are aspartyl proteases with clear sequence similarity to members of the cellular family of aspartyl proteases (362,434,742). The three-dimensional structure of many proteases, including those from ALSV, HIV-1, HIV-2, SIV, feline immunodeficiency virus (FIV), and EIAV, have been determined by x-ray crystallography (406,409,491,509,582,616,748,772). The viral enzymes are small, typically containing about 100 amino acids, and are homodimers as isolated from virions. Each subunit contributes to the active site a single aspartate residue, lying in a loop near the center of the molecule. There is a long cleft at the interface between the subunits where the substrate lies; there are pockets to interact with each of the side chains of the substrate, conferring specificity to the enzyme. Each subunit has a flap consisting of an antiparallel sheet with a b-turn that covers the cleft, and this flap moves out of the way to permit the binding of the substrate into the active site.

Retroviral proteases have a complex specificity for substrate peptides (560). The enzyme makes contact with approximately seven or eight side chains on the substrate and thus can select its cleavage sites on the basis of at least these amino acids. The cleavage sites tend to be within hydrophobic sequences and yet must lie in accessible and extended conformations. Some analyses of the various sites in Gag and Gag-Pol that are recognized by PR suggest that either one of two sequence motifs constitutes a consensus site: One set has an aromatic residue or proline flanking the cleavage site, and the other set has aliphatic residues at these positions. Mutational analyses have allowed further definition of the residues on PR that make specific contacts to the substrate.

Protease Inhibitors

Studies of mutant viruses lacking PR demonstrated that the protease is essential for virus replication. Viruses lacking a functional PR can still express Gag and Gag-Pol precursors, and they can mediate the assembly and release of immature virion particles. Thus, PR is not required for the process of virion assembly per se. However, these particles are noninfectious and are blocked at an early step prior to the initiation of reverse transcription (147,363,390). Because of its essential role in virus infectivity, PR was appreciated early in the course of the AIDS epidemic as an attractive target for antiviral therapy. A number of molecules have been generated that can bind and inhibit PR, including peptide mimetics with uncleavable, nonsessile bonds at the cleavage site (158,494). Some are transition state analogs, and may have inhibition constants (K_i) in the nanomolar or subnanomolar range. These inhibitors have been extremely effective antiviral agents, and because they target a distinct enzyme and a distinct step in the life cycle from the RT inhibitors, they have been particularly effective in combination with earlier drugs targeted at RT. The combination of three drugs that include a protease inhibitor is now the standard of treatment for AIDS, and such highly active antiretroviral therapy (HAART) can keep virus loads below detectable levels in some patients for many years. Ultimately, however, point mutations in PR that confer resistance to the drugs can arise (210), allowing some virus replication in spite of therapy.

Processing of the Gag Precursor

During and after release from the cell, the Gag precursor is cleaved by the protease into a series of products present at equimolar levels in the virion. The number and size of the products vary considerably among the various viruses; the spumaretroviral Gag is exceptional in undergoing the fewest cleavages. A summary of the Gag products of some representative viruses is shown in Table 4. There are many features of these products common to most of the retroviruses.

Protein	ALV	MLV	MMTV	MPMV	HTLV-1	HIV	HFV
MA	p19	p15	p10	p10	p19/15	p17	–
?	p10	p12	p24	p24	–	–	–
CA	p27	p30	p24	p27	p24	p24	p33
NC	p12	p10	p14	p14	p12	p7	–
DU	–	–	p46	–	p15	–	–

TM	gp37	p15E	gp36	gp22	gp20	gp41	gp48

ALV, avian leukemia virus; MLV, murine leukemia virus; MMTV, mouse mammary tumor virus; MPMV, Mason-Pfizer monkey virus; HTLV-1, human T-lymphotropic virus type 1; HIV, human immunodeficiency virus; HFV, human foamy virus.
Proteins: MA, matrix; CA, capsid; NC, nucleocapsid; DU, deoxyuridine triphosphatase; PR, protease; RT, reverse transcriptase; IN, integrase; SU, surface; TM, transmembrane.

TABLE 4. *Virion proteins found in mature particles of various retroviruses*

The Matrix Protein

Beginning at the aminoterminus, most Gags are processed to form a membrane-associated or matrix protein (MA). The MA protein is thought to remain bound to the inner face of the membrane as a peripheral membrane protein, and it can be cross-linked to lipid. MA may make contacts with the cytoplasmic tail of the envelope protein. When the precursor Gag is myristylated at the aminoterminus, the corresponding MA protein retains that myristate and so is presumably bound tightly into the membrane. The compact structure of the MPMV MA protein has been elucidated by NMR (136,473). The MA proteins of HIV-1 and SIV have been shown to form trimers in crystallization studies (56,595) and can contribute to

the ability of a larger Gag precursor to form trimers in solution (500). The protein can form extended sheets of trimers, with a large opening in the network. If similar structures were to form in a sphere, the surface could have openings into which the envelope tail may fit.

The Capsid Protein

Gag proteins are cleaved to generate a large product serving as the major capsid protein (CA) in the virion core. The CA protein is relatively well conserved among Gags and contains the only highly conserved motif among Gags, the major homology region (MHR). The function of this motif remains uncertain; although mutations in the region affect virion assembly in some viruses (145,458,685), it is not absolutely required for this process, as the entire CA domain of ASLV can be deleted without blocking assembly. CA is thought to form the shell of the condensed inner core of the mature virus, and thus it makes either a spherical, a cylindrical, or a conical structure, depending on the virion morphology. The protein has proved difficult to crystallize, and the structure of the complete protein is uncertain (495), but the structures of both the N-terminal and C-terminal fragments of the HIV-1 CA have been determined (261,272). Very recently, the analogous structures of the RSV capsid (393) and of the EIAV CA protein (345) have been determined and used to model a structure of the virion core. The CA protein can form dimers in solution, and recombinant proteins containing CA, or CA plus NC, can assemble to form higher-order structures consisting of either tubes, spheres, or, in the case of HIV-1, cones (262). CA has also been studied after tethering sheets of the protein to membrane (48). Image reconstruction of electron micrographs, coupled to the subdomain structures, have led to models for the packing of CA to form these large assemblies. The major CA-CA contacts must form after processing during the condensation of the virion core, and they may be very different from any contacts that exist in the immature virion particle (211).

The Nucleocapsid Protein

All Gag proteins except for those of the spumaviruses are cleaved to produce a nucleocapsid protein, NC, located near the carboxyl terminus of the precursor. NC proteins are small, highly basic proteins containing one or two copies of the Cys-His motif, Cys-X2-Cys-X4-His-X4-Cys. These sequences bind a single Zn^{2+} ion avidly, and they fold around the ion into a characteristic structure that is smaller and rather different from the better-known zinc-finger structure. The structures of NC proteins in solution have been studied by NMR, which revealed a tightly folded knuckle with disordered flanking sequences (389,499). The interaction with zinc results in the incorporation of substantial levels of Zn^{2+} into all retrovirus virion particles (67).

The NC protein in virions is closely associated with the viral RNA, probably coating the entire RNA molecule; the stoichiometry of binding is such that each NC molecule can bind to about six nucleotides of RNA. NC proteins bind nonspecifically to heteropolymeric single-stranded nucleic acid with moderate affinity (728). However, NCs also exhibit specificity. Tests of binding to nucleic acids of defined sequence have shown that NCs bind poorly to poly(A), and most tightly to nucleic acids containing GT dinucleotides, especially alternating (GT)n polymers (239). In addition, NC has been shown to exhibit sequence-specific binding activity *in vitro* for nucleic acids containing the Psi region, required for packaging of the viral RNA (62,123). The interaction can also be assayed in reconstructed systems in yeast via the so-called three-hybrid method (40,412). This binding presumably reflects at least some aspect of its role in packaging the genome. A specific complex of the HIV-1 NC with a stem-loop derived from Psi has been studied by NMR, and the resulting structure shows a number of specific contacts between hydrophobic residues of NC and bases in the four-nucleotide loop, and between basic residues and specific phosphates in the stem and loop (165).

NC proteins change the base-pairing properties of nucleic acids and thus can have profound effects on the kinetics and thermodynamics of annealing (166,720). Under various conditions *in vitro*, NC can stimulate the dimerization of RNAs, and duplex formation between tRNA and its complementary sequences at the pbs (81). Thus, NC can help promote primer tRNA placement during virion assembly (603). NC can also help melt out secondary structures, and it may facilitate the movement of RT along the template during reverse transcription (775). In addition, it is clear that NC can bind to double-stranded nucleic acid, and thus it is probably retained on the viral DNA after its synthesis by RT. NC mutants have been found that affect the course of DNA synthesis or DNA stability during the early stages of virus infection, suggesting a role in the processing of the DNA and protection of DNA from degradation (282,699). Finally, NC has been shown to promote the concerted integration of the two termini of the viral DNA into a target sequence (see earlier, and ref. 109).

An important class of inhibitors of virus infectivity and replication that act by targeting the NC protein has been identified (615,725). These compounds, disulfide-substituted benzamides (DIBAs), eject the zinc ion from NC and cross-link the cysteines via disulfide bonds. Virions treated with these compounds are potently inactivated without disrupting the virion structure, and the course of virion assembly in infected cells is similarly blocked (531,601,629,727). Drug-resistant variants are not readily recovered.

Other Gag Products

Some retroviral Gag proteins, including those of the alpha-, beta-, and gammaretroviruses, contain one or more poorly conserved domains of 10 to 24 kd lying between MA and CA. The functions of these proteins is unclear. The ASLV p2 protein, the MuLV p12 protein, and the MPMV p24 protein contain a PPPY motif that plays an important role in late stages of virion assembly (see earlier). The MuLV p12 protein has also been shown to play a role in the early stages of infection (146,793).

In the lentiviruses, a p6 domain is present at the carboxyl terminus. The role of p6 is unclear, although it contains the L domain and thus may be important in virion release; it also is required to mediate the incorporation of Vpr into virion particles, perhaps by providing a direct docking site. Proteins can be targeted to virions by generating Vpr-X fusions, which are incorporated into lentiviral virions in a p6-dependent manner.

Processing of the Gag-Pro-Pol Precursor

At the same time that the Gag precursors are cleaved during virion maturation, the Pro and Pol region of the Gag-Pro-Pol precursor is also cleaved, giving rise to the PR, RT, and IN products. The Pro and Pol–containing precursors of different viruses are cleaved in diverse patterns (Fig. 17). In the gammaretroviruses, the Pol region is processed by complete digestion to form PR, RT, and IN (321,701). In the alpharetroviruses, the Pol region is cleaved to produce a heterodimeric RT with a larger b subunit and a smaller a subunit. The larger b subunit contains both RT and IN domains. It is not clear whether the IN domain in the context of this subunit performs an important function, although it is responsible for a weak nuclease activity associated with RT (277). A portion of the Pol precursor undergoes an additional cleavage to produce the a subunit of RT, an aminoterminal fragment of the b subunit, and the separate IN protein. In the lentiviruses, Pol is processed to give rise to PR, a heterodimeric RT, and IN. However, the RT of these viruses is not identical to the heterodimeric RT of the alpharetroviruses. Here, the IN domain is fully removed from RT. One RT subunit remains intact (for HIV-1, this is the p66 subunit), and the other subunit undergoes an additional cleavage to remove a carboxyl-terminal domain (to form the p51 subunit). The functional significance of the different subunit structures of these various RTs is unclear, as they all perform a very similar set of reactions during virus replication. The processing of Pol precursors may be associated with the activation of the DNA polymerase of RT. In the alpharetroviruses, the immature Gag-Pol protein has very low DNA polymerase activity, and its maturation results in a large increase in activity (144,679). However, the immature Gag-Pol protein of MuLV and HIV-1 has high DNA polymerase activity, and there is only a very modest increase upon maturation (147).

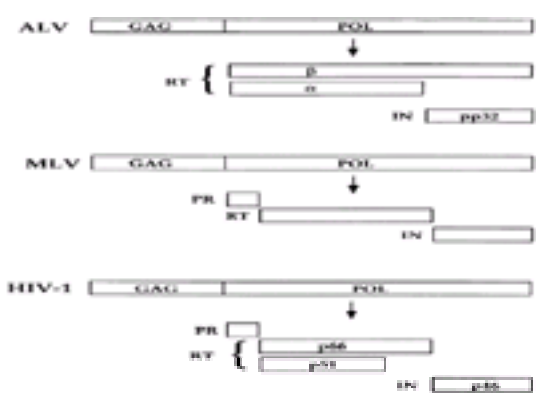

FIG. 17. Cleavage patterns during the processing of the Gag-Pol fusion proteins of various retroviruses. The structure of the mature cleavage products found in the virion particles are shown aligned with their location in the precursor.

The Gag-Pro-Pol precursor of the betaretroviruses and the nonprimate lentiviruses is also processed to produce the dUTPase protein, DU. In the betaretroviruses, the *pro* ORF encodes both DU and PR; in the nonprimate lentiviruses, the enzyme is encoded in the *pol* ORF, and DU lies in between RT and IN in the polyprotein. This enzyme acts to reduce the levels of dUTP that could otherwise be incorporated into viral DNA. Mutants of FIV lacking the function indeed show increased rates of mutation during replication (417), and similar mutants of CAEV tend to accumulate G-to-A substitution mutations (726), presumably as a result of incorporation of deoxyuridine (dU) residues that are subsequently read as deoxythymidine (dT). The FIV enzyme has been crystallized, and the structure of the protein has been determined by x-ray diffraction (583).

Processing of the Env Precursor

The major proteolytic cleavage of the Env protein to form the SU and TM subunits is performed during its transport through the ER and Golgi by host proteases termed furins. This cleavage is essential for virus infectivity (477,564), and it is thought to induce substantial rearrangements of the polypeptide chain. The TM subunit remains embedded in the membrane and contains an extracellular domain, a membrane-spanning segment, and a cytoplasmic tail. The SU subunit lies wholly outside the cell, and after its incorporation into the virion particle, wholly on the extravirion surface. It is held to the virion by contacts to TM, and most often by noncovalent bonds (302), although disulfide links may occur in some viruses (574). SU is heavily glycosylated, and the presence of at least some of these sugars is important for virus infectivity. Perhaps the most important function of this heavy glycosylation is to hide the peptides on the surface of Env from neutralizing antibodies that would otherwise have access to the virion surface.

The Surface Subunit (SU)

For most viruses, the major receptor-binding site is located in hypervariable sequences on the SU subunit, so that SU is a major determinant of host range. Chimeric SU proteins can be generated to demonstrate that the receptor utilization function maps to specific regions of the protein. The key regions of the avian Env proteins have been similarly defined by selecting for changes in host range *in vivo*; these studies show that very small changes can result in the use of new receptors (704). The structures of two SU proteins have been recently determined at high resolution: a fragment of MuLV SU (225), and a fragment of the HIV-1 SU bound to its receptor CD4 (405,618). These structures suggest that the receptors make contacts to the envelope in shallow pockets that may not be readily bound by antibodies.

The Transmembrane Subunit (TM)

The TM subunit contains the so-called fusion peptide at its aminoterminus, and TM is thought to play the major role in fusion of the virion and host membrane (167,251,303,308,639). Many TM mutations are defective for membrane fusion (189,805). However, mutations blocking fusion can lie in SU as well (796). The entire Env protein probably acts as a

unified machine to mediate fusion, with complex interactions between the subunits (155), and with major movements of the subunits during the process of fusion. The fusion peptide of TM may simply insert into the host membrane, or it may make contacts to proteins. The major contacts for oligomer formation of Env are thought to lie in TM (203); isolated TM proteins form trimers in solution (227) and in crystals (225,226,387,454). The trimer is held together by a modified leucine zipper motif that bridges the monomers via hydrophobic interactions. This zipper region is crucial for virus infectivity (422,594,757).

It is possible to separate the two major functions of the Env protein onto two different molecules that cooperate to mediate these steps. Thus, the receptor binding function can be mediated by one Env protein, and the membrane fusion function can be mediated by another Env. This is apparent in the ability of two Env proteins to complement in mixed oligomers (602,802). It is also demonstrated by the ability of a wild-type Env to provide the membrane fusion function for a chimeric Env that on its own can mediate only cell surface binding.

The TM subunit of the MuLVs undergoes a second cleavage during virion assembly (359) that is mediated by the viral protease, PR. This step removes a short sequence called p2E, or the R peptide, from the carboxyl terminus of TM (289). The cleavage step may require presentation of the tail to the protease, or some conformational change in the tail, that is mediated by Gag proteins; alterations in the MA or p12 Gag proteins can modulate the cleavage of TM (377,793). Astonishingly, the cleavage is necessary to activate the fusogenic activity of the envelope protein and thus for virus entry (94,600). Mutants in which the tail is truncated at the site of cleavage are constitutively activated for fusion, and these viruses induce dramatic syncytia in receptor-positive cells. Mutants in which the tail is not removed are inhibited for fusion, and particular residues can be shown to be required (779). How the cytoplasmic tail inhibits the fusogenic activity of Env is very much unclear.

In a similar way, the cytoplasmic tails of the TM of MPMV (670) and EIAV (614) are processed by the protease. In the case of MPMV, the presence of the intact tail is necessary for efficient incorporation of Env into the virion. The majority of the retroviruses, however, do not carry out cleavage of TM, and for these viruses an intact tail is needed for infectivity (190). The replication of some viruses in host cells of foreign species can select for alterations and truncations of the TM tails (388,614,657). The selective advantage conferred by this truncation is not well understood, although various aspects of Env function seem to be enhanced by this truncation (806).

Morphologic Changes upon Virion Maturation

The maturation of retrovirus particles is a complex process that is required for the formation of an infectious virus. The particles that are initially assembled either at the plasma membrane (by most retroviruses) or in the cytoplasm (by the betaretroviruses) have a characteristic immature morphology: The particles are round and stain with an electron-dense ring and a relatively electron-lucent center. After release from the cell, the morphology changes to a more condensed structure, with a central core largely detached from the surrounding envelope. In the alpha-, gamma-, and deltaretroviruses, the core is spherical and concentric with the envelope; in the beta-retroviruses, the core is spherical but eccentrically placed within the envelope; in the lentiviruses, the core is cylindrical or conical, with thin connections to the surrounding shell. In the spumaviruses, the morphology does not change dramatically after assembly.

Mutant viruses lacking the protease show little change in morphology. Thus, cleavage of Gag and Gag-Pol is required for the restructuring of the virion into the mature form (363). The changes in morphology visible in electron micrographs are probably associated with major rearrangements of the Gag proteins. Indeed, the physical properties of the virus change dramatically upon maturation. Whereas the immature core is quite stable to nonionic detergents and harsh conditions, the mature virion core is relatively labile. This change may reflect the inability of the immature virion, and the acquired ability of the mature virion, to uncoat upon infection of new cells and initiate reverse transcription.

RETROVIRAL DISEASES

The Varied Effects of Retroviral Infection

Retroviruses cause an extremely wide range of responses in infected animal hosts. The discussion of retroviral pathogenesis will begin with a little-appreciated but important point: Retroviruses in general are surprisingly benign. The vast majority of the replication-competent retroviruses are not cytopathic, and the infection of cells causes remarkably little impact on their replication or physiology. The morphology, the control of cell division, and the doubling time of cells in culture are not significantly changed after infection. Once a chronic infection is established, only a relatively small amount of the cellular metabolism is committed to virus expression: Typically, a small percentage of the cellular mRNA and protein is viral, and so the cell can perform its normal functions and survive for its normal lifespan. Indeed, animals show few acute affects upon infection. The animals do become viremic, and a vigorous immune response is often mounted that can reduce the levels of virus production. However, infected mice or birds may live relatively normal lives for many months or years, and so it is appropriate to consider the viruses as relatively benign parasites. It is noteworthy that the virus is not eliminated but only suppressed by the immune response, and low-level viremia usually persists in infected animals for life.

Retroviruses often do, however, cause disease. The chronic viremia of the replication-competent retroviruses is tantamount to high-level mutagenesis of the infected cells, for each infection event is associated with a proviral insertion that constitutes a mutation. Eventually, the odds are that a cell will suffer an insertion that alters the normal control of cell division or cell survival, and abnormal proliferation of this cell results in tumorigenesis. Many retroviruses cause disease in this way, including the so-called slow leukemia viruses and agents such as MMTV. A few retroviruses, however, are more pathogenic: A small minority of the retroviruses are directly cytopathic, and many of the infected cells are killed. These agents can thus destroy the infected tissues and directly impair their function. These include the cytopathic avian viruses and, probably, the AIDS virus, HIV-1. Finally, a special class of retroviruses exists, the so-called acute transforming viruses, that can induce a rapid tumor formation. These viruses were among the first filterable oncogenic agents ever discovered, and their dramatic effects were a major motivation for the intense study of all the tumor viruses

throughout the 20th century. We now understand that these agents are transducing viruses; the replication of retroviruses allows recombination events between viral and host sequences that move genes onto the viral genome. These viruses carry and express host genes at inappropriate levels, in inappropriate cells, and often with drastic alterations in gene structure. If the gene product so expressed by the virus is mitogenic or antiapoptotic, the result can be a potent alteration in the physiology of the infected cell. These acute transforming viruses can thus initiate a highly aggressive tumor very efficiently and with minimal latency, because each infection of a cell has the high potential to initiate an oncogenic transformation event. Most often, the acquisition of the host gene comes with a loss of a viral gene essential for its replication; as a result, these viruses are often replication-defective and depend on a helper virus, usually a replication-competent leukemia virus, for their transmission to new cells. Each of these various classes of pathogenic viruses will be discussed in turn.

Diseases Caused by the Replication-Competent Retroviruses

The typical pathology of many of the simple replication-competent retroviruses is the development of leukemia or lymphoma after a very long latency. For this reason, these agents are often called the slow leukemia viruses. Examples are found in rodents, including the many MuLVs, and in birds, including the avian leukemia-leukosis viruses. The symptoms eventually begin with a lymphoid hyperplasia (681), which may be directly attributed to the immune response; not all the affected cells are infected, and the proliferating cells may be stimulated by cytokines that are released in response to the infection (93). These cells may include a preleukemic state of partially transformed cells (164). There may be some cell killing resulting from enhanced apoptosis in these early times (82), although the mechanism of the apoptosis and the relationship to tumorigenesis is unclear. A subset of these expanding cells progress to frank leukemia, which ultimately can be fatal in susceptible animals. These observations strongly suggest that leukemogenesis is a multistep phenomenon, and it is also likely that the virus plays a role in more than one of these steps (221). The cell type transformed by the virus can be very narrowly defined, or more broadly variable, but will depend strongly on viral determinants. For example, the ASLV group of viruses typically cause a bursal or B-cell lymphoma in birds; the MMLV causes a T-cell leukemia; the Friend helper MuLV causes an erythroleukemia; MMTV causes a mammary epithelial tumor.

In some species and settings, the infecting virus is the proximal agent of disease; such is the case with infection of rats by the MMLV. However, the course of leukemogenesis in mice and other animals is often associated with the appearance of recombinant retroviruses derived from the parental infecting virus and endogenous sequences present in the germline (114,218,471). The recombinant viruses are often the true or proximal pathogens. These viruses are heterogeneous in structure and phenotype, but most contain substitutions of the *env* gene and LTR that confer novel properties to the initial virus (172). Some of the viruses arising in mice can be detected through an expanded host range, as an ecotropic virus acquires *env* sequences that allow infection through the xenotropic or dual-tropic receptors; these viruses are the MCF viruses (312). The range of cell types and the replication ability of the input virus can be expanded by recombination to significantly enhance the incidence of leukemia and shorten the latency period to disease. The donor sequences for these recombination events are not all universally present in a given species but are highly variable from strain to strain (16,407,592). The presence or absence of suitable endogenous proviruses in the germline that provide the sequences needed for recombination can control the severity and course of disease.

Leukemogenesis by Insertional Activation

The most common mechanism of action of the replication-competent viruses in initiating tumors is termed proviral insertional mutagenesis, and it leads to the activation of endogenous proto-oncogenes (300,516,559). During replication in the infected animal, an enormous number of cells are infected and so acquire new proviral DNA insertions at near-random sites. Each of these insertions constitutes a somatic mutation, and thus retrovirus infection can be thought of as similar to a massive exposure to a potent mutagen. The vast majority of the insertions are harmless, causing no significant change in host gene expression, and the majority of those that do disrupt genes simply create a recessive mutation at one allele out of two present in the cell, again causing no significant change in the overall pattern of gene expression. But very rarely, a provirus insertion can create a dominant-acting mutation that profoundly alters the physiology of the cell. When a provirus integrates near a gene that controls growth and so alters its expression, the cell may proliferate and ultimately form a clonal tumor in which all cells contain the provirus integrated at the same site.

A large number of cellular genes have been identified as potential targets for insertional activation in retrovirus-induced tumors. Among the most notable are an array of transcription factors, including *c-myc, N-myc, c-myb, Fli1, Fli2, Ets1 (Tpl1), Evi1 (Fim3), Bmi1 (Flvi2),* and *Spi1* (PU.1); a number of secreted growth factors, such as *Wnt1 (Int1), Wnt3 (Int4), Int2 (Fgf3),* and *Fgf8;* growth factor receptors, including *c-erbB, Int3 (Notch4), Mis6 (Notch1), c-fms (Fim2),* the prolactin receptor, and Fit1; and genes implicated in intracellular signal transduction pathways, such as the serine/threonine kinases *Pim1* and *Pim2.* Many of these genes are also known to be involved in or implicated in tumorigenesis in other settings, either when transduced on retroviral genomes or when activated by more conventional mutations. However, a number of the proto-oncogenes have only been identified by virtue of their having served as target sites during tumorigenesis by leukemia viruses, and thus this route has made important contributions to our list of known proto-oncogenes. Many of these genes would not have been obvious candidates to control cell division or transform cells, such as the translation initiation factor eIF3 (35).

The patterns of activation of these proto-oncogenes by retroviral insertion are quite varied. At least four distinct mechanisms have been observed (Fig. 18).

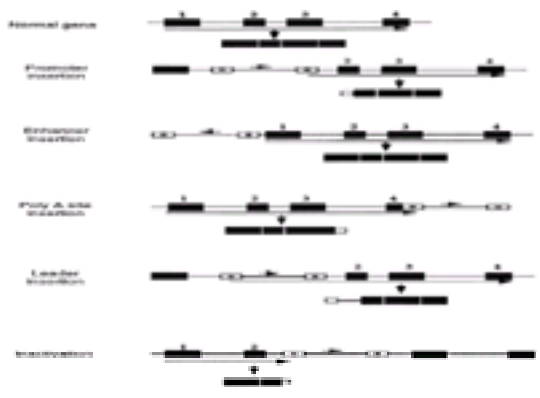

FIG. 18. Genetic alterations in target gene expression induced by retroviral insertional mutagenesis. Various changes in normal gene expression that have been observed upon insertion of retroviral DNA are diagrammed. A target gene containing four exons is used in these examples (*top*). *Promoter insertion:* Insertion of the provirus in the same transcriptional orientation in the first intron is shown to result in the formation of a new mRNA initiated in the 3'LTR and extending into the downstream exons. *Enhancer insertion:* Insertion upstream of the gene, in this case in reverse orientation, is shown enhancing the expression from the natural promoter. *Poly(A) site insertion:* Insertion at the 3' end of the gene in the forward orientation is shown providing a poly(A) addition signal and thereby increasing the levels of a prematurely truncated mRNA. *Leader insertion:* Insertion of the provirus in the same transcriptional orientation is shown to result in the formation of an RNA initiating in the 5' LTR, extending through the provirus and into downstream exons. Splicing results in the retention of only the viral leader on the chimeric mRNA. *Inactivation:* Insertion is shown causing premature end formation of the mRNA, resulting in the formation of an inactive fragment.

1. Promoter insertion. The provirus may insert upstream of the gene or within the gene, and in the same transcriptional orientation as the gene. Transcription beginning in the 3' LTR reads into the gene and results in high-level expression of a transcript with R-U5 sequences at the 5' end. The resulting transcripts may be similar to the natural transcripts, but they may be longer or truncated relative to the normal mRNAs.
2. Enhancer insertion. The provirus may insert either upstream or downstream of the gene, and in either orientation relative to the gene. The insertion brings the powerful transcriptional enhancers present in the U3 regions of the two LTRs into close proximity of the gene, and so activates the endogenous promoter elements. Although the levels are inappropriately high, the structure of the resulting transcript is normal.
3. Posttranscriptional stimulation of expression. The provirus may insert downstream of the coding region and stabilize the formation of an mRNA. The provirus may provide a polyadenylation signal that enhances the formation of stable transcripts, or the insertion may remove RNA destabilization signals in the 3' UTR that would normally mediate the rapid turnover of the RNA. These mechanisms can result in inappropriately high steady-state levels of the mRNA and protein products.
4. Readthrough transcription. The provirus inserts upstream or in the gene, but transcription initiates in the 5' LTR, reads through the provirus, and continues into the gene. The formation of such transcripts is often enhanced by mutations in the provirus, such as loss of the 3' LTR. The transcripts may be spliced aberrantly in complex patterns.

Insertional activation of a proto-oncogene by a provirus is not sufficient on its own to fully transform a cell but represents only one step in a progression to a frank leukemia or tumor. Other mutations are usually required; these mutations can be point mutations in other proto-oncogenes or loss of function mutations of tumor suppressor genes. In some retroviral tumors, more than one oncogene can be activated by insertion of separate proviruses. Similarly, an acute transforming genome is usually not sufficient to transform a cell in one step, and additional mutations must arise. In some tumors induced by a replication-defective transforming virus, the helper virus may provide such mutations by its own insertional activation event (576).

Gene inactivation, as opposed to gene activation, is also an important event in some tumors. Retrovirus insertion can frequently disrupt gene expression to effectively produce a null or hypomorphic mutation (see Fig. 18). These mutations are normally silent, as a second allele would be expected to continue to express a functional gene product. However, if the host animal is already heterozygous due to an inherited germline mutation in one allele, or if the insertional inactivation is coupled to a loss of the other allele by other means, the net result can be homozygous loss of function. When the target gene is a tumor suppressor, the consequence is the promotion of tumorigenesis.

Viral Determinants of Pathogenicity

Several viral genes and sequences can affect the incidence and severity of retroviral disease. The viral LTR contains the most important determinants of leukemogenicity and of the cell tropism for transformation. The enhancer and promoter elements of the LTR are responsible for proto-oncogene activation, and their relative transcriptional activity thus controls the transforming ability of many viruses (220,222,276,335). If these elements are strongly tissue or cell type specific, the virus will be most competent for transformation of those cells in which the LTR is most active. A variety of viruses show profound tropisms for transformation that are controlled in this way (36,84,438,541). For example, the promoter of the MMLV is most active in T cells, and the virus shows strong tropism for the formation of T-cell leukemias. The Friend helper virus LTR contains an enhancer that is most active in erythroid cells, and the virus is correspondingly highly tropic for erythroid cells (86). The promoter of MMTV contains glucocorticoid response elements that provide high-level expression only in cells with high levels of the glucocorticoid receptor and only when exposed to glucocorticoids; as a result, MMTV is specific for mammary tumors (291). Variant betaretroviruses, such as the thymotropic DMBA-LV virus, show selectivity for T cells that is probably attributable to changes in the LTR (42). Determinants of leukemogenicity have also been mapped to *gag*, *pol*, and *env* genes, although in most cases it is not clear what aspects of their functions are required. It may be that vigorous replication *in vivo* is the simple key feature of a highly transforming leukemia virus. There may also be trans-acting functions encoded by the leukemia viruses that modulate expression of specific host genes (219,283). The MuLV and FeLV LTRs encode short RNAs that can trans-activate host genes, apparently through

activation of an AP-1-like activity (270).

Other aspects of infection, distinct from the genetic makeup of the virus or host, can modulate the pathology associated with infection. For example, the route of entry of the virus can affect the disease course (55). Presumably, the route can determine the initial cell types infected and the route of virus spread.

Other Retroviral Diseases

Cytopathic Viruses

Some viruses show distinctive pathogenicity mediated by specific gene products. Cas-Br-E MLV is a well-studied murine virus that induces a hind-limb paralysis with significant neuronal loss in the absence of an inflammatory response (581). Both neurons and glial cells accumulate vacuoles. The virus targets endothelial cells and microglial cells (450) in the brain, and it is likely that the infection of the microglial cells is most crucial to disease induction. Infection may impair or block the neuronal support function of these cells, resulting in loss of neurons, although the mechanism of neuronal cell death is unclear. It is possible that the expression of the Env protein is toxic. The major determinant of pathogenicity is in the SU subunit of the Env protein (449,542). A number of other MuLVs, such as the ts1 mutant of the MMLV TB strain (774), can cause neurologic symptoms, including hind-limb paralysis and spongiform encephalomyelopathy (69), and in these cases too the SU protein is thought to be important (692). TR1.3, a Friend-related MuLV, is a neuropathogenic virus that induces fusion of capillary endothelial cells, leading to a hemorrhagic stroke syndrome (545). The crucial determinant in the virus is a tryptophan residue at position 102 of the SU protein (120,546). In some viruses the LTR is also likely to play a role in disease induction (169,543), perhaps by determining the level of expression and the ability to spread efficiently and access the primary target cell.

A number of the ASLV group of viruses are cytopathic (756) and can cause an acute wasting disease characterized by poor growth, anemia, and immunosuppression associated with atrophy of the bursa and thymus (607). The disease probably reflects the ability of these viruses to lyse infected cells (375,756). Recently, the isolation of the ALV receptor for the subgroup B viruses and its identification as a member of the TNF receptor family suggests the possibility that the binding of Env to the receptor is directly triggering an apoptotic response. The cytopathic and the noncytopathic viruses both seem to be able to trigger similar responses, however, so that it is not clear at this time what aspect of the interaction might be necessary and sufficient for cell killing. The vigorous replication of the virus, and an ability to mediate high-level reinfection before superinfection resistance appears, may also be significant determinants of cytopathology.

Yet another disease caused by a variant virus is the feline acquired immunodeficiency syndrome, or FAIDS. This disease was originally associated with a complex mixture of FeLV isolates. The agent responsible was shown to be an FeLV with mutations affecting the SU subunit of the *env* gene. The mutant FeLV is incapable of establishing superinfection resistance, and so large amounts of unintegrated viral DNA accumulate during superinfection, ultimately leading to high expression of viral gene products and causing cell lysis.

The lentiviruses cause an array of important diseases in animals and humans, most notably AIDS. The major cause of disease is probably cell killing, but the most important target cells and the mechanism by which infection leads to cell death are not clear. The very high level of gene expression mediated by HIV-1 infection in some cell types may be a crucial aspect of the cell killing (668), but the key viral gene products remain obscure. HIV-1 infection eventually leads to depletion of CD4-positive cells and thus to immunodeficiency, culminating in severe opportunistic infections. The lentiviruses also cause a number of other pathologies, including neurologic disease, that are poorly understood. These diseases will be discussed in later chapters.

Stimulation of Host Cell Proliferation

MMTVs lead to the formation of mammary tumors through the insertional activation of a number of proto-oncogenes. However, unlike other simple retroviruses, MMTVs carry an additional gene termed *sag*, for superantigen, that is important for disease induction (see ref. 129 for review). Sag proteins bind to MHC class II molecules in regions that are common to molecules with many different binding specificities, and so they can activate as many as 10% of all T cells. The *sag* gene is located in the U3 region of the MMTV LTR and encodes a low-abundance glycosylated membrane protein (91). The protein must be proteolytically processed for proper export to the cell surface (547). Importantly, expression of a functional Sag protein by MMTV is required to establish infection in an animal. The virus is normally transmitted in mother's milk to newborn mice, infects B cells in the Peyer's patch, and induces a vigorous Sag-mediated stimulation of T cells. There follows a B-cell response that provides a large pool of susceptible B cells for the virus (26), and it is these cells that then carry the virus to the mammary gland. The infection of the mammary epithelial cells ultimately leads to transformation of these cells by insertional activation. This pattern of viral spread through one intermediate cell type, ultimately leading to disease in another cell type, is a paradigm for complex viral pathologies, such as that exhibited by polioviruses.

The *sag* gene of MMTV was also appreciated as acting as a host gene important in disease progression when a number of mouse genes, termed Mls for minor lymphocyte-stimulating antigen, were shown to map to endogenous MMTV proviruses, and were ultimately identified as the *sag* genes. The expression of Mls results in the clonal deletion of many T cells in mice carrying the gene (2). Thus, mice carrying endogenous proviruses will often lose T cells needed for virus replication, and so will be resistant to exogenous MMTV disease.

A number of other viruses carry variants of the normal replication genes that cause specific pathologies in the infected host. One spleen focus-forming virus, SFFV-P, causes a severe polycythemia; infection leads to a massive expansion of erythroid precursors (BFU-E and CFU-E) and a concomitant loss of mature red cells. This agent consists of a complex of a replication-defective variant and a Friend MuLV helper virus to propagate it. The defective genomes carry a mutant *env* gene encoding a shorter SU molecule, termed gp55, that no longer functions to mediate virus entry. However, gp55 can

bind directly to the erythropoietin receptor (EpoR) and stimulate the mitogenic and differentiative responses normally triggered by ligand binding to the receptor. This activity allows the virus to infect these dividing pre-erythroid cells, and the continued expression of the envelope protein in these cells promotes their factor-independent growth and expansion in an autocrine loop (632). Ultimately, a frank erythroleukemia results and may be associated with proviral activation of proto-oncogenes occurring as a result of the continuing infections. It is clear that the *env* gene of the virus is sufficient to cause the disease (773). A very similar virus, the SFFV-A, causes a severe splenomegaly and anemia. This virus is closely related to SFFV-P and also activates the EpoR to expand immature cells. Variation in the envelope between these two strains alters the target cell and the consequences of its expansion (354,631). It should be noted that this mitogenic activity of gp55 is not a completely novel property of the deleted Env. The parental F-MuLV helper Env protein has a weak ability to bind and send mitogenic signals through the EpoR, presumably resulting in expansion of EpoR-positive cells. This increase in target cell number is presumably able to enhance virus spread and so serves as a positively selected trait for the virus. Other Env proteins, including those of the MCF viruses, may activate the interleukin 2 (IL-2) receptor.

Another replication-defective variant, the murine acquired immune deficiency syndrome or MAIDS virus, causes a relatively acute hyperproliferation of B-lineage cells in infected mice (38,327,381). There is a subsequent proliferation of macrophages and CD4+ T cells. The expansion of these cells displaces many other cell types, including T cells, and the animals eventually show a significantly defective immune response. The mechanism of the immunodeficiency is not fully clear, and there is some indication that an antigen-driven stimulation leads to an anergic state. However the immunosuppression occurs, the disease is in reality a lymphoproliferative disorder and is quite distinct from human AIDS in its pathology. The causative agent is again a replication-defective variant carried by a replication-competent helper virus (326). The defective genome encodes a mutant Gag precursor in which the central portion, including the p12 region, is replaced by a foreign Gag derived from endogenous retrovirus sequences (325,398,399). The altered Gag has been shown to interact with the c-Abl protein, a tyrosine kinase first identified as the transduced oncogene of the Abelson MuLV, in that virus expressed as a Gag-Abl fusion protein. Thus, the MAIDS virus seems to act by forming a noncovalent interaction with the c-Abl protein as an approximate mimic of the Gag-Abl protein formed by transduction on the Abelson virus (191).

An ovine disease has recently attracted attention as a potential model for human lung cancer. Sheep pulmonary adenomatosis (SPA) is a contagious bronchiolo-alveolar carcinoma of sheep associated with an exogenous type D/B retrovirus, Jaagsiekte sheep retrovirus (JSRV) (785). The etiology of the disease is unclear, although the epithelial tumor cells are sites of large amounts of viral DNA (537).

Two of the epsilonretroviruses, the piscine (fish) retroviruses, cause a dermal sarcoma that shows a remarkable seasonal appearance and regression. The mechanism of transformation of cells by the virus is not totally clear, but it eems to reflect the activity of a cyclin D homolog encoded by the viral genome. This gene, the *ORF a* gene, may induce inappropriate entry of the cells into cycle by activation of a cyclin-dependent kinase (cdk).

Host Determinants of Retroviral Disease

A number of genes have been identified that determine sensitivity or resistance to retroviral diseases. Some of these genes act at the level of virus replication, directly controlling the ability of the virus to spread. The Fv1 locus is a good example of a gene that acts in a cell-autonomous way to restrict the replication of various MuLVs (348). Fv1 was identified in the early 1970s as mediating resistance to leukemogenesis by the Friend MuLV (424,571). Two naturally occurring alleles provide resistance: the $Fv1^{b}$ allele (in Balb/c mice) allows replication of B-tropic viruses but blocks N-tropic viruses, whereas the $Fv1^{n}$ allele (in NIH Swiss mice) allows replication of N-tropic viruses but blocks B-tropic viruses. Resistance is dominant in heterozygous animals. The tropism of the MuLVs can be characterized by their ability to replicate in cells of particular genotypes: N-tropic viruses grow only on $Fv1^{nn}$ cells, B-tropic viruses grow only on $FV1^{bb}$ cells, and NB-tropic viruses grow on both. The determinants of viral tropism lie in the *gag* gene and affect a small sequence of the CA protein (83,315,532,626). The block to infection in resistant cells is at an interesting stage: largely, it occurs after reverse transcription and before nuclear entry and provirus integration (349,350,782). Curiously, the block to integration that is observed for a particular virus and cell combination *in vivo* is lost when the PIC is extracted and tested for its ability to integrate *in vitro* (585). Recently, the Fv1 gene was cloned and identified as a unique member of an endogenous retrovirus gene family, showing similarity to the *gag* genes of the human endogenous retrovirus (HERV)-L family (68). This family is widely distributed in mammals (58). The two alleles differ by a few point mutations and a different carboxyl-terminal region. Thus, the intracellular expression of this variant Gag protein can somehow interact with the incoming viral DNA and its associated CA protein to block infection. Another gene in this series has an even simpler mode of action: The Fv4 gene (687) restricts virus replication by blocking the receptor. The Fv4 locus is a defective endogenous provirus that encodes an Env protein fragment; the product down-regulates the receptor and renders mice resistant to infection by exogenous viruses (332,394).

A large set of those genes that affect sensitivity to viral disease modify the availability of target cells for virus growth, or the immune response to virus infection, and therefore indirectly control the levels of viremia. The Fv2 gene is an example of such a gene (423). Virus susceptibility is dominant over virus resistance at this locus. The virus-susceptible allele encodes a truncated form of the stem-cell kinase receptor (Stk) that promotes virus-induced erythroleukemia (565); expansion of the Fv2s-expressing cells may provide increased cells for virus replication. The $Fv2^{rr}$ homozygous mice are resistant because of a limited expansion of BFU-E clones and a reduced ability of the Friend MuLV to find sensitive targets (79,688). Finally, mutations in certain genes can sensitize or predispose organisms to oncogenic transformation by retroviruses. Because transformation is almost always a multistep process, mutations in one of the genes in a transforming pathway can increase the frequency with which a virus-mediated loss of another gene becomes manifest as a frank tumor. Thus, knock-out mutations of such tumor suppressors as the p53 or p73 genes can sensitize to transformation by a number of oncogenic retroviruses (53,714). Similarly, a preexisting transgene such as a regulated version of the *myc* oncogene, Eμ-Myc, can predispose particular cells expressing the gene to insertional activation of other proto-oncogenes in viremic animals (733). New integration sites that would not normally be detected in wild-type

mice are often utilized in such mice.

ACUTE TRANSFORMING RETROVIRUSES: TRANSDUCTION OF CELLULAR PROTO-ONCOGENES

There exist more potent transforming retroviruses than the slow leukemia viruses, and these can initiate rapid tumor formation with a quickly fatal outcome. These viruses are recombinant transducing viruses that have acquired portions of cellular genes that are responsible for the transforming activity. The prototype of these viruses is the Rous sarcoma virus, which carries a transforming version of the c-*src* gene. In the exceptional case of RSV, the viral replication functions, including the coding regions for the Gag, Pol, and Env proteins, are all intact so that the resulting transducing genome is replication competent. In nearly all other cases, the acquisition of the transforming gene from the host has occurred with a loss of one or more of the viral replication functions, so that the resulting virus is replication defective. However, these genomes retain all the cis-acting elements needed for their replication, and thus can be transmitted from one cell to another by a replication-competent helper virus. The concerted replication of two viral genomes in a complex—a replication-competent helper virus and a replication-defective acute transforming virus—is a common feature of most of the transforming viruses.

Transforming viral genomes exhibit a range of different structures, but they have some features in common. Those segments required in cis for viral replication are always retained: The LTRs, the pbs, and the ppt are present because they are required for reverse transcription and forward transcription. The RNA packaging signals are retained. Many of the regions required in trans are often deleted, since these functions can be provided by the helper, and are replaced with the host sequences. The host gene may be expressed separately, or, more often, it is fused to Gag, Pol, or Env sequences to form a fusion protein.

The formation of a transducing virus is thought to involve a complex series of events that results in the acquisition of the coding regions of a host gene by the replication-competent parental virus (690). Several models have been proposed to account for the observed structures, including DNA-based events (e.g., see ref. 647) but more often RNA-based events (summarized in ref. 716). The most commonly accepted model includes the following steps (Fig. 19):

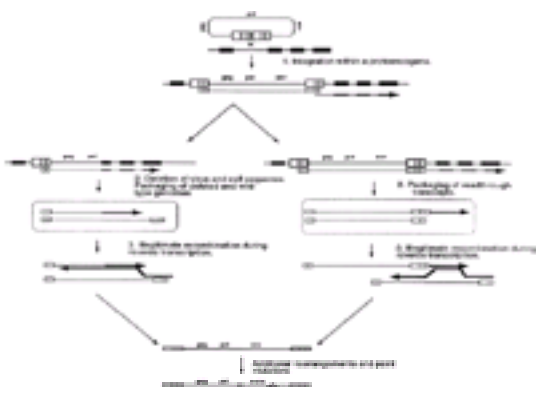

FIG. 19. Two pathways for the acquisition of host oncogenes by a replication-competent retroviruses in the formation of an acute transforming genome. Integration is shown establishing a provirus within a proto-oncogene in the same transcriptional orientation (*top*). Either of two processes then occurs. In one mechanism (*left*), a deletion of the chromosomal DNA fuses the 5'half of the provirus to the downstream portion of the gene. The fused DNA then encodes a fused RNA, which may be spliced and packaged into virion particles along with wild-type helper RNA. During reverse transcription, RT switches from the helper to the fusion RNA to append the 3' portion of the helper onto the hybrid RNA. The completed reverse-transcribed DNA is integrated and transmitted thereafter as a replication-defective viral genome. In the other mechanism (*right*), a readthrough RNA extending from the 5' LTR through the provirus and into the downstream portion of the gene is formed. The RNA is packaged into virion particles along with wild-type helper RNA. During reverse transcription, RT switches from helper to host and back to helper RNAs to form the hybrid genome. As before, the completed reverse transcribed DNA is integrated and transmitted thereafter as a replication-defective viral genome. In either scenario, the transducing genome may undergo additional rearrangements and mutations under selective pressure for more efficient transforming activity and transmission.

- The process begins with the insertion of a provirus upstream of the gene to be transduced. An insertion in the middle of a gene can initiate the transduction of the downstream portion of that gene.
- Next, readthrough transcription beginning in the 5' LTR generates a large RNA containing viral sequences fused to downstream sequences. This event can be enhanced by lesions in the 3' LTR that prevent normal RNA processing and polyadenylation at this site. Alternatively, a deletion in the DNA could fuse the 5' half of the provirus to downstream sequences, again leading to the expression of a fusion RNA.
- In either mechanism, the chimeric RNA can be spliced and is then packaged into virions along with the RNA of a helper virus (307,689).
- Finally, nonhomologous recombination occurs during reverse transcription to append 3' viral sequences to the chimeric genome. A template switch by RT from the helper to the chimeric RNA during minus-strand synthesis can mediate such a nonhomologous event at low but easily detected frequencies (274,710,799). The completion of reverse transcription on this template would result in the generation of a provirus with host sequences flanked by viral termini, similar to those seen in transforming retroviral genomes. Consistent with this model is the appearance of poly(A) sequences at the 3' junction between host and viral sequences in some viruses; if the translocation by RT from viral to host RNA occurs in the host poly(A) sequences, a portion will be retained in the final genome.

A key feature of the resulting genome is the presence of only the mRNA sequences—that is, only the exons—and not the

introns of the host gene. Thus, very large genes can be transduced by retroviruses because they carry only the exonic coding regions of the gene. Most transforming retroviral genomes not only are a result of these relatively simple recombination events but also have undergone multiple rearrangements thereafter. The RNAs encoded by these genomes often exhibit complex patterns of splicing, which can involve cryptic splice sites in both virus and host sequences. Several of the known rodent viruses carry segments of endogenous retroviral or virus-like sequences, especially the virus-like 30S (VL30) elements.

The genes that have been identified on the many acute transforming viruses are wildly diverse in their sequence and functions. These genes are among the most intensively studied of all known genes; their clear involvement in oncogenesis has focused enormous attention on their structures and function. The genes include growth factors (v-*Sis*); growth factor receptors (v-*erbB*); intracellular tyrosine kinases (v-*src*, v-*fps*, v-*fes*, v-*abl*), members of the G protein family (H-*ras*, Ki-*ras*); transcription factors (v-*myc*, v-*erbA*); and many others. The genes are now appreciated as playing major roles in mitogenic signalling pathways, in the control of the cell cycle, and in antiapoptotic pathways that act to limit cell survival. There is no indication that all such genes have been identified, and it is likely that new transforming viruses will continue to provide new examples of genes that can be activated by transduction to initiate tumor formation.

The acquisition of these genes, as noted earlier, is often associated with fusion of the coding region to Gag, Pol, or Env sequences. Thus, the expression of the oncogene results in a fusion protein that may exhibit dramatically altered biochemical activity, intracellular localization, or stability. These changes are often a key aspect of the activation of the normal function of the proto-oncogene to create the fully transforming viral oncogene. In other cases, or in addition to these alterations, there may be specific mutations that arise during or after the transduction process. These mutations, which may be as simple as a point mutation, or as drastic as a frameshift or deletion mutation, can be the major cause of activation of the oncogene. Presumably, the high rate of mutation during viral replication and a selection for tumor formation in enhancing virus spread are responsible for the appearance of these mutations.

ENDOGENOUS VIRUSES AND VIRUS-LIKE SEQUENCES

Virtually all cells contain a large number of retroviral or retrovirus-like DNA elements integrated into the germline (for comprehensive reviews, see refs. 75,439,558, and 682). These endogenous retroviral elements can represent a substantial fraction of the total DNA in a genome; whereas the sequences most closely related to the exogenous retroviruses may represent only a percent or so of the total DNA in many species, the retroelements in total can occupy 10% or more of the genome (709). These elements have presumably accumulated over evolutionary times, with no mechanism by which they can be removed and no strong selection against individuals that acquire them.

The retroviral provirus is closely related in structure and mode of replication to transposable elements—the retroelements—found in the genomes of all living things, from bacteria to humans (74). Many of these elements are remarkably similar to proviruses, with LTRs that function similarly and with sequence similarity to *gag* and *pol* genes (715). The retroviruses have probably existed as parasites of cells from very ancient times and have evolved together with transposable elements (179,180).

Endogenous Elements in Chickens, Mice, Pigs, and Humans

Endogenous retroviruses have been characterized for many avian species. Large numbers of sequences have been characterized in chickens and other birds (329) and can be grouped into at least four families. The ALV-related elements were among the first to be discovered, including the replication-competent provirus RAV-0. Most of the other family members are replication defective and lack *env* sequences. The newer families of such viruses continue to be characterized (665).

There is a vast literature describing the endogenous retrovirus sequences in inbred mice (58,80,138,336,395,683). At least eight families have been described, although only four have been studied in detail. The VL30 (for virus-like 30S) elements are present in the genome at a copy number of perhaps 100 to 200 (4); these elements encode a 30S RNA that is packaged efficiently into the virion particles of exogenous viruses and so contaminates most virion RNAs. They presumably represent a parasitic RNA that spreads by exploiting exogenous viruses. Second, the IAP elements are present at a level of about 1,000 to 2,000 copies in the genome (444,518,525). These elements can express intracellular particles containing RT, but the particles are budded into the ER and not released from cells. Most lack *env* genes and so cannot form infectious particles. However, a few members o contain *env* sequences (608). Some IAPs can transpose intracellularly at low frequencies (301). Third, there are a small number of proviruses (0 to 4 per genome) closely related to MMTV that encode functional B-type viruses. Fourth, there are proviruses related to the exogenous MuLVs, present at 50 to 100 copies per genome (683). These proviruses are all very similar to one another, but they can be divided (according to their similarity to exogenous viruses that utilize particular receptors) into four groups: the ecotropic, xenotropic, polytropic, and modified polytropic. The distribution of these sequences among different murine species and subspecies can help reveal their evolution and spread. For example, xenotropic MLV-related proviruses are present only in *M. musculus* subspecies, whereas polytropic MLV-related proviruses are found in both *M. musculus* and *M. spretus.* Replication-competent members of the family are found in many, but not all, inbred mice (128). (For reviews of the properties of the murine endogenous retrovirus genomes, see refs. 245 and 344).

Recently, the potential to use pig organs or cells in xenotransplantation into humans has raised considerable interest in the presence of endogenous retroviral elements in the pig (522,684). Although viruses can be rescued from porcine cells (9), and although these viruses can infect human cells quite efficiently (557,768), preliminary studies suggest they are not easily transmitted to humans in transplant settings (305,555). There remains a real possibility for their transfer to humans, however, and the consequences could be significant.

Retroviral elements are also abundant in the human genome (73,439,463,468). These elements are collectively termed HERVs, and subgroups are denoted by a letter indicating the amino acid specificity of the tRNA primer. Most are defective, but a very small number of these elements are still actively transcribed in somatic cells and are capable of

transposition to new sites (176). The distribution of the HERV-K family in various primates has been surveyed to help build evolutionary trees of these species (347,678). There are also provirus families distantly related to the lentiviruses (317); some have the potential to encode rev-like elements that could, in principle, be pathogenic (440). A detailed review of the HERVs is presented in Chapter 62.

Properties of the Endogenous Provirus-like Elements

The distribution of elements in a given strain is relatively stable over the course of a few generations. Thus, most individuals in an inbred population show a constant, characteristic pattern of endogenous elements. The rate of loss of a given provirus is very low, and the appearance of new proviruses is rare in most animals. However, the pattern is quite different in different species, and even in different strains of animals, suggesting that rearrangements happen often over longer evolutionary times. It is known that new copies can appear at higher frequency if newborn females are viremic (431,675). Thus, early infection of germ cells can introduce new proviruses into the germline. This route can even be used to create mutations *de novo* in laboratory mice at reasonable frequencies.

Most endogenous proviruses are transcriptionally silent; the DNA is often heavily methylated and so repressed. These may reflect the mechanisms by which the transcription of many exogenous viruses are repressed *in vivo*. Expression of many of the endogenous viral RNAs is induced by agents causing DNA damage, such as ultraviolet light and bromodeoxyuridine, and the expression of others is stimulated by glucocorticoids (207). The IAPs are often induced during the differentiation of various cell types (695), and even more often in immortalized tumor cell lines.

The bulk of the endogenous retroviruses are fossil DNAs, grossly defective, and no longer capable of encoding proteins; the ORFs contain numerous stop codons and frameshifts that would preclude the formation of any functional viral gene products. However, these elements can often give rise to RNAs, and these RNAs can be packaged efficiently by virions encoded by exogenous viruses and thus can give rise to new proviruses. Furthermore, these copackaged RNAs can then recombine with the exogenous viral RNAs and so contribute small sequence blocks to these viruses, potentially altering the host range and replication properties of the virus. The continuous contribution of endogenous sequences to virus evolution is a fact that needs to be considered whenever genetic selections are imposed on a virus. In addition, a few of the elements are functional and can transpose intracellularly (705) or even give rise to replication-competent viruses. Even when viruses are induced from the elements, however, the viruses are most often not highly pathogenic for the host in which they reside. Thus, many of the inducible elements in the mouse are xenotropic and cannot spread in the animal; and those that can, do not cause an acute disease. The LTRs of the endogenous elements are often quite weak as transcriptional promoters as compared to those of exogenous viruses. This may reflect selections against highly pathogenic agents either before or after their introduction into the germline.

The creation of a new provirus in the germline by necessity creates a mutation, and although most such insertions probably have no significant effect, occasionally deleterious germline mutations occur. A number of ancient, “spontaneous” mutations, upon analysis, have been found to have been caused by a proviral insertion. These include such classic mutations as the rd1 allele, which causes a slow retinal degeneration, and which includes an insertion affecting the beta subunit of the retinal cGMP phosphodiesterase; the hr mutation, which causes a hairless phenotype; the dilute coat-color allele d; and a mutation termed Slp (for sex-limited protein) in the C4 complement gene, in which an insertion of a viral LTR renders the gene androgen responsive.

Many of the endogenous elements may be positively selected in their host species. This may be the result of advantageous mutations that are created by the insertion, or antiviral effects mediated by the gene products encoded by the endogenous proviruses. The Fv1 and Fv4 genes are examples of such elements. These virus-like elements confer resistance to exogenous viruses and so may serve to protect the host from leukemia induced by infection. The MMTV *sag* gene, if present on an endogenous provirus, acts to delete T cells that would respond to the superantigen; thus, subsequent infection by an exogenous MMTV cannot use *sag* to induce a proliferation of cells needed for its vigorous replication. Thus, the inherited provirus protects the host from MMTV disease.

RETROVIRAL VECTORS, PACKAGING LINES, AND GENE THERAPY

The structure and mechanism of transmission of the naturally arising replication-defective transforming viral genomes provide a clear model for the directed use of retroviruses to mediate gene transfer. Retroviral vectors that mimic the structure of the transforming viruses can readily be generated, and these vectors can be engineered to carry the cDNA sequences of virtually any gene. These genomes can then be propagated with wild-type virus as helper. However, it is also possible to generate helper-free preparations of particles that transduce the vector genome via the early steps of the life cycle, without delivering the helper genome, thereby preventing subsequent spread of the vector. These helper-free particles are generated in packaging cell lines: cells engineered to express the *gag*, *pol*, and *env* genes but not expressing packageable helper viral RNAs. The first such lines simply carried a provirus lacking the Psi site, the RNA packaging signal (460). These cells produce virions deficient in the helper genome, and introducing a Psi+ vector construct into these cells results in the encapsidation and release of the vector RNA into those particles. These particles can then be harvested and used to deliver the vector and its gene into susceptible cells. It is also possible to generate transducing virus preparations by transiently transfecting cells with DNAs that encode the helper functions and DNAs that encode the vector. This approach is preferable in instances where the viral gene products are toxic and therefore difficult to express stably in a packaging cell line.

A limitation of these packaging systems is that small amounts of the Psi-minus helper RNA are encapsidated along with the vector. Endogenous retroviral genomes, such as VL30 RNAs (4), are also encapsidated efficiently, and recombination events between these RNAs during reverse transcription can recreate a replication-competent virus (556,641). These events are probably similar to recombinational repair of mutations in genomes that occur during growth in cell culture (132,133,470). This issue has raised considerable fears that gene therapy vectors intended for therapeutic use could initiate a viremia, and perhaps a viral leukemia, in patients. More elaborate cell lines, in which the *gag*, *pol*, or *env* genes are expressed via separate RNAs, can reduce the frequency with which such recombination events occur to

very low levels (142,157,465,466).

Retrovirus particles transducing a desirable gene can be directed to target cells through the use of many distinct envelope proteins. This method is possible because retrovirus particles can readily form pseudotypes; that is, they can incorporate and use the envelope proteins of a wide array of different viruses (209,299,676,771). The wide range of pseudotypes that can be formed presumably reflects the flexibility of the core–envelope interaction. The host range can be further expanded or restricted by the engineering of envelopes with new binding specificities (731). Chimeric envelope molecules have been particularly popular tools in targeting virions to new receptors (119,360,464,669). Another approach is to engineer animals that express a foreign receptor in a tissue-specific manner, and deliver genes with a virus envelope that recognizes only the transgenic receptor (228). The envelope–receptor interaction can even be reversed: It is possible to express a particular virus receptor molecule on the virion surface, and thereby to target the virus to those cells expressing the corresponding viral envelope (43).

A major limitation of early retroviral gene therapy efforts is the inability of most helper viruses to mediate the infection and transduction of nondividing cells. The major block is during the early stages of infection, when there is a strong requirement for cell division for infection by most viruses (624). However, the lentiviruses have the ability to infect nondividing cells, and thus gene therapy based on lentiviral packaging systems could overcome this limitation (for review, see ref. 15). Recent efforts have substantiated these expectations: Delivery to nondividing neurons, and to poorly dividing primary lymphocyte cultures, has been demonstrated with vectors based on HIV-1 (72,185,355,506,507) as well as FIV (575).

PERSPECTIVES

The study of retroviruses has led to a detailed characterization of many steps of virus replication but also to important fundamental discoveries concerning host physiology and genetics. The viruses have served as entrés into such phenomena as cell surface receptors, cell division, DNA synthesis, the cell cycle, mechanisms of gene expression, and intracellular transport. The value of focusing on retrovirus functions in unraveling cellular functions is clear: These agents have evolved over huge periods of time to exploit key aspects of the cell, and we should make use of their success to help identify those aspects. There is every reason to believe that their continued study will yet reveal new aspects of cell physiology.

CHAPTER 58 Human T-Cell Leukemia Virus Types 1 and 2

Patrick L. Green and Irvin S. Y. Chen

For nearly two decades, the human T-cell leukemia viruses (HTLVs) have been intensely studied because of their association with neoplasia and neuropathology, and their capacity to transform primary human T-cells in cell culture. The study of HTLV also represents an attractive model that has allowed investigators to dissect the mechanism of various cellular processes, several of which may be critical steps in HTLV-mediated leukemogenesis. This chapter will review the molecular biology of HTLVs, including the organization of their genome, the structure and function of their gene products, and the pathogenic features both in cell culture and in infected patients. Given the enormous amount of material published on HTLV, we apologize to colleagues whose data could not be cited because of space limitations.

HISTORY OF HUMAN T-CELL LEUKEMIA VIRUS DISCOVERY AND ASSOCIATION WITH DISEASE

Human T-Cell Leukemia Virus Type 1

Adult T-cell leukemia (ATL) was first described in 1977 in Japan (346). Since then, ATL has also been found in most other parts of the world. The etiologic role for HTLV-1 in ATL was established by (a) seroepidemiologic surveys associating the virus with disease in patients with ATL and close contacts; (b) the clonality of ATL tumor cells, which correlates with a monoclonal or oligoclonal pattern of integration of the viral genome in the tumor cell DNA; (c) infection of lymphocytes *in vitro*, resulting in immortalization or transformation of the same cell type (CD4+ or CD8+ T-cells) as the tumor cell; and (d) showing HTLV-1 to be oncogenic in animal models.

HTLV-1 was first identified in a T-lymphoblastoid cell line (HUT 102) established from a patient with a cutaneous T-cell lymphoma (269). C-type retrovirus particles were identified in this cell line. In 1981, an independently isolated cell line (MT-1) derived from a patient with ATL also harbored a retrovirus and produced antigens that reacted with sera from patients with ATL (121). The viruses produced from these two distinct cell lines were subsequently shown to be the same and were given the name HTLV-1 (270). Since the initial description of ATL and discovery of HTLV-1, the virus has been recognized as being associated with human diseases other than ATL. The most notable of these is a neurologic degenerative disorder known as tropical spastic paraparesis (TSP) or, more commonly, HTLV-1-associated myelopathy (HAM).

Human T-Cell Leukemia Virus Type 2

HTLV-2 was first identified in a T-cell line established from a patient with hairy-cell leukemia (294). This cell line (Mo-T) was derived from splenic tissue in 1978 and subsequently shown to harbor a retrovirus. Based on serologic cross-reactivity, this virus was related to (but was distinct from) HTLV-1, and it was termed HTLV-2 (150). Since then, HTLV-2 infection has been documented in a number of population groups. Like HTLV-1, HTLV-2 infects and transforms T-lymphocytes *in vitro*. A few HTLV-2-infected patients have been characterized in detail, providing limited molecular evidence supporting an etiologic role of HTLV-2 in a form of atypical hairy-cell leukemia (281). In addition, there have been a few cases of neurologic disease associated with HTLV-2 infection (125,199). The limited number of individuals shown to harbor HTLV-2 in association with specific diseases has, to date, precluded convincing epidemiologic demonstration of a definitive etiologic role for HTLV-2 in human disease.

GENETIC STRUCTURE

The overall genetic structure of HTLV is similar to but distinct from that of other retroviruses (Fig. 1). In addition to the usual structural and enzymatic genes of *gag*, *pol*, and *env*, there is a unique region at the 3' end of the genome not found in other replication-competent retroviruses. Because of its unknown function, this portion of the genome was initially referred to as the X region. There are four (I through IV) open reading frames (ORFs) contained within the X-region of HTLV-1/-2. Two of these ORFs (III and IV) encode well-characterized *rex* and *tax* genes, respectively. The *tax* gene (previously referred to as pX, c, x-lor, tat-I/tat-II, and TA-1/TA-2) encodes a protein responsible for transcriptional activation of the long terminal repeat (LTR). The *rex* gene is necessary for expression of structural and enzymatic proteins, and it partially overlaps *tax* in an alternative reading frame. Three major messenger RNA (mRNA) species have been identified for HTLV (see Fig. 1). Like other retroviruses, full-length RNA is utilized for synthesis of *gag* and *pol* gene products and is also the genomic RNA packaged into virions. The primer used for reverse transcription of the genomic RNA is the cellular tRNAPro. A single-spliced subgenomic mRNA encodes the *env* gene product. A second subgenomic mRNA has two introns removed (doubly spliced or completely spliced) and encodes the *tax* and *rex* gene products. The *tax* gene initiation codon is the same as that used for the *env* gene and is contained within the second exon of the *tax*/*rex* mRNA. The initiation codon for the Rex protein is also located within the second exon of this mRNA, a further 59 nucleotides upstream. Several minor alternatively spliced mRNA species have been detected by reverse transcriptase–polymerase chain reaction (RT-PCR) or RNase protection assays in cells isolated from patients with leukemia or HAM/TSP. These RNAs encode proteins from ORFs I, II, and III of the pX region. Figure 1 shows the arrangement of the HTLV genome, gene products, and ORFs, and the three major and four minor mRNA species. Table 1 gives a comparison of the entire HTLV-1/-2 genomes based on the sequence of HTLV-1 ATK and HTLV-2 MO isolates (301,312).

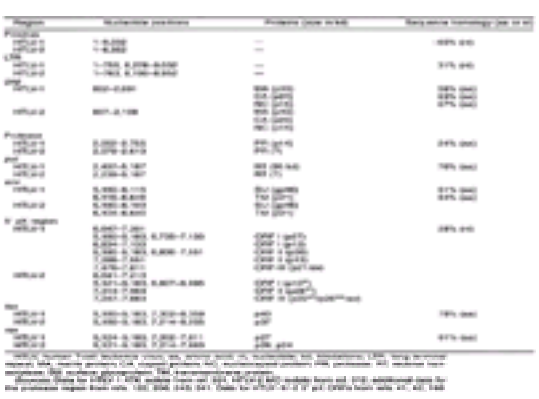

TABLE 1. *Comparison of the HTLV-1 and HTLV-2 genomes*

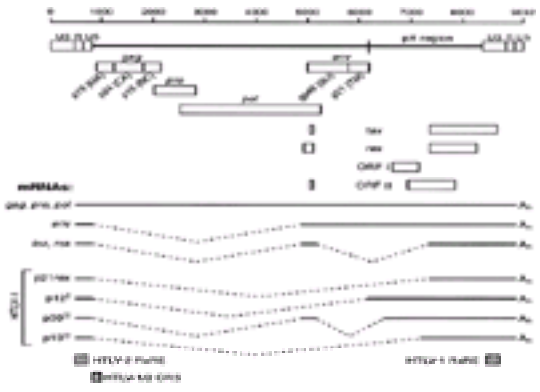

FIG. 1. Structure and organization of the HTLV genome. The HTLV provirus genome is shown at the *top* of the figure. Location of the proteins encoded by the provirus, the RxRE, and cis-acting repressive sequence (CRS) are shown beneath the provirus. The structures of the three major messenger RNA species and four minor RNA species produced are shown at the *bottom* of the figure. [From refs. 168 and 301 (HTLV-1) and ref. 312 (HTLV-2).]

HTLV GENE PRODUCTS

The *gag* Gene

As in other retroviruses, the *gag* region is initially translated as a polyprotein precursor, which is subsequently cleaved to form the mature Gag polypeptides, the 19-kd matrix (MA), 24-kd capsid (CA), and 15-kd nucleocapsid (NC) proteins (259). Like other retrovirus *gag* gene products, p19 is posttranscriptionally modified and contains myristic acid at the NH_2-terminus (259). Myristoylation targets the p55 Gag precursor polypeptide to the inner surface of the cell membrane (114). As is the case with other retroviruses, it is likely that this association is important in the assembly and budding of virus particles from infected cells.

A variety of other Gag-related polypeptides are found in HTLV-infected cells (296), including species of 70, 55, 37, 29, and 28 kd. Peptide mapping of these proteins indicates that some are immature precursors of the three major Gag proteins (e.g., p55 and p29, both of which have determinants related to the mature p24 and p19 peptides), but pulse-chase experiments suggest that p55 is the genuine precursor molecule. At its 3' end, the *gag* ORF overlaps the 5' end of the reading frame that encodes the protease (see Fig. 1).

Protease

In HTLV, a reading frame that spans the 3' part of the *gag* region and the 5' part of the *pol* region encodes the protease. Synthesis of the protease as part of the Gag polyprotein precursor is accomplished by ribosomal frameshifting (243). The function of the HTLV-1 protease has been examined *in vitro*, and these studies have shown that the protease is responsible for processing the mature Gag products and is responsible for generating a mature form of itself by autocatalyzed self-cleavage (243).

The *pol* Region

The polymerase region is potentially able to encode an 896-amino-acid product in HTLV-1 and a 982-amino-acid product in HTLV-2 (301,312). However, a second ribosomal frameshifting event is necessary to express the *pol* gene (243), resulting in polypeptides from the *pol* reading frame of 863 and 864 amino acids in length for HTLV-1 and HTLV-2, respectively. The 5' portion of the *pol* gene encodes the reverse transcriptase protein and sequences further downstream encode the integrase and RNaseH functions. HTLV reverse transcriptase functions most efficiently using Mg^{2+} as the required divalent cation (275).

The *env* Gene

The product of translation of the envelope ORF is a glycoprotein of 61 to 69 kd, depending on the laboratory and cell line studied (186,296,297). This precursor protein is detected on the surface of HTLV-infected cells. Treatment with tunicamycin or endoglucosamine H results in a nonglycosylated precursor species of 54 kd (186,297). Some higher-molecular-weight Env-related species have been shown to be the result of abnormal Env-Tax fusion proteins (219,332). The envelope protein is cleaved into the mature products, the 46-kd surface glycoprotein (SU) (gp46) and the 21-kd transmembrane protein (TM) (p21). Culture media from HTLV-transformed cells contain large amounts of free gp46, which is shed from the surface of the cells (296,371).

The *tax* Gene

Two unique transregulatory genes are found in HTLV, *tax* and *rex* (see Fig. 1). Both genes are essential for viral replication and cellular transformation. The HTLV-1/-2 *tax* genes encode phosphoproteins of 40 and 37 kd, respectively. There is approximately 77% to 85% amino acid homology between HTLV-1 Tax (Tax-1) and HTLV-2 Tax (Tax-2). Both Tax-1 and Tax-2 co-localize primarily in nuclear bodies with RNA polymerase II, splicing complexes, and specific transcription factors (19,88,304,320). Structure/function analysis has revealed at least four functional domains (Fig. 2). The amino-terminal amino acid residues 2 to 58 contain an activation domain and also comprise a nuclear localization signal distinct from the highly basic amino acid sequence that performs this function in most nuclear proteins. The amino-terminal residues 23 to 49 contain the zinc-binding domain (zinc finger) that very likely plays a critical role in protein–protein interactions. The central amino acid residues 161 to 211 constitute the structural domain, and the carboxyl-terminal 289 to 322 residues contain an activation domain. The transactivation phenotypes of specific mutations within these regions will be discussed later. It has been reported that two adjacent serine residues at the carboxyl terminus of Tax-1 (amino acids 300 and 301) are the major sites of phosphorylation. Phosphorylation of at least one of these sites is required for Tax-1 localization to nuclear bodies and Tax-mediated activation of gene expression (20).

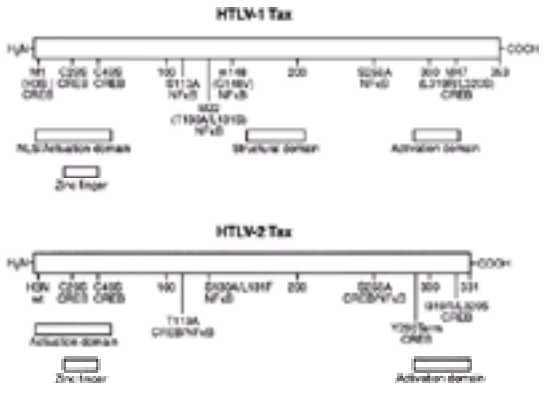

FIG. 2. Structural and functional domains of HTLV-1 Tax and HTLV-2 Tax. Specific mutations and the transcriptional activation pathway interrupted are indicated. [From refs. 305,306,321,323,373, and 376 (HTLV-1 Tax) and ref. 283

(HTLV-2 Tax).]

The Tax protein is a trans-acting transcriptional activator, and it increases the rate of transcription initiation from the promoter in the 5' LTR of the provirus genome. It was originally found that transcription of the HTLV LTR was greatly stimulated in virus-infected cells compared with that in noninfected cells (39,324). The role of the *tax* gene was investigated further in assay systems involving co-transfection of cells with *tax* cDNA and reporter plasmids. By determining what genetic information is necessary to stimulate transcription in trans from the reporter plasmid (trans-activation), it was confirmed that the *tax* gene was responsible for this activity.

The *rex* Gene

The *rex* gene encodes proteins of 27 or 21 kd for HTLV-1, and 26 or 24 kd for HTLV-2. The larger p27 and p26 products are both phosphorylated, which most likely plays a role in their function. Antisera directed against peptides from the carboxyl-terminal portion of the *rex* ORF immunoprecipitate both proteins (see Fig. 1). Originally, a study utilizing *in vitro*-synthesized RNA and selective mutations within the *rex* ORF suggested that deletion of an internal methionine codon (amino acid 79) resulted in loss of the smaller HTLV-1 p21 product (238). It was later shown that a novel, alternatively spliced mRNA transcript was responsible for p21 production in HTLV-1-infected cell lines (see Fig. 1) (258). Experiments have shown that the internal methionine codons of the HTLV-2 *rex* gene are not required for p24 production, and that the p26 product is actually a phosphorylated form of p24 (97,98). Subsequently, in HTLV-2 infected cells, an alternatively spliced mRNA transcript was shown to have the capacity to produce protein products (p22XIII/p20XIII) analogous to HTLV-1 p21 (41).

The larger Rex protein is involved in the control of HTLV gene expression, but the function of the smaller HTLV protein (p21 or p22/p20) has not been established and will not be discussed further here (41,116). Like the Tax protein, the Rex protein is essential for HTLV replication. Unlike Tax, Rex acts at a posttranscriptional level to regulate viral gene expression. Rex has been shown to increase the ratio of the incompletely spliced mRNA to completely spliced mRNA in the cytoplasm of infected cells (138,174). The ultimate effect of expression of the *rex* gene products in HTLV-1-/-2-infected cells is therefore to regulate the levels of expression of genes encoding virion components, and thus determining whether infectious virions are produced.

The effects of Rex are mediated through specific cis-acting sequences in the LTR. Augmentation of 5' LTR-linked gene expression by Rex requires two distinct cis-acting sequences, one termed the Rex-responsive element (RxRE), which allows Rex to overcome the inhibitory effect of a second, termed the cis-acting repressive sequence (CRS). In HTLV-1, the RxRE was first localized to the 3' LTR of the virus (338), but it has subsequently been shown to be present, at least in part, in the 5' LTR as well (5). The U5 region of the LTR contains sequences functionally defined as the CRS (see Fig. 1) (303). The HTLV-2 RxRE is located in the R/U5 region of the 5' LTR, and the CRS is contained within the RxRE downstream of the splice donor site (see Fig. 1) (23,377).

The phosphorylated *rex* gene products of HTLV-1/-2 are localized in the nucleus (and particularly in the nucleoli) of infected cells (1,98,99). Functional analyses have revealed that Rex-1 contains at least three domains. One domain corresponds to an arginine-rich region that mediates RNA binding by direct interaction with the RxRE (27,91). A second domain close to the RNA-binding domain is required for assembly of multimeric Rex complexes onto the RxRE (27). A third activation domain, represented by a short leucine-rich sequence, interacts with Rab and other nucleoporin-like cofactors to mediate nuclear export (28,129,265,362). Dominant negative mutations have been identified, some of which reside in the multimerization domain of the protein (27).

The mechanism by which the Rex/RxRE interactions culminate in the synthesis of viral structural and enzymatic proteins are not yet clear, but the experimental data suggest it may involve stimulation of nucleocytoplasmic transport, increased stability, inhibition of splicing, and/or facilitation of translation of the incompletely spliced RNAs. Studies investigating the intracellular distribution of RNAs transcribed from indicator plasmids containing RxRE DNA demonstrated that Rex-1 stimulates the nucleus-to-cytoplasm transport of incompletely spliced HTLV-1 and human immunodeficiency virus (HIV)-1 RNA (110,137). Another study demonstrated that Rex-1 activity resulted in large increases in the amounts of unspliced viral RNA by reducing the rates of intron excision and degradation in the nucleus (103). A more recent study investigating Rex-2 function in T-cells following transfection of full-length proviral clones indicated that Rex-2 increases the stability of the unspliced *gag*/*pol* RNA and promotes the nucleus-to-cytoplasm transport of the incompletely spliced RNAs (174). The increase in incompletely spliced RNAs was associated with a slight reduction in completely spliced *tax*/*rex* RNA, a result consistent with the possibility that Rex inhibits pre-mRNA splicing, which has been reported *in vitro* (9), but which may also be caused by a redistribution of the completely spliced RNA pools. It has been suggested that Rex-1 stabilizes human interleukin-2 receptor (IL-2R)-a chain mRNA and may therefore contribute to cell transformation (151). Prevented from accumulating in the nucleus, Rex-1 fails to stabilize IL-2R mRNA (365). Because Rex is critical for viral replication, it has been difficult to directly assess its role in cellular transformation.

pX Region ORFs I and II

A region of approximately 600 nucleotides is present between the end of the *env* gene and the beginning of the third exon of the *tax* and *rex* genes in HTLV-1, HTLV-2, and the related bovine leukemia virus (BLV). These pX sequences were originally referred to as the nontranslated or untranslated region, because expression of the ORFs within this region had not been documented in virus-infected cells. This region of the genome has been evolutionarily conserved in the HTLV family of viruses. However, the nucleotide sequence homology of the 5' pX sequences between HTLV-1 and HTLV-2 is relatively low compared to the rest of the genome (see Table 1).

Reverse transcriptase-PCR and RNase protection analyses have been used to identify viral RNAs in HTLV-1- and

HTLV-2-infected cells that splice into ORFs contained within the pX region (18,42,169). These RNAs have been detected in *in vitro* infected cells, in cells isolated from infected asymptomatic individuals, and in cells from patients with ATL or HAM/TSP. Characterization of three of these alternatively spliced HTLV-1 RNAs revealed that they have the potential to encode proteins from pX sequences termed ORF I and ORF II (ORF III and ORF IV encode Rex and Tax, respectively) (see Fig. 1). Using mRNAs from ORF I and ORF II, cDNAs were constructed to express hemagglutinin 1 tagged proteins in COS-1 and HeLa-tat cell lines (169). It appears that the preferential product expressed from ORF I is a 12-kd protein, $p12^{I}$, although a protein of 27 kd has also been reported. This $p12^{I}$ is highly hydrophobic and localizes to cellular endomembranes (168). It contains four minimal SH3 binding motifs (PXXP) and when overexpressed it associates with the vacuolar H^{+} ATPase, and it appears to bind the b and g chains of the IL-2 receptor complex (69,169,233). It was demonstrated that $p12^{I}$ had similar structural features to and cooperated with the E5 oncoprotein of bovine papillomavirus type 1 in transformation of mouse C127 cells (69). In HTLV-2, the protein product expressed from ORF I is $p10^{XI}$ (41).

ORF II-containing HTLV-1 RNAs encode two proteins, a full-length $p30^{II}$, and a truncated $p13^{II}$ that is derived from initiation at the first internal methionine codon in ORF II and corresponds to the carboxyl-terminal 87 residues of $p30^{II}$ (see Fig. 1). ORF II, in an alternate reading frame, extends into the last exon of *rex* and *tax* (ORF III and ORF IV, respectively). The $p30^{II}$ and $p13^{II}$ proteins are localized to the nucleus/nucleolus and mitochondria, respectively (43,168). The cellular segregation of ORF II gene products suggests that these proteins may serve a regulatory function. $p30^{II}$ has distant homology to transcription factors Oct-1 and 2, Pit-1, and POU-M1. Cells transformed by HTLV-1 molecular clones with mutations in $p30^{II}$ and $p13^{II}$ have differential patterns of phosphorylation of the signal transduction adaptor protein Vav, suggesting their role in alteration of T-cell signaling (202). However, ORF II sequences from ATL patients frequently contain premature stop codons, suggesting that this ORF may not be important for the long-term maintenance of the transformed phenotype. In HTLV-2, the protein product expressed from ORF II is $p28^{XII}$ (41).

Several studies indicated that pX sequences contained between *env* and the last exon of *tax*/*rex* of HTLV-1 and HTLV-2 are not required for viral replication and cellular transformation of human T-lymphocytes *in vitro* (96,277). However, further characterization using an infectious rabbit animal model revealed that these ORF-containing sequences or their expression are important for maintaining high viral load and a long-term productive infection *in vivo* (15,48,49). Additional studies are necessary to determine the precise contribution of the protein products of ORFs I and II to HTLV pathogenesis.

Structure of the LTR

Like those of other retroviruses, the HTLV LTR is divided into three regions, U3, R, and U5. The U3 region contains sequences that control transcription of the provirus (Fig. 3). In particular, three imperfect 21-nucleotide repeats, termed Tax response element 1 (TRE-1), are necessary for trans-acting transcriptional activation by Tax (31,74,313). The U3 region also contains sequences responsible for termination and polyadenylation of mRNAs. The polyadenylation signal in U3, AATAAA, is an unusually long distance away from the polyadenylation site in R (about 250 nucleotides), and it is hypothesized that it is brought into proximity of the polyadenylation site by the secondary structure of the RxRE (13). The 5' part of the U3 region also encodes the carboxyl terminus of the Tax protein. Comparison of the LTRs of HTLV-1 and HTLV-2 (see Table 1) reveals that those elements that are found to be critical for viral gene expression (e.g., the 21-nucleotide repeats, polyadenylation signal, and TATA box) are well conserved, whereas other regions of the LTR are not. The R and U5 regions are unusually long in comparison to those of other retroviruses. These regions form the leader sequence encoded at the 5' end of the messenger RNAs. Their role in posttranscriptional control of gene expression was discussed earlier.

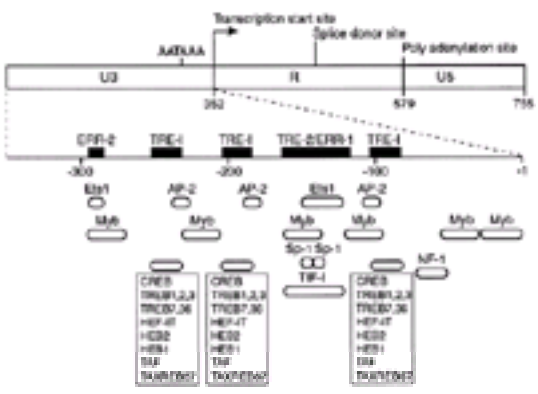

FIG. 3. Structure of the HTLV-1 long terminal repeat (LTR). The total sizes of the provirus LTRs are 755 nucleotides for HTLV-1 and 763 nucleotides for HTLV-2. The sizes of the U3, R, and U5 regions are 352 and 314; 227 and 249; and 176 and 200 nucleotides, for HTLV-1 and HTLV-2, respectively. [From refs. 300 and 302 (HTLV-1), refs. 311 and 312 (HTLV-2), and refs. 87,95, and 252 (nuclear factor binding factors).]

The interaction of the HTLV LTR with proteins involved in regulation of transcription has been investigated (87), and it was shown that multiple factors bind to different regions of the LTR in a complex pattern (see Fig. 3). DNase-protected regions are evident over each of the three 21-nucleotide repeats, as well as other regions within U3, and binding of these factors is critical for regulation of HTLV transcription. The DNase protection pattern of U3 is the same in the presence or absence of Tax, indicating that transcriptional activity of Tax is indirect and does not involve direct binding to the LTR (251). The most important functional interaction appears to be that of the cyclic AMP response element binding protein/activating transcription factor (CREB/ATF) family of DNA-binding proteins within the 21-nucleotide repeats or TRE-1. TRE-1 contains three conserved domains, designated (from 5' to 3') as A, B, and C. Tax responsiveness requires domains A and B or domains B and C. Domain B consists of the first five of the eight-base cAMP-response element (CRE), TGACGTCA, found in many promoters (68). Several techniques have been used to identify cellular proteins that

interact with the TRE-1 elements and that include formulated complexes of proteins composed of CREB homodimer, CREB/ATF-1 heterodimer, and ATF-1 homodimer, as well as others (see Fig. 3). Although the Tax protein does not bind directly to the LTR, it is predicted to stabilize binding of these complexes to the weak viral CRE sequences (328,382). A second Tax response element (TRE-2) or Ets response region 1 (ERR-1) is located between the two proximal TRE-1 domains. TRE-2 contains binding sites for Sp1, Ets1, Myb, and Tif-1 (30,250). An additional Ets binding region has also been described, ERR-2 (see Fig. 3). The cooperative binding of Tax to several of these proteins to the promoter region may position Tax to interact with basal transcription factors CBP, TFIIA, and TFIID (59,176).

Genetic Variation of HTLV

HTLV-1 and HTLV-2 share about 65% overall similarity at the nucleotide sequence level. The homology is lowest in the LTR and 5' pX region and highest in the *tax* and *rex* genes (see Table 1). Among different HTLV-1 isolates, the genome shows little nucleotide sequence variation. Isolates from Japan show 97% to 99% homology, and even isolates obtained from geographically diverse regions such as the Caribbean basin, Japan, and Africa show 96% to 99% homology (92,119,206,298,301,341).

Phylogenetic analysis of nearly 300 HTLV-1 strains originating from nearly all known endemic areas has revealed four distinct HTLV-1 molecular subtypes (A through D) or clades (for extensive review, see ref. 83). Subtype A (Cosmopolitan) is the most widespread and is found in many geographic areas and populations. Subtype A is the least divergent (<2%) and comprises four distinct molecular groups (Japanese, Transcontinental, North African, and West African). The global distribution of this subtype can be traced to large-scale human migration of infected populations such as the slave trade from Africa to the New World. Subgroups also exist in subtype B (central African clade) specific to the geographic origin of the strain. Subtype C, or the Australo-Melanesia clade, was shown to be present in Papua New Guinea and the Solomon Islands. Subtype D (central African Pygmies) was shown to be present in some individuals living in Cameroon, Central African Republic, and Gabon. In spite of considerable effort, there is no indication that specific subtypes of HTLV-1 are associated with particular pathologic consequences. For example, there are no consistent differences between strains from patients with ATL and those from patients with HAM/TSP. Epidemiologic and phylogenetic analyses indicate that HTLV-1 and the related simian virus (STLV-1) have been present in Africa and Asia for tens of thousands of years. The picture of the origin of HTLV-1 is not entirely clear, but some evidence suggests that it has arisen from interspecies transmission between STLV-1-infected monkeys and humans, followed by evolution in the human host (83,203).

Sequence homology among different HTLV-2 isolates is equally high. There have been two major but closely related molecular subtypes of HTLV-2, designated HTLV-2A and HTLV-2B, that differ in the p21 *env* gene by 4% (81,108). HTLV-2A is mainly present in U.S. intravenous drug abusers (IVDA), whereas HTLV-2B is found in most of the Amerindian groups in North, Central, and South America. Recently, a divergent variant of subtype A, labeled by one group as HTLV-2C, was found in Amerindian tribes and IVDA in Brazil (61). Because of the low incidence of HTLV-2 worldwide, it had been difficult to draw firm conclusions about the origins and spread of the virus. HTLV-2 was thought to be a New World virus brought from Asia to the Americas some 10,000 to 40,000 years ago by migration of populations infected with the virus (81,351). However, there does not appear to be an endemic population in Asia to support this. In addition, both HTLV-2 subtypes have recently been found in Africa. HTLV-2B was found in remote Pygmy populations, considered to be the oldest inhabitants of Africa (90). Interestingly, the discovery of STLV-2 in African monkeys might suggest interspecies transmission similar to what has been proposed for HTLV-1.

The lack of genetic variability in HTLV may be the result of the relatively low levels of viral replication in infected individuals. The genome replicates primarily by clonal expansion of infected cells rather than by reverse transcription (361). Replication of the provirus in dividing cells would result in a mutation frequency much lower than that of reverse transcription (189). In addition, cell-associated replication (i.e., passive replication of integrated viral genomes in dividing cells) may allow the HTLV to escape a degree of evolutionary pressure from antibody responses. Compared with that of HIV, the HTLV *env* gene appears to be unable to tolerate many mutations without becoming nonfunctional. This might provide an additional basis for conservation of what might otherwise be a highly variable region of the virus genome (267).

HTLV INFECTIVITY

Cells Susceptible to HTLV Infection

Direct cell-to-cell contact is usually required for efficient HTLV infection; however, infection with cell-free virus preparations can occur, but with low efficiency. *In vitro* infection of cells with HTLV is usually accomplished by co-cultivation of target cells with gamma-irradiated or mitomycin-C-treated virus-producing cells. Compared with that by other retroviruses, infection of susceptible cells by HTLV is inefficient, with a slow course. Usually, only a small proportion of cells express viral antigens, and this number may gradually increase over a course of weeks. The reasons for the slow kinetics may relate to positive and negative regulation by *tax*/*rex* genes or other unknown processes of infection. Infection of human cord or peripheral blood mononuclear cells by HTLV-1/-2 results in virus production and efficient transformation of the cells. Only T cells have been shown to be transformed by HTLV. Productive infection with HTLV has been demonstrated only in a few cells of nonlymphoid origin (44,127,130,364,366).

HTLV-1 appears to infect but not transform a number of different cell types *in vivo*. Epstein-Barr virus (EBV)-transformed B-cell lines productively infected with HTLV have been established from patients (370). B cells can also be infected in culture. There is also evidence that HTLV is capable of infecting immature cells from human bone marrow that do not have a T-cell phenotype (210). Infection of macrophages and cells of neural origin has been documented *in vitro* but not *in vivo* (3,128). Although cases of ATL with central nervous system (CNS) involvement are rare, direct infection of the CNS may account for such symptoms in a few patients. There is evidence of infection of dendritic cells *in vivo*, which may play a key role in antigen presentation, immune activation, and subsequent neurologic disease (205). From 90% to 99% of the HTLV-1 DNA in peripheral blood from infected patients is found in CD4+/CD8+ T cells (276). This is consistent

with one *in vitro* study indicating that HTLV-1 transcription is enhanced in primary CD4+ T lymphocytes (248). In contrast, HTLV-2 is found predominantly in CD8+ cells (136,271).

The HTLV Receptor

The cellular receptor for HTLV has not been identified, but it has been demonstrated by various assays to exist on a wide variety of human and animal cells, including primate, canine, feline, and rodent cells (45,170,369). The presence of a cell-surface receptor for HTLV has also been demonstrated by virus-induced cell fusion, leading to syncytium formation (131,239). The absence of syncytium formation when HTLV-1- and HTLV-2-infected cells are mixed has been cited as evidence that the two viruses utilize the same receptor molecule, whereas the receptor for BLV is distinct (325). Other experiments showed that interference to vesicular stomatitis virus (VSV) pseudotypes of HTLV-1/-2 were established when cells were preinfected with HTLV-1. Thus, it is likely that HTLV is able to penetrate and infect a number of cell types. However, productive infection is observed in only relatively few cells, and the block to productive infection by HTLV is still not understood. The most specific evidence about the HTLV receptor comes from experiments with human–mouse somatic cell hybrids (325). In these experiments, the only human chromosome common to all cell hybrids susceptible to HTLV infection was chromosome 17, and the gene responsible was localized to the 17q region. However, it is formally possible that this gene does not encode the actual receptor but may be required for effective display.

T-CELL IMMORTALIZATION/TRANSFORMATION BY HTLV

Both HTLV-1 and HTLV-2 will immortalize primary human peripheral blood T cells *in vitro*. Immortalization is defined as IL-2-dependent, long-term growth in culture. Subsequently (2 months to years in culture), cells become fully transformed as defined by continuous cellular proliferation in the absence of exogenous IL-2. Cellular transformation is an early step in the pathogenic process and is distinct from oncogenesis or malignancy. In addition to human T cells, T cells from monkeys (223), rabbits (226), cats (133), and rats (336) have been transformed *in vitro* by HTLV-1. *In vitro* transformation by HTLV-1/-2 of human peripheral blood lymphocytes (PBL) or cord blood lymphocytes results primarily in transformation of CD4+ or CD8+ T cells. However, CD4+/CD8+ cells, and immature CD4–/CD8– cells from bone marrow can also be transformed by HTLV-1 or HTLV-2 *in vitro*. Following co-cultivation of PBL or cord blood lymphocytes with irradiated HTLV-producing cells, proliferating immortalized/transformed cells predominate in the cultures after 4 or more weeks. Initially (4 to 8 weeks after co-cultivation), the population of transformed cells shows a polyclonal pattern of integration of HTLV proviruses. With continued long-term passage, a few dominant clones of cells often arise, resulting in an oligoclonal pattern of integration. In patients with ATL, tumors are almost invariably of the CD4+ type, although occasional CD8+ tumors have been reported.

HTLV-transformed cells typically display phenotypes and surface markers associated with T cells functionally activated by specific antigens or lectin. In addition to proliferation, this includes (a) production of a wide spectrum of lymphokines, including g-interferon, granulocyte-macrophage colony-stimulating factor (GM-CSF), CSF-1, or M-CSF and IL-3; (b) altered surface marker expression, including markers associated with an activated state, such as IL-2R, transferrin receptor, and major histocompatibility complex class II molecules (e.g., HLA-DR) (Table 2). Transformed cells not only display an activated phenotype but in some cases also retain T-cell functional properties. Among the functional activities of HTLV-transformed cells that have been reported are (a) the ability to induce suppressor-cell activity (although not directly functioning as suppressor cells) (232), (b) the ability to retain antigen-specific responses (217), and (c) cytotoxic function (65). However, in other cases, aberrant function such as loss of accessory cell requirement is evident (217).

Continuous proliferation
Surface marker expression
Usually CD4+
Occasionally CD4−CD8+
Invariably IL-2R+
Express transferrin receptor (101)
May show altered HLA expression (208)
Increased expression of adhesion molecules (75)
Jak/STAT constitutively activated, HTLV-1 only (215)
Expression of cytokines
IL-1 (358)
IL-2 variable
IL-3 (249)
IL-5 (7)
IL-6 (353)
IL-9 (159)
γ-IFN (34)
CSF-1 (M-CSF) (158)
GM-CSF (158)
TNF-α and -β (164)
TGF-β (161)
NGF (93)
EGR-1 (269)
GCPF (17)

HTLV, human T-cell leukemia virus; IL, interleukin; HLA, human lymphocyte antigen; IFN, interferon; CSF, colony-stimulating factor; M, macrophage; G, granulocyte; TNF, tumor necrosis factor; TGF, transforming growth factor; NGF, nerve growth factor; EGR, epidermal growth factor receptor; GCPF, glial growth promoting factor.

TABLE 2. *Properties of HTLV-transformed cells*

Cell types other than T cells transformed by HTLV have not been reported. Cells transformed *in vitro* actively transcribe HTLV RNA, produce virions, and can themselves be used to transform other normal cells. This contrasts with the lack of HTLV gene expression in ATL tumor cells, suggesting that the process of *in vitro* transformation by HTLV does not directly parallel formation of a leukemic clone *in vivo*, but probably represents the first step in the malignant process. The polyclonal pattern of transformation *in vitro* is reminiscent of B-cell transformation by EBV and may be related to events, which occur *in vivo* in the early stages of HTLV-associated disease, prior to the formation of a leukemic clone. It has been shown that HTLV-1-transformed cells are associated with constitutive activation of Jak/STAT pathway, whereas in HTLV-2-transformed cells Jak/STAT is not activated (215,235). The significance of this difference is not clear, but it might suggest that the mechanism of *in vitro* transformation is distinct between HTLV-1 and HTLV-2.

The HTLV genome does not contain an oncogene (i.e., a viral homolog of a normal cellular sequence); therefore, HTLV does not fall into the category of acutely transforming retroviruses. In ATL, a common integration site for HTLV is not found in different tumors. Therefore, promoter insertion mechanisms are not operative, and the mechanism of HTLV transformation must also differ from that found for chronic-transforming retroviruses. Several lines of evidence strongly

implicate the Tax protein as the transforming component of HTLV. These include induction of tumors in Tax transgenic mice (104,246), morphologic transformation of cells by Tax in traditional *in vitro* rodent cell transformation assays (322,334), and immortalization of human T cells using various Tax viral transduction systems (2,282). More recent studies using infectious HTLV-1 and HTLV-2 molecular clones have directly shown that HTLV-mediated cellular transformation requires expression of the Tax oncoprotein (278,285). The precise mechanism by which Tax initiates the malignant process is unclear, but it most likely involves several points of transcriptional and posttranscriptional dysregulation in the infected T lymphocyte.

Mitogenic Stimulation Mechanisms

HTLV virions are mitogenic for quiescent human T cells (80,379). Both CD4+ and CD8+ T cells are stimulated to divide, and unlike T-cell activation by specific antigens, accessory cells (monocytes/macrophages) are not required. This mitogenic activity of the virion preparations does not require infection by HTLV, as heat-inactivated virions show similar properties. Mitogenic stimulation is probably a consequence of interaction between a virion surface molecule and a specific receptor on the surface of the T cell. Neither the virion protein responsible nor its receptor has as yet been definitively identified. Likely candidates are the virus *env* gp46 (SU) protein and receptors on the surface of the cell that normally participate in T-cell activation responses. Several reports have indicated that this mitogenic activity operates via the CD2 receptor activation pathway with an important contribution by the adhesion molecule, leukocyte function-associated antigen 3 (LFA-3) (58,105,162).

One important function for the mitogenic activity induced by HTLV virions might be to enable the virus to establish infection once it has penetrated the cell. Previously activated and dividing T cells are more easily transformed by HTLV than are quiescent T cells (214). Retroviruses are generally blocked from productive infection unless the cells have traversed through the S phase of the cell cycle. By inducing its target cell to divide, HTLV is thus able to overcome this block to productive infection. This may be of particular importance to HTLV, because 95% of the T cells in the peripheral circulation are in a quiescent state. The mitogenic activity of HTLV virions suggests a model for HTLV transformation whereby continual stimulation of the T cell by a virion component via a T-cell surface receptor results in continuous cell proliferation. Continued virion stimulation does not allow continued proliferation of the cells. Transformation of T cells most likely requires (a) mitogenic activity of the virion at the cell surface and (b) the pleiotropic effects of the *tax* gene product within the cell. This process may be analogous to that of transformation of primary rodent fibroblasts *in vitro*, where coexpression of two oncogenes, one acting in the nucleus and the other acting at the cell membrane, are required to effect transformation of the cell.

TAX MECHANISMS OF ACTION

Transcriptional Control

The discovery that the *tax* gene positively regulates HTLV gene expression gave rise to the idea that it may aberrantly regulate cellular gene expression. Indeed, Tax is capable of trans-activating many cellular promoters in addition to its own LTR. Much of the data on this subject has been compiled for Tax-1 and is summarized in Table 3. The promoters of IL-2 and the IL-2R-a chain, two genes centrally involved in the control of T-cell proliferation, are activated by Tax (10,52). This observation provides support for a possible autocrine model of T-cell transformation whereby activation of IL-2 and IL-2R-a genes leads to continuous proliferation of HTLV-infected cells. Although the majority of HTLV-transformed T cells possess an activated phenotype and express surface markers characteristic of T-cell activation (including IL-2R), not all HTLV-transformed T cells express IL-2.

TABLE 3. *Promoters whose expression is influenced by the Tax protein*

In addition to the IL-2 and IL-2R genes, T cells transformed by HTLV-1 constitutively express a high proportion of early response or serum-responsive genes normally transiently induced following antigenic or mitogenic activation of T cells (160). Some of these include proliferating cell nuclear antigen, *erg*-1, and *erg*-2, and proto-oncogenes c-*fos*, c-*myc*, c-*jun*, and c-*sis* (72,144,191,274,339). Again, the mechanism responsible for the activation of these genes is an increased rate of transcription rather than a change in mRNA stability. Tax has also been shown to repress transcription of b-polymerase, a host-cell DNA repair enzyme, and the *bax* gene, whose gene product accelerates apoptosis (32,145).

The mechanism of Tax protein action on various promoters is indirect through activation of a number of different transcription factors including CREB/ATF (328,381), NFkB/Rel (10,191), serum response factor (SRF) (73), NF-AT (89), and basic helix-loop-helix proteins (bHLH) (348) (see Table 3). Tax activates HTLV gene expression via interaction with CREB/ATF proteins and the transcriptional coactivators CREB binding protein (CBP)/p300, resulting in increased binding of these factors to three 21-bp repeats present in the LTR (21,86,113,176). Likewise, Tax activates NFkB/Rel-responsive

genes by interacting with members of the NFkB family of proteins and their inhibitors including p50, RelA, p100/NFkB2, and p105/NFkB1. NFkB subunits are sequestered in the cytoplasm through high affinity binding with the labile cytoplasmic inhibitors IkBa and IkBb (85). The mechanism of activation of NFkB by Tax involves site-specific phosphorylation of the inhibitors IkBa and IkBb, followed by their ubiquitination and degradation and the nuclear translocation of the active NFkB subunits. Phosphorylation involves a large multiprotein complex containing Tax; IkB kinases (IKK) IKKg/NEMO, IKKa, and IKKb; mitogen-activated kinase kinase 1 (MEKK1); NFkB-inducing kinase (NIK); NFkB/Rel; and IkBa or IkBb (40,56,148,184,213,245,273,375).

A number of mutations in both Tax-1 and Tax-2 proteins have been described that selectively abrogate the ability of Tax to activate transcription through the CREB/ATF or NFkB/Rel signaling pathways (283,306,321) (see Fig. 3). These mutants have been invaluable tools in dissecting cellular signaling and in determining the interplay between Tax and cellular transcription factors and cellular transformation. Several approaches have been used to evaluate domains of Tax-1 required to immortalize or transform rodent cell lines or primary human T lymphocytes. These analyses have yielded conflicting results about whether Tax-1 activation of the CREB/ATF or the NFkB/Rel pathway is critical for cellular transformation (2,140,278,282,322). A recent study has indicated that Tax-2 activation of both NFkB/Rel and CREB/ATF are required to induce IL-2-independent T-lymphocyte transformation. It appears that the activation of NFkB/Rel provides a critical proliferative signal early in the cellular transformation process, whereas CREB/ATF activation promotes sustained cell growth and IL-2 independent cellular transformation (284).

Posttranscriptional Control and Cell Cycle

Progression through the cell cycle and apoptosis is controlled through the interplay between key positive and negative regulators. Viral oncoproteins interfere with this regulation by increasing the expression of growth-promoting genes as described earlier and/or by altering the function of cell cycle regulatory proteins through direct physical association. This probably contributes to uncontrolled cell growth early, followed by subsequent cell damage or mutations, and ultimately malignancy. For example, Tax can inhibit apoptosis via its effects on the p53 tumor suppressor and *bax.* Tax stabilizes p53 and inhibits its transactivation function while repressing *bax* gene expression (32,111,234,268). Tax induces unscheduled transition of cells from G_0/G_1 into S phase by altering the activity of cyclin D, cyclin-dependent kinases cdk4 and cdk6, and the cdk inhibitors $p21^{waf}$ and $p16^{INK4A}$ (198,247,295,327). The dysregulation of these important cell cycle regulatory pathways may represent a key step in T-cell transformation.

Tax has also been shown to directly bind the mitotic checkpoint protein, MAD1, interfere with the function resulting in the induction of multinucleated cells and chromosomal abnormalities (147). A complete understanding of the mechanism of T-lymphocyte transformation and malignancy will require correlation of Tax domains important in modulating gene transcription, cell cycle control, and induction of DNA damage with those required for cellular transformation.

ANIMAL MODELS FOR HTLV INFECTION

The development of a small animal model for HTLV infection and disease manifestation would be extremely useful. HTLV has successfully been transmitted to rats and to rabbits via inoculation of *in vitro*-infected T cells. Infection of rats with HTLV-1 has been shown to be a potential model for HAM rat disease (173). Recently, rats infected with HTLV-1 were shown to develop a chronic progressive myeloneuropathy with paraparesis of the hind limbs after an incubation period of 15 months (156). The microglia/macrophages were determined to be one of the dominant viral reservoirs in the spinal cord and lymph nodes in these animals, suggesting that pathology may result from neurotoxic cytokine synthesis. Rabbits have been used to examine HTLV-1 infection, replication, cellular transformation, transmission, induced immune responses, disease manifestations, vaccine candidates, and treatment methods (reviewed in ref. 272). The use of the rabbit model has been more recently used in the characterization of molecular clones of HTLV-1/-2. Most notable is its use in determining that the pX region sequences containing ORF I and ORF II are important for viral infectivity and maintenance of viral load *in vivo* (15,48,49).

Technical advances in recent years have allowed new approaches to animal studies beyond direct infection of experimental animals with virus. Transgenic mice containing the HTLV-1 genome or the HTLV-1 *tax* gene have been generated by *in vitro* manipulation and selective cross-breeding. However, although these animals became symptomatic, they did not develop a syndrome similar to ATL. Different genetic lines of mice transgenic for HTLV have shown distinct patterns of pathology dependent on the promoter/enhancer driving gene expression and the composition of the HTLV transgene. In one case, mice carrying the HTLV-1 genome or HTLV Tax developed chronic arthritis resembling rheumatoid arthritis, suggesting the possibility that HTLV-1 is one of the etiologic agents of chronic arthritis in humans (106,139). Subsequent clinical reports have borne out the hypothesis that chronic inflammatory arthropathy does occur in HTLV-infected individuals as a rare complication of infection. LTR Tax transgenic mice have been shown to develop neurofibromas (246) as well as an exocrinopathy resembling Sjögren's syndrome (94). A more recent experiment targeting expression of the *tax* gene to the mature T-lymphocyte compartment using the human granzyme B promoter resulted in the development of large granular lymphocytic leukemia (104). The common link to pathology by the different transgenic approaches is the expression of the *tax* gene.

Severe combined immunodeficient (SCID) mice can support the survival of human lymphoid cell populations by reconstituting their immune systems with human tissues. Reconstituted SCID mice have been infected with HTLV-1, and many of these mice became persistently infected with the virus (67). Lymphoblastic lymphomas of human origin developed in several animals injected with PBL from two patients with ATL. The tumor cells represented an outgrowth of the original ATL leukemic clone with monoclonal or oligoclonal integrations of the HTLV-1 provirus identical to the original leukemic clone. In contrast, cell lines derived by HTLV transformation of T cells *in vitro* did not persist or form tumors when inoculated into SCID mice. These distinct growth properties indicate differences between *in vitro* transformed cells and ATL leukemic cells and may relate to differential sensitivities to NK cells (66).

DISEASES OF HTLV-1 INFECTION

ATL and HTLV-1

Several categories have been proposed as stages in ATL (315). These have been termed as follows: (a) asymptomatic carrier state, (b) preleukemic state (pre-ATL), (c) chronic/smoldering ATL, (d) lymphoma type, and (e) acute ATL (Table 4). In some cases, these categories may be temporally related. The majority of HTLV-1-infected individuals are asymptomatic carriers of the virus. These infected individuals are capable of transmitting the virus because the proviral genome is integrated into host-cell DNA sequences. An infected individual has about a 1% chance of developing a tumor over a lifetime of infection (167), although the cumulative lifetime chance of developing any HTLV-associated condition is slightly higher, approximately 5% to 10%.

Stage	Monoclonal proviral	Skin lesions	Visceropathy	White blood count
Carrier Clinical status: no clinical signs.	+	-	-	Normal (<4 × 10⁹/L)
Pre-ATL Clinical status: variable-uncertain category.	+	-	-	Slightly elevated? (>4 × 10⁹/L)
Smoldering ATL Clinical status: 5% abnormal lymphocytes, no hypercalcemia, variable course, may progress to ATL.	+	+	-	Normal (<4 × 10⁹/L)
Chronic ATL Clinical status: 5% abnormal lymphocytes, no hypercalcemia, variable course, may progress to ATL.	+	+	-	>4 × 10⁹/L
Lymphoma type Clinical status: <1% abnormal lymphocytes, lymphadenopathy, median survival ~10 months.	+	+/-	+	Normal (<4 × 10⁹/L)
Acute ATL Clinical status: >5% abnormal lymphocytes, hypercalcemia, median survival ~6 months.	+	+	+	>4 × 10⁹/L

These clinical phases may be but are not necessarily temporally related (264).

TABLE 4. *Clinical Phases of HTLV-1 infection*

ATL generally occurs in adulthood, at least 20 to 30 years following infection. Some patients manifest a disorder known as pre-ATL, which is usually asymptomatic. This condition was originally diagnosed by incidental detection of leukocytosis and/or morphologically abnormal lymphocytes, but more recently it is diagnosed as a result of serologic screening. HTLV-1 can be identified in the cells of these individuals by PCR amplification, and the provirus can be found to be integrated in abnormal T lymphocytes in a monoclonal or oligoclonal pattern by Southern blot hybridization. These findings indicate the beginnings of the development of a clonal population of cells, some of which may progress to the malignancies found in acute ATL. Approximately 50% of patients with pre-ATL undergo spontaneous regression of lymphocytosis. In the remaining group, T-cell lymphocytosis persists, and some of these patients progress to the acute stage.

About 30% of patients with clinical manifestations of HTLV-1 infection have chronic or smoldering ATL (317). These forms of ATL are less aggressive than the acute stage of the disease and are characterized by skin lesions, low levels of circulating leukemic cells, and an absence of visceral involvement. Patients in the smoldering ATL category present with skin lesions and marrow involvement, whereas patients with chronic ATL generally have elevated numbers of circulating ATL cells, accounting for an increased leukocyte count. Patients in both the smoldering and chronic stages of ATL can progress into acute ATL within a period of months. Pre-ATL, smoldering ATL, and chronic ATL may represent transitional states in the development of the malignant clone that is evident in acute ATL.

In acute ATL (315,317), a dominant clone of malignant cells is present, as evidenced by the presence of (a) a single rearrangement of T-cell antigen receptor gene and (b) one or a few proviruses arranged in an oligoclonal fashion in the population of tumor cells. These patients have an elevated white blood cell count, with many morphologically abnormal T lymphocytes (Fig. 4). Also, there is often prominent eosinophilia and neutrophilia. Findings in acute ATL include lymphadenopathy that does not involve the mediastinum, hepatosplenomegaly, and skin lesions caused by infiltration of leukemia cells (Fig. 5). Interstitial pneumonitis, also caused by leukemic cell infiltration, is sometimes present. Patients manifest abnormalities in certain serum chemistries, including elevation of lactate dehydrogenase (LDH), hyperbilirubinemia, and hypercalcemia. Hypercalcemia is associated with the presence of lytic bone lesions detected on the skull (Fig. 6) and long bones (26). Recent work has shown that hypercalcemia in acute ATL may involve production of IL-1a and parathyroid hormone–related protein by HTLV-1-infected cells (62,230,360). Patients with ATL are also immunocompromised and may present with opportunistic infections, including disseminated fungal infections, *Pneumocystis carinii* pneumonia, cytomegalovirus pneumonia, and various bacterial infections. The only significant prognostic factor in acute ATL is the presence of ascites, which is associated with shorter survival. The median survival in acute ATL is approximately 6 months (142,319), despite aggressive intervention with chemotherapy.

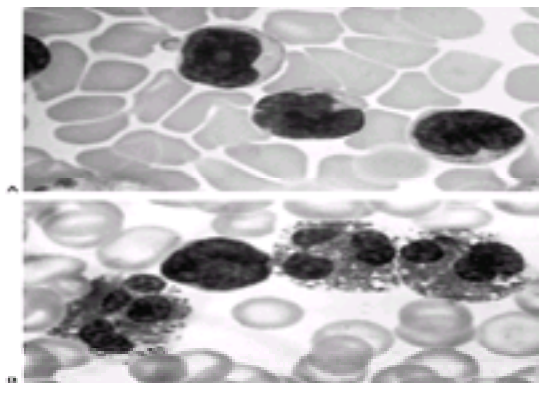

FIG. 4. A: Typical morphology of ATL tumor cells, showing convoluted nuclei. (From ref. 280, with permission.) **B:**

Prominent eosinophilia in ATL.

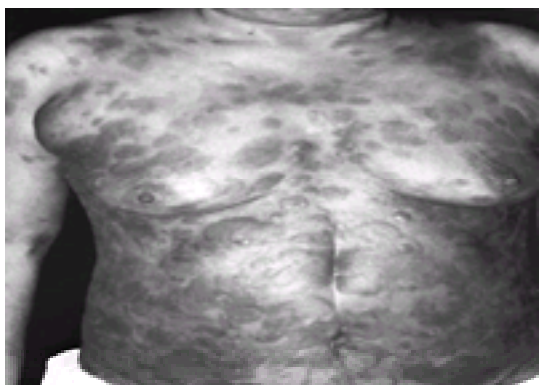

FIG. 5. Skin lesions on a patient with acute ATL.

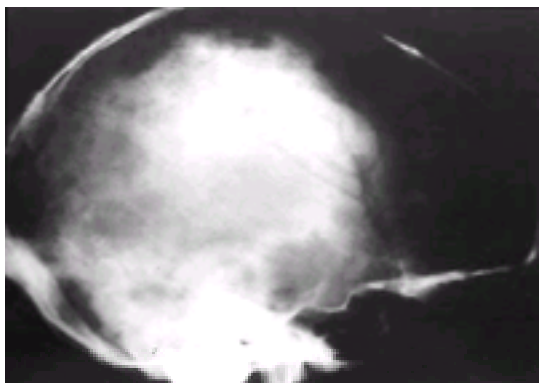

FIG. 6. Lytic bone lesions in the skull of a patient with ATL.

The morphology of peripheral blood cells in ATL is variable. Typical ATL cells have highly lobulated or flower-shaped nuclei, but the degree of nuclear irregularity is variable (253) (see Fig. 4). This aberrant nuclear morphology is consistent with the observed pleiotropic effects of Tax, including induction of micronuclei and chromosomal abnormalities (147,204). The histopathology of lymph nodes from patients with ATL is also heterogeneous, but it most frequently falls into the large-cell, immunoblastic classification. Nodal histopathology has no correlation with the patient's prognosis or therapy. Immunologic studies of ATL cells have revealed phenotypic heterogeneity for T-cell subset markers (232). owever, virtually all ATL cells have markers for CD4 antigen, with rare exceptions having CD8 markers. Although these markers usually indicate a helper/inducer phenotype, assays revealed that these cells have suppressor activity for immunoglobulin synthesis (354). Further studies suggested that this suppression is not directly caused by ATL cells but is, instead, mediated via suppressor CD8+ cells that are activated by the ATL cells (232). One characteristic marker of ATL tumor cells is high levels of expression of the IL-2R-a chain, Tac antigen (345), both attributed to the transactivation effects of Tax.

The form of disease in some patients with ATL is predominantly that of a T-cell lymphoma rather than a leukemia (315). These non-Hodgkin's lymphomas have differing histologic patterns and can involve any organ. Lymph node biopsy specimens from these patients contain oligoclonally integrated HTLV-1, indicating a clonal malignancy. The differential diagnosis of ATL includes other T-cell malignancies such as non-Hodgkin's lymphoma, mycosis fungoides, Sezary's syndrome, and T-cell chronic lymphocytic leukemia. However, most cases of these secondary conditions are not associated with HTLV infection. A variety of laboratory studies can help establish a diagnosis of ATL, including a HTLV-1 serum positivity, hypercalcemia, elevated serum LDH, staining for terminal deoxynucleotidyl transferase (typically negative in ATL), and immunologic typing of ATL cells for CD4 and Tac antigen (IL-2R-a chain). Definitive evidence for the disease is obtained if monoclonally or oligoclonally integrated HTLV-1 genome is present.

HTLV-1–Associated Myelopathy/Tropical Spastic Paraparesis

In 1985, a group of West Indian patients with a neurologic disease known as tropical spastic paraparesis were found to be seropositive for HTLV-1 (84). Subsequently, a report from Japan described a number of patients with a slowly progressing myelopathy and pyramidal disturbances, all of whom had elevated HTLV-1 antibody titers (262). This neurologic disease was termed HTLV-associated myelopathy, now considered to be identical to TSP. HAM/TSP has been described in all areas of the world known to be endemic for HTLV-1, and the risk factors are the same as those for HTLV infection. The lifetime risk for development of HAM/TSP has been estimated at below 1% (154).

Neurologic findings in HAM/TSP include weakness and spasticity of the extremities, hyperreflexia, Babinski sign, urinary/fecal incontinence, and mild peripheral sensory loss (260). The cerebrospinal fluid (CSF) of these patients contains anti-HTLV-1 antibodies and may show a lymphocytic pleocytosis as well as elevated protein levels. Patients with HAM/TSP generally have normal lymphocyte numbers, but morphologically atypical lymphocytes resembling ATL cells can be seen in peripheral blood or in the CSF (77). Magnetic resonance imaging has demonstrated lesions in both the white matter and the paraventricular regions of the brain in patients with HAM/TSP (216). However, other diseases such

as multiple sclerosis show similar lesions. Autopsy studies show significant abnormalities in the thoracic spinal cord, including demyelination, capillary proliferation, and perivascular cuffing with lymphocytic infiltration (4).

Other Diseases Associated with HTLV-1

A number of clinical reports have suggested that hematologic malignancies other than ATL are associated with infection with HTLV-1. Cases of T-cell non-Hodgkin's lymphoma, T-prolymphocytic leukemia, Sezary's syndrome, mycosis fungoides, small cell carcinoma, and large granular lymphocytic leukemia have been described to be serologically or molecularly linked to HTLV-1 infection. However, most of these studies base their association on limited data, making it difficult to determine the role played by HTLV-1 in these conditions. HTLV-1 may play an indirect role in certain cases of chronic lymphocytic leukemia of B-cell origin (B-cell CLL). In Jamaica, where HTLV-1 infection is endemic, HTLV seropositivity was significantly higher in patients with B-cell CLL than in the general population (24). It has been proposed that B-cell CLL is derived from the clonal outgrowth of a B-cell clone reactive against an HTLV-1 antigen (207). If HTLV-1 infection is associated with B-cell CLL, then additional factors must also be involved, because B-cell CLL is not common in Japan.

There is evidence that chronic inflammatory arthropathy and uveitis may occur in a few HTLV-infected individuals as a rare complication of infection (228,292). Certain lines of mice transgenic for HTLV have developed chronic arthritis resembling rheumatoid arthritis, suggesting that HTLV-1 is one of the etiologic agents of chronic arthritis in humans (139). Uveitis has also been observed in a rabbit experimentally infected with HTLV-1 (329).

There is some evidence for functional impairment of the cellular immune response in patients with ATL as well as among some HTLV-1 carriers (37). Defects in cell-mediated immunity may result in particular problems with parasitic infections. Immunosuppressive effects may lead to opportunistic infections. Several epidemiologic surveys have indicated the existence of groups of individuals who are concurrently infected with both HTLV-1/2 and HIV. This is particularly common among IVDA who become infected by sharing contaminated needles and syringes, a major route of transmission of both viruses. There is evidence that coinfection may accelerate progression to AIDS. HTLV can form enveloped pseudotypes with HIV particles, which broadens the cell tropism of HIV *in vitro*, potentially increasing the spread of virus through the body (183,200), although this has not been formally demonstrated *in vivo*.

HTLV-2 DISEASE

HTLV-2 infection has been reported in a number of locations worldwide, primarily among IVDA (185,279,337), in the Amerindian population of North, Central, and South America (115,126,179,192), and in Africa (82,90,351). However, the absolute role of HTLV-2 in the few cases of leukemia and neurologic disease associated with viral infection remains unclear, since insufficient cases are available for clear epidemiologic studies of transmission. A clearer understanding of the etiology of HTLV-2 in T-cell malignancies may emerge over the next decade as further isolates of the virus are made in association with malignancy. At the present time, the evidence is growing that HTLV-2 is a cause of human disease. Comparative studies between HTLV-2 and HTLV-1 will probably be essential to understand the different pathobiologies of these two distinct but related viruses.

PATHOGENESIS OF HTLV INFECTION

Oncogenesis

When HTLV-infected lymphocytes are present in individuals at a level sufficiently high to allow detection of viral sequences by Southern blotting, the viral sequences are always present as integrated forms and are generally oligoclonal or monoclonal with respect to integration sites (300). An exception is in some healthy carriers and in some patients with smoldering ATL, where polyclonal integration can be detected. Similar observations have been made for BLV in the early phase of the disease known as persistent lymphocytosis, where polyclonal integration of BLV is evident (36). Rare cases of cancer similar in pathology to ATL have been identified in which HTLV-1 infection is not present (316). In these cases, the HTLV-1 sequences may have been lost, or, alternatively, other agents or factors may give rise to a related disease.

These observations strongly suggest that the initial infection by HTLV results in transformation of a polyclonal population of cells (dependent on the Tax oncoprotein), and that subsequent selection processes result in the evolution of clones that may ultimately develop into the malignant cells. Chromosomal abnormalities commonly exist in ATL cells (76,290), and the degree of cytogenetic aberration is often related to the severity of the disease (i.e., abnormalities are frequently found in acute ATL but are less likely to be seen in chronic or smoldering ATL, suggesting the possibility of clonal evolution during disease progression). Viewed in this context, HTLV transformation of T lymphocytes results in a pool of proliferating cells that are not oncogenic themselves but that provide a population from which a malignant clone may subsequently arise. This accounts for the long latent period between infection and manifestation of a tumor in HTLV disease. Therefore, Tax may also contribute to these later events as a result of its pleiotropic effects on proteins regulating mitosis, apoptosis, and DNA repair.

During the acute phase of ATL, when patients have an elevated leukocyte count with many malignant lymphocytes, the viral DNA can be easily detected and is generally monoclonal with respect to integration sites. However, examination of viral integration sites in ATL cells from several patients demonstrates that these are distinct and present on different chromosomes (300). Unlike some animal retroviruses, where common integration sites are found about particular cellular oncogenes, the integration of HTLV is random. Therefore, integration sites provide little clues as to the mechanism of oncogenesis. As discussed earlier, it is likely that trans-activation mechanisms are responsible for this process.

One of the distinguishing features of the virus in the acute phase, and perhaps also in pre-ATL and chronic/smoldering ATL, is that, although the viral genome is present as a provirus in all of the tumor cells, there is no (or a very low level of) detectable expression of viral genes within the cells. No viral RNA transcripts can be detected by Northern hybridization

or S1 nuclease analysis (70). If fresh ATL cells are placed into culture *in vitro*, virus expression can be detected shortly (130), indicating that the block to expression is not a result of an intrinsic genetic defect in the virus genome. Most isolates of HTLV-1/-2 have been obtained in this manner, wherein virus is expressed from leukemic cells and then infects other cells in the culture. Most HTLV-infected cell lines derived from patients are not the same clone as the original tumor cells (130). It is unclear whether there is any viral expression during the pre-ATL or chronic/smoldering phase of the disease. Lack of viral expression may relate to either a latent state of the virus or an immune selection against those cells that express recognizable viral antigens on their surface. Evidence supports the role of the immune system in suppressing the emergence of oncogenic clones of cells during the asymptomatic phase of the disease (11,343). The immunosuppression seen in HTLV-infected individuals may also be implicated in the development of leukemia. Presumably, the virus is expressed in some cells of the body. However, the source and frequency of expression and factors that may induce expression are not known.

HTLV-Associated Myelopathy/Tropical Spastic Paraparesis

The pathogenesis of HAM/TSP remains poorly understood. In contrast to ATL, which generally occurs 20 to 30 years following HTLV-1 infection, HAM/TSP may develop in some patients within a few years of infection, often after transfusion of infected blood. The presence of intrathecal antibody titers to HTLV-1 indicates that the virus has infected the CNS in addition to the blood (124,260). Immune complexes have also been detected in the blood of patients with HAM/TSP (310). A number of studies have demonstrated the presence of HTLV-1 DNA in blood and lymphocytes of the CSF (22,378). One study provided evidence that HTLV-1 Tax RNA is expressed in astrocytes of HAM/TSP patients (187). It is noteworthy that polyclonal integration of the virus is detected in patients with HAM/TSP, as opposed to oligoclonal or monoclonal integration in ATL. Thus, development of HAM/TSP is not a consequence of the development of a malignant clone of cells. Characterization of viral isolates from patients with HAM/TSP does not show any distinguishing features from HTLV-1 from those with ATL and provides no evidence that a variant virus is involved in the disease. Some investigators have concluded that persistent active replication of HTLV-1 is an important factor in the pathogenesis of HAM/TSP, compared with the mostly quiescent state of the virus in ATL. Indeed, one recent comparative analysis of proviral load in the peripheral blood of HAM/TSP patients (compared to asymptomatic HTLV-1 carriers) has indicated that high proviral load strongly predisposes to HAM/TSP (237).

The mechanisms underlying the neurologic damage observed in HAM/TSP patients remain to be determined. CNS damage may directly result from HTLV invasion of resident cells, indirectly via autoimmune or neurotoxic cytokine-mediated mechanisms, or a combination of both. In support of these models are (a) the ability of HTLV to infect cells of nervous system origin *in vitro*, and its detection in cells of neuro origin *in vivo* (see preceding); (b) the finding that expression of cytokines (including TNF-a, GM-CSF, INF-g, and IL-1a) is higher in HAM/TSP patients then in asymptomatic carriers (359); and (c) the detection of high levels of cytotoxic T-lymphocytes (CTLs), which predominantly recognize HTLV-infected cells, in patients with HAM/TSP (102,141). Primary demyelination and remyelination by oligodendrocytes has been shown to occur in the spinal cord lesions of patients with HAM/TSP (254). Of note is the observation that patients with HAM/TSP tend to have higher levels of circulating antibody to HTLV-1 antigens than do those with ATL (260). There is also an association between development of HAM/TSP and certain HLA haplotypes (146,350), whereas there is no association with the development of ATL.

IMMUNE RESPONSE TO HTLV

All patients with ATL make humoral antibodies to various HTLV-1 antigens. The major viral gene products recognized by sera from infected individuals are those of the *gag*, *env*, and *tax* genes. As in all retroviruses, the Gag proteins are the major immunogens and are responsible for the earliest antibodies to appear. Sera from infected individuals usually recognize all three Gag proteins, p15, p24, and p19. There is considerable cross-reactivity between HTLV-1 and HTLV-2, particularly in the region encoding p24 (182) (see Table 1). This similarity was initially responsible for the discovery of HTLV-2, but it has also resulted in considerable confusion over serodiagnosis of HTLV-1/-2 infection, and in a common diagnosis of HTLV-1/-2 positive. However, the presence of endogenous retroviruses may also provide a possible explanation for the HTLV-1 Gag-reactive autoantibodies that have been noted in some cases (12).

Antibodies are also directed against both the external envelope glycoprotein, gp46, and, to some extent, the transmembrane protein, p21 (45,64,130,372). These antibodies react with the envelope precursor protein, gp61, in infected cells. The amino-terminal regions of HTLV-1 and -2 gp46 contain type-specific, linear, neutralizing determinants (263). A recent study has found that antibodies to conformational epitopes of gp46 comprise the majority of the immune responses to HTLV-1 Env, and the epitopes are distinct from previously recognized immunodominant linear epitopes (107). Antibodies directed against the envelope proteins may be an important means of modifying the course of virus infection, but seroconversion does not lead to elimination of virus infection, as individuals infected with HTLV (both patients with ATL and HAM/TSP and apparently healthy carriers) all typically possess such antibodies.

Many individuals also have antibodies against nonstructural viral proteins, in particular Tax. This antigen may be released from the nucleus of infected cells and recognized by the immune system on lysis. Some antibodies against HTLV-1 have been found to be present in antigen–antibody complexes (225,299). Rare antibody-negative cases of ATL have also been reported (314,318). The time course of seroconversion has been examined in patients infected by receiving HTLV-contaminated blood transfusions (209). In the early posttransfusion period, antibodies to the Gag proteins were predominant, with anti-p24 appearing before anti-p19. Envelope protein p21(TM) was the earliest Env reactivity detected, while anti-gp46 and anti-gp61 appeared later. Anti-Tax antibodies were the last to appear (several months after infection).

The serologic profile of HTLV-infected individuals varies considerably and includes some individuals who display a virtually monospecific pattern of antibodies. Natural immunity to HTLV appears to be different from that to other retroviruses, in that human complement–mediated virolysis was not effective for HTLV virions, using either normal human serum or human serum from an HTLV-antibody carrier. Thus, the virions may have an intrinsic resistance to humoral

immune mechanisms (132).

Cellular immunity against HTLV-infected cells has also been described. However, there has been only limited mapping of specific determinants. CTL lines have been established from patients with ATL that are specific for HTLV-1-infected cells (152,218), but the majority of information regarding HTLV-specific CTLs has come from the study of CTLs in HAM/TSP. In HAM/TSP patients, some HTLV-1-specific CTLs recognized the envelope region, but the majority were predominantly restricted to the *tax* gene product (63,141,165). Further study indicated that HTLV-specific CTLs that recognize Tax are specific for a peptide at the amino terminus (amino acids 11 to 19). The presence of these CTLs as well as alterations in immune recognition may play a key role in HTLV-induced pathogenesis. Antibody-dependent cellular cytotoxicity (220,380) and natural killer cell activity (287) have also been described. As in HIV, the immune response induced by HTLV is not capable of clearing the viral infection resulting in long-term viral persistence.

EPIDEMIOLOGY OF HTLV INFECTION

HTLV-1

HTLV-1 virus infection was originally discovered in Japan but has now been found worldwide. In general terms, HTLV-1 predominates in south-western Japan, the Caribbean basin, equatorial Africa, parts of South America, the Middle East, and parts of Melanesia. The number of people around the world infected with HTLV-1 has been estimated as between 15 and 25 million.

Initial data demonstrating that patients with ATL in southwestern Japan were seropositive for HTLV-1 provided the first evidence for an etiologic association (79,121). Since then, a large amount of data has been compiled regarding HTLV-1 infection in Japan. It is currently estimated that the number of infected individuals is over 1 million (119), among a population of approximately 121 million. Rates of seropositivity in different regions vary widely: 35% in Okinawa, 8% to 10% in Kyushu Province, and 0% to 1.2% in nonendemic areas (120,211,330). Infection with HTLV-1 generally occurs quite early in life, probably perinatally, but it has been estimated that 30,000 to 50,000 Japanese have also been infected through blood transfusions (291).

The incidence of HTLV-1-infected individuals appears to be increasing worldwide, especially in western Europe and the United States, particularly among IVDA and homosexuals. The estimated numbers of HTLV-1 infection in different parts of the world are as follows: the Kyushu district in Japan, 8%; Uganda, 8%; Ghana, 9%; Zaire, 3.2%; Dominican Republic, 2%; Mashhad, Iran, 3%; and the United States, 0.003% to 0.04%. However, specific pockets or regions are higher. For example, one published study of IVDA in New York City reported a prevalence of 9%, 18%, and 41% for HTLV-1, HTLV-2, and HIV, respectively (279). Also, in Trinidad, 15% of homosexuals were seropositive for HTLV-1, as opposed to 2.4% of the general population (14). Although HTLV-1 is endemic in Trinidad and HIV was only relatively recently introduced into the country, approximately 40% of homosexuals were found to be infected with HIV, compared with less than 1% of the general population, suggesting that the same populations are at risk for infection with HTLV and HIV, but that HTLV is spread less efficiently than HIV.

HTLV-2

HTLV-2 infection appears to be more common than previously thought. However, the distribution of HTLV-2 tends to be localized to certain population groups. HTLV-2 clusters in IVDA worldwide; in Amerindian populations in North, Central, and South America; and in parts of Africa. The absolute incidence of HTLV-2 infection is low compared with the worldwide incidence of HTLV-1, but HTLV-2 infection has been reported throughout the world. More recent pockets include Spain and Venezuela (57,326).

TRANSMISSION OF HTLV

HTLV transmission occurs by three different modes. Although much of the experimental data has been compiled for HTLV-1, transmission for HTLV-2 is similar. The overall mode of HTLV-1 transmission is similar to that of the AIDS virus, with the exception that the virus is apparently not readily transmitted by cell-free body fluids. These observations are consistent with the *in vitro* studies of HTLV, where infection of target cells requires co-cultivation of the infected with the uninfected cells.

First, mothers infected with HTLV-1 can transmit the virus to the fetus or newborn (163,166,331). The mode of transmission here is either through transplacental passage of infected maternal lymphocytes or through infected lymphocytes in breast milk. In one study, the overall prevalence of HTLV-1 among children born to infected mothers was 16%. The prevalence of HTLV-1 among children breast-fed for over 3 months was significantly higher (27%) than that of those breast-fed for under 3 months (5%). Of 78 bottle-fed children, 13% were positive for HTLV-1, suggesting that about 13% of bottle-fed children born to carrier mothers are infected with HTLV-1 by routes other than breast milk (123). Polymerase chain reaction amplification has detected HTLV proviral DNA in the peripheral blood and milk of all carrier mothers examined, but only rarely in cord blood from carriers' neonates, indicating that transplacental infection with HTLV-1 is rare and that postpartum infection via breast milk is the major perinatal transmission route (288). These observations have produced recommendations that carrier mothers should refrain from breast-feeding to reduce the incidence of HTLV-1 transmission to their offspring.

Second, HTLV-1 can be transmitted from man to woman during sexual intercourse via HTLV-1-infected cells in semen (242,331). Similar results were obtained in studies of the related STLV-1 in Japanese macaques maintained in captivity (222). It is possible that that female-to-male sexual transmission also occurs, but only at a very low rate.

The third route of transmission is through infected blood or blood products via transfusion. However, unlike for HIV, only blood products that involve passage of whole lymphocytes from donor to recipient can transmit the virus (143,180,201,221). Studies of HTLV-1/-2 among United States blood donors indicated that a significant proportion of

blood samples are infected. HTLV seroprevalence is about three times greater than that for HIV-1 (0.043% versus 0.013%); 52% of these cases are the result of HTLV-2 infection and 43% the result of HTLV-1. Up to 2,800 individuals per year may have been infected in the United States through blood transfusion before routine donor testing began in 1988. In Europe, the general incidence of HTLV infection appears to be lower than in the United States, although the virus is found at higher frequencies in populations with known risk factors—in particular, in people of Caribbean origin and in IVDA as a result of passage of infected blood lymphocytes in shared needles (352). In the United Kingdom, a survey of nearly 100,000 blood donors indicates an overall seroprevalence of approximately 1:20,000 (33). Although a few European countries have started to screen blood supplies for HTLV, this has not yet been started in all countries, as the low seroprevalence rate probably does not justify the cost of screening. For example, it was recently reported that Sweden has an HTLV seroprevalence of 2:100,000 blood donors; their current screening policy is to test only new blood donors (344).

DIAGNOSIS OF HTLV INFECTION

Antibodies

The diagnosis of HTLV-1 or HTLV-2 infection requires the ability both to detect and to discriminate between infection by either virus. Several methods have been utilized. The development of suitably rapid and sensitive assays has been complicated by the relatively low antibody titers in individuals infected with HTLV-1/-2, as compared to individuals infected with HIV. Several commercial assays based on enzyme-linked immunosorbent assay (ELISA) or particle agglutination formats are licensed for screening of HTLV antibodies. An ELISA/agglutination assay is used as the primary screen, followed by confirmatory assays using Western blotting, radioimmunoprecipitation, or PCR. In spite of recommendations on interpretation of test results from the United States Public Health Service and World Health Organization, there is still some concern over problems with testing. False-positive results mean that use of a second confirmatory technique is absolutely essential. These difficulties arise from the variability in the serologic response to HTLV infection and the relatively low antibody titers in some infected individuals. Screening of blood supplies since 1988 has reduced the overall rate of HTLV-1 transmission via blood transfusions to an extremely low level. Initial ELISA kits had difficulty detecting HTLV-2-infected blood, but newer modified versions have been improved dramatically (78). However, these kits have not been adopted for use by the Federal Drug Administration because of questions about the cost/benefit ratio.

Nucleic Acid

Another complication in antibody screening methods is an age-dependent increase in seropositivity (25,46,175,255), indicating that certain individuals may not develop antibodies until some time after infection. Detection of HTLV genetic material provides an alternative. In patients with ATL, the majority of lymphocytes harbor the provirus, so detection of this DNA by Southern blotting is relatively straightforward and reliable. However, asymptomatic carriers are more problematic, as only a small proportion of cells are infected with the virus. One means formerly employed was to first culture the cells for 3 to 5 weeks, allowing (a) replication and spread of the virus and (b) consequent amplification of viral genetic material. The virus can then be detected in these cultured cells by Southern hybridization or *in situ* hybridization to HTLV RNA. The disadvantage of this method is that *in vitro* culture of cells is time consuming and expensive and is therefore not suitable as a rapid clinical screening assay.

These problems have been solved by the application of PCR amplification of specific sequences in the virus genome (177). PCR can be used to detect a single HTLV-1/-2 provirus and is now the method of choice for detection of HTLV DNA directly from blood and many other tissues. Commercial PCR kits for HTLV are available. However, the unmatched sensitivity of PCR also has drawbacks. False-positive results from inadvertent contamination of samples are a major problem. Target inactivation protocols are available to circumvent this problem in diagnostic laboratories. Although PCR is now a common research tool, its use still presents problems of cost in large-scale screening operations, particularly in underdeveloped countries where HTLV infection may be endemic.

Differential Diagnosis of HTLV-1 and HTLV-2

Earlier serologic methods for diagnosis of HTLV infection did not conclusively distinguish between HTLV-1 and HTLV-2. Competition radioimmunoassays or competition ELISAs have been developed to distinguish between HTLV-1 and HTLV-2. Most monoclonal antibodies to p19 and p24 core antigens detect both HTLV-1 and HTLV-2 and do not discriminate between the viruses. However, some monoclonals are capable of distinguishing between HTLV-1 and HTLV-2 (264) and allow positive identification to be made. Western blotting can distinguish between the two (286), but the use of PCR amplification provides the ideal tool for the differential diagnosis. In addition to its unrivaled sensitivity, the nucleotide sequence of the amplified products can easily be determined, allowing rapid, sensitive, and definitive diagnosis of HTLV infection.

TREATMENT OF HTLV DISEASE

Therapeutic Agents

Adult T-cell leukemia is a highly malignant disease; median survival in subacute or acute ATL is measured in months. However, as only a small proportion (1%) of infected individuals progress from an asymptomatic to a disease state, treatment is reserved for the subacute and acute forms of ATL. Standard combination chemotherapy regimens, particularly those designed for treatment of aggressive non-Hodgkin's lymphoma or acute lymphoblastic leukemia, have not proved valuable for ATL (35,47,158,197,342,367). Some reports have suggested that deoxycoformycin is an effective drug, whereas other trials have shown variable therapeutic efficacy (53,196,368). There has been one report of successful treatment of chronic ATL with ubenimex (257) and one successful report of treatment with chlorodeoxyadenosine (347). Other agents that have been used to treat ATL include b-interferon, g-interferon (212,333), and administration of anti-Tac antibody, because high levels of IL-2R are generally present on ATL tumor cells

(100,333,356). This latter treatment has been shown to induce remission in at least some patients with ATL (357). More recently, combination therapy using zidovudine and a-interferon and the two in combination with etretinate have proven successful (16,38).

Treatment of HAM/TSP has been attempted with oral corticosteroids with variable clinical efficacy (109,112,240,261,355). High-dose intravenous gammaglobulin has shown beneficial effect but only for a short duration (172). The use of a-interferon in patients with HAM has been also been investigated and shown to be effective in a minority of patients (171,308,374). The data from one study suggested that the sustained clinical benefits of long-term a-interferon therapy is causd by immunomodulation and the reduction of HTLV-1 proviral load (374). A recent study showing clinical benefits using anti-Tac antibody also supports this theory (188). However, it is likely that significant progress will not be made in the treatment of HAM/TSP until the pathogenesis of this condition is better understood.

Vaccine Development

The number of people around the world infected with HTLV-1 is estimated to be between 15 and 25 million. The cumulative lifetime incidence for developing ATL or HAM/TSP is approximately 5%, which places HTLV-1 in the category of viruses for which efficient vaccines are made and used. There are several factors favoring the feasibility of a vaccine against HTLV-1: The virus displays relatively low antigenic variability, natural immunity occurs in humans, and experimental vaccination with envelope antigens has been shown to be successful in animal models (54). Using recombinant DNA methods, several groups have begun the development of a vaccine against HTLV-1. HTLV-1 envelope proteins synthesized in bacteria were used to immunize cynomolgus monkeys (241). Several of the monkeys developed adequate antibody titers and were able to withstand an infectious challenge with HTLV-1. Similar results were obtained using a recombinant vaccinia virus expressing *env* (134).

Trials of subunits vaccines in monkeys have also shown that it is possible to achieve protection against STLV infection (55). Marmosets have been infected with HTLV-1 by feeding with breast milk from infected women (135). This might in the future provide a useful model for testing vaccines designed to prevent neonatal infection. Miyoshi and others (224,307) have demonstrated that (a) rabbits can be successfully infected with HTLV-1; (b) transmission of the virus can be achieved using rabbit cells; and (c) tumors will develop in some cases. The rabbit model has been used to show that passive immunization can protect rabbits against HTLV infection (157) and milk-borne transmission to offspring (293). Investigators have introduced the *env* gene into recombinant vaccinia viruses and reported successful immunization of rabbits (309). Some studies have shown that rabbits can be protected against HTLV-1/-2 infection with synthetic peptides corresponding to HTLV-1/-2 *env* neutralization regions, whereas others have shown no protection (8,155,181). One report has shown that the humoral immune response to HTLV *env* is directed primarily against conformational epitopes (107). It is likely that long-term protection form HTLV-associated diseases will require a vaccination approach that induces both neutralizing antibodies and specific cell-mediated immunity. This will require both *env* and *gag* coding sequences in the vaccine preparation. It appears that the rabbit model is an excellent one for testing candidate HTLV vaccines prior to human clinical trials.

CHAPTER 59 HIVs and Their Replication

Eric O. Freed and Malcolm A. Martin

In the late 1970s and early 1980s, previously healthy patients with symptoms of immunologic dysfunction sought advice and treatment from physicians in the United States and Europe. This new and unusual syndrome was characterized by generalized lymphadenopathy, opportunistic infections (typically *Pneumocystis carinii* pneumonia, but also *Toxoplasma gondii* encephalitis, cytomegalovirus-associated retinitis, and cryptococcal meningitis), and a variety of unusual cancers (non-Hodgkin's lymphoma and Kaposi's sarcoma). A common accompanying laboratory finding in affected individuals was marked depletion of the CD4+ T-lymphocyte subset in the peripheral blood. The disease was first brought to the attention of the general medical community in June 1981, when the Centers for Disease Control described five California men with severe immunodeficiency in the *Morbidity and Mortality Weekly Report* (79). This notification was followed by several reports describing male homosexuals and intravenous drug users with impaired immune systems and T lymphocytes that responded poorly to antigen and mitogen stimulation in functional assays. Within several months, it became clear that a similar immunodeficiency disease was also affecting other groups, including hemophiliacs, blood transfusion recipients, recent Haitian immigrants, and, most significantly, sexual partners and/or children of members of the various risk groups.

The emerging epidemiologic pattern suggested that the new disease was transmitted by a novel pathogen in contaminated blood or following sexual intercourse with an affected individual. Between late 1981 and early 1983, numerous microorganisms were proposed as possible etiologic agents for the acquired immunodeficiency syndrome, or AIDS, as the disease was soon called. The presence of lymphadenopathy in many affected individuals was reminiscent of the clinical course associated with several different human viral pathogens, and it focused attention on virus families known to infect cells of the immune system. A strong case was made for members of the human herpesviruses, particularly cytomegaloviruses (CMVs), which were frequently isolated from AIDS patients and known to replicate efficiently in human lymphocytes (514). Others favored a retroviral etiology based on the presence of antibodies purported to react with human T-cell leukemia virus type-I (HTLV-I), and/or the actual isolation of HTLV-I from AIDS patients (166,216).

In 1983, scientists at the Pasteur Institute recovered an agent from the lymph nodes of an asymptomatic individual who presented with generalized lymphadenopathy of unknown origin (21). During its replication in cultured cells, the lymphadenopathy-associated virus, or LAV as it was subsequently named, released high titers of progeny virions that contained magnesium-dependent reverse transcriptase activity and exhibited electron microscopic (EM) features typical of retroviruses. However, unlike the commonly studied retroviruses of diverse vertebrate origin such as the avian leukosis viruses (ALVs) and the murine and feline leukemia viruses (MuLV, FLV), LAV was highly cytopathic in human peripheral blood mononuclear cells (PBMC), specifically killing the CD4+ T-lymphocyte subset in the cell cultures (441). Gallo and colleagues at the National Institutes of Health subsequently reported the isolation of retroviruses from AIDS patients, which they named HTLV-III to distinguish them from the noncytopathic HTLV-I, and obtained the first convincing serologic evidence linking exposure to LAV-like retroviruses and immunodeficient individuals from the various groups at risk (507,551). Contemporaneously, Levy and associates (371) recovered a similar retrovirus from both AIDS patients and healthy individuals from the various risk groups, which they named the AIDS-associated retrovirus (ARV). This latter report suggested that the newly discovered human pathogen could induce both asymptomatic and symptomatic infections. The new retrovirus, associated with AIDS in the United States, Europe, and central Africa and exhibiting morphologic and genetic characteristics typical of the *Lentivirus* genus, was named human immunodeficiency virus, or HIV (102) (and subsequently HIV-1). In 1986, a related, but immunologically distinct and less pathogenic human retrovirus (now called HIV-2), was recovered from individuals residing in several west African countries such as Senegal, Ivory Coast, and Guinea-Bissau (97).

CLASSIFICATION OF THE HUMAN IMMUNODEFICIENCY VIRUSES

One of the first features the Pasteur Institute group noted about HIV-1 was its particle-associated reverse transcriptase, a property that placed the new agent in the retrovirus family. This was consistent with EM analyses of particles released from infected cell cultures, which revealed 100- to 120-μm enveloped virions, similar in size and morphology to previously studied retroviruses. The mature HIV-1 particles contained a cone-shaped cylindrical core or nucleoid reminiscent of that previously described for visna virus (Fig. 1A) (242,441). The cloning and sequencing of proviral DNA, initially purified from productively infected cultures of T-lymphocytes/T-cell leukemia lines (T-cell lines), indicated that

HIV-1 not only possessed a genomic organization related to other replication-competent retroviruses but placed it, taxonomically, in the *Lentivirus* genus (517,648). This relationship is shown diagrammatically in Figure 1 of Chapter 57. As their name suggests, lentiviruses were known to cause slow, unremitting disease in sheep, horses, and cattle, and to target various lineages of hematopoietic cells, particularly lymphocytes and differentiated macrophages.

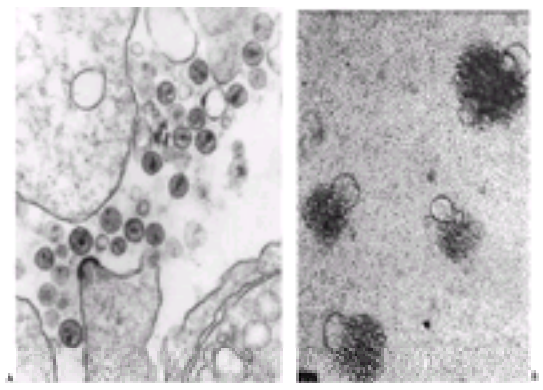

FIG. 1. Primate lentiviruses have a distinct morphology and can induce syncytia during productive infections. **A:** Electron micrograph showing a single HIV-1 particle in the process of budding from an infected cultured human PBMC, and several mature virions containing the characteristic conical/bullet-shaped nucleoid (×100,000). (Photomicrograph kindly provided by Dr. Jan Orenstein.) **B:** Typical ballooning syncytia induced by primate lentiviruses as visualized by inverted light microscopy at the time of peak virus production.

Following the isolation, molecular cloning, and initial classification of HIV-1, several genetically distinct primate lentiviruses were discovered and their phylogenetic relationships to HIV-1 were ascertained. For example, viruses isolated from captive macaques or feral monkey species in Africa were shown to possess particle morphologies and genomic organizations similar to those of HIV-1. Because inoculation of Asian macaque species, such as rhesus monkeys, with these newly discovered agents frequently induced an AIDS-like illness, these viruses were named simian immunodeficiency virus (SIV) to distinguish them from the human viruses, HIV-1 and HIV-2.

The phylogenetic relationships of the human lentiviruses are shown in Figure 2; the detailed genetic interrelationships of all members of the *Lentivirus* genus are presented in Figure 2 of Chapter 61. HIV-2 is more closely related to SIV_{smm} (285), a virus isolated from sooty mangabey monkeys in the wild, than to HIV-1. It is currently believed that HIV-2 represents a zoonotic transmission of SIV_{smm} to man (224). A series of lentiviral isolates from captive chimpanzees, designated SIV_{cpz}, are close genetic relatives of HIV-1. Unlike the other SIVs, which are endemic to African monkeys, the SIV_{cpz} genome contains a *vpu* gene (see below), also present in HIV-1 (298).

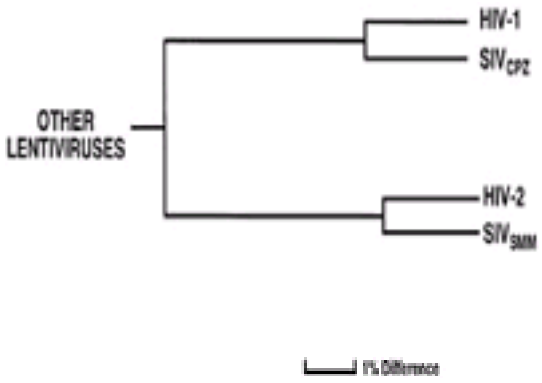

FIG. 2. Phylogenetic relationships of HIV-1 and HIV-2 based on identity of *pol* gene sequences. SIV_{cpz} and SIV_{smm} are subhuman primate lentiviruses recovered from a chimpanzee and sooty mangabey monkey, respectively. (Adapted from ref. 454, with permission.)

It was originally thought that HIV-1, like previously studied replication-competent retroviruses (e.g., MuLVs, ALVs, HTLVs), would be genetically homogeneous. However, as proviral DNAs corresponding to HIV-1 isolates from Europe, North America, and Africa became available and were compared, initially by restriction enzyme digestion, their extensive genetic heterogeneity became apparent (28). No two HIV-1 isolates were identical. When subjected to nucleotide sequence analysis, even HIV-1 samples recovered from a single individual exhibited significant heterology (545). Some of the nucleotide changes (nonsynonymous) resulted in amino acid substitutions, whereas others (synonymous) did not alter the protein sequence. Although nucleotide changes were distributed throughout the HIV-1 genome, the greatest variability occurred in the *env* gene when either intra- or interpatient virus specimens were compared. Hypervariable regions (designated V_1 to V_5), present in the gp120 envelope coding sequences, were sandwiched between relatively conserved (C_1 to C_5) sequences (see Fig. 27 for their locations) (596,666). The term *quasi-species* was subsequently coined to describe the heterogeneous and changing populations of virus present in an HIV-1-infected individual (435). Despite the heterologous nature of different HIV-1 isolates and, in particular, their envelope glycoproteins, a highly conserved and immunodominant domain, located within the gp41 envelope protein, still elicited antibody in infected individuals, which was reactive with (and diagnostic for) HIV-1 samples of diverse geographic origin (238).

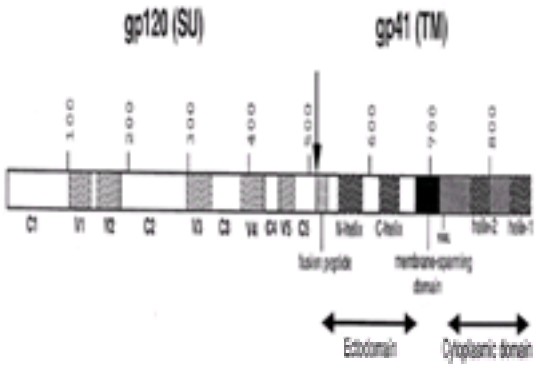

FIG. 27. Linear representation of the HIV-1 Env glycoprotein. The *arrow* indicates the site of gp160 cleavage to gp120 and gp41. In gp120, *cross-hatched areas* represent variable domains (V_1 to V_5) and *open boxes* depict conserved sequences (C_1 to C_5). In the gp41 ectodomain, several domains are indicated: the N-terminal fusion peptide, and the two ectodomain helices (N- and C-helix). The membrane-spanning domain is represented by a *black box.* In the gp41 cytoplasmic domain, the Tyr-X-X-Leu (YXXL) endocytosis motif and two predicted helical domains (helix-1 and -2) are shown. Amino acid numbers are indicated.

The earliest phylogenetic analyses of HIV-1 isolates focused on samples from Europe/North America and Africa; discrete clusters of viruses were identified from these two areas of the world. Distinct genetic subtypes or clades of HIV-1 were subsequently defined and classified into three groups: M (major); O (outlier); and N (non-M or O) (Fig. 3A). The M group of HIV-1, which includes over 95% of the global virus isolates, consists of at least eight discrete clades (A, B, C, D, F, G, H, and J), based on the sequence of complete viral genomes (384,453,673). Members of HIV-1 group O have been recovered from individuals living in Cameroon, Gabon, and Equatorial Guinea; their genomes share less than 50% identity in nucleotide sequence with group M viruses (604). The more recently discovered group N HIV-1 strains have been identified in infected Cameroonians, fail to react serologically in standard whole-virus enzyme-linked immunosorbent assay (ELISA), yet are readily detectable by conventional Western blot analysis (580).

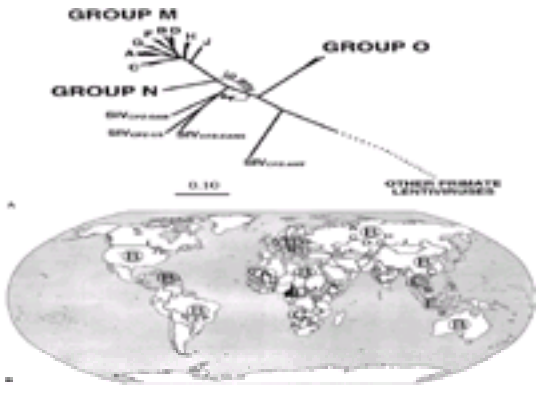

FIG. 3. HIV-1 genetic subtypes and their worldwide distribution. **A:** Phylogenetic relationships of HIV-1 groups M, N, and O with four different SIV_{cpz} isolates. This maximum likelihood tree, based on full-length *pol* gene sequences (115,344) from the indicated primate lentiviruses, was constructed by Bette Korber. The *bar* indicates a genetic distance of 0.1 (10% nucleotide divergence) and the *asterisk* positions group N HIV-1 isolates based on *env* sequences. **B:** The 1998 global prevalence of HIV-1 subgroups is shown with the predominant clade in each geographical region indicated by the *large circled letters.* Based on data collected by the Joint United Nations Programme on HIV/AIDS (UNAIDS). The location of Cameroon on the west coast of Africa is *shaded*.

Most current knowledge about HIV-1 genetic variation comes from studies of group M viruses of diverse geographic origin (383,384,604). Data collected during the past decade indicate that the HIV-1 population present within an infected individual can vary from 6% to 10% in nucleotide sequence. HIV-1 isolates within a clade may exhibit nucleotide distances of 15% in *gag* and up to 30% in gp120 coding sequences. Interclade genetic variation may range between 30% and 40% depending on the gene analyzed. HIV-1-like isolates from chimpanzees (SIV_{cpz}) are positioned at two locations in the maximum likelihood tree shown in Figure 3A. $SIV_{cpz\text{-}ant}$ is not closely related to any of the three HIV-1 groups, whereas $SIV_{cpz\text{-}gab}$, $SIV_{cpz\text{-}us}$, and $SIV_{cpz\text{-}cam3}$ cluster between group N and group O isolates, based on *pol* gene sequences (115,261).

All of the HIV-1 group M subtypes can be found in Africa (Fig. 3B). Clade A viruses are genetically the most divergent (362) and were the most common HIV-1 subtype in Africa early in the epidemic. With the rapid spread of HIV-1 to southern Africa during the mid to late 1990s, clade C viruses have become the dominant subtype and now account for 48% of HIV-1 infections worldwide (465). Clade B viruses, the most intensively studied HIV-1 subtype, remain the most prevalent isolates in Europe and North America. It should be emphasized, however, that in the context of the different HIV-1 clades, there has been no demonstrated association between antigenic serotypes and HIV-1 genetic subtypes (711).

Approximately 1% to 6% of the HIV-1 isolates in Cameroon are members of group O (424). A somewhat variable immunodominant gp41 region accounts for a 20% failure rate in identifying HIV-1 group O infected individuals by ELISA

assays, capable of detecting virtually all persons exposed to HIV-1 group M isolates. Interestingly, unlike group M viruses, group O strains do not require cyclophilin A for biologic activity (see the Gag protein section later) (52).

High rates of genetic recombination are a hallmark of retroviruses. It was initially believed that simultaneous infections by genetically diverse virus strains were not likely to be established in individuals at risk for HIV-1. By 1995, however, it became apparent that a significant fraction of the HIV-1 group M global diversity included interclade viral recombinants. It is now appreciated that HIV-1 recombinants will be found in geographic areas such as Africa, South America, and Southeast Asia, where multiple HIV-1 subtypes coexist and may account for more than 10% of circulating HIV-1 strains (222). Molecularly, the genomes of these recombinant viruses resemble patchwork mosaics, with juxtaposed diverse HIV-1 subtype segments, reflecting the multiple crossover events contributing to their generation. Most HIV-1 recombinants have arisen in Africa and a majority contain segments originally derived from clade A viruses. In Thailand, for example, the composition of the predominant circulating strain consists of a clade A *gag* plus *pol* gene segment and a clade E *env* gene (76). Because the clade E *env* gene in Thai HIV-1 strains is closely related to the clade E *env* present in virus isolates from the Central African Republic, it is believed that the original recombination event occurred in Africa, with the subsequent introduction of a descendent virus into Thailand (223). Interestingly, no full-length HIV-1 subtype E isolate (i.e., with subtype E *gag*, *pol*, and *env* genes) has been reported to date.

Recombination very likely occurred during the evolution of the three HIV-1-related chimpanzee isolates ($SIV_{cpz\text{-}gab}$, $SIV_{cpz\text{-}us}$, and $SIV_{cpz\text{-}cam3}$) based on their different tree locations when *pol* and *env* genes are used to establish phylogenetic relationships (see asterisk, Fig. 3A). When *env* sequences are used, these nonhuman lentiviruses cluster with group N HIV-1 isolates, whereas they map between groups N and O on the basis of their *pol* genes. This discordance points to an ancestral recombinational event between this group of SIV_{cpz} and group M HIV-1 strains (221). An intergroup (groups M and O) recombinant virus has recently been described (496), but no recombination between HIV-1 and HIV-2 has been reported, although mixed *in vivo* infections involving the latter are known to occur (254).

The origin of HIV-1 as a human pathogen remains an unsolved enigma of the AIDS epidemic. As noted earlier, HIV-2 appears to have been transmitted to man from SIV_{smm}-infected sooty mangabeys, which are endemic to west Africa, the same geographical region where HIV-2 is prevalent (224). Previous studies have shown that distinct phylogenetic lineages of SIV_{agm} are associated with different substrains of African green monkeys, each with nonoverlapping geographical ranges (447). This type of association implies exogenous infections hundreds of thousands of years ago and subsequent virus–host coevolution. In this regard, three of the four HIV-1-like viruses recovered from chimpanzees ($SIV_{cpz\text{-}gab}$, $SIV_{cpz\text{-}us}$, and $SIV_{cpz\text{-}cam3}$) were isolated from the central African *Pan troglodytes troglodytes* chimpanzee substrain, whereas the fourth ($SIV_{cpz\text{-}ant}$) was recovered from a completely different chimpanzee lineage, *P. t. schweinfurthii*, whose natural range is in eastern Africa (221). HIV-1 phylogenetic relationships based on *pol* genes (see Fig. 3A) indicate that not only do the viruses recovered from *P. t. troglodytes* subspecies cluster with the three main HIV-1 groups but also their *env* genes are very closely related to the group N virus strains. In contrast, the *P. t. schweinfurthii*–associated virus, $SIV_{cpz\text{-}ant}$, is the outlier, mapping to a highly divergent phylogenetic lineage. These results imply that, as in the case of SIV_{agm} and African green monkeys, host-dependent HIV-1 diversification occurred in discrete chimpanzee substrains. Given the fact that the natural range of *P. t. troglodytes* overlaps geographically with the region in Africa (Cameroon/Gabon) where all three HIV-1 groups are endemic, it seems likely that this chimpanzee subspecies is the source of a zoonosis to humans. A survey of HIV-1 prevalence in feral chimpanzees and in humans living in the same locale will be needed to verify this association.

GENOMIC ORGANIZATION OF THE HUMAN IMMUNODEFICIENCY VIRUSES

The nucleotide sequencing of the original HIV-1 isolates revealed an unexpected result. In contrast to prototypical retroviruses such as ALV and MuLV, whose genomes contain only three genes that encode the three groups of structural proteins [group-specific antigen (*gag*), polymerase (*pol*), and envelope (*env*)], the HIV-1 genome included several additional and overlapping open reading frames (ORFs) of unknown function (Fig. 4). Although an extra ORF, now known to encode a superantigen, had been previously identified within the 3' long terminal repeat (LTR) of mouse mammary tumor virus proviral DNA (136), the existence of additional, functionally important retroviral genes was generally unappreciated until the discovery and genomic analysis of HTLV-I (270). The sequencing of HTLV-I proviral DNA revealed the presence of three short, overlapping ORFs, located between the *env* gene and the 3' LTR. One of these encoded a regulator of transcription, the Tax protein. Not only did HIV-1 and HIV-2 contain multiple additional ORFs, but superficially, their genomic organizations appeared to be identical. However, further analyses demonstrated that HIV-1 contains the distinguishing *vpu* gene (107,602), and HIV-2 encodes the unique *vpx* (321) gene product (see Fig. 4).

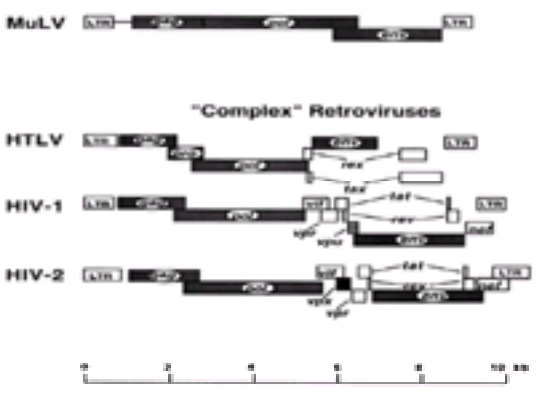

FIG. 4. Genomic organization of simple and complex retroviruses. The genes of Moloney murine leukemia virus (MuLV), HTLV-I, HIV-1 and HIV-2 are depicted as they are arranged in their respective proviral DNAs. The sizes of the different proviral DNAs are shown in proportion to the 9.7-kb HIV provirus.

As is the case for all replication-competent retroviruses, the three primary HIV-1 translation products, all encoding structural proteins, are initially synthesized as polyprotein precursors, which are subsequently processed by viral or cellular proteases into mature particle-associated proteins (Fig. 5). The 55-kd Gag precursor $Pr55^{Gag}$ is cleaved into the matrix (MA), capsid (CA), nucleocapsid (NC), and p6 proteins. Autocatalysis of the 160-kd Gag-Pol polyprotein, $Pr160^{Gag\text{-}Pol}$, gives rise to the protease (PR), the heterodimeric reverse transcriptase (RT), and the integrase (IN) proteins, whereas proteolytic digestion by a cellular enzyme(s) converts the glycosylated 160-kd Env precursor gp160 to the gp120 surface (SU) and gp41 transmembrane (TM) cleavage products. The remaining six HIV-1-encoded proteins (Vif, Vpr, Tat, Rev, Vpu, and Nef) are the primary translation products of spliced mRNAs.

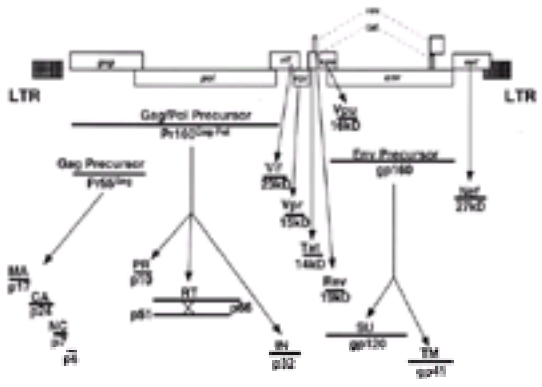

FIG. 5. HIV-encoded proteins. The location of the HIV genes, the sizes of primary translation products (in some cases polyproteins), and the processed mature viral proteins are indicated.

HIV-1 and HIV-2 have incorporated multiple sequence elements into their genomic RNAs that are required for the balanced and coordinated production of progeny virions. Most of these so-called cis-acting RNA elements (Fig. 6) are present in other retroviral genomes, but a few are unique to the primate lentiviruses. The $tRNA^{Lys}$ primer binding site (pbs), the major splice donor sequence (MSD), the encapsidation element (y), and an RNA dimerization initiation sequence (DIS), are all located within the 5'-terminal 400 nt (nucleotides) of the HIV-1 genome. In addition to the pbs, the HIV-1 genome contains other elements that help stabilize the encapsidated $tRNA^{Lys3}$ primer. These include an A-rich region located upstream of the pbs, which binds the anticodon loop of the tRNA primer, and a series of complex structural U5 motifs (301,319,374). Furthermore, the $Pr55^{Gag}$ precursor polyprotein appears to play the role of chaperone by catalyzing the annealing of the primer tRNA to the pbs/U5 region during virus assembly (178), a subject discussed in further detail in the Gag section of this chapter. The principal packaging signal for HIV-1 genomic RNA consists of three stem-loop structures, SL1, SL3, and SL4 (Fig. 6, inset A), which span the MSD (99,425). Elements located (a) at the 5' terminus of the genome (231), (b) within the so-called poly(A) stem-loop (125), and (c) at the base of the TAR stem (98) are also required for efficient RNA encapsidation. The DIS contains complementary and exposed sequences (GCGCGC in Fig. 6, insets A and B) located at the crown of SL1. It participates in the formation of viral RNA dimers, which are recruited into progeny particles by first forming “kissing loop” intermediates (35,484). Although two polyadenylation signals are present in HIV-1 genomic RNA, only the 3' AAUAAA hexameric motif directs poly(A) addition. A polyadenylation enhancer, situated upstream of the 3' polyadenylation signal, stabilizes the binding of the cleavage-polyadenylation-specifying factor to the AAUAAA hexamer (236,631), whereas the upstream poly(A) stem-loop structure has been reported to block poly(A) addition at the 5' end of the viral RNA (124).

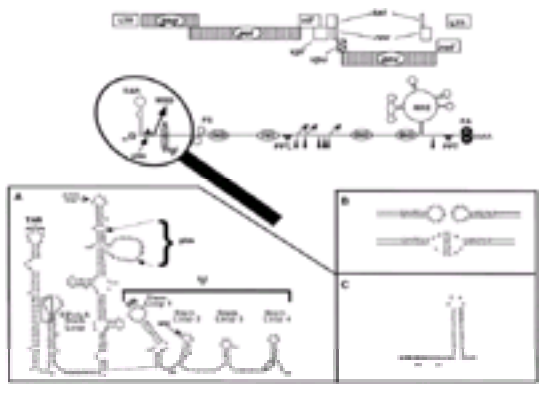

FIG. 6. Cis-acting elements present in the HIV-1 genome. Elements associated with HIV-1 genomic RNA include the methyl capped terminal G residue at the 5' terminus of viral RNA (*mG*); the Tat-responsive stem-bulge-loop structure (*TAR*); the binding site for the $tRNA^{Lys}$ primer (*pbs*); the major splice donor (*MSD*); the major RNA packaging site (y); the frameshifting motif (*FS*); RNA instability/nuclear retention elements (*INS*); the central polypurine tract (*PPTc*); splice acceptors (*arrowheads*); internal splice donors (*small arrows*); the Rev-responsive element (*RRE*); the canonical 3' polypurine tract (*PPT*); and the polyadenylation signal (*PA*). **A:** The putative secondary structure at the 5' terminus of HIV-1 mRNAs. The positions of the TAR stem-loop, the poly(A) stem-loop and the boxed poly(A) addition signal, the pbs, the dimerization initiation sequence (*DIS*), the major splice donor (*MSD*), and the translation initiation AUG codon for Gag are indicated. (Adapted from ref. 98, with permission.) **B:** The self-complementary DIS sequences, located at the crown of stem-loop 1, participate in the formation of “kissing loop” intermediates, an initial step in the RNA dimerization reaction. **C:** RNA stem-loop structure downstream of the UUUUUUA HIV-1 frameshifting sequence.

The HIV-1 genome is unique in having a novel central polypurine tract (PPT) in addition to a traditional U3-proximal PPT, both of which are used for the synthesis of plus-strand viral DNA (81). The genomic RNA also contains a heptameric U UUU UUA shift sequence within the *gag* gene, which functions in conjunction with a downstream hairpin (see Fig. 6, inset C) to mediate –1 translational frameshifting (305). The viral RNA folds into two additional complex structures (TAR and RRE), which are involved in RNA synthesis and transport, respectively. The TAR element has also been reported to be required for the efficient initiation of reverse transcription (268). Multiple inhibitory sequences (designated INS in Fig. 6), associated with the instability/ nuclear retention of HIV transcripts, are scattered throughout genes encoding Gag, Pol, and Env proteins (403,535). Finally, although adenosine deoxyribonucleotide (A) is not strictly considered a cis-acting element, it is worth noting that HIV-1 genomic RNA contains a significantly higher A content (approximately 39%) than mammalian DNA; this bias contributes to an unusual codon usage (34).

THE BIOLOGY OF HIV INFECTIONS

A quintessential property of HIV-1 and the other primate lentiviruses is to sequentially use CD4 and a second cellular receptor during entry into susceptible cells, a subject discussed more extensively in the section dealing with the envelope glycoproteins. Consequently, the main cellular targets for HIV-1 are the CD4+ T-helper/inducer subset of lymphocytes, CD4+ cells of macrophage lineage, and some populations of dendritic cells. Because HIV-1 infections *in vivo* are limited to humans and chimpanzees and no tractable animal model for HIV-1 currently exists, our current understanding about virus replication derives primarily from retrospective analyses of clinical specimens collected from seropositive individuals and a voluminous body of work examining virus infections in tissue culture systems. The very earliest studies indicated that mitogen-activated human PBMC were the cells of choice for isolating virus from infected persons. Some early HIV-1 isolates were also able to infect continuous CD4+ T leukemia cell lines such as CEM, Jurkat, Hut 78, and the HTLV-I-containing MT-2 and MT-4. Human T-cell lines were clearly more logistically tractable than PBMC, and their use greatly facilitated molecular and genetic studies of HIV-1. Most human T-cell lines released large quantities of virions while undergoing a typical cytopathic infection and cell death, but a few (e.g., H9 cells) became persistently infected and exhibited only minimal cytopathic effects.

Many of the early HIV-1 isolates were classified on the basis of their replicative, cytopathic, and tropic properties. A majority of primary virus isolates, which characteristically replicate slowly and generate small amounts of progeny particles, were labeled “slow/low” to distinguish them from “rapid/high” HIV-1 strains, which exhibit faster infection kinetics and release high titers of virions (179). Some HIV-1 primary isolates, frequently those recovered from symptomatic individuals, induced syncytia formation following co-cultivation of virus-producing PBMC with MT-2 cells (see Fig. 1B) (343). These isolates were designated SI (syncytium-inducing) to distinguish them from non-syncytium-inducing (NSI) strains. Tropism was a third property used to classify HIV-1 primary isolates. For many retroviruses, the determinants of tropism reside in both the external envelope glycoprotein and the LTR. Although changes in the LTR may modulate the efficiency of replication in a variety of T-cell types, the principal determinant of HIV host range resides in the SU Env glycoprotein. All HIV-1 strains can productively infect activated PBMC; some are also able to replicate in cultures of monocyte-derived macrophage (MDM) and have been classified as macrophage- or M-tropic (112). Virus isolated from individuals shortly after they have been infected with HIV-1 are frequently M-tropic (533). Other isolates, often obtained late in the disease course, can establish infections in continuous human CD4+ T-cell lines but not in MDM, and they have been designated T-cell-line or TCL-tropic. Subsequent studies reported primary HIV-1 isolates able to infect both MDM and T-cell lines; such strains have been classified as dual tropic (111). Although exceptions exist, M-tropic isolates, in general, are NSI and “slow/low,” whereas TCL-tropic strains are frequently SI and exhibit the “rapid/high” replication phenotype. Forced passage of some primary isolates in continuous CD4+ human cell lines has resulted in T-cell-line adapted (TCLA) HIV-1 strains, which possess altered tropic properties and increased sensitivity to neutralizing antibodies and soluble CD4 (606). In molecular clones corresponding to one of the original TCLA strains, HIV-1_{IIIB}, which had been extensively propagated in Hut 78 cells, the reading frames for the *vpr*, *vpu*, and *nef* genes are not open, suggesting that these three genes are not required for efficient replication in certain human T-cell lines. This is discussed in greater detail in the section dealing with accessory proteins.

The discovery that a and b chemokine receptors function as coreceptors for virus fusion and entry into susceptible CD4+ cells (92,134,177) has led to a revised classification scheme for HIV-1 (Table 1). Isolates can now be grouped on the basis of chemokine receptor utilization in fusion assays in which HIV-1 gp120 and CD4+ coreceptor proteins are expressed in separate cells (43). As indicated in Table 1, HIV-1 isolates using the CXCR4 receptor [now designated X4 viruses (30)] are usually TCL-tropic SI strains, whereas those exclusively utilizing the CCR5 receptor (R5 viruses) are predominantly M-tropic and NSI. The dual-tropic R5/X4 strains, which may comprise the majority of patient isolates and exhibit a continuum of tropic phenotypes, are frequently SI (579). However, because the expression levels of chemokine receptor, CD4, or gp120 may be unphysiologically high in fusion assays for assessing coreceptor usage, the classification of a particular gp120 based on these criteria may not accurately predict coreceptor utilization during actual spreading virus infections of PBMC, T-cell lines, and MDM (91).

Chemokine coreceptor used	PBMC replication	Macrophage replication	T-cell-line replication	Replicative phenotype	Syncytium-inducing phenotype
X4	+	-	+	Rapid/high	++
R5	+	+	-	Slow/low	-
R5X4	+	+	+	Rapid/high	+

PBMC, peripheral blood mononuclear cells.

TABLE 1. *Tropic and biologic properties of HIV-1 isolates*

The exclusive use of tissue culture systems to classify HIV-1 isolates and to define their replicative phenotypes clearly fails to address a myriad of biologic issues attending viral infections in exposed humans. For example, *in vivo*, most T lymphocytes circulating in the blood or present in lymphoid tissues are resting in the G_0 phase of the cell cycle; potential tissue macrophage targets exist as nondividing cells in G_1 (263). Early studies demonstrated that resting human PBMC do not support productive HIV infections unless they are stimulated with mitogens and propagated in the presence of interleukin (IL)-2 (430). This could reflect the extremely small pool sizes of ribonucleotides, deoxyribonucleotide triphosphates, and ATP in quiescent T lymphocytes (467). Although it is still unclear whether the reverse transcription or the integration step of the HIV-1 replication cycle is dysfunctional in unstimulated T lymphocytes, there is general agreement that no viral proteins or progeny virions are produced (598,696). Activation of resting PBMC up to 14 days following an initial abortive infection is still able to resurrect a productive infection (696).

Growth factors, cytokines, and antigens are physiologic activators of T lymphocytes *in vivo*. Antigen-mediated activation of the T-cell receptor leads to increased expression of several regulatory factors and the transition of lymphocytes from the G_0 resting state to the G_1 phase of the cell cycle. Co-stimulation of CD28 results in increased production of IL-2, surface expression of the IL-2 receptor, and progression through G_1, S, and mitosis. The absence of a co-stimulatory signal, however, leads to the unresponsive anergic state and arrest at the G_1a/G_1b transition point of the cell cycle (235). G_1a cells have a 2N DNA content, produce higher levels of RNA than G_0 cells, but are not committed to progress to S phase; in G_1b, cellular RNA levels are equivalent to those present in S phase and cells pass through the G_1/S checkpoint. Cell-cycle studies have shown that progression into G_1b is required to achieve productive HIV-1 infections of circulating CD4+ T lymphocytes (345). Incubation of resting T lymphocytes with IL-2, IL-4, IL7, or IL-15, in the absence of other stimuli, has also been reported to confer susceptibility to HIV-1 (630).

One of the most prominent and earliest recognized clinical features of AIDS is the selective depletion of CD4+ T cells, a property that correlates with tropism of HIV-1 and its cytopathicity for this lymphocyte subset in tissue culture infections. More detailed studies, primarily using X4 HIV-1 strains, indicated that memory CD4+ cells, rather than naive CD4+ T cells, were preferentially infected and killed (96,557). However, selective loss of CD4+ memory cells is not commonly observed in HIV-1 seropositive individuals. More recent work, employing CD3/CD28 co-stimulation to activate CD4+ T lymphocytes, has confirmed the greater susceptibility of memory cells to X4 viruses but it has also shown that naive but not memory CD4+ cells are infectable by R5 strains of HIV-1 (528). When lymphocytes from HIV-1-infected individuals were, in fact, examined, integrated proviral DNA was detected and virus could be recovered from both memory and naive CD4+ T cells with no evidence of selective chemokine coreceptor usage for either lymphocyte subset (478).

In addition to quiescent CD4+ T lymphocytes, nondividing pleuripotent hematopoietic stem cells (HSC) in G_0 have attracted considerable attention as targets for HIV-1, in the context of both natural infections and development of HIV-1 vectors for gene therapy. HSC are a subset of CD34-positive bone marrow cells that express CD4; some HSC also produce functional cell-surface CXCR4 and CCR5 proteins (571). Unfortunately, conflicting results have been obtained about their susceptibility to HIV-1, most likely reflecting (a) the criteria used for selecting G_0 HSC and not more mature progenitor cells, (b) the purity of the fractionated HSC, and (c) the transduction/infection protocol employed (571,629).

Dendritic cells (DCs) are antigen-presenting cells that capture, transport, and present antigens to CD4+ and CD8+ T lymphocytes. They include Langerhans cells in skin, follicular DCs in germinal centers, interdigitating DCs in T-cell areas of lymph nodes, interstitial DCs in intestinal and genital mucosa, and circulating, blood-derived DCs. It is currently thought that DCs associated with mucosal surfaces may represent the first line of defense against sexually transmitted HIV-1, transporting recently inoculated virus particles from portals of entry to secondary lymphoid organs. Nonetheless, productive HIV-1 infections of different types of purified DCs have been difficult to demonstrate *in vitro* (71), although vigorous virus replication is observed when DCs are first pulsed with virus and then cocultivated with CD4+ T lymphocytes (627). Interestingly, the infectious virions released from such cell conjugates bear T-cell-, not DC-, specific surface proteins acquired during the budding process, implying that a complete virus replicative cycle occurs in the T lymphocyte and that DCs may, in fact, be refractory to HIV-1 infection (189). It has recently been reported that DCs express a C-type lectin (named DC-specific ICAM-3-grabbing nonintegrin, or DC-SIGN) that “captures” HIV by binding to virion-associated gp120 and transmits the virus to T cells expressing CD4 and the appropriate chemokine coreceptor (232). Intriguingly, the virus bound to dendritic cells via DC-SIGN retains infectivity even on long-term culture (>4 days), suggesting that the dendritic cells are able to sequester or “protect” bound virions from degradation. These findings have significant implications for the transmission and dissemination of HIV *in vivo* and may present a novel target for antiviral therapy.

Virtually all lentiviruses have retained the capacity to replicate in nonproliferating, terminally differentiated tissue macrophages. Thus, unlike the oncoretroviruses, which require mitosis and dissolution of the nuclear membrane to complete a cycle of replication, HIV-1 is able to productively infect these G_1- (not G_0-) arrested cells. This property, thought to be mediated by one or more of the viral-encoded proteins, requires that the HIV-1 preintegration complex be translocated through intact nuclear pores. *In vitro*, differentiation of blood-derived monocytes is required for vigorous replication by M-tropic viral strains (562). As is the case for productive infections of T lymphocytes, HIV-1 replication in MDM requires integration of the reverse transcript (163), but only minimal cytopathicity has been reported and morphologically mature virus particles may accumulate intracellularly within intracytoplasmic vacuoles (477).

A variety of approaches have been used to measure the kinetics of HIV-1 infections in cell cultures and to determine the intrinsic infectivity of a virus stock. For example, the end-point dilution of a virus preparation (ID_{50}) is commonly reported as the amount of inoculum having a 50% probability of initiating an infection during a defined observation period. For

many commonly used cell-free HIV-1 stocks, the number of physical particles released from 10^6 virus-producing cells in 1 mL of medium can be more than 10^9 physical particles or approximately 10^3 virions per cell (138,429). Such culture supernates will typically contain 10^5 to 10^6 tissue culture ID_{50} (or $TCID_{50}$) per mL. These values will vary depending on the cell type (PBMC versus T-cell line) used and the virus source (primary versus TCLA isolate), but the time required for one complete cycle of HIV-1 infection *in vitro* is usually 3 to 4 days. It is worth noting that the particle-to-infectivity ratio for HIV-1 calculated from these values is quite low (10^{-3} to 10^{-4}). In contrast, the infectivity of virus-producing cells, as measured in co-culture systems, is approximately 10^2 to 10^3 times higher than the infectivity of all of the cell-free particles present in the culture supernate from the same infected cells (138). Taken together, these data suggest that, like many other retroviruses, HIV-1 relies on cell-to-cell transmission for dissemination of virus *in vivo*. Certainly the high density and proximity of virus-infected cells in lymphoid tissue would favor this mode of virus spread.

Although HIV-1 causes the selective loss of cultured CD4+ cells and induces depletion of the same T-lymphocyte subset in virus-infected individuals, the mechanisms responsible for this cytopathic effect are still unknown. Cell death is currently thought to occur by either necrosis or apoptosis, processes that can be distinguished morphologically and biochemically. Direct cell killing by HIV-1 in tissue culture systems can occur as a consequence of single-cell lysis or syncytium formation and is frequently associated with the presence or expression of the viral envelope glycoproteins (74,339). Apoptosis of T lymphocytes, characterized morphologically by nuclear condensation and DNA fragmentation and the absence of an inflammatory response *in vivo*, has been observed in lymph node biopsies from HIV-1-infected individuals (451). It has also been reported that cultured PBMC from HIV-1 seropositive persons undergo spontaneous apoptosis at higher rates than cells from uninfected individuals (255). A critical issue, pertaining specifically to apoptosis, is whether HIV-1 and related primate lentiviruses kill only cells they infect or indirectly cause the death of uninfected bystander cells including CD8+ T lymphocytes. Although many studies have shown that HIV-1-infected cells undergo apoptotic death, the use of reporter virus systems indicates that in cultures of purified T lymphocytes, infected CD4+ cells, not bystander cells, undergo apoptosis (219). The specific apoptotic pathway responsible for cell killing in HIV-1-infected cells has not yet been elucidated.

HIV-1 ANIMAL MODELS

Chimpanzees

Because HIV-1 establishes infections only in humans and chimpanzees and, with rare exceptions (464), induces disease only in humans, multiple questions about the biology of HIV-1 and the capacity of this virus to induce immunodeficiency remain unanswered. These include (a) the mechanism(s) underlying the transient depletion of CD4+ cells that occurs immediately following exposure to the virus; (b) the functional reversibility of this initial CD4+ T cell loss; (c) the pathogenic process(es) leading to the gradual destruction or aberrant functioning of the immune system despite the rapid and nearly complete elimination of the virus from the blood after the acute infection; (d) the irreversible loss of CD4 positive T lymphocytes which accompanies clinical progression to disease onset; (e) the contribution, if any, of specific HIV-1 phenotypes (SI versus NSI; T-cell-line tropic versus macrophage tropic) to virus transmission and disease progression; and (f) the biologic role of “auxiliary” viral genes such as *vpr*, *vif*, and *nef* during the establishment of the initial infection and its subsequent spread to other sites in the body.

In the search for an HIV-1 animal model during the very early phase of the AIDS epidemic, cell suspensions from virus-infected individuals were inoculated into a variety of animals including nonhuman primates, but only chimpanzees consistently became infected. It was later shown that chimpanzees could be reliably infected with relatively low doses of HIV-1 (13), but no longstanding impairment to the immune system was observed. Like the acute infection in man, a primary HIV-1 infection of chimpanzees is characterized by a brief period, lasting several weeks, during which virus can be readily recovered. Unlike in humans, however, the primary HIV-1 infection in chimpanzees is usually asymptomatic, and virus is infrequently recovered from the plasma of inoculated animals (209). Antibodies directed against several of the viral proteins can be detected within several weeks of inoculation, and a rapid decline of the virus load, typically measured by the number of PBMCs needed for HIV-1 isolation or containing viral DNA, is commonly observed. In most instances, virus isolation from persistently infected chimpanzees becomes intermittent after resolution of the primary infection (13,234).

The absence of virus-induced immunodeficiency in any of the more than 150 chimpanzees inoculated with HIV-1 led to a variety of hypotheses to explain the failure of the infection to progress to clinical disease. These included (a) the predominant use of clade B T-cell-line tropic virus isolates; (b) the generally poor replicative capacity/cytopathicity of HIV-1 in chimpanzee PBMC; (c) a failure of HIV-1 to induce apoptosis of CD4+ chimpanzee cells; and (d) the ability of the chimpanzee to mount a potent, long-lived protective response to HIV-1, similar to that reported for SIV-infected (and asymptomatic) sooty mangabeys, the natural host of SIV_{smm}. One chimpanzee, however, did develop high virus loads and a CD4+ T-lymphocyte depletion to the 100 cell/μL range nearly 10 years after documented exposure to two different virus strains ($HIV\text{-}1_{SF2}$ and $HIV\text{-}1_{LAV\text{-}1b}$) (464). These laboratory findings were associated with a nonregenerative anemia, chronic intermittent diarrhea, and the presence of opportunistic microorganisms (e.g., *Blastocytis hominis*, *Balantidium coli*, and *Cryptosporidium*). The transfusion of whole blood from this animal to a second chimpanzee resulted in extremely high plasma viral RNA loads ($>1\times10^7$ copies/mL) and a rapid decline of CD4+ T cells. Biologic and molecular analyses of the HIV-1 recovered from the two affected animals revealed (a) an augmented replication phenotype in chimpanzee PBMC/macrophages, and (b) that the pathogenic variant which had emerged was very likely a recombinant between the original $HIV\text{-}1_{SF2}$ and $HIV\text{-}1_{LAV\text{-}1b}$ input viruses (452).

The failure of chimpanzees to develop disease in a timely fashion following inoculation of tissue culture– adapted or patient-derived virus isolates coupled with their endangered species status has greatly dampened enthusiasm for their use as an animal model of HIV-1– induced immunodeficiency.

Transgenic Mice

When it became apparent, in the late 1980s, that HIV-1 infections could be established only in chimpanzees and humans, potentially more tractable and novel rodent systems were developed to model specific steps of *in vivo* HIV-1 infections. In one approach, transgenic mice, containing varying portions (individual viral genes/cis-acting elements up to the entire HIV-1 genome) of molecularly cloned viral DNA were constructed. Because HIV-1 transgenic mice contain copies of proviral DNA in every cell, they represent *in vivo* systems for modeling the postintegration phase of the virus life cycle. They provide a means for assessing possible deleterious effects of HIV-1–encoded proteins *in vivo* and for monitoring the mammalian responses to different viral gene products.

The earliest and simplest DNA constructs introduced into mice consisted of the HIV-1 LTR linked to a reporter gene [most commonly, chloramphenicol acetyltransferase (CAT)]. Animals bearing the viral promoter/enhancer of transcription usually expressed extremely low levels of CAT activity in specific tissues (skin, eye lens, lymph nodes, spleen, and thymus) (365). It was also reported (641) that HIV-1 LTR-directed expression of the viral *tat* gene induced dermal lesions in mice with features of Kaposi's sarcoma, although this result has not been independently confirmed. Animals harboring copies of full-length and potentially infectious HIV-1 DNA were also constructed and initially maintained in a biosafety level 4 (BL4) facility (367). In these transgenic mice, HIV-1 LTR-directed expression was barely detectable in 23 of 25 founder animals. In one of the two instances of high-level HIV-1 gene activity, heterozygous offspring, generated from a mosaic founder female, exhibited a spontaneous and fatal disease syndrome characterized by severe runting/growth retardation; splenomegaly; lymphadenopathy; dry, scaly skin; and perivascular pulmonary lymphoid infiltrates (367). The second transgenic line, also carrying a complete copy of the HIV-1 genome, has been used to assess the effect of opportunistic microorganisms on the expression of the HIV-1 transgene. Interestingly, *Toxoplasma gondii* or *Mycobacterium avium* infections of these transgenic mice resulted in marked elevations of HIV-1 RNA synthesis in multiple lymphoid tissues (142,230). In both cases, splenic macrophages represented a major target of increased HIV-1 expression.

To overcome the intrinsically low levels of HIV-1 LTR-directed expression in rodents, transgenic mice have also been generated that carry viral genes under the control of cell- or tissue-specific promoters. Mice harboring a transgene consisting of the mouse mammary tumor virus LTR-driving HIV-1 structural genes synthesized substantial amounts of HIV-1 Gag and Pol proteins in mammary and salivary glands, but no associated disease was observed (314). In another study, central nervous system disease developed in mice carrying HIV-1 gp120 coding sequences linked to the murine fibrillary acid protein promoter (621).

Several independent transgenic mouse lines have also been constructed to assess the *in vivo* function(s) of the Nef protein. These included animals in which *nef* expression was directed to T cells by using promoter/enhancers for the d subunit of the mouse CD3 gene (586), the human CD2 gene (54), and the mouse TCR b gene (375). Altered T-cell activation, CD4+ T-cell down-regulation, and immunologic dysfunction, respectively, were observed in these three lines of transgenic animals. More recently, transgenic mice bearing a complete copy of HIV-1 coding sequences, directed by a chimeric (human–mouse) CD4 promoter/enhancer, were constructed. These animals spontaneously developed muscle wasting, weight loss, severe depletion of lymphocytes from lymphoid organs, diarrhea, and death within 2 to 4 weeks of birth. When individual or combinations of HIV-1 genes within the full-length viral transgene were inactivated, only those animals expressing a functional *nef* gene exhibited the same debilitating clinical syndrome (266). Thus, targeting HIV-1 Nef synthesis to mouse CD4+ cells, in the absence of a spreading viral infection or the expression of other HIV-1 gene products, was sufficient to elicit a disease with some of the characteristics of human AIDS.

Severe Combined Immunodeficient Mice

In addition to their use for investigations of human immune responses, severe combined immunodeficient (SCID) mice, engrafted with human cells, have been used as a small animal model for HIV-1. In one protocol, 10^7 to 10^8 human PBMC are implanted intraperitoneally to create SCID-hu-PBMC animals (445). Human CD8+ T cells in these animals tend to remain in the peritoneal cavity, whereas the CD4+ T lymphocytes migrate to lymphoid tissue; both human T-cell subsets may persist for up to 6 months. The HIV-1-susceptible CD4+ T cells in SCID-hu-PBMC animals represent a population of mature, activated memory cells, functionally similar to those present in adult humans. In a modification of the SCID-hu-PBMC model, PBMC from HIV-1-infected individuals have been implanted into mice and the induction of virus from the transferred cells monitored.

In the second SCID mouse system used for HIV-1 studies (SCID-hu-thy/liv), fragments of human fetal thymus and fetal liver are engrafted under the renal capsule (457). The implanted organs increase in size for several months with CD4+/CD8+ double-positive T-lymphocytes predominating in the differentiating engrafted thymus. The SCID-hu-thy/liv system therefore models the fetal/neonatal human thymus and is relevant for studies of maternal–fetal virus transmission and pediatric HIV-1 infections.

In both SCID-hu systems, HIV-1 infections peak 3 to 4 weeks after inoculation and lead to variable (partial to complete) depletion of CD4+ T cells, depending primarily on the replication phenotype of the virus used (7,446). Any T-cell replacement that occurs is caused by proliferation of the implanted human cells. In general, both macrophage and T-cell tropic HIV-1 strains or primary viral isolates exhibiting rapid infection kinetics are more pathogenic in both SCID-hu mouse systems than more slowly replicating virus strains (311). Although the engrafted human tissue possesses demonstrable functional immunologic activity (299,426), the inoculation of HIV-1 fails to elicit a primary immune response in infected animals. Thus both of the SCID-hu systems model uncontrolled HIV-1 infections characterized by moderate to profound CD4+ T-cell depletions and no humoral or cellular responses to the virus. In some experiments, virus-specific antibodies and cytotoxic T lymphocytes have been adoptively transferred to SCID-hu-PBMC mice prior to virus challenge (489,632).

SIV–HIV Chimeric Viruses

A nonhuman primate lentivirus, initially isolated from a captive rhesus monkey in the mid 1980s, was shown to induce an

AIDS-like disease following inoculation of Asian macaques (123,368). As noted earlier, these SIVs establish asymptomatic chronic infections in their natural hosts, different species of African monkeys. The SIV genomic organization, while similar to that of HIV-1, can be distinguished by the presence of the *vpx* and the absence of the *vpu* genes (Fig. 7). When it became apparent that humans and chimpanzees were the only mammalian species that could be reliably infected by HIV-1, attention turned to the SIV–Asian macaque model with the idea of constructing chimeric SIV–HIV viruses (SHIVs) capable of infecting small, nonendangered, nonhuman primates. The earliest versions of SHIVs contained 3 to 4 kilobases (kb) of HIV-1 sequences, including the *tat*, *rev*, *vpu*, *env*, and, in some instances, portions of *vpr* and *nef* genes, which were inserted into the genetic backbone of SIV_{mac239} (see Fig. 7). The first generation of SHIVs successfully established chronic infections and elicited immunologic responses in inoculated macaques, but the virus did not replicate to high levels or cause clinical disease (372,573). Nonetheless, subsequent serial animal-to-animal transfers of blood, lymphoid cells, and/or bone marrow resulted in the emergence of pathogenic SHIV strains containing alterations affecting gp120-coding sequences (313,521). In contrast to SIV_{mac239} and HIV-1, which, on average, will induce immunodeficiency in 1 and 10 years following infection of macaque monkeys or man, respectively, some of the highly pathogenic SHIVs cause an unremitting and irreversible depletion of CD4+ T cells within 3 to 4 weeks of inoculation and death due to AIDS in 3 to 4 months. Because they possess and express the HIV-1 *env* gene, these new versions of SHIVs provide a disease endpoint for monitoring the effectiveness of HIV-1 envelope-based vaccine strategies.

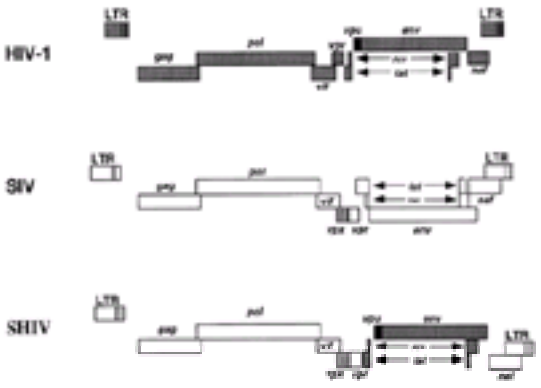

FIG. 7. Genomic organization of HIV-1, SIV, and SHIV lentiviruses. The *vpu* gene of HIV-1 and the *vpx* gene of SIV are highlighted. Some SHIV constructs contain an HIV-1–SIV chimeric *vpr* gene.

THE MOLECULAR BIOLOGY OF HIV-1 REPLICATION

Overview

More than 10,000 papers have been published on HIV-1 since its discovery as the cause of AIDS in 1984. A dizzying array of biochemical, genetic, and immunologic techniques, and biologic systems have been used to study the structure and function of HIV-1-encoded proteins and the host cell mechanisms that regulate virus replication. In addition to the production of HIV-1 proteins in bacterial, yeast, and insect cells, much of this effort has involved transfections of mammalian cells with vectors expressing individual viral proteins or cloned HIV-1 proviral DNA (Table 2). Transfection experiments have been important for elucidating (a) the intracellular location and trafficking of viral proteins, (b) the interaction of HIV-1 proteins with other viral or cellular proteins, (c) the binding of viral and cellular proteins to cis-acting elements associated with the viral genome or proviral DNA, (d) the fusion/entry steps of the virus life cycle, and (e) the assembly and release of progeny virions. In a majority of instances, the cells used for these transfection studies have been both CD4 negative and of nonhematopoietic origin, and they include HeLa, COS, and 293T.

TABLE 2. *Experimental systems used in HIV-1 research*

Transfection experiments are to be distinguished from HIV-1 infections, which are characterized by particle-mediated cell entry, in conjunction with the use of one or more surface receptors, and the spread of progeny virions through the culture, in successive cycles of replication. Thus, infections provide an opportunity to integrate the function(s) of an individual viral-encoded protein (or even a subdomain thereof) into the entire HIV-1 replicative cycle. For many studies, single-cycle infections, involving defective HIV-1 genomes, pseudotyped with a heterologous envelope protein, have been used to obtain answers to specific questions, even though the newly produced virus particles are incapable of sustaining a virus infection. It is worth keeping in mind that although transfection experiments and *in vitro* studies such as the yeast

two-hybrid system have yielded invaluable information about the function and interacting cellular partners of HIV-1-encoded proteins, the results obtained must always be verified in assays that monitor spreading viral infections.

The HIV-1 replicative cycle (Fig. 8) begins with adsorption of virus particles to CD4 molecules on the surface of susceptible cells. While binding of virions to CD4 is essential for HIV infectivity, their subsequent interaction with a coreceptor, one of which are now known to be the seven membrane-spanning CC or CXC families of chemokine receptors, is required for membrane fusion and entry (92,134,145,177). Although multiple chemokine receptors exhibit activity in fusion/entry assays with HIV-1 gp120 (see the Env section below), the two most important are CXCR4 (previously called fusin, or LESTR) and CCR5. Unlike other enveloped viruses, which utilize receptor-mediated endocytosis to enter cells, HIV-1 and most other retroviruses directly fuse with the plasma membrane of a susceptible cell. Following entry, subviral particles are partially uncoated in the cytoplasm and initiate the reverse transcription of their viral RNA genomes (see Fig. 8, steps 2 to 4). Investigations of these early events in the virus life cycle have been greatly hampered by the very high (>100:1) retrovirus particle-to-infectivity ratios noted earlier. Thus, simply monitoring the fate of tagged viral proteins during the entry and uncoating steps is unlikely to provide useful information about the composition and trafficking of biologically active virions.

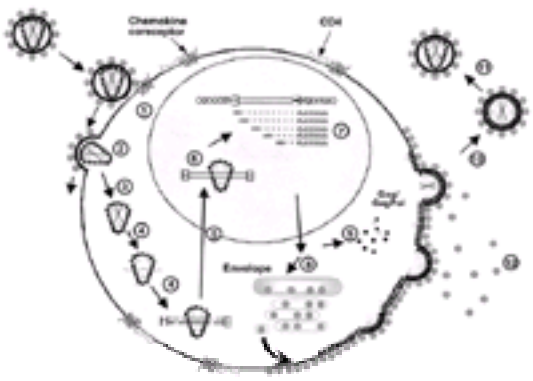

FIG. 8. The HIV-1 replication cycle. Productive HIV-1 infections begin with the adsorption of cell-free virions to cells and their interactions with both the CD4 and chemokine receptors (*step 1*). In the case of HIV, virus entry (*step 2*) is a pH-independent process that occurs following the fusion of viral and cellular membranes and results in the partial uncoating (*step 3*) of incoming virions. Reverse transcription occurs within subviral particles in the cytoplasm of infected cells (*step 4*), and the double-stranded DNA product is transported to the nucleus (*step 5*), where integration into chromosomal DNA (*step 6*) is mediated by the virus-encoded integrase (*open circles*), a component of a subviral preintegration complex. The integrated viral DNA serves as a template for DNA-dependent RNA polymerase (*Pol II*) and leads to the production of mRNAs (*step 7*) that are translated into viral proteins in the cytoplasm of infected cells. Envelope (*step 8*) and Gag plus Gag/Pol (*step 9*) polyproteins are transported via independent pathways to the plasma membrane, where progeny virus particles begin “budding” from cells and are released as immature particles (*step 10*). Subsequent proteolysis by the virion-encoded protease generates mature particles (*step 11*) containing a characteristic condensed core. Non-virion-associated gp 120 envelope protein is also released from cells (*step 12*).

As is the case for other retroelements (51,58,206), the partially double-stranded DNA reverse transcription product is transported through the cytoplasm and into the nucleus as a component of a nucleoprotein–preintegration complex (PIC) containing a subset of the Gag and Pol proteins (see Fig. 8, step 5). This poorly understood process very likely depends on host factors that actively transport the PICs from the plasma membrane to the nuclear pore. These “early” steps in the retrovirus replication cycle undoubtedly require the participation of multiple cellular factors for their successful completion. Following the import of the PIC into the nucleus, full length linear copies of the reverse transcript are integrated into the chromosomal DNA of the infected cell, a step required for the efficient viral RNA synthesis and infectious particle production (568). As noted earlier, the lentiviruses are unique among retroviruses in generating PICs that are actively transported by the nuclear import machinery into the interphase nucleus of nondividing cells arrested in the G_1 phase of the cell cycle. In activated T lymphocytes, integrated copies of HIV DNA serve as templates for RNA polymerase II (Pol II)-directed viral RNA synthesis (see Fig. 8, step 7). The coordinated interaction of the HIV-encoded Tat protein and the cellular transcriptional transactivator proteins NF-kB and Sp1 with the Pol II transcriptional apparatus ensures the production of high levels of viral RNA. Unspliced or partially spliced HIV transcripts are exported from the nucleus to the cytoplasm by a unique transport mechanism mediated by the shuttling virus-encoded Rev protein. The subsequent translation of the gp160 Env precursor occurs in the endoplasmic reticulum, whereas the Gag and Gag-Pol polyproteins are synthesized on free cytoplasmic ribosomes, and they are transported via independent pathways to the plasma membrane (see Fig. 8, steps 8 and 9). The Gag and Gag-Pol polyproteins, in association with dimers of genomic RNA, condense at the plasma membrane to form an electron-dense “bud” (see Fig. 1) that gives rise to a spherical immature particle containing the mature TM and SU envelope glycoproteins. Proteolytic processing of the Gag and Pol proteins by the HIV PR during or immediately after particle release generates the cone-shaped nucleoid characteristic of mature HIV virions (see Fig. 8, steps 10 and 11).

Thus HIV-1 uses the same replicative strategy as the so-called simple retroviruses, which encode only the Gag, Pol, and Env proteins. However, during its evolution, HIV-1 acquired six additional genes to carry out functions that are performed by cellular proteins that are either (a) already present in the cells infected by the simple retroviruses or (b) uniquely required for virus replication, transmission, and survival in hematopoietic cells targeted by the primate lentiviruses. Some of the HIV-1 accessory proteins (Vif, Vpr, Vpu, and Nef) are not required for replication in certain human T-cell lines, although virus infectivity may be affected up to several thousand-fold depending on the accessory gene and the type of infected cell. In view of their conservation, however, these additional genes must be required for functions unique to HIV-1 replication *in vivo*.

Because many of the HIV-1-encoded proteins individually mediate critical functions at both early and late times in the virus life cycle (see Fig. 8), the synthesis, processing, and utilization of the various viral gene products will be presented in the order of their location within the HIV-1 genome rather than the usual temporal format. The multiplicity of biologic functions is particularly true for the Gag and Env proteins, which play important roles during both the initial phases and the final steps of the infectious cycle. Thus, rather than sequentially discussing the production and subsequent spread of progeny virions (virus entry, uncoating, reverse transcription, integration, transcription, translation, virus assembly, particle release), and to minimize unnecessary redundancy, the following sections will integrate the synthesis, structure, and function of individual HIV-1 nucleic acids and proteins in a context of HIV-1 biology both *in vitro* and *in vivo*.

The HIV Long Terminal Repeat

The retroviral LTR is a useful starting point for understanding the complex interplay between HIV and its principal target, human CD4+ T lymphocytes. LTRs are generated during the process of reverse transcription and therefore exist only as "repeats" in viral DNA. During the replicative cycle, LTR sequences serve a multitude of functions in the context of both proviral DNA and genomic RNA (Fig. 9). DNA and RNA sequences, mapping to the R region of the LTR, participate in one of the early steps of reverse transcription by forming intermolecular DNA–RNA hybrid "bridges" linking the newly synthesized DNA strand ("minus" polarity) with the 3' end of the same or a different genomic RNA template ("plus" polarity). During the integration step of the virus life cycle, LTR elements (*att* sequences) located at the termini of full-length linear viral DNA molecules mediate their insertion into the chromosomal DNA of host cells (109). Other LTR sequences, located in the context of U5 RNA sequences, have been shown to contribute to the packaging of progeny HIV-1 RNA genomes during virus assembly (637).

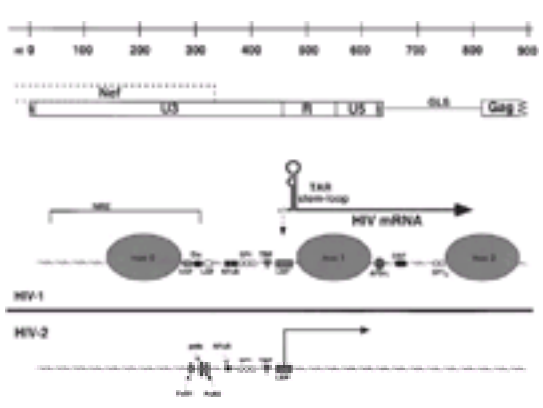

FIG. 9. Structure of the HIV-1 long terminal repeat (LTR). The HIV-1 LTR is a duplicated 630+ bp element located at the termini of integrated proviral DNA and has been divided into three functional subregions. The R (repeat) domain is defined as a 96-bp-nt repeat present at the 3' and 5' termini of HIV-1 genomic RNA and all viral mRNAs; U5 is an 84-nt segment located immediately 3' to the R region; and U3 is a 454-nt segment situated immediately 5' to R. The region of *nef* gene overlapping U3 and the position of LTR terminal *att* sequences (in the context of full-length viral DNA) are shown at the *top.* The 5' LTR and adjacent *gag* leader sequence (GLS) are aligned with the subdivided LTR (*middle*) to indicate functionally important binding sites for transcriptional regulatory proteins. For HIV-1, the "enhancer" domain contains three Sp1 binding elements and two NF-kB binding motifs. The transcription start site is located at map position +1, which is defined as the border between U3 and R. The NRE contains binding sites for USF and the Ets proteins. Sequence motifs that interact with the TATA binding protein (TBP), the leader binding protein (LBP), the LEF, AP3-like (AP3-L), the DBF-1, and two downstream Sp1 elements ($SP1_D$) are shown. The position of nucleosomes nuc0, nuc1, and nuc2 are indicated. An HIV-1 RNA transcript, which is initiated at the first nucleotide within the R region (designated +1) and contains the TAR element near its 5' terminus, is also shown. For HIV-2 (*bottom*), the unique binding sites for the PuB1, pets, and PuB2 transcriptional factors are indicated.

In the context of integrated viral DNA, the major function of the retroviral LTR is the regulation of viral RNA synthesis. The HIV-1 transcriptional promoter and adjacent regulatory elements, both of which are involved in recruiting the RNA Pol II holoenzyme to the start site of viral RNA synthesis, are located within the U3 region and function in the context of the 5' LTR (see Fig. 9). In primate lentiviruses, the *nef* ORF overlaps 60% to 70% of the U3 region, directly contributing to the relatively large size (400 to 500 nt) of the HIV-1 U3 compared to other retroviruses. Nef coding sequences of HIV-1, in fact, extend into the 5' 331 of the 454-nt U3 region (see Fig. 9). The polyadenylation signal (AATAAA) and polyadenylation addition site are also located in the R region but, as noted previously, are active only as components of the 3' LTR.

Like other eukaryotic cellular promoters, the integrated HIV LTR contains several elements that facilitate the loading of Pol II on the DNA template. The initial recognition of the HIV promoter requires the participation of several general transcription factors (GTFs), including TFIID, which specifically binds to the TATA element, located –29 to –24 nts upstream of the transcriptional start site, and to adjacent viral DNA sequences. This process generates a platform upon which a functional transcriptional complex can be assembled. The bound TFIID is then recognized by a single GTF, TFIIB, which recruits Pol II to the promoter, a critical interaction that definitively establishes the location of the transcription start site (373).

Another GTF (TFIIH), which modifies Pol II allosterically and allows the transcription complex to initiate RNA polymerization and "escape" from the promoter, must be incorporated into the Pol II complex (385,470). TFIIH is a multicomponent transcription factor that includes a kinase activity able to phosphorylate a unique region within the largest Pol II subunit, the C-terminal domain (CTD). The phosphorylated state of the CTD critically determines the functional activity of Pol II. Whereas hypophosphorylated Pol II (Pol IIa) is readily recruited into the preinitiation

transcription complex, the hyperphosphorylated form of the enzyme (Pol IIo) efficiently mediates elongation of nascent RNA transcripts (466). Three kinases, associated with the transcriptional apparatus, are known to phosphorylate the CTD. These include (a) the CDK7/cyclin H subunits of the cdk-activating kinase (CAK) complex associated with TFIIH, (b) the CDK8/cyclin C component of the Pol II holoenzyme, and (c) the CDK9/cyclin T subunits of the positive transcription elongation factor b (P-TEFb). Hyperphosphorylation of the CTD induces conformational changes in Pol II that allow the transcription complex to clear the promoter and begin elongating nascent RNA molecules.

In eukaryotic cells, regulatory transcriptional factors, which bind to DNA elements near the promoter, modulate the basal rate of RNA synthesis in response to physiologic cues. These regulatory factors function in a combinatorial fashion via protein–protein interactions to recruit GTFs, as well as the Pol II enzyme itself, to the promoter. This results in the more frequent assembly of stable transcription complexes that are able to readily escape the promoter and generate full-length primary transcripts. As is the case for other eukaryotic cellular promoter/enhancers, the HIV LTR contains its own ensemble of DNA elements to which transcriptional regulatory factors bind (see Fig. 9). Some of these were identified by mutagenesis of LTR-driven reporter gene constructs in transfection experiments, some were found as a result of gel-retardation or DNA footprinting studies, and others were discovered from searches of nucleotide sequence databases. Although early studies of HIV LTR-directed expression of reporter genes suggested that a large domain (–410 to –157) within U3, designated the negative regulatory element (NRE), might “silence” viral gene activity (534), there is little convincing evidence that the NRE plays a significant role during virus replication. Furthermore, mutations located in the region of the SIV *nef* gene that overlaps the NRE segment of the U3 LTR did not specifically affect viral replicative properties in infected rhesus monkeys (300). However, mutations altering the recognition sites for USF, Ets, and LEF-1 (572,575), which are located in the promoter-proximal portion of the *nef* overlap of U3, markedly impaired HIV-1 replication in activated PBMC (332). It is also worth noting that the U5 portion of the HIV LTR and *gag* leader sequences, both of which are situated *downstream* of the transcription start site, also contain cognate binding sites for cellular factors (see Fig. 9) that potentially regulate RNA synthesis during productive viral infections (see later).

The LTRs of HIV and other primate lentiviruses contain three tandemly arranged binding sites for the constitutively expressed Sp1 transcription factor (267); these DNA elements are situated upstream of a canonical Pol II TATA box (see Fig. 9). The Sp1 and TATA elements constitute the HIV-1 core promoter and must be present for basal levels of LTR-directed RNA synthesis. Sp1 was originally identified in HeLa cells and shown to bind to the multiple GGGCGG motifs (GC box) associated with the 21 base-pair (bp) repeats in SV40 DNA, activating both early and late SV40 transcription *in vitro*. Functional analyses of HIV-LTR-driven reporter constructs have shown that mutations of individual or pairs of Sp1 sites have little, if any, effect on the basal or Tat-transactivated levels of expression (267). Mutation of all three HIV Sp1 sites, however, markedly reduced the response to the HIV-1-encoded Tat transactivating protein (32,267). In the context of virus infections, the role of the Sp1 elements is cell type dependent (366,536). Mutations that functionally inactivate all three Sp1 motifs eliminated detectable replication in Jurkat cells, delayed progeny virus production in CEM and H9 cells, and had little effect on infectivity in activated PBMC.

Adjacent to the Sp1 binding sites, the two tandem recognition sites for the NF-kB/Rel family of transcription factors constitute an activatable enhancer for HIV-1 LTR-directed expression (see Fig. 9) (455). Although the LTRs of HIV-2 and SIV retain the triplicated Sp1 motifs, they contain only a single NF-kB binding site. NF-kB is a member of a large family of cellular transcription factors, which include the c-Rel protein of chickens and the dorsal gene product of *Drosophila*, a regulator of pattern development in embryos. Selected members of this NF-kB/Rel gene family are shown diagrammatically in Figure 10. Several contain a highly conserved N-terminal Rel homology domain (RHD), approximately 300 residues in size, that includes DNA binding and dimerization regions and a nuclear localization signal (NLS). A conserved protein kinase A site is present in several but not all RHDs. The p65/Rel A protein contains a potent transcription activation domain located downstream from its RHD. The p50 protein is derived from the p105 precursor, which contains a glycine-rich hinge linked to an ankyrin repeat domain; the p65/Rel A protein, in contrast, is a primary translation product. The inhibitory IkB proteins all contain multiple 30- to 34-amino-acid ankyrin motifs, which provide the interface for binding to various species of NF-kB.

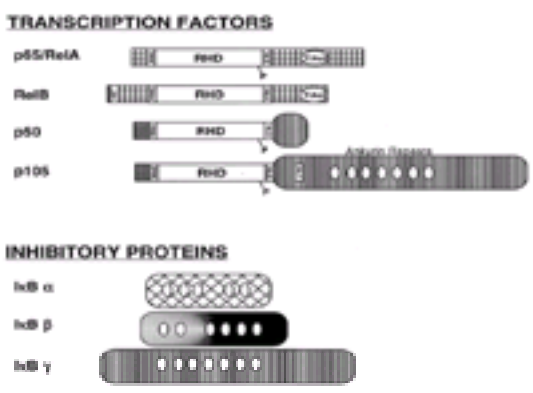

FIG. 10. NF-kB transcriptional regulatory proteins and IkB inhibitors. The NF-kB/Rel family of transcriptional factors shown may contain a Rel homology domain (*RHD*), DNA binding motifs (*DNA*), a leucine zipper (*ZIP*), a nuclear localization signal (*NLS*), a glycine hinge (*GLY*), a transactivation domain (*T/Act*), and a protein kinase A phosphorylation site (*P*). The ankyrin repeats are indicated by the *white ovals*.

NF-kB “binding activity” was originally identified as the p50-p65/Rel A heterodimer, the most abundant and functionally active form of NF-kB in human T cells (17). Because the various members of the c-Rel family are able to form dimeric NF-kB molecules, a heterogeneous population of homo- and heterodimers with different functional specificities could potentially bind to the two NF-kB sites present in the HIV-1 LTR. NF-kB functional activity is controlled by its intracellular location. In the cytoplasm, NF-kB dimers are complexed to IkB proteins or other Rel family members containing ankyrin repeats, such as the unprocessed p105 protein (see Fig. 10), and cannot be imported into the nucleus (326). The binding

of IkBa to the RHD of the p65 subunit of heterodimeric NF-kB results in its sequestration in the cytoplasm due, perhaps, to a masking of the p65 NLS (26). Nearly all of the T lymphocytes encountered by HIV-1 *in vivo* will be quiescent and lack NF-kB binding activity. Activation of mammalian T cells results in the phosphorylation of the bound IkB, the rapid degradation of IkB via the ubiquitin pathway, and the translocation of NF-kB into the nucleus where it can activate multiple eukaryotic genes (326,485). Convergent signal transducing pathways associated with T-cell activation, including those initiated at the IL-1 and tissue necrosis factor (TNF) receptors have been experimentally studied for their contributions to NF-kB activation (75,540).

The nuclei of activated human T lymphocytes and T-cell lines contain amounts of NF-kB capable of binding to cognate sites in the HIV-1 LTR and stimulating both basal and Tat-induced levels of expression, as monitored with reporter genes in transient transfection assays (455,574). When the NF-kB motifs are altered in the context of HIV, infectivity is affected, depending on the type of mutant constructed and the endogenous cellular levels of NF-kB. Deletion of both HIV-1 NF-kB binding motifs resulted in no (366) or modest (536) delays in peak virus production in activated human PBMC, whereas point mutations affecting specific nucleotides involved in NF-kB recognition but not the spatial organization of the NF-kB elements within the HIV-1 LTR, reduced progeny virus production by more than 10-fold (83). The replication of HIV-1 NF-kB mutants in several human T-cell lines was found to be inversely proportional to the basal levels of NF-kB. It is likely that the binding of other transcription factors present in these cell lines can compensate for the absence of NF-kB at the HIV-1 promoter in these virus mutants. The simultaneous mutation of the two NF-kB motifs and all three Sp-1 sites completely abolishes HIV-1 replication (366,536), consistent with the demonstration that the cooperative interaction of NF-kB and Sp-1 promotes the binding of both factors to the HIV-1 LTR and induces transcriptional activation (499). A synthesis of all of these results is that NF-kB mediates a more rapid and robust production of HIV-1 progeny in activated human T lymphocytes.

The HIV-2 LTR also contains three Sp1 binding sites adjacent to its TATA box, but the organization of its upstream enhancer region is different from that of HIV-1 (see Fig. 9). This portion of the HIV-2 U3 LTR contains only a single functional NF-kB motif as well as three other binding sites (PuB1, PuB2, and pets) not present in the HIV-1 LTR (415). The purine-rich PuB1 and PuB2 sequences are recognized by members of the Ets family of proto-oncogenes (mainly Elf-1) and the human autoantigen DEK binds to the pets site (203,361). Thus, while activation of HIV-1 LTR-directed expression following T-cell activation is mediated primarily through the binding of NF-kB to its two cognate sites, induction of HIV-2 gene expression depends on a different set of cellular transactivators.

Most of what is currently known about regulated HIV gene expression comes from experiments in which naked DNA was transiently transfected into mammalian cells. In eukaryotic cells, however, the interactions of transcriptional regulatory proteins with their cognate cis-acting elements is further modulated by the packaging of DNA into chromatin. This is clearly the case for HIV-1 proviral DNA, which becomes stably integrated into host cell chromosomal DNA during productive viral infections. DNA footprinting and restriction enzyme accessibility studies of integrated viral DNA have in fact revealed the presence of nucleosomes located both upstream and downstream of the HIV-1 promoter (designated nuc-0 and nuc-1 in Fig. 9). Nucleosome positioning defines two open chromatin regions encompassing (a) promoter/enhancer sequences [–250 to +11 (relative to the transcription start site)], and (b) a downstream segment that begins within the 3' portion of U5 and extends into the Gag leader (+150 to +250) (159,635). This chromatin organization is independent of the provirus integration site. The nucleosome-free region promoter-distal to nuc-1 and located downstream of the transcription start site contains recognition sites for three different transcription factors: Ap-3-like, DBF-1, and Sp1 (see Fig. 9). Mutagenesis of these binding motifs effectively abolishes the downstream nucleosome-free zone and markedly inhibits the transcriptional activity of the HIV-1 promoter in the context of both stably integrated LTR constructs and infections mediated by mutagenized cell-free virus (159,633). Taken together, these results are consistent with a model in which the positioning of nucleosome nuc-1 immediately downstream of the transcription start site sterically interferes with transcription, resulting in the characteristically low basal/uninduced levels of HIV-1 RNA synthesis. The positioning of nuc-1 is thought to reflect the binding of transcriptional regulatory factors to upstream promoter/enhancer motifs (viz. Sp 1 and NF-kB sites) and downstream recognition sequences situated in the U5/Gag leader region (Ap-3-like, DBF-1, and Sp1), a combination that creates two nucleosome-free regions. Transcriptional activation of cells containing the integrated HIV-1 LTR with TNF-a or inhibitors of histone deacetylation specifically results in the rapid disruption of nucleosome nuc-1 and generates a 500-bp open chromatin region (635,636). It is not presently known whether the chromatin associated with the HIV-1 template must be remodeled prior to the initiation of transcription or is an inevitable consequence of the RNA synthetic process.

Proteins encoded by several heterologous animal viruses have been reported to transactivate the HIV LTR. Although this effect has been touted by some as indicating that these agents contribute to disease progression, the co-infection of individual human T cells by HIV-1 and other viruses has been difficult to document. On the basis of tropism for CD4+ human mononuclear cells, viruses capable of directly or indirectly transactivating the HIV LTR would include HTLV-I, human CMV (HCMV), human herpes virus type 6 (HHV6), and possibly human adenoviruses (460). In the case of HTLV-I, it has been proposed that elevated levels of NF-kB induced by the viral-encoded Tax protein (18) activate HIV replication by binding to the two NF-kB motifs in its LTR.

HIV-Encoded Regulatory Proteins

Tat

Although the mechanism underlying Tat transactivation of HIV LTR-directed expression was hotly debated for several years, it is now generally agreed that Tat increases the steady-state levels of viral RNA several hundred fold by directing the formation of a more processive Pol II transcription complex in virus-infected cells. Tat is an indispensable viral protein; when the *tat* gene of an infectious molecular proviral clone of HIV is mutagenized, no detectable progeny virions are produced as monitored in either transfection or infectivity assays (128,182). HIV-1 Tat is a nuclear protein containing 101 amino acid residues encoded by two exons (Fig. 11). A shorter 72-amino-acid, “one-exon” HIV-1 Tat protein possesses all the transcriptional activating properties of full-length Tat, as measured in tissue culture infections or in LTR-driven reporter gene experiments. The termination codon following the first Tat exon is highly conserved among diverse HIV-1 isolates, suggesting that the “one-exon” and “two-exon” Tat proteins mediate different functions during

productive viral infections *in vivo*.

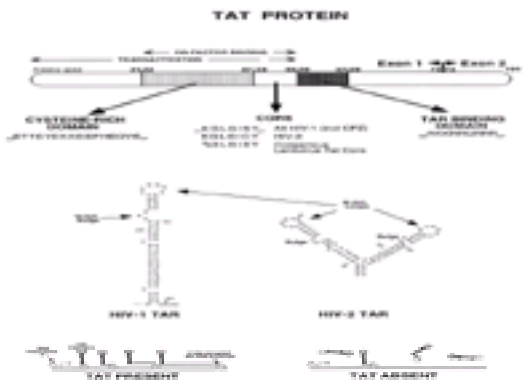

FIG. 11. Tat and its TAR response element. Schematic representation of the HIV-1 Tat protein (*top*) with the cysteine-rich activation, core, and TAR-binding domains indicated. The stem-bulge-loop configurations of HIV-1 and HIV-2 TAR elements are shown in the *middle*; the release of prematurely terminated HIV-1 transcriptional complexes from the DNA template in the absence of Tat is depicted at the *bottom*.

As previously noted, RNA synthesis in eukaryotic cells is usually modulated by transcription activator proteins, which bind to DNA motifs located *upstream* of their respective promoters and recruit GTFs and the Pol II holoenzyme to the transcription initiation complex. Visna virus, another member of the *Lentivirus* genus, in fact encodes a DNA-binding Tat protein, which binds to Ap-1 sites located in its LTR (283). In contrast, the immediate target of all primate lentiviral Tat transactivating proteins are sequences situated *downstream* of the start site for viral RNA synthesis (534). This unusually situated transactivation response region, or TAR element, also differs from typical binding sites for Pol II transactivators because it is inactive when present (a) in an inverted orientation, (b) 5' to the promoter, or (c) downstream of the transcription termination site (i.e., in the U5 region of the 3' LTR) (309). These unusual properties were subsequently reconciled when it was demonstrated that TAR did not function as a DNA recognition site but as an RNA element (33).

The HIV-1 TAR encompasses the 5'-terminal 59 nts of *all* viral RNAs and folds into a stable stem-loop structure (see Fig. 11, middle). It was subsequently shown that the minimal TAR element (mapping between bases +19 and +43) contains three critical components: a base-paired stem, a trinucleotide bulge (containing the sequence UCU at positions +23 to +25), and a hexanucleotide G-rich loop (176). Interestingly, the HIV-2 TAR forms a double stem-loop structure, each arm of which possesses a dinucleotide bulge and the hexanucleotide G-rich loop (see Fig. 11) (160). Sequences located in both the hexanucleotide loop and the bulge of the HIV-1 TAR are required for Tat function. *In vitro*, purified preparations of Tat bind to TAR RNA with high affinity and moderate specificity (140). HIV-1 Tat binds to both wild-type or “loop” mutants of TAR but *not* to TAR elements containing alterations affecting the bulge region (139,542). Modification of the invariant “bulge” U_{+23} nucleotide and elimination of the base pairs immediately above and below the bulge (see Fig. 11) significantly reduce the binding of Tat to TAR (650). Nuclear magnetic resonance (NMR) studies have shown that the binding of a large Tat peptide to TAR causes the major groove in the RNA duplex to widen, thereby generating multiple points of contact between Arg residues in the Tat-binding domain with critical nucleotides (e.g., U_{+23}) and several phosphate groups comprising the TAR backbone (1). This distortion of the TAR structure also brings the loop and bulge regions into close proximity, which could facilitate the interactions of proteins binding to both of these TAR domains.

The functional organization of the HIV-1 Tat protein has been deduced from TAR binding and transcriptional activation experiments using both wild-type and mutagenized derivatives of the Tat protein. The tripartite Tat activation (or effector) domain encompasses the amino-terminal 48 residues, which include (a) a string of highly acidic amino acids (residues 1 to 21), (b) a Cys-rich region (seven invariant, six of which are required for function) between positions 22 and 37, and (c) a hydrophobic core segment (amino acids 38 to 48), which is highly conserved among different HIV isolates (see Fig. 11). The activation domain is critical for recruiting an essential cellular cofactor to TAR; mutations affecting this region of the Tat protein drastically reduce or eliminate transactivation activity (543). The RNA binding domain of Tat has been mapped to a Lys/Arg-rich region between residues 49 and 57 (see Fig. 11); peptides from this Tat segment bind to the TAR bulge region as well as to a few base pairs surrounding the bulge, but with somewhat less affinity and specificity than do purified preparations of Tat protein (116). A nuclear/nucleolar localization signal ($_{48}$Gly-Arg-Lys-Lys-Arg_{52}) also overlaps the RNA-binding region of Tat.

At first glance, the functional organization of HIV-1 Tat is highly reminiscent of many other transcriptional regulatory proteins, which contain modular nucleic acid binding and activation domains. However, a growing body of work has revealed that Tat/TAR interactions are more complex *in vivo* and involve the participation of several cellular cofactors. This became apparent from experiments showing that the Arg-rich domain of the Tat protein did not function as an independent RNA-binding module *in vivo*. These experiments indicated three things: (a) The targeting of heterologous fusion proteins to TAR required *both* the RNA binding and activation regions of Tat (392). (b) The RNA binding domain of Tat failed to function as a transdominant negative inhibitor of wild-type Tat, as did analogous domains from other RNA binding proteins such as HIV Rev (see later). This result implied that the Tat RNA binding region was neither autonomous nor able to form functional Tat/TAR interactions *in vivo* (398). (c) Wild-type TAR, but not mutant TAR decoys containing changes limited to the G-rich loop, rendered CEM cells resistant to HIV infection (605). The failure of excess Tat protein to relieve the blockade induced by wild-type TAR decoys suggested that at least one loop-binding cellular cofactor, present in limiting amounts, was required for functional Tat/TAR interaction *in vivo*.

Other studies demonstrated that Tat chimeric proteins, which could be targeted to the promoter via heterologous (non-TAR) RNA binding sites, also exhibited high levels of transactivation (569,620). This implied that, if necessary, Tat could function in the absence of TAR and recruit cellular factor(s) to the transcription complex. It was also reported that

inefficient Tat transactivation in rodent cells (269) could be overcome if Tat was delivered to the promoter using a surrogate RNA binding site (9). This latter result indicated that a cellular cofactor required for Tat transactivation was indeed present in rodent cells but could not be recruited to or bind TAR. Collectively, these findings are consistent with a model in which Tat uses its transactivation domain to recruit a cellular cofactor (or cofactors) to TAR; in such a scenario, Tat would bind to the TAR bulge and the cofactor(s) to the TAR loop.

The hallmark of HIV LTR-directed RNA synthesis in the absence of Tat is the accumulation of prematurely and randomly terminated transcripts, which are converted to longer RNA species when Tat is expressed (see Fig. 11, bottom). This Tat-deficient phenotype has been observed in *in vitro* transcription experiments, following transient transfection of LTR-driven reporter gene constructs, and in cells harboring integrated HIV proviruses with mutated *tat* genes (173,355,622). Because Tat expression markedly stimulated transcriptional elongation in many of these experimental systems, attention shifted to the possible involvement of the CTD of Pol II, which, as noted earlier, is hyperphosphorylated in highly processive transcription complexes. This line of reasoning was also consistent with the reported inhibition of Tat-stimulated transcription by the adenosine analog DRB, which blocks Pol II–mediated elongation *in vitro* and *in vivo* by inactivating protein kinases (53). The demonstrated requirement of the Pol II CTD for Tat-mediated transactivation of viral RNA synthesis also supported such a model (487,682).

Reports describing the specific interaction of HIV-2 Tat [or just the effector domain of HIV-1 Tat (residues 1 to 48)] with a cellular kinase linked many of these disparate findings and provided the first mechanistic clues about Tat function (280,281). The novel enzymatic activity identified, initially named Tat-associated kinase or TAK, was able to phosphorylate the CTD of Pol II. Contemporaneous studies evaluating Tat-stimulated Pol II processivity in cell-free systems suggested that Tat interacted with components of the TFIIH complex to enhance transcriptional elongation and raised the possibility that TAK might be a TFIIH-associated kinase (227,487). However, it was subsequently shown that Tat binds with high affinity to a Pol II CTD kinase complex (710) related to the *Drosophila* multicomponent P-TEFb mentioned previously, which is catalytically independent of TFIIH (418,497). Moreover, Tat interaction with TFIIH is weak and not dependent on the integrity of its activation domain (84). P-TEFb shares no subunits in common with the TFIIH elongation factor complex, and it regulates the transition from abortive to fully processive transcriptional elongation (417). Additional experimentation revealed that TAK hyperphosphorylated the CTD of Pol II, independent of TFIIH (and its associated CDK7 kinase), and was more sensitive to DRB inhibition than was CDK7 (279,417,418). A recent study indicated that TFIIH activity is not required for HIV-1-mediated transcriptional elongation (84).

The Tat-related kinase component in human P-TEFb was subsequently identified to be PITALRE, a 42-kd CDC2-related kinase. When antibodies directed against PITALRE (now named CDK9) were used to deplete the kinase in nuclear extracts, the residual activity for Tat-simulated RNA chain elongation was reduced nearly 100-fold (498,710). Tat activity could be restored by adding purified P-TEFb to the cell-free system. Furthermore, the identification of novel Tat inhibitors, which specifically abolished CDK9 activity *in vivo* and *in vitro*, coupled with the demonstrated dominant negative effects of a CDK9 mutant on Tat transactivation (409,710), provided strong evidence that CDK9 was intimately involved in regulating Tat function. Taken together, these results suggested that TAK and P-TEFb were functionally indistinguishable transcription factors, sharing the common CTD kinase activity, CDK9. The subsequently demonstrated identity of the cloned catalytic subunit of P-TEFb and the kinase subunit of TAK provided conclusive evidence for this idea (681,710).

Although, as noted previously, earlier studies had shown that TAK/P-TEFb interacted with the activation domain of HIV-1 Tat, the CDK9 catalytic subunit itself failed to bind to Tat in *in vitro* assays. Equally perplexing was the identification of the TAK/P-TEFb kinase activity in nuclear extracts migrating not as the 42-kd CDK9 but as a 110-kd complex (682). This suggested the existence of a possible cyclin-related partner for CDK9, which might provide substrate specificity. These unresolved issues were clarified with the isolation of the “missing link”—an 87-kd protein from nuclear extracts, which bound to wild-type HIV-1 Tat but not to a mutant Tat protein containing a nonfunctional activation domain (651). The sequence of a cDNA clone encoding the 87-kd protein revealed the presence of an amino-terminal cyclin box that was nearly 40% identical to human cyclin C. The new protein, initially named cyclin T (because it bound to Tat), is encoded by a gene mapping to human chromosome 12. The CDK9 family of kinases are now known to interact with cyclin regulatory subunits, many of which have been cloned and characterized (497). Several human cyclins (T1, T2a, and T2b) can functionally partner CDK9, greatly increasing its kinase activity (498); of these, only cyclin T1 is able to directly bind to the HIV-1 Tat activation domain and is a component of P-TEFb (651).

The binding of Tat to TAR has traditionally been the centerpiece of models for Tat-mediated transactivation. Following the identification of CDK9/cyclinT1 as cellular cofactors of Tat, attention turned to determining how they interacted with Tat, TAR, and the cellular transcriptional machinery. A large body of work revealed the following information: (a) CDK9 and cyclin T1 are components of the large human P-TEFb transcription complex that promotes RNA chain elongation. (b) CDK9/cyclin T1 is present in the nucleus (possibly also the cytoplasm) of eukaryotic cells as an assembled heterodimer, and its recruitment into the Pol II complex is associated with highly processive transcriptional activity. (c) Recombinant cyclin T1 directly binds to the effector domain of wild-type Tat but not to Tat proteins containing mutations affecting this region. This is consistent with the reported interaction of Tat and purified human P-TEFb in the absence of TAR (681,710). (d) The binding of Tat to TAR RNA is markedly enhanced in the presence of cyclin T1. Several reports have, in fact, shown that the Tat/cyclin T1 heterodimer has greater affinity for TAR than does either Tat or cyclin T1 alone (39,225,651). As expected, the interaction of Tat with purified P-TEFb greatly increased the affinity of Tat for TAR (706). (e) The Tat–cyclin T1 complex will bind only to TAR RNA in which both the loop and the bulge are intact, whereas Tat alone requires only the trinucleotide bulge for stable TAR interaction. These results suggest that multiple pair-wise interactions are involved in stabilizing the binding of Tat to TAR: (a) Tat with P-TEFb, (b) Tat with the TAR bulge, (c) cyclin T1 with the TAR loop, and (d) the TAR bulge/TAR loop with Tat/P-TEFb.

As noted earlier, Tat transactivation of HIV-1 LTR-driven gene expression is quite low in rodent cells but can be greatly augmented in rodent somatic cell hybrids containing human chromosome 12 (269). This defect can also be corrected by overexpressing human cyclin T in rodent cells, which results in enhanced Tat transactivation of the HIV-1 LTR to levels measured in human cells (651). Recent studies have shown that the murine homolog of human cyclin T is able to bind to HIV-1 Tat, but the resulting Tat/murine cyclin T heterodimer is not efficiently recruited to TAR (204,225). Substitution of a

single amino acid residue in murine cyclin T with its human analog (Tyr to Cys at residue 260) also restores Tat activity in rodent cells (39,225). Thus, the extremely weak Tat transactivation in rodent cells is not caused by a failure to form the Tat/cyclin T heterodimer; rather, the cross-species heterodimer that does form is apparently unable to bind to TAR and deliver P-TEFb to a poorly processive transcription complex.

A model of HIV Tat transactivation is shown in Figure 12. Tat interacts, via its activation domain, with the cyclin T1 subunit of cyclin T1/CDK9, a component of the P-TEFb elongation complex present in the nuclei of virus-infected cells. The binding of human P-TEFb to Tat most likely induces a conformational change in the structure of Tat, which alters its affinity and specificity for binding to TAR RNA. Thus, the function of Tat is to recruit the critical P-TEFb elongation factor to a promoter-proximal location where it can hyperphosphorylate the Pol II CTD, thereby stimulating transcriptional processivity. It is worth noting that expression of both CDK9 and cyclin T1 increases following activation of resting PBMC with phytohemagglutinin (PHA), phorbol myristic acid (PMA) plus ionomycin, anti-CD3 antibody plus IL-2, or antibodies to both anti-CD3 and the CD28 receptor (278). Thus T-cell activation increases steady-state levels of both NF-kB as well as the two cellular cofactors of Tat, resulting in high levels of HIV-1 LTR-directed gene activity.

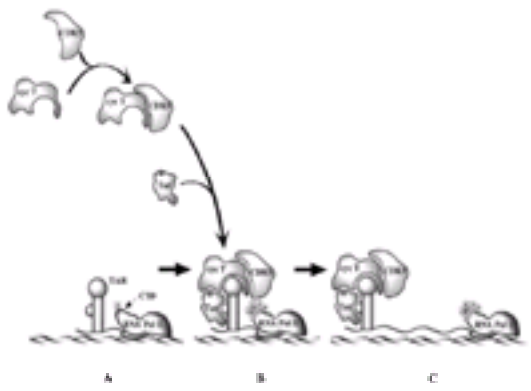

FIG. 12. Tat promotes the phosphorylation of the carboxy terminal domain (*CTD*) of RNA Pol II. **A:** In the absence of Tat binding to TAR, the processivity of the RNA Pol II complex is inefficient. **B:** When the activation domain (*) of Tat interacts with the cyclin T (*cyc T*)/CDK9 complex, the conformation of Tat changes and its affinity and specificity for TAR RNA increases. **C:** By recruiting cyc T and CDK9 (the TAK complex) to a promoter proximal location, Tat mediates the hyperphosphorylation of the CTD and promoter clearance (elongation) of transcriptional complex. (Drawing kindly provided by Dr. Michael Cho.)

Possible extracellular roles for Tat have been suggested from studies showing that Tat is taken up by cultured cells, enters the nucleus, and transactivates genes linked to the HIV LTR (191). Tat purified from *Escherichia coli* has also been reported to inhibit antigen-induced, but not mitogen-induced, proliferation of PBMC (639). In a similar vein, it has been reported that low concentrations of Tat modestly stimulate the growth of cultured Kaposi sarcoma cells from patients with AIDS (164). The significance of these extracellular Tat activities in HIV-infected individuals is currently unclear.

Rev

Like other primary RNA transcripts synthesized in eukaryotic cells, HIV pre-mRNAs undergo a series of modifications (capping, 3'-end cleavage, polyadenylation, and splicing) prior to their export to the cytoplasm. Retroviruses utilize the cellular posttranscriptional processing machinery to carry out these functions. With few exceptions, introns present in nascent cellular mRNAs must be removed prior to their export from the nucleus, presumably to prevent their translation into nonfunctional proteins. This requirement poses an obvious problem for retroviruses such as HIV, which must export a variety of intron-containing mRNAs into the cytoplasm (e.g., the unspliced 9.2-kbp primary transcript for encapsidation into progeny virions and production of Gag and Pol proteins, as well as several other partially spliced mRNAs such as those encoding Env, Vif, and Vpr proteins). In part, retroviruses have solved the requirement for the removal of all intronic sequences from pre-mRNAs prior to nuclear export by incorporating suboptimal splice sites into their genomes. These sites are inefficiently processed by splicing factors, resulting in the accumulation of unspliced viral RNAs in the nucleus. The nuclear export of intron-containing retroviral RNAs may be additionally impeded as a result of their interaction/retention with the cellular splicing apparatus (456).

All retroviruses must splice their primary RNA transcripts to generate *env* mRNAs, eliminating upstream *gag* and *pol* sequences in the process. For simple retroviruses such as the ALVs and MuLVs, this is the only splicing reaction that the viral pre-mRNA undergoes (Fig. 13, top). In contrast, the splicing of HIV RNA is far more complex because of the presence of both constitutive and alternatively used splice-donor and splice-acceptor motifs scattered through its genomic RNA. Three general classes of HIV mRNAs have been identified in productively infected cells: (a) unspliced genomic RNA, which serves as the mRNA for synthesis of Gag and Pol proteins; (b) partially spliced RNAs, approximately 4.3 to 5.5 kb in size, which are translated into Vif, Vpr, Vpu, and Env proteins; and (c) multiply or completely spliced viral mRNAs, ranging from 1.7 to 2.0 kb in size, which encode the Tat, Rev, and Nef proteins (see Fig. 13, bottom). The first two classes of viral mRNA contain several spliceable introns yet are efficiently exported from the nucleus into the cytoplasm.

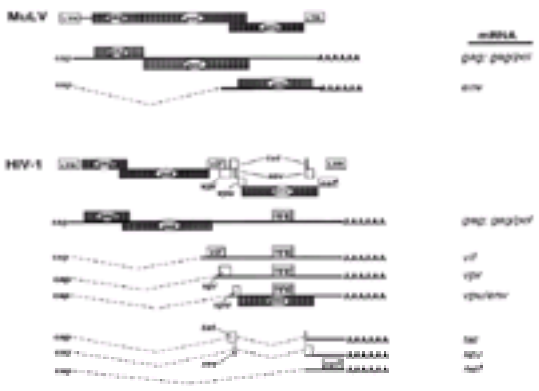

FIG. 13. Retrovirus splicing patterns. In contrast to murine leukemia virus (MuLV), which generates only two discrete mRNA species (the unspliced *gag*/*pol* and the singly spliced *env*), HIV-1 produces several alternatively spliced mRNAs ranging from the unspliced *gag*/*pol* to the multiply spliced *tat*, *rev*, and *nef* RNA transcripts. The genomic organization of the proviral DNA, the location of protein coding sequences, and the position of the Rev-responsive element (*RRE*) in intron-containing mRNAs encoding viral structural proteins are indicated. The *dashed lines* connect the major splice donor to a downstream splice acceptor; alternative forms of *tat*, *rev*, *vpu*/*env*, and *nef* mRNAs, some of which contain short upstream noncoding exons, are not shown.

Analyses of viral mRNAs by RT polymerase chain reaction (RT-PCR) have revealed the existence of more than 30 different HIV transcripts in virus-producing cells (513,566). These mRNAs are generated as a consequence of alternative selection of the five splice donors (sd) and the more than 10 splice acceptors (sa) embedded in the viral genome (some of which are shown at the top of Fig. 14). Variable usage of this ensemble of splicing signals gives rise to several sets of distinct, closely related RNAs that serve as alternative templates for translation into the same protein. For example, 12 different *rev*, 5 different *nef*, 8 different *tat*, and 16 different *env* mRNAs have been identified (513). This HIV mRNA diversity is caused, in part, by the variable inclusion of two upstream 50- and 74-nt noncoding exons (generated from sa2/sd2 and sa3a/sd3, respectively; Fig. 14) in many of these spliced RNA species. The functional significance of multiple spliced mRNAs encoding the same viral protein, their relative abundance, and the hierarchy of HIV splice site usage are not presently understood.

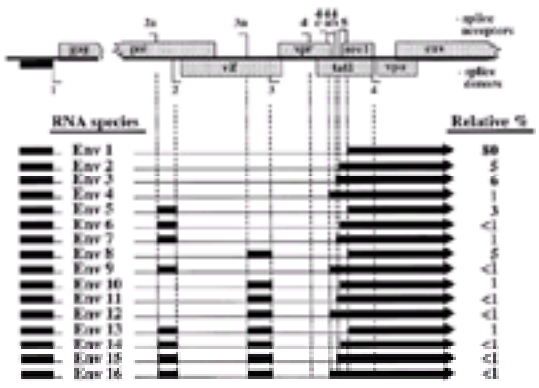

FIG. 14. Structure and relative abundance of differentially spliced HIV-1 *env* mRNAs. For each RNA species, the *dark bars* and associated 3' *arrows* represent exons included in the spliced transcript as determined by semiquantitative PCR analysis. The relative proportion of each mRNA is indicated at the right.

Complex retroviruses, such as HIV, have dealt with the restriction to the nuclear export of unspliced and incompletely spliced transcripts by incorporating a novel reading frame, encoding the Rev (which stands for regulator of expression of viral proteins) protein, into their genomes. In the absence of Rev, the unspliced *gag*/*pol* and the partially spliced *vif*, *vpr*, and *vpu*/*env* mRNAs fail to accumulate in the cytoplasm, thereby rendering the Rev mutant virus replication incompetent (174,264,588).

HIV-1 Rev is a 19-kd, predominantly nucleolar phosphoprotein containing 116 amino acid residues. Like Tat, Rev is encoded by two exons and contains two functional regions: (a) an Arg-rich domain that mediates RNA binding and nuclear localization, which is flanked by sequences that facilitate Rev multimerization; and (b) a hydrophobic segment, located between residues 73 and 84, that contains several Leu residues, now known to promote nuclear export (see Fig. 15, top) (404,406,407,698). Mutation of any one of three critical Leu residues (at position 78, 81, or 83) within this domain eliminates Rev activity. Unlike those of *tat*, both coding exons of *rev* are required for function (546).

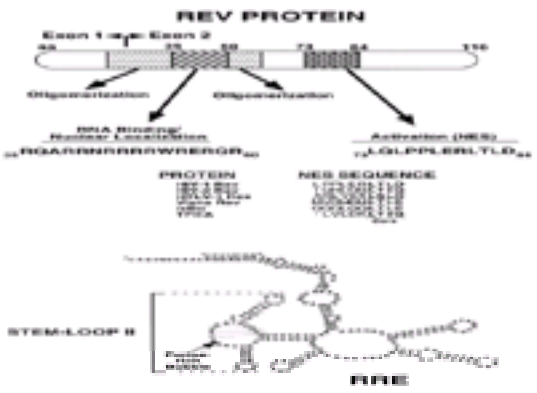

FIG. 15. Rev and its response element, the RRE. A schematic representation of the HIV-1 Rev protein with its RNA-binding, activation, and oligomerization domains is shown at the top. The amino acid sequence of the leucine-rich nuclear export signal (*NES*) present in retroviral Rev/Rex proteins and two cellular proteins are also shown. The core tetramer motif, LxLy, where y is usually a charged residue and x is highly variable, is indicated. The structure of the RRE is presented at the *bottom* with the high-affinity target of HIV-1 Rev (*stem-loop II*) shown. The "bulged" G residues in stem-loop II able to form noncanonical purine–purine base pairs are *circled.*

The HIV Rev protein regulates the expression and utilization of viral transcripts by binding to a cis-acting target, the Rev response element (RRE), present in all unspliced and partially spliced viral mRNAs (see Fig. 13). The RRE, located in a 250-nt segment spanning the junction between gp120 and gp41 coding sequences of the *env* gene, is a complex RNA structure containing multiple stem-loops branching from a large central bubble (174,405,535) (see Fig. 15, bottom). The RRE must be present *within* a Rev-responsive transcript and in the *sense* orientation for Rev responsiveness. Nuclease protection, chemical modification, and mutagenesis studies indicate that Rev specifically interacts with a 60+ nt portion of the RRE, designated stem-loop II (see Fig. 15) (129,288,407). This region of the RRE binds to Rev even when isolated from the complete RRE structure, and it mediates Rev responsiveness in functional assays (294). The determinants for high-affinity binding of Rev to RRE reside in the central purine-rich "bubble" in stem-loop II; this bubble contains unusual G:G and G:A base pairs that distort the duplex RNA structure and widen the major groove to accommodate the Rev protein (22,289,407). NMR analyses have shown that an alpha helical, Arg-rich, 17-residue peptide, from the RNA binding domain of Rev, burrows deep into the major groove of a stem-loop II oligonucleotide, stabilizing the non-Watson-Crick base pairs through specific interactions involving the Arg side chains (23). It is now believed that Rev initially makes high-affinity contact with nucleotides in the RRE loop II bubble as a monomer, thereby generating a nucleation point for the multimerization of additional Rev molecules through cooperative protein–protein and protein–RNA interactions (698,700). The functionally complete RRE is most likely 350 nt in size, and an individual element may accommodate eight or more Rev molecules (410). Although not yet developed into usable antiviral agents, some aminoglycosides are able to block the binding of HIV Rev to its RRE target and inhibit the production of progeny virions (699).

Mutations affecting either the RNA binding or the Leu-rich activation domains of the Rev protein result in loss of function. For example, activation domain mutants are able to bind to the RRE but are functionally inactive. They interfere with the transactivation mediated by wild-type Rev, exerting a trans-dominant effect in assays for Rev function (404). Rev also possesses the unique property of continuously shuttling between the nucleus and the cytoplasm (434). Mutations affecting the Rev activation domain abolish the shuttling and restrict Rev to the nucleus. Multimerization-defective Rev mutants can still bind to the high-affinity RRE site but are unable to form oligomeric complexes (399).

Although the total amount of viral RNA in cells infected with wild-type or Rev-deficient HIV mutants is quite similar, *gag-pol*, *env*, *vif*, and *vpr* mRNAs are either absent or markedly underrepresented in the cytoplasm of cells infected with Rev mutants compared to the relatively normal levels of multiply spliced *tat*, *rev*, and *nef* transcripts in the same cellular compartment (174,405,588). This pattern of RNA expression initially led to a plethora of proposed posttranscriptional functions mediated by Rev, including (a) the regulation of splicing, (b) nuclear to cytoplasmic transport, (c) RNA stabilization, and (d) stimulating the translation of RRE-containing HIV RNAs. As noted earlier, the HIV-1 genome contains multiple sequence motifs, located in *gag*, *pol*, and *env* genes (and designated INS in Fig. 6), which contribute to a requirement for Rev. These cis-acting AU-rich elements markedly impair the expression of fused reporter genes by impeding RNA transport to the cytoplasm and/or decreasing RNA stability (403,535). It is quite likely that cellular proteins bind to these inhibitory sequences, contributing to the nuclear retention and the intrinsic instability of intron-containing viral RNAs. Rev is able to reverse these effects, provided that an RRE is present in such transcripts.

Careful analyses of HIV RNA expression patterns in different cellular compartments indicated that the ratios of unspliced (or partially spliced) to completely spliced viral transcripts in the nucleus did *not* change in the presence or absence of Rev (174,405). Rather, as noted previously, the hallmark of insufficient Rev expression was a superabundance of the 1.7- to 2.0-kb, completely spliced RNAs. and greatly reduced or no detectable RRE-containing mRNAs *only* in the cytoplasm. Because splicing of viral RNA in the nucleus was not affected by the absence of Rev, attention shifted to the role that Rev might have on HIV RNA transport.

The first unambiguous demonstration that Rev could promote the nuclear export of intron-containing viral RNA came from experiments in which purified Rev protein and RRE-containing RNA molecules were microinjected into cell nuclei (180,656). These studies showed that the RRE-containing unspliced RNA substrates were transported from the nucleus into the cytoplasm only in the presence of Rev. Interestingly, the excised exon (containing the RRE element), derived from those transcripts that did undergo splicing, was also detected in the cytoplasm, indicating that Rev was able to mediate nuclear export *without* inhibiting RNA splicing (181). Other microinjection studies revealed that the Leu-rich Rev activation domain was indeed a nuclear export signal (NES) because, when fused to bovine serum albumin (BSA), it promoted the transport of NES/BSA molecules into the cytoplasm (180,656). In contrast, NES/BSA fusion proteins containing a mutated, nonfunctional Leu-rich Rev domain remained in the nucleus. The nuclear export mediated by the

Rev NES was also shown to be energy dependent and was blocked by high concentrations of NES/BSA, a result that implied that the amounts of intracellular nucleus-to-cytoplasm transporting proteins were limiting. Surprisingly, the nuclear export of 5S rRNA and spliceosomal U small nuclear (sn)RNAs, but not Pol II–derived cellular mRNAs, were also inhibited when high concentrations of NES/BSA conjugates were microinjected. In this regard, a growing list of viral and cellular proteins involved in RNA metabolism and signal transduction have been shown to contain a Rev-like, Leu-rich NES (see Fig. 15, middle), which mediates the transport of a variety of substrates from the nucleus to the cytoplasm (303,423). Taken together, these results are consistent with a model in which the Rev effector domain functions as a NES, directing RRE-containing viral RNAs to the cytoplasm via a pathway used by some cellular mRNAs.

The bi-directional passage of proteins between the nucleus and cytoplasm occurs through the nuclear pore complex (NPC) and depends on the presence of NLS and NES transport signals. The NPC is an extremely large (over 100 megadaltons) gated structure composed of 50 to 100 different proteins, called nucleoporins, only a few of which have been characterized (168,603). One class of nucleoporins, thought to directly participate in nuclear-cytoplasmic transport, contains Phe-Gly (FG) repeat domains and are located primarily at the periphery of the NPC. Proteins destined to be imported into the nucleus (e.g., bearing a typical basic-type NLS) initially associate with a member of a growing family of transport “receptors” in the cytoplasm. The first receptor of this type discovered, importin-b, shares structural features and interacting partners with other family members and is considered to be the prototypical transporter. Proteins bearing the basic-type NLS usually begin the import process by first binding to a related transport protein, importin-a. Importin-a serves as a bridge, linking the NLS-containing substrate to importin-b. However, in contrast to most other proteins that carry a classic NLS, Rev appears to bind directly to importin-b, and this heterodimeric complex is transported to the NPC where the importin-b subunit successively binds to and dissociates from the resident nucleoporins, translocating the Rev substrate through the pore and into the nucleoplasm (148).

It is now known that the reverse process, nuclear export, utilizes transport receptors that are also members of the importin-b family. The most well studied of these is named CRM1 (for chromosome region maintenance 1), or exportin 1 (184,595). Studies of HIV-1 Rev and related viral and cellular proteins bearing Leu-rich NES motifs (see Fig. 15) have led to the discovery and established the functions of many proteins involved in nuclear export. A critical experiment linking the Rev NES mechanistically to the nuclear export machinery was the demonstration that the antibiotic leptomycin B (LMB) blocked the nuclear export of Rev-dependent RNAs in HeLa cells and human PBMC (672). A follow-up study, using microinjected *Xenopus* oocytes, indicated that LMB inhibited the nuclear-to-cytoplasmic transport of both the Rev protein and several UsnRNAs (184). Completely unrelated experiments, examining the antimicrobial effects of LMB in yeast, had mapped LMB resistance to the antibiotic to the CRM1 gene (463), an observation reported prior to the time when the role of CRM1 in nuclear export was appreciated. Additional experiments demonstrating that LMB binds directly to *in vitro* translated CRM1 and that overexpression of CRM1 eliminates the LMB blockade of Rev NES-mediated nuclear export suggested that Crm 1 might be the long-sought “export receptor” for proteins containing the Leu-rich NES. This conclusion was also supported by studies showing that CRM1 shuttled between the nucleus and cytoplasm and interacted with the FG repeats present in nucleoporin proteins (184,461,595).

The small GTPase molecule, Ran (41), also plays a central role in nuclear-cytoplasmic transport and is intimately involved in the Rev-mediated nuclear export of intron-containing HIV-1 pre-mRNAs. Ran is a guanine nucleotide-containing enzyme that provides both the energy and the directionality cues for nuclear import and export. Intracellularly, Ran cycles between two forms, RanGTP and RanGDP, which are concentrated primarily in the nucleus and cytoplasm, respectively (304). The specificity of Ran activity in nuclear transport is regulated by the nature of the bound nucleotide. Several cellular proteins are able to modulate the nucleotide-bound state of Ran and, therefore, contribute to the asymmetric distribution of the two Ran forms (42). One of these, the chromatin-associated regulator of chromosomal condensation 1, or RCC1, stimulates the replacement of GDP with GTP when Ran is in the nucleus. On the other hand, two other factors, Ran GTPase activating protein 1 (Ran GAP1) and Ran binding protein 1 (Ran BP1) both augment Ran activity in the cytoplasm by promoting the hydrolysis of the Ran-associated GTP. The net effect of these interactions is the maintenance of the observed RanGTP/RanGDP intracellular gradient required for nuclear import and export functions.

The complete Rev nuclear transport cycle and its critical interacting partners are shown in Figure 16. During the early, postintegration phase of the virus life cycle, the HIV-1 mRNAs transported to the cytoplasm consist almost entirely of intronless, multiply spliced transcripts encoding the Tat, Rev, and Nef proteins. As noted earlier, Rev uses its NLS to bind directly to importin-b in the cytoplasm and is translocated through the nuclear pore as a Rev/importin-b heterodimer. When the complex reaches the nucleus, the binding of RanGTP triggers the Rev/importin-b heterodimer to dissociate and release the Rev subunit. In the nucleoplasm, Rev initiates its role as a nuclear exporter by binding to the high-affinity site on stem-loop II of RRE-containing HIV-1 pre-mRNAs and then multimerizes via cooperative protein–protein and protein–RNA interactions over the entire length of the RRE. When Rev oligomerizes on the RRE, its NES elements become aligned on the outside of an enlarging protein–RNA complex and are available to interact with other proteins (275). Although CRM1 is able to directly bind to Rev (14,184,207), this interaction is nonspecific because it does not require an intact NES and is unaffected by the antibiotic LMB. Instead, to form a functional complex, the multimerized Rev/RRE must interact with CRM1 in the presence of Ran in its GTP bound form. The formation of this complex (RRE/Rev/CRM1/RanGTP) is (a) blocked by the antibiotic LMB, (b) sensitive to Rev NES mutations, and (c) dissociated when RanGTP is hydrolyzed to the RanGDP state (14). The most likely scenario linking all available data is that the entry of RanGTP into a preexisting Rev/CRM1 heterodimer converts it into a functional export complex. This is supported by the results of *in vitro* protease protection experiments showing that the addition of RanGTP further stabilizes the Rev–CRM1 complex, making it more resistant to enzymatic digestion (14). Once a functional REV export complex is formed, it is transported to the NPC where the CRM1 subunit interacts with nucleoporins (185), translocating the entire complex into the cytoplasm. There, in the presence of Ran GAP1 and Ran BP1, the RanGTP component of the export complex is converted to the RanGDP form and the complex disassembles (245,462). Rev is released along with its unspliced and partially spliced HIV-1 RNA “cargo,” allowing the latter to be incorporated into progeny virions or be translated into viral proteins. It should be noted that microinjection studies utilizing *Xenopus* oocytes have shown that the export of Rev-responsive RNAs is blocked in the presence of a RanGTP mutant unable to undergo GTP hydrolysis (336). Rev therefore enables lentiviral intron-containing RNAs to elude the cellular splicing machinery and to be transported to

the cytoplasm via an export pathway not used by most cellular mRNAs.

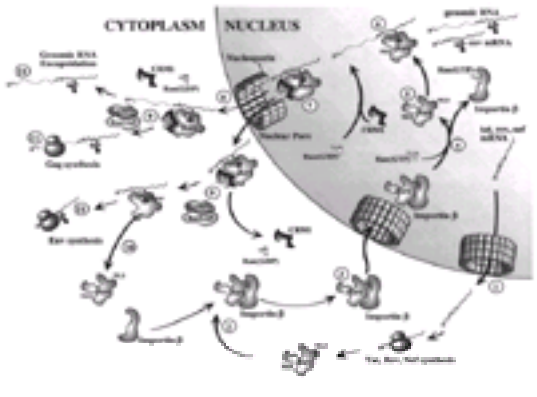

FIG. 16. Rev nuclear export pathway. Intronless multiply spliced HIV-1 mRNAs (*tat*, *rev*, and *nef*) use a Rev-independent pathway to exit the nucleus (*1*). Using its nuclear localization signal (NLS), newly synthesized Rev protein binds to importin b (*2*) and the resulting heterodimer (*3*) is translocated through the nuclear pore. In the nucleus, Rev/ importin b dissociation is mediated by Ran(GTP) (*4*) and the free Rev protein binds (*5*) to RRE-containing viral pre-mRNAs (*6*). The Rev/RRE RNA complex is converted to a functional export structure following the addition of CRM1 and Ran(GTP) (*7*) and is transported through the nuclear pore (*8*). In the cytoplasm, RanBP1/RanGAP mediate the conversion of Ran(GTP) in the export complex to Ran(GDP) (*9*), which then disassembles. Following the release of Rev from intron-containing HIV-1 transcripts (*10*), the full-length viral RNA may be encapsidated into progeny virions or, as is the case for the partially spliced mRNAs, may be translated into viral proteins (*11*). (Drawing kindly provided by Dr. Michael Cho.)

It is also worth noting that a constitutive transport element (CTE), isolated from the genomes of type D retroviruses such as Mason-Pfizer monkey virus (MPMV) and simian retrovirus-1, can functionally substitute for the Rev protein and facilitate the nuclear export of unspliced or partially spliced HIV RNAs (55,712). CTEs are likely to be present in the genomes of simple retroviruses that do not encode their own Rev-like transactivating proteins and presumably bind to cellular factors that mediate nucleocytoplasmic transport (433,469,585). One such candidate is the human TAP protein, which binds to CTE loop sequences and mediates nuclear export of CTE-containing RNAs, as monitored in the *Xenopus* oocyte system (256). Microinjection of the MPMV CTE blocks mRNA but not Rev/NES or tRNA nuclear export, suggesting that in *Xenopus* cells, at least, CTE-containing substrates and cellular mRNAs use a nucleus-to-cytoplasm transport system different from that employed by Rev (490).

Gag

The Gag proteins of HIV, like those of other retroviruses, are necessary and sufficient for the formation of noninfectious, virus-like particles. Retroviral Gag proteins are generally synthesized as polyprotein precursors; the HIV-1 Gag precursor has been named, based on its apparent molecular mass, $Pr55^{Gag}$. As noted previously, the mRNA for $Pr55^{Gag}$ is the unspliced 9.2-kb transcript (Fig. 5 and Fig. 13) that requires Rev for its expression in the cytoplasm. When the *pol* ORF is present, the viral protease (PR) cleaves $Pr55^{Gag}$ during or shortly after budding from the cell to generate the mature Gag proteins p17 (MA), p24 (CA), p7 (NC), and p6 (see Fig. 5). Two spacer peptides are also cleaved out of the Gag precursor: p2, located between CA and NC, and p1, situated between NC and p6. In the virion, MA is localized immediately inside the lipid bilayer of the viral envelope, CA forms the outer portion of the cone-shaped core structure in the center of the particle, and NC is present in the core in a ribonucleoprotein complex with the viral RNA genome (Fig. 17). The location of p6 in the virion remains to be precisely defined. Retroviral Gag proteins perform several principal functions during virus assembly, including (a) forming the structural framework of the virion, (b) encapsidating the viral genome, (c) targeting the nascent particle for export from the cell, and (d) acquiring a lipid bilayer and associated envelope (Env) glycoproteins during particle release (for review, see ref. 192, and Chapter 8). These processes require that Gag proteins participate in protein–protein, protein–RNA, and protein–lipid interactions. As described later, Gag proteins also play critical roles in the early stages of the virus replication cycle.

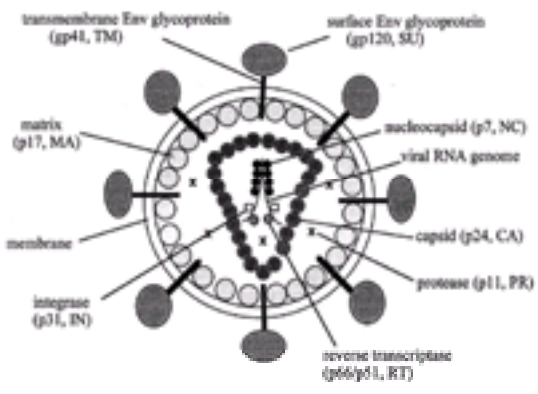

FIG. 17. Schematic representation of a mature HIV-1 virion. (Adapted from ref. 192, with permission.)

The HIV $Pr55^{Gag}$ precursor oligomerizes following its translation and is targeted to the plasma membrane, where particles of sufficient size and density to be visible by EM are assembled. Formation of virus-like particles by $Pr55^{Gag}$ is a self-assembly process, with critical Gag–Gag interactions taking place between multiple domains along the Gag

precursor. The assembly of virus-like particles does not require the participation of genomic RNA (although the presence of nucleic acid appears to be essential), *pol*-encoded enzymes, or Env glycoproteins, but the production of infectious virions requires the encapsidation of the viral RNA genome and the incorporation of the Env glycoproteins and the Gag-Pol polyprotein precursor $Pr160^{Gag\text{-}Po}$. Processing of the Gag and Gag-Pol precursor proteins by PR concomitant with budding results in a major structural and morphologic rearrangement, referred to as maturation, during which the core condenses into the cone-shaped structure characteristic of the mature HIV particle (see Fig. 1A). Disruption of this maturation process abolishes virus infectivity.

Detailed NMR and x-ray crystallographic data have provided significant insights into the structure–function relationship of HIV-1 MA, CA, and NC (see later). It remains to be seen, however, to what extent the structures of the mature Gag proteins will reflect those of the corresponding domains of $Pr55^{Gag}$. In some instances, for example at the N-terminus of CA, major refolding accompanies PR-mediated $Pr55^{Gag}$ cleavage. We can hope that future technologic advances will allow this issue to be addressed as structures of larger portions of $Pr55^{Gag}$ are solved.

Matrix Domain

The MA domain of $Pr55^{Gag}$ (Fig. 18A) performs several essential functions during the viral life cycle. Following Gag synthesis, MA directs $Pr55^{Gag}$ to the plasma membrane via a multipartite membrane binding signal. The affinity of the MA domain for membrane is provided in part by a myristic acid moiety covalently attached to the N-terminal Gly of MA. Mutation of this residue significantly impairs binding of Gag to membrane and abolishes virus assembly in most systems. Sequences in MA downstream of the myristate also contribute to membrane binding. NMR and x-ray crystallographic analyses of HIV-1 MA [as well as MA of SIV, bovine leukosis virus (BLV), HTLV-II, and MPMV] suggest that residues in a highly basic patch cluster on the face of MA predicted to juxtapose the plasma membrane (Fig. 19) (422; for review, see ref. 114). It has been proposed that these basic residues interact with the negatively charged acidic phospholipids on the inner leaflet of the lipid bilayer, thereby stabilizing membrane interactions (277,422,708). Mutations affecting these basic residues can be detrimental to virus assembly (194,695,707). The finding that $Pr55^{Gag}$ binds membrane more tightly than MA itself led to the suggestion that MA undergoes a conformational switch following Gag cleavage that triggers its partial release from membrane (708). An analogous switch in membrane binding potential has been described in detail for the retinal rod sensor protein recoverin, which upon binding calcium undergoes a conformation change, referred to as a “myristyl switch,” that exposes the myristate moiety and induces membrane binding. A prediction of this model is that mutations in MA downstream of the myristylation consensus signal might increase or decrease Gag membrane binding, perhaps by altering MA conformation; indeed, such mutations have been reported (330,474,483,593). The ability of MA to partially dissociate from membrane after PR-mediated Gag cleavage would in theory allow it to participate in post-entry steps in virus replication (see later).

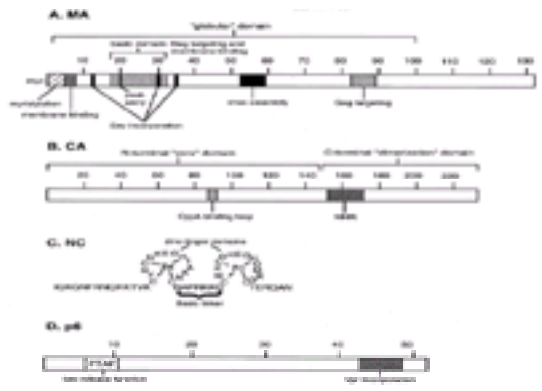

FIG. 18. Linear organization of the major HIV-1 Gag proteins. *Panel A*, matrix (MA); *panel B*, capsid (CA); *panel C*, nucleocapsid (NC); *panel D*, p6. Amino acid positions are indicated, as are major functional domains. (Adapted from ref. 192, with permission.)

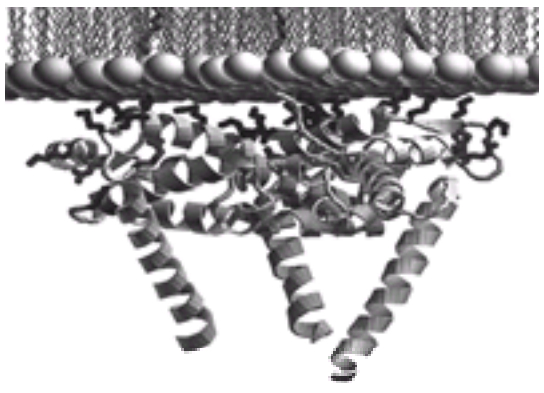

FIG. 19. Structure of a MA trimer bound to membrane. At the *top* is depicted the lipid bilayer; myristate moieties are shown embedded in the bilayer. The helical C-terminal tail of MA is shown projecting away from the globular core. (Reprinted from ref. 284, with permission.)

The mechanism by which Gag traffics specifically to the plasma membrane rather than to intracellular membranes is still under investigation. Deletion of a large portion of MA (169), as well as single amino acid changes between MA residues 84 and 88 (202,476), cause virus assembly to be redirected to cytoplasmic compartments. Thus, MA appears to contain

determinants not only of membrane binding, but, more specifically, of plasma membrane targeting. A role for MA in targeting is supported by the finding that substitution of MA with a heterologous membrane binding signal results in promiscuous assembly both at the plasma membrane and at intracellular sites (520). That a substitution in the MA highly basic domain corrected the mistargeting induced by a residue-86 mutation (475) supports the notion that the basic domain may be a determinant not only of membrane binding but also of plasma membrane targeting. This hypothesis is consistent with the finding that a basic domain deletion appeared to cause a defect in Gag transport (695), and that more subtle mutations in this region retargeted virus assembly to an intracellular site (476).

After Gag binds the plasma membrane, it assembles into particles that bud from the cell. During budding, the viral Env glycoproteins are incorporated into the nascent virions. MA plays a crucial role in this process; small deletions, insertions, and specific point mutations in MA block Env incorporation without perturbing virus assembly. Interestingly, the block to Env incorporation imposed by MA mutations can be reversed by pseudotyping virions with heterologous Env glycoproteins containing short cytoplasmic tails, or by removing sequences within the long cytoplasmic tail of the HIV-1 TM glycoprotein gp41 (196,197,408). These results imply that a specific interaction takes place between MA and gp41, or that MA has evolved to accommodate the long gp41 cytoplasmic tail. Although a direct interaction has been difficult to demonstrate in virus-infected cells, *in vitro* data supporting an HIV-1 MA–gp41 interaction have been reported (117). A direct interaction is also suggested by the ability of HIV-1 Env to induce basolateral Gag budding in polarized epithelial cells (380), and by the recent finding that a single amino acid substitution in MA reversed the Env incorporation defect imposed by a small deletion near the center of the gp41 cytoplasmic tail (448). X-ray crystallographic analysis of both SIV and HIV-1 MA reveals that MA may form trimers that assemble into a higher-order lattice containing holes into which the long cytoplasmic tail of gp41 could insert (284,516). Although this hypothesis provides an appealing model for Env incorporation that is consistent with mutational analyses, the biologic relevance of MA trimerization is currently unclear.

In addition to its function in virus assembly and Env incorporation, it has also been proposed that MA plays a role early in the virus life cycle after Env-induced membrane fusion. Early postfusion steps, which are collectively referred to as uncoating, are poorly understood, and it is not clear mechanistically how MA functions in this process. Nevertheless, it has been reported that mutations in MA impair the synthesis of viral DNA early postinfection, suggesting an early post-entry block (78,330,690). It has also been observed that MA mutants with this “early” defect display impaired endogenous RT activity and increased Gag membrane binding (330). A correlation between increased MA membrane binding and a post-entry defect is consistent with the hypothesis that an inability of MA to disengage from the lipid bilayer after membrane fusion results in an uncoating defect and destabilization of the subviral complex in which reverse transcription takes place (330).

Lentiviruses, including HIV-1, are unique among retroviruses in their ability to infect nondividing cells. It has been proposed that the basic domain of MA, discussed earlier in the context of membrane binding, plays a role in translocating the viral preintegration complex to the nucleus (63,274,645). It was also reported that phosphorylation of a Tyr residue at the C-terminus of MA is required for infectivity in fully differentiated (nondividing) macrophages (214). However, certain key aspects of these studies have been questioned (62,186,193,194 and 195,520). Currently, it appears that Vpr (see section on Vpr) and perhaps IN (213), but not MA, play the dominant role in transporting the preintegration complex to the nucleus. It has also recently been proposed that a central DNA “flap” that is a product of lentiviral reverse transcription (see section on reverse transcription) may promote nuclear import of the viral preintegration complex (701).

Capsid Domain

Like MA, CA functions in both early and late steps in virus replication. CA is composed of two structural and functional domains: the N-terminal two-thirds of the protein forms the so-called core domain, and the C-terminal one-third is referred to as the dimerization domain (see Fig. 18B). NMR and x-ray crystallographic data are available for both domains (217,237,440), but the structure of the entire protein has not yet been resolved. The core domain (residues 1 to 146) is highly helical, with an exposed, cyclophilin A–binding loop (217, and see later); the C-terminal domain (residues 148 to 231) is also highly helical and globular (218). The N-terminus of the dimerization domain contains the major homology region (MHR) (668), which, apart from the zinc-finger motifs in NC, is the only sequence in Gag that displays significant amino acid identity between divergent retrovirus genera. The structures of the N- and C-terminal domains of CA have been combined to create a hypothetical structure for the intact CA (Fig. 20) (218,674).

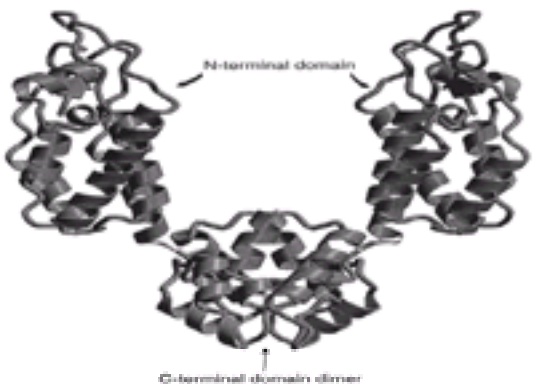

FIG. 20. Model of an HIV-1 CA dimer. The N-terminal core domain is shown at the *top*; the C-terminal dimerization domain is depicted at the *bottom.* The two domains are connected by CA residues 146 and 147. (Reprinted from ref. 674, with permission.)

Mutations within CA produce a range of phenotypes: Those in the C-terminal, dimerization domain often elicit assembly defects, whereas changes in the N-terminal core domain generally do not affect the efficiency of virus production, but

rather can inhibit proper virion maturation after release and severely impair infectivity. These results have led to the proposal that the C-terminus of CA promotes Gag multimerization, whereas the N-terminus plays a role in core condensation and morphogenesis. Mutations in the MHR disrupt virus assembly, maturation, and infectivity. Structural analysis of the dimerization domain revealed that MHR residues form a network of intramolecular hydrogen bonds that stabilize the structure of the entire domain (218). Residues 146 to 151 appear to promote the creation of a high-affinity CA interface, which, in conjunction with a more N-terminal b-hairpin interface, is postulated to drive the formation of higher-order CA interactions during assembly and maturation (218).

Using the yeast two-hybrid system, it was demonstrated that HIV-1 Gag binds members of the cyclophilin family of proteins, which function in the cell as peptidyl-prolyl cis-trans isomerases (389). Further investigation indicated that one of these proteins, cyclophilin A, is specifically incorporated into HIV-1 virions (190,618); this incorporation is mediated by an interaction between cyclophilin A and a Pro-rich region near CA amino acid 90 (190). It is noteworthy that the Gag–cyclophilin A interaction is unique to HIV-1; HIV-2 and SIV Gag proteins neither bind cyclophilins nor incorporate them into virions. Treatment of HIV-1-infected cells with cyclosporin A or its analogs, or mutation of CA residues that participate in the CA–cyclophilin A interaction, block the incorporation of cyclophilin A into virions and reduce virus infectivity. Mutant or drug-treated virions, which are impaired for cyclophilin A incorporation, are defective at an early step in the virus life cycle, apparently after membrane fusion but before the initiation of reverse transcription. The mechanism by which cyclophilin A incorporation enhances infectivity is currently unclear. The N-terminal domain of CA forms planar strips between which cyclophilin A intercalates at a Gag-to-cyclophilin A ratio of approximately 10:1; it has been proposed that cyclophilin A might destabilize CA-CA interactions, thereby promoting efficient uncoating after virus entry (217). Alternatively, cyclophilin A in the virion may function as a chaperone during maturation by promoting proper CA refolding and by minimizing unfavorable CA aggregation after Gag processing (250,658).

Several studies have reported that HIV-1 CA, when expressed *in vitro*, is capable of assembling into tubular or spherical particles (157,647). CA-NC fusion proteins form tubes *in vitro* at protein concentrations lower than those required to assemble into similar structures with CA alone; in the case of CA-NC, tube formation appears to depend on the presence of RNA (72). Interestingly, adding as few as four residues of MA to the N-terminus of CA converts *in vitro* particle assembly from tubes to spheres (647). This observation led to the hypothesis that PR-mediated processing at the MA-CA junction causes a major refolding of the CA N-terminus, and that this structural rearrangement plays a key role in promoting the morphologic changes that occur during core condensation. Recently, it was reported that core-like cones can be assembled *in vitro* using CA-NC fusion proteins and RNA; these cones are organized in a manner reminiscent of the fullerene structures formed by elemental carbon (220).

Nucleocapsid Domain

The third major domain synthesized as part of the Gag precursor is the NC (see Fig. 18C). A principal function of NC involves the specific encapsidation of full-length, unspliced (genomic) RNA into virions, although, as is the case with the other Gag proteins, NC serves multiple roles during the virus life cycle. With the exception of the spumaretroviruses, all retroviral NC proteins contain one or two zinc-finger motifs. Unlike most cellular zinc-finger domains, those of retroviruses are of the CCHC type (Cys-X_2-Cys-X_4-His-X_4-Cys). HIV-1 NC contains two zinc-finger motifs, which bind zinc tightly both *in vitro* and in virions (38,591). NMR data indicate that the two HIV-1 NC zinc fingers are brought together into a central globular domain by a highly basic linker domain (see Fig. 18C), which appears to be very flexible (443,608). Mutations that abrogate zinc binding abolish genome encapsidation and virus infectivity. Other mutations within the zinc-finger domains increase the level of spliced versus unspliced viral RNA encapsidated into virions. NC also contains two clusters of basic residues flanking the first zinc finger; mutations in these sequences impair the binding of NC to RNA *in vitro* and RNA encapsidation into virions. NC engages in both sequence-specific and sequence-nonspecific interactions with nucleic acid; in general, the sequence-specific interactions involve the zinc fingers in conjunction with the basic residues, whereas nonspecific interactions are driven largely by the highly basic nature of NC. The specificity of HIV genome encapsidation results from an interaction between NC and an approximately 120-nt sequence located between the 5' LTR and the Gag initiation codon. This sequence, variously known as the packaging signal, encapsidation element, or y-site, folds into a series of four stem-loops (see Fig. 6; for review on RNA encapsidation, see ref. 36). It appears that this secondary structure, rather than the primary nucleotide sequence itself, confers RNA encapsidation specificity. The structure of the HIV-1 NC protein complexed with stem-loop 3 of the y-site was determined by NMR spectroscopy (Fig. 21) (130); this structure indicates the involvement of both basic and zinc-finger residues in the NC–y interaction. In addition to this specific interaction with the y-site, NC may coat the viral RNA in the mature virus particle.

FIG. 21. Complex between NC and stem-loop 3 (SL3) of the HIV-1 packaging signal. The two zinc ions coordinated by the zinc-finger domains are shown as gray balls. (Reprinted from ref. 628, with permission.)

Many HIV-1 NC mutations cause defects in virus assembly and release. This observation suggests a role for NC in Gag

multimerization, a function mapping largely to the N-terminal basic domain, rather than the zinc fingers. NC appears to play a role in the tight packing of Gag in virions, leading to the production of particles with a density characteristic of retroviral particles (29). It is suspected that NC-RNA interactions are critical for promoting Gag multimerization; according to this model, RNA provides a template along which molecules of $Pr55^{Gag}$ can align and pack. Binding between the NC domain of $Pr55^{Gag}$ and components of the host cell cytoskeleton (F-actin in particular) may also facilitate Gag assembly and transport (376,524,660). It has been proposed that NC plays an important role in binding of HIV-1 Gag to membrane (503,550). However, using membrane flotation centrifugation methods, which effectively distinguish membrane-bound from non-membrane-bound protein, it was determined that a truncated Gag molecule containing only MA and the N-terminal domain of CA exhibited steady-state membrane binding properties comparable to those of $Pr55^{Gag}$ (473).

In addition to its role in RNA encapsidation and Gag assembly, other functions for HIV-1 NC have been observed. Many of these functions can be attributed to a “nucleic acid chaperone” (282) activity. This property of NC enables it to catalyze the refolding of nucleic acid molecules into structures with the most thermodynamically favorable conformation (i.e., the greatest number of base pairs) (for review, see ref. 522). NC, or the NC domain of $Pr55^{Gag}$, contributes to RNA dimerization, binding of the $tRNA^{Lys3}$ primer to the primer-binding site, stabilization or “maturation” of the intermolecular interactions between the dimeric RNAs in the virion, initiation of reverse transcription from the $tRNA^{Lys3}$ primer, and strand transfers during reverse transcription. The nucleic acid chaperone activity of NC appears to require that NC molecules coat nucleic acid at near-saturating levels of approximately one molecule of protein per seven nucleotides. The basic nature of NC plays a more critical role in this activity than the integrity of the zinc fingers (522).

Several additional functions for NC early in the virus replication cycle have been reported. Mutations in HIV-1 NC may impair infectivity by destabilizing newly reverse-transcribed viral DNA (37). Studies performed with MuLV demonstrated that changing the single CCHC zinc-finger motif to CCCC or CCHH had no effect on zinc binding, tRNA incorporation, RNA encapsidation, or RNA maturation but profoundly impaired virus infectivity (243). Detailed examination of viral DNA in mutant-infected cells revealed that full-length, circular DNA products were formed inefficiently and that a variety of mutations (deletions and insertions) were present at the DNA ends (243). Such aberrations, if present at the ends of linear DNAs, would render these DNAs unsuitable for integration. Similar mutations in the N-terminal zinc finger of the HIV-1 NC have been reported; these changes resulted in defects late in reverse transcription, leading to a lack of circular DNA production (612). It has also been reported that NC stimulates “coupled joining” (wherein both ends of the viral genome integrate into a target DNA) in *in vitro* integration reactions (77) (see section on integrase). Mutations in the NC zinc fingers modulated this stimulatory effect (77).

Because NC participates in multiple steps in the virus life cycle, and because the retroviral CCHC-type zinc-finger motif is relatively rare among cellular proteins, NC presents an attractive target for antivirals. Promising anti-NC compounds attack the sulfurs on the zinc-coordinating Cys residues and cause zinc to be “ejected” from the zinc fingers (526,527). These compounds effectively inhibit virus replication in culture without significant cytotoxicity. Fourteen compounds that demonstrated anti-NC activity *in vitro* were tested for their effect on MuLV replication *in vivo*. One of these compounds, Aldrithiol-2 (2,2'-dithiopyridine), delayed the onset of MuLV-induced disease and reduced virus loads in infected mice (480). Such compounds could also in theory be used to render stocks of HIV particles noninfectious for use in vaccine studies (538).

p6 Protein

In addition to the MA, CA, and NC proteins, retroviral *gag* genes encode a variety of additional ORFs that are generally unique to a particular genus of retrovirus (for review, see ref. 668). HIV-1 encodes a Pro-rich, 6-kd protein, known as p6, at the C-terminus of $Pr55^{Gag}$ (see Fig. 18D). Mutation of p6, specifically within a highly conserved Pro-Thr-Ala-Pro (PTAP) motif, blocks a late step in virus assembly such that virions accumulate at the plasma membrane but fail to release efficiently (248,293). Interestingly, mutation of PR largely reverses this defect (293), suggesting a functional interplay between p6 and PR function, and perhaps explaining why some groups, using Gag-only expression systems, failed to detect a requirement for p6 in virus production. p6 also functions to direct the incorporation of Vpr and Vpx into virions (494,678).

In addition to HIV-1 p6, domains encoded by other retroviral Gag proteins serve analogous “late” roles in virus release. These include p2b of Rous sarcoma virus (667), pp16 of MPMV (685), p9 of equine infectious anemia virus (EIAV) (511), and p12 MuLV (693). Interestingly, at least in certain cases, these late domains can function independently of their position in Gag and can be exchanged from one retrovirus to another (488). These late domain proteins all contain motifs that have been implicated in protein–protein interactions: Pro-X-X-Pro in HIV-1 p6; Pro-Pro-Pro-Tyr in RSV p2b, MPMV pp16, and MuLV p12; and Tyr-X-X-Leu in EIAV p9 (228). It has been proposed that these proteins interact with host cell plasma membrane proteins to facilitate the final release step during virus budding (228). Indeed, p2b of RSV binds proteins containing so-called WW motifs (228), and EIAV p9 has been reported to interact with the AP-2 adapter protein complex (512). Recent evidence implicates the host ubiquitination machinery in the function of retroviral late domains 642a).

Pol

Downstream of *gag* lies the most highly conserved region of the HIV genome, the *pol* gene, which encodes three enzymes: PR, RT, and IN (see Fig. 5). RT and IN are required, respectively, for reverse transcription of the viral RNA genome to a double-stranded DNA copy, and for the integration of the viral DNA into the host cell chromosome. PR plays a critical role late in the life cycle by mediating the production of mature, infectious virions. The *pol* gene products are derived by enzymatic cleavage of a 160-kd Gag-Pol fusion protein, referred to as $Pr160^{Gag\text{-}Pol}$. This fusion protein is produced by ribosomal frameshifting during translation of $Pr55^{Gag}$ (see Fig. 5 and Fig. 6C). The frame-shifting mechanism for Gag-Pol expression, also utilized by many other retroviruses, ensures that the *pol*-derived proteins are expressed at a low level, approximately 5% to 10% that of Gag. Like $Pr55^{Gag}$, the N-terminus of $Pr160^{Gag\text{-}Pol}$ is myristylated and targeted to the plasma membrane.

Protease

Early pulse-chase studies performed with avian retroviruses clearly indicated that retroviral Gag proteins are initially synthesized as polyprotein precursors that are cleaved to generate smaller products (643,644). Subsequent studies demonstrated that the processing function is provided by a viral rather than a cellular enzyme, and that proteolytic digestion of the Gag and Gag-Pol precursors is essential for virus infectivity (120,323). Sequence analysis of retroviral PRs indicated that they are related to cellular “aspartic” proteases such as pepsin and renin (for review, see ref. 126). Like these cellular enzymes, retroviral PRs use two apposed Asp residues at the active site to coordinate a water molecule that catalyzes the hydrolysis of a peptide bond in the target protein. Unlike the cellular aspartic proteases, which function as pseudodimers (using two folds within the same molecule to generate the active site), retroviral PRs function as true dimers. X-ray crystallographic data from HIV-1 PR (352,458,671) indicate that the two monomers are held together in part by a four-stranded antiparallel b-sheet derived from both N- and C-terminal ends of each monomer (Fig. 22). The substrate binding site is located within a cleft formed between the two monomers. Like their cellular homologs, the HIV PR dimer contains flexible “flaps” that overhang the binding site and may stabilize the substrate within the cleft; the active-site Asp residues lie in the center of the dimer. Interestingly, although some limited amino acid homology is observed surrounding active-site residues, the primary sequences of retroviral PRs are highly divergent, yet their structures are remarkably similar.

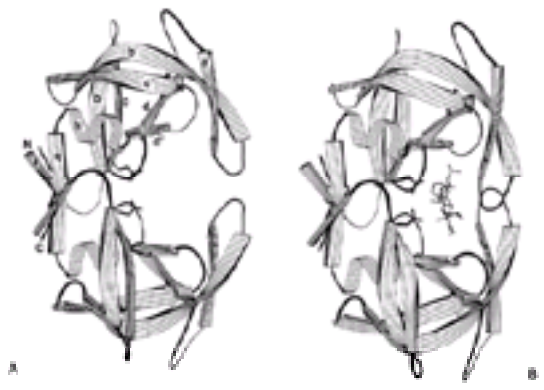

FIG. 22. Structure of the HIV-1 PR dimer uncomplexed (**A**) or complexed (**B**) with the PR inhibitor Ro-31-8558. The following domains are indicated in the first half of the molecule: b-strands *a* (residues 1 to 4), *b* (residues 9 to 15), *c*, and *d* (residues 30 to 35). The active-site residues are at positions 25 to 27. The second half of the molecule is structurally related to the first half, with the following domains indicated: b-strands *a′* (residues 43 to 49), *b′* (residues 52 to 66), *c′* (69 to 78),*d′* (83 to 85), and helix *h′* (86 to 94). The inner portion of the dimer interface is formed by b-strand *q* (residues 95 to 99). (Reprinted from ref. 670, with permission.)

The first cleavage events catalyzed by retroviral PRs during or immediately after virion release from the cell serve to liberate PR from the Gag-Pol precursor. It is still unclear whether this initial cleavage event takes place in cis (intramolecularly) or in trans (intermolecularly); in either case, following the release of PR from the Gag-Pol precursor, the dimeric enzyme cleaves a number of sites in both Gag and Gag-Pol (see Fig. 5). The efficiency with which PR cleaves the individual target sites in Gag and Gag-Pol varies widely and is influenced by two major factors: the amino acid sequence at the site of cleavage, and the context (i.e., the degree of exposure or accessibility) of the cleavage site. The proteolytic processing of model proteins and substrate analogs by the HIV-1 PR indicates that the binding cleft can accommodate a peptide of approximately seven residues in length, and synthetic peptides of this size are cleaved *in vitro* (40). Although a number of studies have attempted to define a consensus target sequence for HIV-1 PR, the rules governing which sites can be cleaved are fairly loose. As a consequence of the relatively divergent PR target sequences present in Gag, and the varying efficiencies with which these sites serve as substrates for PR activity, Gag cleavage takes place as an ordered, step-wise cascade. Processing at the amino terminus of NC is the most rapid *in vitro*, whereas the cleavage converting p25 to p24 CA is the slowest. Mutations in Gag that disrupt the ordered nature of PR-mediated processing severely disrupt virus assembly or subsequent maturation. Furthermore, HIV-1 mutants engineered to synthesize a linked PR dimer (i.e., a duplicated PR-coding region) exhibit rapid, premature processing of Gag and Gag-Pol polyproteins and a block in virus production (349).

PR appears to be most active during the budding process just prior to particle release from the cell (320). PR cleavage of the Gag and Gag-Pol precursors leads to a dramatic change in virion morphology, a process known as maturation. Immature retroviral particles (for example, those produced in the presence of PR inhibitors or an inactive PR) appear doughnut-shaped by EM. In contrast, mature virions contain condensed cores, which in the case of the lentiviruses are cone-shaped (Fig. 1A). Cryo-EM studies have suggested that in immature virions, Gag precursors are aligned in a rodlike fashion like spokes on a wheel, with the N-terminal MA domain associated with the viral lipid and the C-terminus projecting inwards toward the center of the virion (208,686). According to this model, cleavage of Gag by PR releases CA, NC, and p6 from their attachment (via MA) to the lipid and allows CA to form a shell around the NC–RNA complex. One would predict that numerous conformational changes take place within the Gag proteins upon cleavage that allow this structural reorganization to take place. In one case, a major, cleavage-induced refolding has been characterized (see section on CA); however, much remains to be learned about the molecular details of core condensation.

It is clear that premature Gag and Gag-Pol cleavage is severely detrimental to virus assembly. Thus, the activation of PR must be tightly controlled to prevent significant processing prior to the completion of assembly. It is not yet understood how premature PR activation is prevented. One model proposes that the concentration of Gag and Gag-Pol precursor proteins plays the key role in PR activation; sufficiently high concentrations are not achieved until assembly has taken place. This model fails to account for the fact that type B/D retroviruses assemble in the cytoplasm, yet the particles that

form maintain an unprocessed, immature state until budding and release have occurred. It has also been suggested that the plasma membrane may provide an environment uniquely compatible with Gag/Gag-Pol processing and virion maturation. However, MA mutations have been described that redirect assembly to the Golgi apparatus or Golgi-derived vesicles; the resulting redirected virus particles can undergo Gag processing and maturation at the intracellular site (202,476). In the case of HIV-1 PR, but not all retroviral PRs, some Gag cleavage can occur in the absence of membrane binding. This point is illustrated by the observation that mutations that block Gag myristylation, and consequently impair membrane binding, do not fully block Gag processing (249). The assembly of high-molecular-weight Gag complexes in the absence of, or prior to, membrane binding (360) suggests that processing of non-membrane-bound Gag may still take place within a large, multimeric Gag/Gag-Pol complex.

HIV-1 PR activity is not limited to cleavage of the Gag and Gag-Pol precursors. Nef is a substrate for PR cleavage, although the implications for Nef function remain unclear (see section on Nef). The cytoplasmic domains of some retroviral Env proteins (e.g., MuLV and MPMV) are also cleaved by PR; in such cases, the cleavage event is essential for Env function (515,523,590). Although no evidence exists that HIV PR cleaves the cytoplasmic tail of gp41, it efficiently cleaves the cytoplasmic domain of the MuLV TM Env protein in HIV-1 virions pseudotyped by MuLV Env (329). The finding that PR-mediated processing of the MuLV TM can be blocked by HIV-1 MA mutations (329) has implications for the use of HIV-based vectors pseudotyped with MuLV Env. In addition to cleavage of viral proteins, PR has been reported to act on a number of cellular proteins (for review, see ref. 642). The role of such events in virus replication and virus-induced cytotoxicity has not been fully elucidated.

Compounds that inhibit HIV-1 PR function have proven to be the most effective antiviral drugs presently available. The development of PR inhibitors represents a classic example of structure-based drug design; detailed knowledge of the topology of the substrate binding site, the enzyme–substrate interaction, and the chemistry of the cleavage reaction enabled investigators to synthesize a large number of inhibitors that potently inhibit PR in culture at nanomolar concentrations. The earliest PR inhibitors were small oligopeptide derivatives that mimicked PR target sequences but contained nonhydrolizable groups (e.g., hydroxyethylenes, hydroxyethylamines, and dihydroxyethylenes) at the P1 and P1' positions flanking the scissile bond that PR would normally cleave. The early, peptide-based inhibitors were subsequently modified to improve stability and bioavailability, and the structure of the PR active site was used to design novel inhibitory compounds (670). When PR inhibitors are used to treat HIV-infected patients, virus loads decline precipitously, but drug-resistant variants soon emerge. Sequencing of the PR coding region of drug-resistant variants often reveals consistent changes. For example, saquinavir escape mutants frequently contain changes at PR residue 48 and/or 90 (308); ritonavir resistance is often associated with mutations at PR residue 82 (439). The initial changes that confer drug resistance generally result in only partial resistance and may be accompanied by decreased “fitness” (i.e., impaired PR function relative to wild type in the absence of drug) (121). With time, however, additional changes take place within PR that increase resistance and improve fitness. The same secondary mutations are often observed during escape from different PR inhibitors; these changes increase resistance and allow adaptation to the original drug-resistance-conferring mutation. Unfortunately, mutations that arise in the presence of one inhibitor frequently induce at least partial resistance to others (113), a phenomenon known as cross-resistance. In addition to changes in PR, mutations that affect the natural PR targets (i.e., the Gag and Pol cleavage sites) have also been observed (149). Whereas monotherapy with PR inhibitors generally leads to rapid resistance, longer-lasting benefits are achieved with so-called triple therapy (also known as highly active antiretroviral therapy, or HAART), in which a PR inhibitor (e.g., indinavir or saquinavir) is combined with two RT inhibitors (e.g., AZT and 3TC).

Reverse Transcriptase

By definition, retroviruses possess the ability to convert their single-stranded RNA genomes into double-stranded DNA during the early stages of the infection process (20,615). The enzyme that catalyzes this reaction is RT, in conjunction with its associated RNaseH activity. Retroviral RTs have three enzymatic activities: (a) RNA-directed DNA polymerization (for minus-strand DNA synthesis), (b) RNaseH activity (for the degradation of the tRNA primer and genomic RNA present in DNA–RNA hybrid intermediates), and (c) DNA-directed DNA polymerization (for second- or plus-strand DNA synthesis).

The retroviral genome is packaged in the virion as two copies of single-stranded RNA. The two RNAs, which are identical or at least highly homologous, are held together in part by a sequence near their 5' ends known as the dimer initiation signal (see Fig. 6). Although each retroviral particle carries two strands of RNA, it appears that only one provirus is formed per virion (291). Retroviruses are therefore referred to as pseudodiploid. As with other DNA polymerase reactions, reverse transcription is dependent on the 3'-OH group of a primer to initiate polymerization. Retroviruses employ specific tRNAs for this function—$tRNA^{Lys3}$ in the case of HIV-1. The mechanism of tRNA selection and placement on the template is complex, involving interactions with RT and NC as well as with the 18-nt pbs near the 5' end of the viral genome. Although the interaction between $tRNA^{Lys3}$ and the HIV-1 genomic RNA involves primarily the tRNA 3' end and the pbs, more extensive base pairing between these two RNAs has been proposed (301).

Reverse transcription of the retroviral RNA genome to a double-stranded DNA copy proceeds via a series of steps that are outlined briefly later. (For a more detailed description of this process, refer to recent reviews in refs. 246 and 613; and see Chapter 57.)

1. Minus-strand DNA synthesis is initiated from the 3'-OH of the tRNA bound to the pbs. DNA synthesis then proceeds to the 5' end of the genome.
2. RNaseH digests the RNA portion of the newly formed RNA/DNA hybrid, releasing the resulting short, single-stranded DNA fragment (known as the minus-strand strong-stop DNA).
3. The minus-strand strong-stop DNA is transferred to the 3' end of the genome where it hybridizes by virtue of a short region of homology (the “repeated” or R region) present at both 5' and 3' ends of the RNA genome. Whether this first strand transfer is intermolecular, intramolecular, or both has been the subject of some debate.
4. Minus-strand synthesis, accompanied by partial degradation of the RNA in the resulting RNA–DNA hybrid by RNaseH, continues to the pbs at the 5' end of the genome.
5. Fragments of RNA that were not removed by RNaseH serve as primers for plus-strand synthesis. The major site of

such priming occurs at the PPT; however, residual RNA fragments that remain hybridized to regions outside the PPT can also be used for priming plus-strand synthesis. In the case of HIV-1, one such region, known as the central PPT, appears to be particularly important in this regard (81).

6. RNaseH removes the tRNA that initially served as the primer for minus-strand synthesis. This exposes the pbs at the 3' end of the plus-strand DNA, allowing the plus-strand DNA to transfer (this is the second-strand transfer) and hybridize with the homologous region at the 3' end of the minus-strand DNA.
7. Plus- and minus-strand syntheses proceed to completion. Plus-strand synthesis terminates at the end of the minus strand and, for HIV, at a sequence known as the central termination signal (CTS) (82). The position of the central PPT upstream of the CTS results in the displacement of approximately 100 nt of plus-strand DNA and the formation of a triplex DNA structure. Interestingly, it has been suggested recently that this triplex, or “flap” structure may play a role in nuclear import of the viral preintegration complex (701). The final product of reverse transcription is a double-stranded DNA molecule capable of serving as the substrate for integration. Some discontinuities may remain in the final product; these can be resolved following integration (436).

In addition to serving an essential function in the virus life cycle, the enzymatic activity of RT is routinely used in the laboratory to quantitatively monitor levels of virus present in the supernate of infected cultures and to elucidate details of replication at the molecular level. Two types of assays are most commonly employed to measure RT activity. In the “exogenous” assay, virions are disrupted with detergent and the presence of RT is detected by its ability to extend a short oligonucleotide primer (e.g., oligo-dT) using an exogenously provided template [e.g., poly-r(A)] and a radiolabeled deoxynucleoside triphosphate (dNTP) (e.g., a-[^{32}P]TTP). In the “endogenous” reaction, virions are gently disrupted with a mild detergent treatment and provided with dNTPs (one of which is generally radiolabeled), and RT activity is monitored using the viral RNA genome as a template. Depending on the assay conditions, endogenous reactions result in the synthesis of discreet reverse transcription products (e.g., minus-strand strong-stop DNA) or a continuum of DNA species. The endogenous assay is less efficient than the exogenous assay, but because it measures the activity of RT in a relatively native complex, it more closely mimics the conditions of reverse transcription in an infected cell. These assays monitor RT activity in a cell-free setting. Although a limited amount of reverse transcription can take place in the virion under physiologic conditions (382, 626), the overwhelming majority of DNA synthesis does not occur until after entry into the target cell. Thus, the detection of postinfection viral DNA synthesis by polymerase chain reaction (PCR) provides the most reliable method for detecting entry and post-entry steps in the virus replication cycle. As mentioned elsewhere in this chapter, PCR amplification of viral DNA after infection has been used extensively to study defects imposed by mutations in Gag, Env, and accessory proteins.

The mature HIV-1 RT holoenzyme is a heterodimer of 66 and 51 kd subunits. The 51-kd subunit (p51) is derived from the 66-kd (p66) subunit by proteolytic removal of the C-terminal 15-kd RNaseH domain of p66 by PR (see Fig. 5). The structure of HIV-1 RT has been determined by x-ray crystallography in a number of studies. The enzyme was crystallized in several contexts: (a) complexed with the nonnucleoside inhibitor nevirapine (340), (b) bound to a short DNA duplex and the Fab portion of an anti-RT antibody (11, 306, 307), (c) unbound to DNA or inhibitor (165, 532), and, most recently, (d) covalently linked to a complex of primer/template, and dNTP (292). The crystal structure of HIV-1 RT reveals a highly asymmetric folding in which the orientations of the p66 and p51 subunits differ substantially. The p66 subunit can be visualized as a right hand, with the polymerase active site within the palm, and a deep template-binding cleft formed by the palm, fingers, and thumb subdomains (11, 307) (Fig. 23). The polymerase domain is linked to RNaseH by the connection subdomain. The active site, located in the palm, contains three critical Asp residues (110, 185 and 186) in close proximity, and two coordinated Mg^{2+} ions (Fig. 24). Mutation of these Asp residues abolishes RT polymerizing activity. The orientation of the three active-site Asp residues is similar to that observed in other DNA polymerases (e.g., the Klenow fragment of *E. coli* DNA polI) (10). The p51 subunit appears to be rigid and does not form a polymerizing cleft; Asp 110, 185, and 186 of this subunit are buried within the molecule. Approximately 18 base pairs of the primer–template duplex lie in the nucleic acid binding cleft, stretching from the polymerase active site to the RNaseH domain.

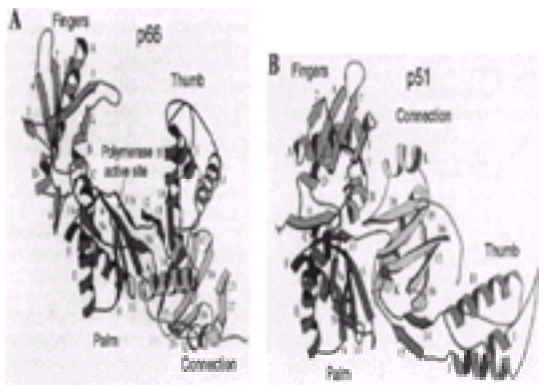

FIG. 23. Ribbon diagrams of the p66 (**A**) and p51 (**B**)RT subunits. Fingers, palm, thumb, and connection domains are shown. (Reprinted from ref. 307, with permission.)

FIG. 24. Active site of a covalently trapped HIV-1 RT catalytic complex. The deoxynucleoside triphosphate (dNTP) pocket is presented, with fingers at the *upper left*, palm in the *center*, and thumb at the *lower right.* The triphosphate of the incoming dNTP is coordinated by residues 65, 72, 113, and 114, and two Mg^{+2} ions. The three active-site Asp residues (110,185 and 186) are shown. A dideoxynucleotide chain terminator at the 3' end of the primer traps the complex prior to attack of the incoming dNTP. (Reprinted from ref. 292, with permission.)

In the RT-primer–template-dNTP structure (292) (see Fig. 24), the presence of a dideoxynucleotide at the 3' end of the primer allows visualization of the catalytic complex trapped just prior to attack on the incoming dNTP. This structure has been particularly informative regarding the orientation of RT with respect to the primer–template, and the location of mutations that confer resistance to RT inhibitors (see later). Comparison with previously obtained structures (see, e.g., ref. 307) suggests a model whereby the fingers close in to trap the template and dNTP prior to nucleophilic attack of the 3'-OH of the primer on the incoming dNTP. After the addition of the incoming dNTP to the growing chain, it has been proposed that the fingers adopt a more open configuration, thereby releasing the pyrophosphate and enabling RT to bind the next dNTP (292). The structure of the HIV-1 RNaseH has also been determined by x-ray crystallography; this domain displays a global folding similar to that of *E. coli* RNase H (127).

The high rate of variation among HIV populations poses one of the fundamental challenges to effectively controlling this pathogen (for reviews, see refs. 412,491, and 509). Variation in a retroviral population is influenced by several factors, including the mutation rate per replication cycle, the replication rate (i.e., number of cycles of virus replication per unit time) and the fixation rate (determined by the selective advantage or disadvantage conferred by a particular mutation) (104,105). High mutation rates are largely a consequence of the error-prone nature of RT, which lacks an exonucleolytic proofreading activity, and frequent template switching during reverse transcription (614). Cell-free error rates for purified RTs have been determined (24,510,530), as have *in vivo* retrovirus mutation rates (147,413,492,493). The cell-free error rate measured for HIV-1 RT is more than 10-fold higher than the mutation rate, suggesting that the *in vitro* reaction lacks factor(s) that increase fidelity (413). The total HIV-1 *in vivo* mutation rate (a composite of substitutions, frameshifts, simple deletions, and deletions with insertions) was measured at 3×10^{-5} per cycle of replication (413). Using similar methods, *in vivo* mutation rates of other retroviruses (e.g., spleen necrosis virus, MuLV, and BLV) were observed to be between 2-fold and 10-fold lower than that of HIV-1 (412).

As discussed earlier, retroviral particles contain two copies of single-stranded RNA. The requirement for template switching during reverse transcription appears to have selected for a low affinity between RT and template (614). As a result, template switches occur frequently during reverse transcription (491). Intramolecular jumps lead to mutations (e.g., deletions, insertions, and duplications), whereas intermolecular jumps generate recombinants.

Two general models have been suggested to explain recombination during reverse transcription. The first, which is operative during minus-strand synthesis, is referred as forced copy-choice (103). The second, which applies during plus-strand synthesis, has been named strand displacement-assimilation (317). The forced copy-choice model proposes that when RT encounters a break in the template RNA it jumps to the copackaged RNA and resumes DNA synthesis. This model has been refined more recently with the suggestion that jumps during minus-strand synthesis can occur in the absence of strand breaks (315). According to the strand displacement-assimilation model, the recombination process begins with the displacement of one fragment of internally initiated plus-strand DNA by another plus-strand transcript. The displaced fragment then binds, at a transient gap, to the complementary region of the minus-strand DNA derived from reverse transcription of the copackaged RNA. This intermediate is then resolved, most likely by cellular enzymes, to generate a recombinant double-stranded DNA copy of the viral genome (317). The impact of high rates of recombination on HIV populations is substantial; as noted earlier, 5% to 10% of sequenced virus isolates have been reported to be intersubtype recombinants (531), and recombinants comprise the predominant strains currently circulating in certain parts of the world. Recombination also provides a mechanism for the rapid generation of multiple-drug-resistant HIV variants. It should be noted that rates of mutation and recombination during reverse transcription can be affected by a variety of viral and cellular factors. Imbalances in the dNTP pools in the infected cell can increase the rate of mutation and template switching (316,421,634), and the fidelity of reverse transcription and frequency of recombination can be influenced by the composition of the large macromolecular complex in which reverse transcription takes place. For example, it has been reported that Vpr increases fidelity (411) and that NC promotes recombination (459).

RT has long been a target in the search for antiviral compounds. A number of RT inhibitors have been developed, including the nucleoside analogs [e.g., 3'-azido-3'-deoxythymidine (AZT or zidovudine), 2'-deoxy-3'-thiacytidine (3TC or lamivudine), 2',3'-dideoxyinosine (ddI or didanosine), and 2',3'-dideoxycytidine (ddC or zalcitabine)] and the nonnucleoside inhibitors (e.g., nevirapine and delavirdine). The nucleoside analogs act as chain terminators, whereas the nonnucleoside compounds inhibit DNA polymerization by binding a small hydrophobic pocket near the RT active site, thereby inducing an allosteric change at the active site (340). Unfortunately, resistance to these compounds develops rapidly in patients, probably reflecting the fact that resistant variants exist even before the initiation of therapy (105). As is the case for mutations that allow escape from PR inhibitors (see earlier), some changes in RT provide drug resistance whereas others appear to be adaptations to resistance-conferring mutations or function to increase levels of drug resistance. Analysis of the location of resistance mutations in the RT structure has provided important insights into the mechanism of resistance and should be useful in designing additional inhibitors that delay the appearance of escape mutants or effectively combat drug-resistant strains.

Integrase

A distinguishing feature of retrovirus replication is the insertion of a DNA copy of the viral genome into the host cell chromosome following reverse transcription. The integrated viral DNA (the provirus) serves as the template for the synthesis of viral RNAs and is maintained as part of the host cell genome for the lifetime of the infected cell. Retroviral

mutants deficient in the ability to integrate generally fail to establish a productive infection.

The integration of viral DNA is catalyzed by integrase, a 32-kd protein generated by PR-mediated cleavage of the C-terminal portion of the HIV-1 Gag-Pol polyprotein (see Fig. 5). The steps in the integration process were originally elucidated in studies using MuLV (59,206), but these findings apply to HIV as well. In all retroviral systems, integration proceeds in the same series of steps (Fig. 25):

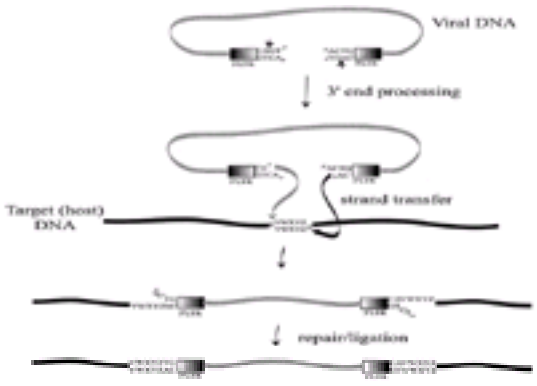

FIG. 25. Schematic depiction of the integration process. Details are provided in the text.

1. IN removes two to three nucleotides from the initially blunt 3' termini of both strands of full-length, linear viral DNA, generating a preintegration substrate with 3'-recessed ends (3'-end processing). This reaction can take place in the cytoplasm of the infected cell.
2. In the nucleus, IN catalyzes a staggered cleavage of the cellular target. Selection of the host DNA target site by IN is essentially sequence independent. The 3' recessed ends of viral DNA are joined to the 5' “overhanging” termini of the cleaved cellular DNA (strand transfer).
3. Cellular repair machinery, perhaps in conjunction with IN, fills the gaps, thereby completing the integration process (59,206,539). The integrated HIV provirus is flanked by a 5-bp direct repeat and terminates with the dinucleotides 5'-TG and CA-3'. The direct repeat results from the duplication of cellular target sequences.

Our understanding of the chemistry of the retroviral integration reaction has been greatly assisted by the development of *in vitro* integration assays. Purified IN, expressed in *E. coli*, can carry out 3'-end processing and strand transfer reactions *in vitro* when combined with short synthetic oligonucleotides that mimic the viral DNA ends and a divalent metal ion (Mg^{2+} or Mn^{2+}) (119,324). Using such systems, IN also catalyzes a reaction, known as disintegration, which in essence is the strand transfer reaction in reverse (93). The predominant product in *in vitro* assays using purified HIV-1 IN is a single end joined to one strand of the target, rather than the more physiologically relevant product in which both ends are integrated into the target. To obtain the integration of both ends with high efficiency requires additional proteins as part of a high-molecular-weight complex (see later), or, at a minimum, the presence of NC (77).

Retroviral IN proteins are composed of three structurally and functionally distinct domains: an N-terminal, zinc-finger-containing domain, a core domain, and a relatively nonconserved C-terminal domain (Fig. 26). Because of its low solubility, it has not yet been possible to crystallize the entire 288-amino-acid HIV-1 IN protein. However, the structure of all three domains has been solved independently by x-ray crystallography or NMR methods. The crystal structure of the core domain of the avian sarcoma virus IN has also been determined (60). The N-terminal domain (residues 1 to 55), whose structure was solved by NMR spectroscopy (68), is composed of four helices with a zinc coordinated by amino acids His-12, His-16, Cys-40, and Cys-43. The structure of the N-terminal domain is reminiscent of helical DNA binding proteins that contain a so-called helix-turn-helix motif; however, in the HIV-1 structure this motif contributes to dimer formation. Initially, poor solubility hampered efforts to solve the structure of the core domain. However, attempts at crystallography were successful (153) when it was observed that a Phe-to-Lys change at IN residue 185 greatly increased solubility without disrupting *in vitro* catalytic activity. Each monomer of the HIV-1 IN core domain (IN residues 50 to 212) is composed of a five-stranded b-sheet flanked by helices; this structure bears striking resemblance to other polynucleotidyl transferases including RNaseH and the bacteriophage MuA transposase (153,525). Three highly conserved residues are found in analogous positions in other polynucleotidyl transferases; in HIV-1 IN these are Asp-64, Asp-116 and Glu-152, the so-called D,D-35-E motif (see Fig. 26). Mutations at these positions block HIV IN function both *in vivo* and *in vitro*. The close proximity of these three amino acids in the crystal structure of both avian sarcoma virus (60) and HIV-1 (153) core domains supports the hypothesis that these residues play a central role in catalysis of the polynucleotidyl transfer reaction that is at the heart of the integration process. The C-terminal domain, whose structure has been solved by NMR methods (158,381), adopts a five-stranded b-barrel folding topology reminiscent of a Src homology 3 (SH3) domain. Recently, the x-ray structures of SIV and Rous sarcoma virus IN protein fragments encompassing both the core and C-terminal domains have been solved (89,683).

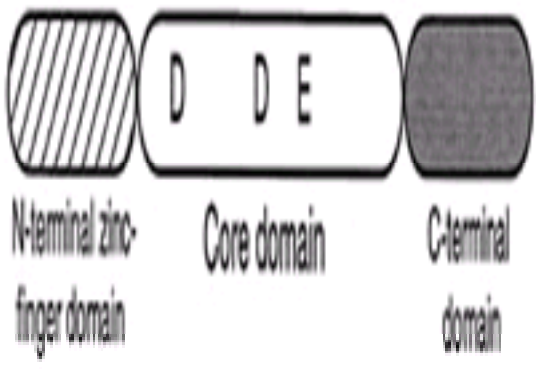

FIG. 26. Schematic representation of an IN monomer. The three structural domains are shown. The catalytic triad of Asp-64, Asp-116, and Glu-152 is represented as D-D-E.

Although it is clear that the core domain of IN plays the central role in catalysis, the functions of the N-terminal and C-terminal domains are less clear. The core domain alone can catalyze the disintegration reaction (66); however, the finding that mutations in the zinc-finger domain disrupt IN tetramerization and catalytic activity suggest a role for this region in stabilizing overall IN structure and promoting the formation of higher-order IN multimers (705). The C-terminal domain is required for both 3'-end processing and integration reactions. Unlike the core domain, which binds DNA only in the presence of a divalent metal ion, the C-terminal domain exhibits strong, and nonspecific, DNA binding even in the absence of metal ion (162). The non-sequence-specific nucleic acid binding properties of the C-terminal domain has led to the suggestion that this region of IN may contribute to the ability of IN to remain associated with the viral genome during reverse transcription (57). It has also been proposed that basic sequences near the junction of the core and C-terminal domains of IN contribute to the nuclear import of the viral preintegration complex (213) (see later).

During reverse transcription and transport of viral DNA to the nucleus, the viral nucleic acid remains associated with a high-molecular-weight PIC composed of both viral and cellular proteins (51,58). Lentiviruses are unique among retroviruses in that the host cell does not have to pass through mitosis for productive infection to occur. The lentiviral PIC must therefore contain determinants that facilitate its transport to, and across, the nuclear membrane. As mentioned earlier, although purified IN can catalyze single-ended integration *in vitro*, such events would be dead-end reactions in an infected cell and would fail to produce an integrated provirus. Additional viral proteins are required for the concerted two-ended reactions *in vitro* that mimic the physiologic integration process. In addition to RT and IN, MA, Vpr, and NC have been reported to be present in HIV-1 PICs, whereas CA is absent (64,214,215). The nonhistone chromosomal protein HMG I(Y) also cofractionates with HIV-1 PICs (171) and the human homolog of the yeast protein SNF5 (referred to as IN interactor 1, or INI1) stimulates HIV-1 IN activity *in vitro* (318). The latter protein, which functions as a transcriptional activator, was postulated to promote integration by targeting viral DNA to transcriptionally active regions of the host chromosome (318). Of particular interest is a host-derived protein that prevents suicidal autointegration events (i.e., reactions in which the DNA ends integrate into internal sites within the same viral DNA molecule). This so-called barrier-to-autointegration (BAF) protein was originally identified by its ability to protect MuLV from autointegration (358) and was subsequently proposed to play a similar role for HIV-1 (85). An additional level of complexity is suggested by footprinting studies demonstrating that the ends of the viral DNA are organized into a large complex composed of both viral and cellular proteins (86,652). These complexes have been termed intasomes to distinguish them from the larger PIC.

The development of *in vitro* assays that faithfully reproduce aspects of the integration reaction provide powerful tools with which to screen for agents that block this critical step in HIV replication. Because PICs catalyze reactions that more faithfully reproduce authentic integration, and because they contain additional viral and cellular proteins, they will prove more useful than purified IN in identifying compounds that exhibit antiintegration activity *in vivo*. Several classes of agents inhibit IN function *in vitro*; these include polyanions, nucleotide analogs, and DNA binding compounds (170). Most of these agents are fairly nonspecific in their mode of action, and many compounds that block activity of purified IN are not inhibitory in assays using purified PICs (172). However, certain compounds, such as the dicaffeoylquinic acids, inhibit integration both *in vitro* and in infected cells and appear to be relatively selective for retroviral IN proteins relative to other DNA modifying enzymes and phosphoryltransferases (709). Recently, diketo acid inhibitors have also been shown to be specific and potent inhibitors of the IN-mediated strand transfer reaction (271).

Env

The HIV Env glycoproteins play a major role in the virus life cycle. They contain the determinants that interact with the CD4 receptor and coreceptor, and they catalyze the fusion reaction between the lipid bilayer of the viral envelope and the host cell plasma membrane. In addition, the HIV Env glycoproteins contain epitopes that elicit immune responses that are important from both diagnostic and vaccine development perspectives.

Biosynthesis and Transport

The HIV Env glycoprotein is synthesized from the singly spliced 4.3-kb Vpu/Env bicistronic mRNA (see Fig. 5, Fig. 13, and Fig. 14); translation occurs on ribosomes associated with the rough endoplasmic reticulum (ER). The 160-kd polyprotein precursor (gp160) is an integral membrane protein that is anchored to cell membranes by a hydrophobic stop-transfer signal in the domain destined to be the mature TM Env glycoprotein, gp41 (Fig. 27). The gp160 is cotranslationally glycosylated, rapidly associates with the host chaperone BiP/GRP78, forms disulfide bonds, and undergoes oligomerization in the ER (154,662). The predominant oligomeric form appears to be a trimer, although dimers and tetramers are also observed. The gp160 is transported to the Golgi, where, like other retroviral envelope precursor proteins, it is proteolytically cleaved by cellular enzymes to the mature SU glycoprotein gp120 and TM glycoprotein gp41

(see Fig. 27). The cellular enzyme responsible for cleavage of retroviral Env precursors following a highly conserved Lys/Arg-X-Lys/Arg-Arg motif is furin or a furin-like protease (262), although other enzymes may also catalyze gp160 processing. Cleavage of gp160 is required for Env-induced fusion activity and virus infectivity (199,427). Subsequent to gp160 cleavage, gp120 and gp41 form a noncovalent association that is critical for transport of the Env complex from the Golgi to the cell surface. The gp120–gp41 interaction is fairly weak, and a substantial amount of gp120 is shed from the surface of Env-expressing cells.

The HIV Env glycoprotein complex, in particular the SU (gp120) domain, is very heavily glycosylated; approximately half the molecular mass of gp160 is composed of oligosaccharide side chains. During transport of Env from its site of synthesis in the ER to the plasma membrane, many of the side chains are modified by the addition of complex sugars. The numerous oligosaccharide side chains form what could be imagined as a sugar cloud obscuring much of gp120 from host immune recognition. As shown in Figure 27, gp120 contains interspersed conserved (C_1 to C_5) and variable (V_1 to V_5) domains. The Cys residues present in the gp120s of different isolates are highly conserved and form disulfide bonds that link the first four variable regions in large loops (364).

Following its arrival at the cell surface, the gp120–gp41 complex is rapidly internalized. Several studies have demonstrated that a Tyr-X-X-Leu sequence in the gp41 cytoplasmic tail (approximately five residues from the membrane-spanning domain) (see Fig. 27) is at least partially responsible for this rapid internalization (351,541). Analogous motifs are also present in the TM Env proteins of HIV-2, SIV, and several other retroviruses. Tyr-based motifs are known to mediate endocytosis of cellular plasma membrane proteins by binding the μ2 chain of clathrin-associated AP-2 complexes (472), and such interactions have been observed with the HIV-1 and SIV gp41 cytoplasmic domains (44,471). It is currently unclear why retroviral Env glycoproteins would evolve a mechanism to promote rapid internalization, although such a strategy could help evade the host immune response and limit Env-induced cytopathicity. Interestingly, it has been reported that $Pr55^{Gag}$ suppresses HIV-1 Env internalization, perhaps by masking the gp41 endocytosis signals (156). By preventing rapid Env internalization in the presence of Gag, Env incorporation into budding particles might be enhanced.

Env Incorporation into Virions

The mechanism by which the Env glycoproteins are incorporated into budding virus particles remains incompletely characterized. Several lines of evidence suggest that HIV-1 Env glycoproteins are actively recruited into virions via direct interactions between Env and MA:

1. Mutations in the HIV-1 MA can block HIV-1 Env incorporation (146,196,197,691); this incorporation defect can be reversed by pseudotyping virions with heterologous Env glycoproteins or by removing the gp41 cytoplasmic tail (196,197,408).
2. HIV-1 Env directs basolateral budding of Gag in polarized epithelial cells (380,481).
3. A direct binding between HIV-1 MA and peptides derived from the gp41 cytoplasmic tail was reportedly detected *in vitro* (117).
4. A single amino acid change in MA reverses an Env-incorporation defect caused by a small deletion in the gp41 cytoplasmic tail (448).

Some evidence, however, supports a more passive mode of Env incorporation. Heterologous Env proteins [e.g., those of MuLV, HTLV, and vesicular stomatitis virus (VSV)] can be incorporated into HIV-1 virions, and some studies observed that most or all of the cytoplasmic tail of HIV-1 can be removed without blocking Env incorporation. A model that is consistent with currently available data would propose that Env incorporation (and the incorporation of multiple cellular membrane proteins) can occur, in some cases, in the absence of an interaction with Gag; however, the incorporation of full-length HIV-1 Env requires a specific interaction between the gp41 cytoplasmic tail and MA. The effect of gp41 cytoplasmic tail truncation was observed to be strongly cell-type dependent (197); recent characterization of this phenomenon revealed that whereas Env complexes lacking the gp41 cytoplasmic tail could be incorporated into virions produced in certain cell lines (e.g., HeLa, MT-4), in most cell lines and cell types, including primary human PBMC and macrophages, such truncations blocked Env incorporation (449). Thus, it is clear that the gp41 cytoplasmic tail plays a crucial role in Env incorporation. The cell-type dependence of this function suggests the involvement of host cell factors.

In addition to the viral Env glycoproteins, HIV-1 virions incorporate substantial levels of a number of cellular surface proteins. These include the histocompatibility leukocyte antigens class I and II (HLA I and II) and the cell adhesion molecules CD44, LFA-I, and ICAM-1 (for review, see ref. 479). The mode of incorporation of these host-derived proteins, and the significance of their incorporation to HIV biology, are not fully understood.

Tissue Tropism

Distinct HIV/SIV isolates display a striking pattern of selective tropism for subsets of CD4+ cells. As noted earlier, many laboratory-adapted isolates (e.g., $HIV\text{-}1_{IIIB}$, $HIV\text{-}1_{LAI}$ or $HIV\text{-}1_{SF\text{-}2}$) readily infect activated human PBLs and T-cell lines but cannot replicate efficiently in primary human monocyte-derived macrophages, which are major *in vivo* HIV/SIV targets in the brain, spinal cord, lung, and lymph nodes. In contrast, the host range of macrophage-tropic (M-tropic) strains of HIV, isolated from asymptomatic individuals, is usually limited to PBLs and cells of the monocyte/macrophage lineage; continuous T-cell lines are usually refractory to infection by these isolates. Over time, the virus present in an infected individual gradually changes and cytopathic isolates capable of inducing syncytia and infecting PBLs and T-cell lines become more prevalent. In fact, the evolution of isolates from primarily M-tropic to T-cell-line (TCL-) tropic may play a major role in disease progression (616). The determinants of M- versus TCL-tropism reside primarily in the V_3 loop of gp120; however, amino acids located in the V_1/V_2 domain may be required for full infectivity of recombinant viruses. Observations indicating that isolates of primate lentiviruses displayed selective tropism for distinct populations of CD4+ cells are consistent with the idea that molecules in addition to CD4 are required for HIV Env-induced fusion and entry;

this hypothesis was confirmed by the discovery of the HIV/SIV coreceptors (see later).

Membrane Fusion

A primary function of viral Env glycoproteins is to promote a membrane fusion reaction between the lipid bilayers of the viral envelope and host cell membranes. This membrane fusion event enables the viral core to gain entry into the host cell cytoplasm. A number of regions in both gp120 and gp41 have been implicated, directly or indirectly, in Env-mediated membrane fusion. Studies of the HA_2 hemagglutinin protein of the orthomyxoviruses and the F protein of the paramyxoviruses indicated that a highly hydrophobic domain at the N-terminus of these proteins, referred to as the fusion peptide, plays a critical role in membrane fusion (657). Mutational analyses demonstrated that an analogous domain was located at the N-terminus of the HIV-1 (200), HIV-2 (198), and SIV (46) TM glycoproteins (see Fig. 27). Nonhydrophobic substitutions within this region of gp41 greatly reduced or blocked syncytium formation and resulted in the production of noninfectious progeny virions.

C-terminal to the gp41 fusion peptide are two amphipathic helical domains (see Fig. 27) which play a central role in membrane fusion. Mutations in the N-terminal helix (referred to as the N-helix), which contains a Leu zipper-like heptad repeat motif, impair infectivity and membrane fusion activity (73,88,152), and peptides derived from these sequences exhibit potent antiviral activity in culture (659). The structure of the ectodomain of HIV-1 and SIV gp41, the two helical motifs in particular, has been the focus of structural analyses in recent years (67,80,611,653). Structures were determined by x-ray crystallography or NMR spectroscopy either for fusion proteins containing the helical domains, a mixture of peptides derived from the N- and C-helices, or in the case of the SIV structure (67), the intact gp41 ectodomain sequence from residue 27 to 149. These studies obtained fundamentally similar trimeric structures, in which the two helical domains pack in an antiparallel fashion to generate a six-helix bundle (Fig. 28). The N-helices form a coiled-coil in the center of the bundle, with the C-helices packing into hydrophobic grooves on the outside. Peptides corresponding to the helical domains presumably inhibit fusion (and virus infectivity) by interacting with their complementary binding partner on gp41 and preventing gp41 itself from adopting the six-helix bundle structure. Binding studies using native HIV-1 Env indicated that gp41 could interact with C-helix-derived peptide only after CD4 binding (211). These results, which extend previous observations of CD4-induced conformational changes in the gp41 ectodomain (552), suggest that the N- and C-helices undergo conformational changes (exposure) following CD4 binding, and that these rearrangements are required for membrane fusion (211). In certain respects, the gp41 ectodomain structure bears a strong resemblance to that of the fusion-competent (low-pH-induced) form of influenza HA_2 (65), although in the latter case the N-helices are outside, not inside, the bundle. Structures for both “resting” and fusion-competent forms of influenza HA_2 have been solved. Upon activation of the resting state by low pH, a dramatic conformational change takes place that causes the fusion peptide to move from the center to the end of the trimer, where it can insert into the target membrane. The similarity between the HIV/SIV gp41 and influenza HA_2 ectodomain structures raises the intriguing possibility (80,611,653) that HIV and SIV Envs trigger membrane fusion by the same “spring-loaded” mechanism proposed for influenza (65). However, as only one structure has been determined for HIV/SIV, strong inferences concerning the rearrangements that ultimately trigger membrane fusion may be somewhat premature. An alternative fusion model that does not require major conformational changes in the gp41 core structure has been proposed (67). In any case, the gp41 ectodomain presents a potential target for drug intervention; indeed, a peptide (referred to as T20) corresponding to the C-helix potently inhibits HIV-1 replication in infected patients (331).

FIG. 28. Trimeric structure of SIV gp41 ectodomain residues 27 to 149. The N-terminal helices are located on the inside of the six-helix bundle; the C-terminal helices pack into hydrophobic grooves on the outside. (Reprinted from ref. 67, with permission.)

Whereas gp41 appears to interact directly with the lipid bilayer to catalyze the membrane fusion reaction, a variety of domains within gp120 are involved in activating Env fusogenicity. The V_3 loop of gp120, which elicits isolate-specific neutralizing antibodies, is an essential player in the membrane fusion reaction. Mutations throughout the V_3 loop of HIV-1 block syncytium formation and virus infectivity without perturbing the processing, transport, and CD4 binding properties of gp120 (201,482). The analogous domain of the HIV-2 Env glycoprotein is also required for fusion and infectivity (198). The importance of V_3 in membrane fusion appears to be a consequence of its role in gp120–coreceptor interactions (see later). In addition to V_3, the V_1/V_2 region participates in some manner in the fusion reaction, as illustrated by the observations that mutations in these variable loops impair fusion (607) and antibodies that bind this region can neutralize virus infectivity (210,431).

CD4 Binding

CD4, the major cell-surface receptor for SIV/HIV, was the first retroviral receptor protein identified (for review, see ref.

48). CD4 is a 55-kd member of the immunoglobulin (Ig) superfamily; it is composed of a highly charged cytoplasmic domain, a single hydrophobic membrane-spanning domain, and four distinct extracellular domains D1 to D4 (397). CD4 normally functions to stabilize the interaction between the T-cell receptor on the surface of T lymphocytes and class II major histocompatibility complex (MHC II) molecules on the surface of antigen-presenting cells. CD4 also recruits $p56^{lck}$ to the T-cell receptor. The high-affinity CD4 binding site for gp120 has been localized to a small segment of the N-terminal extracellular domain, analogous to the second complementarity-determining region (CDR-2) loop of an immunoglobulin light chain variable domain. The cytoplasmic domain of CD4 is not required for its viral receptor function, and mutations that disrupt CD4 internalization do not block HIV entry (25,396). CD4 binding determinants in Env map to the C_3 and C_4 domains of gp120, although a more discontinuous, conformation-dependent domain is clearly involved in high-affinity gp120–CD4 binding. CD4 binding serves not only to promote virion attachment to the target cell but also to induce conformational changes in gp120 and gp41 that are required to activate Env fusogenicity (552,619).

The recent crystallization of a gp120 “core” domain (an unglycosylated gp120 derivative lacking the V_1/V_2 and V_3 loops and the N- and C-termini) complexed with fragments of CD4 and a neutralizing antibody has further refined our understanding of the gp120–CD4 interaction (350,679). The core structure reveals two major domains (referred to as the inner and outer domains) connected by a so-called bridging sheet (Fig. 29). The latter is composed of a four-stranded, antiparallel b-sheet derived from sequences in the V_1/V_2 stem and portions of C_4. Of particular significance is the observation that the CD4 binding site in gp120 (which includes parts of the outer domain and the bridging sheet) is deeply recessed and predicted to be flanked by heavily glycosylated variable regions (350,679). A CD4 residue (Phe-43), shown previously to be critical for gp120 binding, occupies the opening of the CD4-binding cavity while many of the gp120 amino acids important for CD4 binding line the opening of the cavity. A number of the interatomic contacts between gp120 and CD4 are clearly resolved in this structure (350).

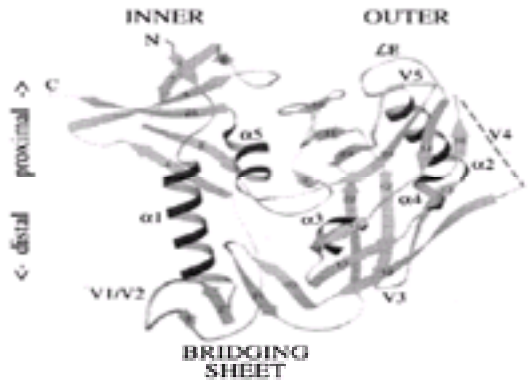

FIG. 29. Ribbon diagram of the gp120 core. In this orientation, the viral membrane would be at the top, the target cell membrane at the bottom. The inner and outer domains are connected by a four-stranded b-bridging sheet. The remnants of variable loops V_1/V_2, V_3, V_4, and V_5 are shown. (Reprinted from ref. 350, with permission.)

The HIV-1 Env glycoprotein binds CD4 not only during the early phase of infection, but also during the transport of gp160 to the cell surface (290). As a consequence of this intracellular association, CD4 is downmodulated from the cell surface, and Env-expressing cells are partially resistant to further infection (47,597). This process, known as superinfection interference, was described many years ago for avian retroviruses (544). In the case of HIV-1, the accessory protein Vpu degrades the CD4 component of gp160–CD4 complexes in the ER, thereby releasing Env for transport to the cell surface (see section on Vpu).

The identification of CD4 as the primary receptor for HIV raised the hope that soluble forms of CD4 (sCD4) might display antiviral activity. Indeed, sCD4 can effectively inhibit syncytium formation and HIV infectivity in tissue culture systems primarily by inducing gp120 shedding (442). Unfortunately, this strong inhibitory effect is generally limited to laboratory-adapted isolates. Primary virus strains are neutralized poorly by sCD4, and sCD4 therapy of HIV-infected individuals has little if any impact on the levels of p24 antigenemia or viremia (122).

Coreceptor Interactions

Soon after the identification of CD4 as the major HIV/SIV receptor, it was recognized that this protein is not sufficient for HIV-induced membrane fusion and virus entry. Mouse cells expressing human CD4 were not infectable (395), whereas CD4+ mouse–human cell hybrids could be induced to fuse upon expression of HIV-1 Env (56,150). Furthermore, as mentioned earlier, different HIV-1 isolates often infected only a subset of CD4+ cells. These observations suggested that, in concert with CD4, secondary receptor(s), or coreceptor(s), expressed on human cells functioned in the membrane fusion process. For more than a decade, the identity of potential HIV coreceptors remained elusive. Then, in a remarkably short period of time, a number of studies demonstrated that members of the G protein–coupled receptor superfamily of seven-transmembrane domain proteins provided the long-sought coreceptor function. By screening a human library for cDNAs that could confer on nonhuman cells the ability to fuse with HIV-1 Env-expressing cells, the a-chemokine receptor CXCR4 (originally designated fusin) was identified as the primary coreceptor for TCL-tropic isolates of HIV-1 (177). A separate line of investigation was stimulated by the observation that several b-chemokines produced by CD8+ T-cells (i.e., RANTES, MIP-1a, and MIP-1b) could suppress infection by M-tropic strains of HIV-1, HIV-2, and SIV (100). This finding simultaneously led a number of investigators to test whether the cell-surface proteins that bound these molecules, the b-chemokine receptors, could function as HIV-1 coreceptors. The results indicated that the b-chemokine receptor CCR-5 could, in fact, render CD4+ nonhuman cells permissive for infection by M-tropic isolates of HIV-1 (8,92,134). In recognition of the importance of coreceptors in determining HIV tropism, a nomenclature scheme was devised based on coreceptor usage; isolates (generally M-tropic) that utilized CCR5 were denoted R5 isolates, strains (generally TCL-tropic) that preferentially used CXCR4 were named X4 viruses, and dual-tropic strains that utilized

both CCR5 and CXCR4 were denoted R5X4 isolates (30).

In the last several years, numerous additional studies have refined our understanding of coreceptor activity and function. Some of the more important findings are described here. (For further information, refer to more detailed reviews in refs. 31 and 143).

1. It is clear that, depending on the virus isolate, multiple sequences in the N-terminal domain and extracellular loops of CCR5 and CXCR4 can influence coreceptor function, and that the gp120–coreceptor interaction is complex.
2. Signaling through the chemokine receptors is not required for their virus coreceptor function (15).
3. Certain isolates of HIV-1, HIV-2, and SIV use coreceptors in a CD4-independent manner (i.e., as primary receptors) (161,419,508). In fact, the designation of the chemokine receptors as coreceptors may be a misnomer; the observation of CD4-independent HIV/SIV infection, together with the finding that feline immunodeficiency viruses utilize the chemokine receptors but not CD4 (661) suggest that the use of chemokine receptors in lentiviral infection may have predated the involvement of CD4.
4. Direct interactions between coreceptor and gp120 have been detected. This interaction is greatly stimulated by, or is dependent on, the presence of CD4 (353,625,676). Association between CD4 and CCR5 in the absence of gp120 has also been reported (680).

Several domains within gp120 directly or indirectly function in Env/coreceptor interactions. Consistent with its influence on HIV-1 tropism, the V_3 loop plays a major role: Single amino acid changes or deletions in V_3 shift or impair coreceptor usage (92,101), V_3 peptides reportedly interact with CXCR4 (547), antibodies to V_3 block gp120–CCR5 binding (625,676), and an HIV-1 variant that escaped the CXCR4 inhibitor AMD3100 contains substitutions within and in close proximity to the V_3 loop (131) . The V_1/V_2 region also helps determine coreceptor usage (537). In addition to the involvement of variable regions in coreceptor interaction, highly conserved portions of gp120 that are exposed upon CD4 binding appear to interact with coreceptor. The binding of antibodies whose epitopes are revealed upon CD4 exposure can block gp120–CCR5 interaction; these epitopes include residues within the gp120 bridging sheet (350,679). By analyzing a number of Env mutants, a highly conserved structure adjacent to V_3 was recognized as playing a major role in CCR5 binding (529).

A generalized scheme for coreceptor utilization is presented in Table 1. TCL-tropic (X4) isolates infect T-cell lines via CXCR4; M-tropic (R5) strains infect macrophages via CCR5. Dual-tropic (R5X4) isolates can utilize either CCR5 or CXCR4 and can therefore infect both T-cell lines and macrophages. Because primary lymphocytes express both CCR5 and CXCR4, they are infectable by X4, R5, and R5X4 isolates. Although this simple model explains many aspects of coreceptor utilization, it fails to account for certain observations. In particular, the details of coreceptor utilization in macrophages remain to be fully elucidated. Some R5 strains do not efficiently infect primary macrophages (90,141), and b-chemokines, which block CCR5, do not always inhibit HIV infection in macrophages (444,556). Furthermore, macrophages have been reported to express relatively high levels of CXCR4 and yet generally (with some exceptions—e.g., see refs. 578 and 688) cannot be efficiently infected with X4 isolates. Several models have been proposed to explain this latter observation, including (a) X4 strains enter macrophages but are blocked at a post-entry step (555), (b) higher-order CD4–CXCR4–gp120 interactions required for membrane fusion do not take place efficiently in macrophages (137,354), and (c) CCR5 out-competes CXCR4 for binding to CD4, thereby rendering CXCR4 nonfunctional as a coreceptor in macrophages (359). Intriguingly, some dual-tropic isolates are reportedly able to use CXCR4 to infect macrophages that lack CCR5 (687); it thus appears that dual-tropism may arise not only from the ability to utilize both CCR5 and CXCR4 but also from the ability to use CXCR4 on macrophages (687).

The observation that CD4 induces conformational changes in gp120 that enhance interaction with coreceptors suggests that events leading up to membrane fusion occur sequentially (Fig. 30). First gp120 interacts with CD4, then a ternary complex forms between coreceptor, CD4, and gp120, and finally conformational changes take place in gp41 that trigger membrane fusion. This step-wise Env activation pathway is also suggested by the finding that binding of antibodies to the putative coreceptor interacting surface of gp120 (350) is enhanced by CD4 (553,619). Thus, interaction of gp120 with CD4 exposes epitopes that are normally hidden in the native Env structure; such epitopes can be constitutively exposed by selecting for HIV-1 variants that replicate in a CD4-independent fashion (286,341).

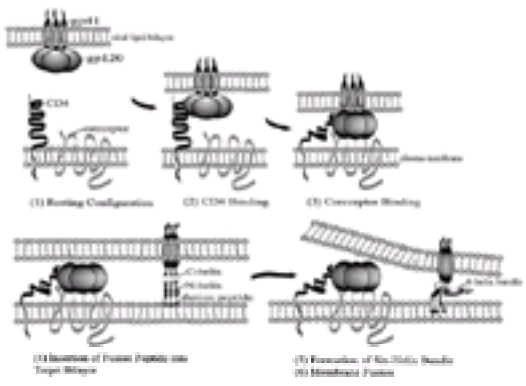

FIG. 30. Schematic representation of the steps leading to membrane fusion. In the resting configuration, the Env glycoprotein complex is in its native state (*1*). CD4 binding (*2*) induces conformation changes in Env that facilitate coreceptor binding (*3*). Following the formation of a ternary gp120/CD4/coreceptor complex, gp41 adopts a hypothetical conformation that allows the fusion peptide to insert into the target lipid bilayer (*4*). The formation of the gp41 six-helix bundle (which involves antiparallel interactions between the gp41 N- and C-helices) (*5*) brings the viral and cellular membranes together and membrane fusion takes place (*6*).

In addition to CXCR4 and CCR5, a number of other chemokine receptors and related “orphans” (receptors whose physiologic ligands are unknown) have been demonstrated to serve as coreceptors for HIV/SIV fusion and infection in culture. These include CCR2b, CCR3, CCR8, APJ, Bonzo (STRL33), BOB (GPR15), and US28 (for review, see ref. 31). The significance of this diverse array of potential coreceptors is currently unclear. Many of the studies that defined the ability of HIV/SIV to utilize these alternative coreceptors employed cell culture systems in which very high levels of coreceptor and CD4 were expressed, and membrane fusion or infectivity could be detected with great sensitivity. Evaluation of coreceptor usage of numerous primary isolates has led some investigators to conclude that CCR5 and CXCR4 are likely to account for most if not all coreceptor activity *in vivo* (702,703). However, the possibility remains that in certain tissues alternative coreceptors may play some role. For example, CCR3 has been implicated in HIV-1 infection of microglial cells (272), and the prevalence of APJ expression in the central nervous system has led to the suggestion that this orphan receptor may perform a role in neuropathogenesis of HIV infection (155).

Certain individuals, despite persistent high-risk behavior, remain HIV-1 uninfected (495). The discovery of CCR5, CXCR4, and related molecules as HIV coreceptors raised the possibility that these individuals might have inherited mutant coreceptor alleles. In some instances, this turned out to be the case. The most clear-cut example of this phenomenon involves a CCR5 allele that is relatively common in Caucasian populations. This mutant allele, referred to as CCR5/D32, contains a 32-base-pair deletion and encodes a truncated protein that is not efficiently expressed at the cell surface and cannot function as an HIV-1 coreceptor (133,295,379,549). Homozygotes for CCR5/D32 are only very rarely infected with HIV-1, highlighting the protective benefits of inheriting this allele. Some limited evidence suggests that CCR5/D32 heterozygosity may confer some protective benefits in slowing disease progression (133,379,549). Since the identification of the CCR5/D32 mutation, other inherited polymorphisms in the CCR5 coding region or its regulatory sequences have been reported to influence HIV-1 transmission or HIV-induced disease progression (420,428). A CCR2 mutation known as CCR2-64I has also been associated with a delay in disease progression, perhaps because of its linkage with the CCR5 gene regulatory region (346,587). It should be emphasized that mutations in genes for currently recognized coreceptors appear to be present in only a minority of multiply exposed, uninfected individuals, suggesting the existence of other mechanisms of protection from HIV infection. One such mechanism associated with altered infectability or disease progression involves the regulation of expression of the chemokines themselves. Analysis of a large number of hemophiliacs exposed to HIV-1-contaminated factor VIII (697) and 100 subjects participating in a Multicenter AIDS Cohort study group (229) revealed that protection correlated with high levels of b-chemokine production. Additionally, a mutation in the regulatory region of the CCR5 ligand RANTES (377), and a single nucleotide polymorphism in the 3' untranslated region of the mRNA encoding the CXCR4 ligand (SDF-1) (669) were reportedly associated with a delay in disease progression.

The identification of HIV coreceptors presents novel opportunities for antiviral therapy. A derivative of RANTES was synthesized by modifying its N-terminus with aminooxypentane. This molecule, known as (AOP)-RANTES does not induce chemotaxis but potently inhibits infection by a variety of HIV-1 isolates (577). Several low-molecular-weight compounds, including the bicyclam AMD3100 (144) and the polyphemusin analog T22 (450), potently block entry via CXCR4. A chemokine agonist encoded by human herpesvirus 8 (Kaposi's sarcoma–associated virus) was reported to inhibit virus entry through CCR3, CCR5, and CXCR4 (337). In addition to chemokine derivatives and low-molecular-weight coreceptor inhibitors, antibodies against coreceptors have displayed antiviral properties (432,677). Some concern about potential undesirable side effects of treatment with anti-coreceptor agents is warranted; although no observable negative consequences of CCR5 deletion are evident among individuals homozygous for the CCR5/D32 mutation, CXCR4 knock-out mice display a range of severe defects including abnormal hematopoiesis, cerebral development, and gastrointestinal tract vascularization (610,713). It is also unclear whether effective therapy would require that multiple coreceptors be targeted simultaneously. Despite these reservations, much effort will undoubtedly continue to be focused on developing coreceptor-based antiviral strategies.

The Accessory Proteins

In addition to the viral structural proteins (Gag and Env), the *pol*-encoded enzymes (PR, RT, and IN), and the regulatory proteins (Rev and Tat), the HIV genome encodes several additional “accessory” proteins: Vif, Vpu, Vpr, Vpx, and Nef (see Fig. 5). Early studies indicated that disruption of the ORFs for these proteins had little or no effect on virus replication in culture; indeed, laboratory-adapted virus isolates often acquire inactivating mutations in several of these genes. However, more recent tissue culture and *in vivo* experiments have revealed a strong requirement for these gene products for efficient virus replication and disease induction. The elucidation of the often-complex functions of these proteins continues to be the focus of active investigation.

Vif

The *vif* (virus infectivity factor) gene is located near the middle of the HIV genome, overlapping with *pol* and *vpr.* The presence of *vif* is a highly conserved feature among lentiviruses; a *vif* product is encoded by all lentiviruses except EIAV (325). Early reports indicated that Vif is not required for efficient virus assembly or release but is necessary for the generation of fully infectious virions (589,600). In subsequent studies, it became apparent that the phenotype of *vif*-defective mutants is strikingly cell-type dependent, and that this phenotype is imposed by the cell in which virus is produced (212). Thus, certain cell lines (e.g., 293T, HeLa, COS, SupT1, CEM-SS, and Jurkat) are “permissive” for *vif*-defective mutants, whereas others, including primary lymphocytes, monocyte-derived macrophages, and some T-cell lines, are “nonpermissive.” This observation suggests that host-cell factors in the virus-producing cell play a role in Vif function. Such a role was highlighted by studies in which the activity of different primate lentiviral Vif proteins was evaluated in cells of both human and nonhuman primate origin (584). The infectivity of HIV-1, HIV-2, and SIV_{agm} could be enhanced by HIV-1 Vif when these viruses were expressed in human cells. In contrast, although SIV_{agm} Vif could modulate infectivity of SIV_{agm} produced in African green monkey cells, it was inactive when expressed in human cells.

The important role of the producer cell in Vif function implies either that Vif-permissive cells express a factor that substitutes for Vif, or that nonpermissive cells contain a factor that suppresses virus replication in the absence of Vif. In

an attempt to distinguish between these possibilities, transient heterokaryons were formed between Vif-permissive (293T) and nonpermissive (HUT78) cell lines (581). The infectivity of virus produced by the resulting heterokaryons was significantly enhanced by the expression of Vif, suggesting that the nonpermissive phenotype is dominant and implying that Vif may suppress a host factor that inhibits virus infectivity. Similar results were obtained by fusing the nonpermissive T-cell line H9 with permissive HeLa cells (394). Intriguingly, the observation that HIV-1 Vif enhances infectivity of MuLV produced in human cells (584) suggests either that Vif suppresses the activity of divergent host factors, or that the putative host factor possesses the ability to inhibit widely divergent (i.e., HIV-1 and MuLV) retroviruses.

The Vif^- defect, while imposed in the producer cell, becomes apparent at an early post-entry step in the virus life cycle. Vif-defective virions, produced from nonpermissive cell types, fail to efficiently reverse-transcribe their genomes following infection (592,646), perhaps as a result of instability of the complex in which reverse transcription takes place (582). Vif-defective virions have also been reported to display morphologic abnormalities evident by EM (45,287) and defects in endogenous RT activity (241). Some investigators reported that Vif mutation causes a defect in Gag processing, such that Vif^- virions contain increased levels of the Gag precursor $Pr55^{Gag}$ (45,576). An effect of Vif on Gag processing has also been observed *in vitro* (347). However, detailed analyses of Vif^- virions obtained from nonpermissive cells failed to reveal any effect of Vif mutation on viral protein composition (50,188,468).

Several groups have detected the presence of small amounts of Vif in virions (70,188,322,378,583). It is currently not clear whether virion incorporation is necessary for the ability of Vif to enhance virus infectivity, or whether its incorporation is nonspecific and not linked to function. Several studies have raised doubts about the relevance of virion incorporation:

1. Vif is incorporated into MuLV particles (70), suggesting that the incorporation of Vif into virions does not require a specific interaction with other virion components.
2. Using cells that express variable levels of Vif, it was observed that the amount of Vif incorporated into virions is influenced by the levels of Vif expressed by the virus-producing cell, and that the resulting variations in the amount of virion-associated Vif have no effect on virus infectivity (583).
3. At least in some cell culture systems, virus preparations may be contaminated with Vif-containing microvesicles, raising the possibility that even the low levels of virion-associated Vif observed in previous studies may represent an overestimate of the amount actually present in virus particles (135).

Vpr

The *vpr* gene, which overlaps with *vif* at its 5' end (see Fig. 5), encodes a 14-kd, 96-amino-acid protein that is incorporated at high levels into virus particles (106,694). The incorporation of Vpr into virions appears to be mediated through an interaction with a $(Leu\text{-}X\text{-}X)_4$ motif near the C-terminus of the $p6^{Gag}$ protein (342,387,494). Vpr contains two predicted helical motifs, one near the N-terminus, the other near the middle of the protein, and a C-terminal Arg-rich domain. Vpr has been predicted to dimerize via residues in the helical domains (563,704). The presence of Vpr is highly conserved among primate lentiviruses. Although Vpr has little influence on HIV replication kinetics in proliferating PBMC or T-cell lines in culture, in nondividing monocyte-derived macrophages its effects are more substantial. Three major functions for Vpr have been proposed: (a) stimulation of gene expression driven by the HIV LTR, (b) transport of the viral preintegration complex to the nucleus during the early stages of the infection process, and (c) arrest of infected cells in the G_2 phase of the cell cycle.

Early studies of HIV-1 Vpr reported that Vpr weakly transactivated expression from the HIV-1 LTR (106). More recent experiments have confirmed this activity and suggest that it may be mediated via interactions between Vpr, Sp1 (554,649), TFIIB (2,334), and TFIID (334). The ability of Vpr to stimulate transcription may be linked to its cell-cycle arrest function (see later).

High levels of virion incorporation suggest a role for Vpr early in the virus life cycle prior to *de novo* gene expression. The observations that deletion of Vpr significantly reduces virus replication in terminally differentiated, nondividing, monocyte-derived macrophages (19), that the HIV-1 preintegration complex contains Vpr (215,274), and that Vpr localizes to the nucleus in HIV-infected or Vpr-expressing cells (388), suggested that Vpr might participate in the nuclear import of the HIV preintegration complex. As discussed previously, this nuclear import capability enables HIV to infect nondividing cells, including monocyte-derived macrophages. Initially, it appeared that MA might play the key role in nuclear import (see section on MA); subsequent studies, however, suggested that MA either has no role or is a relatively minor player in the process compared with Vpr and perhaps IN and a DNA triplex (or flap) structure resulting from lentiviral reverse transcription (see earlier). A number of recent studies have attempted to further define the role Vpr plays in nuclear localization. Mutational analyses have suggested that residues involved in nuclear localization are located at a variety of positions in Vpr, and that the protein lacks a canonical basic-type NLS, such as those found in karyophilic proteins—for example, SV40 large T antigen or nucleoplasmin (for reviews, see refs. 244 and 245). In some cases, Vpr mutations that disrupt nuclear localization may do so by inducing global protein misfolding or instability, complicating the precise mapping of determinants involved in nuclear import. As noted earlier, in the classical basic-type NLS pathway, the importin a (karyopherin a) component of the importin a/b heterodimer binds NLS-containing proteins, whereas the importin b (karyopherin b) component functions in part to mediate docking to the nucleoporins to mediate translocation through the nuclear pore complex (see Fig. 16). This pathway can be blocked by peptides containing the SV40 large T antigen NLS. Other distinct nuclear transport pathways exist, and the process by which cytoplasmic proteins and macromolecular structures destined for the nucleus traffic to the nuclear membrane, associate with components of the nuclear pore complex, and translocate through the nuclear pore is only partially understood. Thus it is perhaps not surprising that no clear consensus exists concerning the mechanism by which Vpr promotes nuclear localization. Divergent observations are in part a result of different experimental systems used to monitor localization, and, perhaps more importantly, due to the fact that some studies assessed the nuclear import of Vpr itself, whereas others followed the fate of a variety of Vpr fusion proteins or HIV-1 PICs containing or lacking Vpr. The diversity of findings is reflected in the results of several recent studies:

1. The observation that Vpr-mediated nuclear localization is not blocked by an SV40 large T antigen NLS suggested that Vpr functions independently of the importin pathway.
2. Based on data using purified PICs either containing or lacking Vpr, it was proposed that Vpr interacts with importin a and increases its affinity for proteins containing basic-type NLSs; it was suggested that Vpr interacts with importin a at a site distinct from that used by either a basic-type NLS or importin b (505,506). This model proposes that Vpr acts to stimulate importin a/b-dependent nuclear import (505,506). Interaction of Vpr with importin a was also reported in a study examining the localization of Vpr itself in both human and yeast cells (640).
3. The analysis of the nuclear transport properties of Vpr fused with heterologous proteins suggested that Vpr interacts directly with nucleoporins (187).
4. The import of Vpr to the nucleus was analyzed using an *in vitro* nuclear transport assay; it was concluded that Vpr contains two independent NLSs that utilize two different nuclear transport pathways, both of which are distinct from the importin a/b pathway (312).

The third major function widely described for Vpr is its ability to arrest cells in the G_2 phase of the cell cycle. Cell-cycle arrest reportedly occurs within hours of infection and is not blocked by antiviral agents, suggesting that it is initiated by the Vpr carried into the cell on virus particles (504). Several studies have indicated that G_2 arrest is linked to inhibition by Vpr of the activity of the $p34^{cdc2}$-cyclin B kinase complex (273,518), perhaps via an interaction with the host protein MOV34 (401). Although the biologic implications of Vpr-induced cell-cycle arrest remain unclear, it has been proposed that increased HIV-LTR-driven transcription in the G_2 phase of the cell cycle could provide a rationale for the evolution of a Vpr cell-cycle arrest function (175,239). This Vpr-induced enhancement of LTR-driven transcription is reportedly mediated by the p300 transcriptional coactivator (175). The nuclear import and cell-cycle arrest functions appear to involve distinct domains in Vpr, as mutations have been reported that disrupt one function but leave the other intact (400). The ability of Vpr to induce cell-cycle arrest not only in primate cells but also in yeast (393) underscores the involvement of highly conserved cellular factors in this phenomenon.

In addition to the properties described earlier, a number of additional functions for Vpr have been described. These include the ability to induce differentiation of rhabdomyosarcoma cells (369), trigger or suppress apoptosis (16,599), interact with the glucocorticoid receptor (519), kill cells by forming ion channels (502), activate HIV gene expression via a transcellular mechanism (370), and reduce mutation rates during reverse transcription (411). The interrelatedness of these diverse functions, and their implications for virus replication and pathogenesis *in vivo*, remain to be characterized.

Vpx

Members of the HIV-2/SIV_{sm}/SIV_{mac} lineage of primate lentiviruses carry an additional gene known as *vpx*. Because of the high degree of relatedness between the *vpr* and *vpx* genes, it was initially proposed that *vpx* was created by a *vpr* gene duplication event after the HIV-2/SIV_{sm}/SIV_{mac} lineage diverged from other primate lentiviruses (623). More recently, it was argued that *vpx* likely arose by acquisition of the SIV_{agm} *vpr* gene by nonhomologous (570) or homologous (624) recombination.

Like Vpr, Vpx is incorporated at high levels in virus particles, also via an interaction with the C-terminus of Gag (276,328,678). Interestingly, in the HIV-2/SIV_{sm}/SIV_{mac} viruses, two of the major functions of HIV-1 Vpr seem to be shared between Vpx and Vpr: Vpx is required for efficient infection of nondividing cells (692), whereas Vpr induces cell cycle arrest but has no role in nuclear targeting (183).

Vpu

A distinguishing feature of the HIV-1 lineage of primate lentiviruses is the presence of the *vpu* gene (see Fig. 4); it is absent from HIV-2 and all SIVs examined to date, with the exception of the closely HIV-1-related SIV_{cpz} (107,298,602). Vpu is a multimeric, 81-amino-acid, integral membrane phosphoprotein containing an N-terminal transmembrane anchor sequence and an approximately 50-amino-acid cytoplasmic domain (402). Three a-helical domains have been predicted: one in the transmembrane sequence (residues 6 to 29), the others in the cytoplasmic domain (residues 32 to 51 and 57 to 72) (675). The sites of phosphorylation have been mapped to two Ser residues at positions 52 and 56 (560). Vpu is translated from a *vpu-env* bicistronic mRNA (567) and is synthesized at intracellular levels comparable to Gag in virus-infected cells. It has not been detected in virus particles. Two principal functions for Vpu have been described: enhancement of virus release and degradation of CD4.

Early studies observed that HIV-1 clones lacking a functional *vpu* gene displayed a pronounced defect in virus particle production (601,602,617). The absence of the Vpu gene product had no discernible effect on the processing or transport of Gag proteins but caused virus particles to be retained at the plasma membrane and in intracellular vesicles (338). The mechanism by which Vpu enhances particle release remains poorly understood; however, a number of observations have been made regarding this property.

1. Enhancement of virus release is independent of Env or CD4 (233,684).
2. Vpu can increase virus production of highly divergent retroviruses (e.g., MuLV, visna, and HIV-2), even though these viruses do not carry a *vpu* gene (247).
3. The N-terminal transmembrane domain appears to be largely responsible for stimulating virus release (558).
4. This function of Vpu does not require phosphorylation (561) but may rely on the ability of Vpu to form cation-selective ion channels (167,559).
5. It was reported that a member of the tetratricopeptide repeat protein family interacts with HIV-1 Gag and suppresses virus release. The ability of Vpu to also interact with this protein and diminish its association with Gag could contribute to the ability of Vpu to enhance virus release (69).

The mechanism by which Vpu induces CD4 degradation has been characterized more completely than its ability to

stimulate virus particle release. Vpu directly binds the cytoplasmic tail of CD4 in the ER; residues in the cytoplasmic domain of Vpu, and Vpu phosphorylation, are critical for this process (49,87,363,561,638,663). The degradation of CD4 by Vpu appears to liberate the Env glycoprotein precursor gp160 from its interaction with CD4, thereby enabling Env to continue its transport to the cell surface (664,665). The presence of Env is not required for CD4 degradation (87,665). Progress has been made recently in elucidating the strategy used by Vpu to induce CD4 degradation: Vpu simultaneously interacts with CD4 and with a protein known as h-bTrCP via WD repeat elements present in the latter protein. The ternary CD4/Vpu/h-bTrCP complexes, which can be detected by coimmunoprecipitation, are then targeted for ubiquitin-mediated proteolysis via interaction between the cellular factor Skp1 and an “F box” motif on the h-bTrCP component of the ternary complex (414). Consistent with this model, inhibition of proteosome activity blocks Vpu-mediated CD4 degradation (205).

Nef

The *nef* gene, present only in primate lentiviruses, overlaps with the 3' LTR and encodes a 27-kd membrane-associated phosphoprotein (see Fig. 5). Membrane binding, mediated by a covalently attached myristic acid moiety and a cluster of N-terminal basic residues (654), is critical for Nef function. Nef is synthesized at high levels from the first mRNA transcript detected after infection. Although Nef was originally labeled a “negative factor” because of reports that it down-regulated virus replication by suppressing transcription from the HIV LTR (3,390), it is now clear that in cultured cells Nef expression either has no effect on virus spread or modestly enhances replication kinetics. The NMR structure of the Nef “core” domain (lacking the N-terminus) has been determined (257,258), and x-ray crystal or NMR structures of the Nef core have been solved for the protein in a complex with Src homology 3 (SH3) domains (12,357) or with the cytoplasmic tail of CD4 (259). In general, the overall folding of Nef is similar to that of helix-turn-helix DNA binding proteins; it contains an unstructured N-terminus, followed by a poly-Pro type II helix (which contains the SH3 binding motif Pro-X-X-Pro), several a-and 3_{10} helices, and a five-stranded antiparallel b-sheet. Residues 150 to 180 form a disordered loop. Interestingly, the binding between Nef and proteins containing SH3 domains (e.g., the Hck Tyr kinase) involves not only the consensus SH3-binding motif (Pro-X-X-Pro) but also discontiguous residues downstream of the poly-Pro type II helix (257).

Several distinct functions for Nef have been widely reported: (a) down-regulation of CD4 and MHC I expression from the cell surface, (b) enhancement of virus infectivity, and (c) modulation of cellular activation pathways. In contrast to the situation in HIV-1-infected cultures, where the role of Nef in virus replication is relatively difficult to measure, Nef appears to be critical for maintaining the high virus loads that are a prerequisite for disease induction *in vivo*. It is currently unclear which of the many activities attributed to Nef in tissue culture are required for its functions *in vivo*.

Like the HIV-1 Env and Vpu proteins, Nef possesses the capacity to down-regulate cell-surface expression of CD4 (226,260). Nef-induced CD4 down-regulation proceeds in a step-wise fashion:

1. Nef interacts with a di-Leu-based motif in the cytoplasmic domain of CD4 (5) and then associates with adapter protein (AP) complexes in clathrin-coated pits to promote rapid CD4 internalization. CD4 endocytosis probably results from a direct interaction between Nef and the µ2 subunit of the AP-2 complex (251,356,500) and perhaps the catalytic subunit of the vacuolar ATPase (386).
2. In the endosome, Nef connects CD4 with the b-subunit of COP I coatomers (b-COP), thereby targeting CD4 for degradation in the lysosome (27,501). Nef may also stimulate CD4 internalization by dissociating CD4 from $p56^{lck}$, which binds the CD4 cytoplasmic tail and normally inhibits CD4 endocytosis (333).

In addition to reducing cell-surface CD4 expression, Nef has been reported to down-regulate MHC I molecule expression (565). In contrast to CD4 down-regulation, which involves a di-Leu-based endocytosis signal in the CD4 cytoplasmic tail, MHC I degradation requires the presence of a Tyr-based motif (356). Cell-surface down-regulation of MHC I by Nef may be accomplished not only by increased rates of protein endocytosis from the cell surface but also as a consequence of reduced trafficking from the trans-Golgi network to the plasma membrane (252,356). Intriguingly, MHC I down-regulation may limit the ability of cytotoxic T lymphocytes (CTLs) to recognize and eliminate virus-infected cells, thus providing HIV and SIV with a mechanism for partially evading at least one component of the host immune response (110). Removing MHC I molecules from the cell surface exposes infected cells to attack by natural killer (NK) cells (689); HIV-1 may avoid this latter problem by not down-regulating those class I molecules (HLA-C and HLA-E) responsible for protection from NK cell lysis (108).

In single-cycle assays, Nef modestly stimulates virus infectivity (95,240,438,594). This function appears to be manifested at an early step in the virus life cycle, since *nef*-deleted mutants fail to efficiently reverse-transcribe their genomes after infection (6,94,564). Mutations in the Pro-X-X-Pro motif, which have no effect on CD4 down-regulation, impair Nef-mediated enhancement of infectivity (240,548), although this phenotype may in part reflect effects of the mutations on protein stability (118). Interestingly, the infectivity defect observed with *nef*$^{-}$ virus can be partially suppressed by pseudotyping with the vesicular stomatitis virus G glycoprotein (VSV-G) (4). VSV-G directs entry via fusion in a low pH endosome following endocytosis, whereas HIV-1 Env mediates entry via direct fusion at the plasma membrane. This observation implies that the role Nef plays early after entry depends on the route of HIV-1 entry. At this time, however, the mechanism by which Nef enhances virus infectivity remains to be elucidated. It is also unclear to what extent this relatively modest effect contributes to the strong requirement for Nef *in vivo*.

Deletion of the *nef* gene has a profound effect in the SIV/rhesus macaque animal model system. Monkeys inoculated with *nef*-deleted virus develop high-level antibody responses but produce no detectable circulating virus (327); these results indicate that Nef plays a critical role in initiating and sustaining SIV infection *in vivo*. Nef has also been proposed to play a major role in pathogenesis in HIV-1–infected humans. This hypothesis stems in part from the findings of some (132,335), but not others (296,297), that virus isolates derived from individuals who progress to disease slowly harbor *nef* mutations. Nef has been shown to be required for HIV-1 replication and pathogenicity in SCID mice containing human fetal thymus and liver implants (310), and transgenic mice expressing Nef in CD4+ T cells and in cells of the monocytic

lineage develop a variety of AIDS-like pathologies (265,266).

A number of studies have suggested that HIV and SIV Nef influence cellular signal transduction pathways and affect the activation state (in either a positive or a negative sense) of Nef-expressing cells (for review, see ref. 416). This area of research remains highly controversial, perhaps owing to differences in the cell culture systems used in various studies, to the inherent complexities of cellular signaling pathways, and to potential differences in the mode of action of SIV versus HIV-1 Nef. As mentioned earlier, HIV and SIV Nef contain a highly conserved consensus binding site for the SH3 domain of Src-family Tyr kinases (Pro-X-X-Pro). Nef has been reported to interact with a Ser/Thr (p21-activated or PAK) kinase and Src-family kinases (e.g., Lyn, Hck, and Lck) and modulate their catalytic activities. As cellular kinases are intimately involved in signaling pathways, such interactions may play a critical role in Nef function. The identification of a naturally occurring mutant SIV *nef* allele has provided some clues into Nef function. A strain of SIV_{mac} known as SIV_{pbj14} induces a rapidly fatal disease in infected macaques characterized by marked T-lymphocyte proliferation, retrafficking of T cells to the gastrointestinal tract, and unremitting diarrhea. In culture, SIV_{pbj14} causes extensive T-lymphocyte activation and displays the unusual property of being able to replicate efficiently in resting PBMC (151). These features are the result of an Arg-to-Tyr mutation that creates a sequence reminiscent of an immunoreceptor tyrosine-based activation motif (ITAM). ITAMs, present in the cytoplasmic tails of T-cell and B-cell receptors, are essential for lymphocyte activation, and the putative ITAM of the SIV_{pbj14} Nef protein appears to activate T-cell signaling (391). Despite the usefulness of the SIV system in understanding Nef function, particularly *in vivo*, caution should be used in extrapolating SIV data to HIV-1 in light of differences observed for SIV versus HIV-1 Nef activities in culture (for example, see ref. 253). In addition to potential direct effects of Nef on stimulating T-cell activation, a recent study demonstrated that Nef expression in macrophages induces the expression and release of the b-chemokines MIP-1a and MIP-1b, which in turn activate resting T lymphocytes (609). Such an effect could help explain the positive effect of Nef on HIV-1 replication *in vivo*.

It has been reported by several groups that Nef is incorporated into virions. Interestingly, as a result of viral PR-mediated cleavage, much of the HIV-1 Nef in virus particles is smaller than the full-length protein detected in infected cells (61,486,655). However, as is the case for Vif, it is not clear what, if any, function is served by virion incorporation, particularly since HIV-1 Nef is incorporated with equivalent efficiency into HIV-1 and MuLV virions (61). The significance of PR-mediated Nef cleavage also remains undefined. In fact, preventing Nef cleavage does not alter its ability to stimulate virus infectivity (437). Recent results suggest that Nef localizes to the viral core (348).

A summary of the major proposed functions of the HIV-1 accessory proteins is presented in Table 3.

Protein	Major proposed functions	Comments
Vif	Enhancement of virus infectivity	Phenotype producer cell-dependent Incorporated at low levels in virions
Vpr	Cell cycle arrest Nuclear import	Incorporated at high levels in virions
Vpx	Nuclear import	Incorporated at high levels in virions Present in HIV-2/SIV_{sm}/SIV_{mac} only
Vpu	Increased particle release CD4 degradation	Not detected in virions Present in HIV-1 only
Nef	CD4 and MHC I down-regulation Enhancement of virus infectivity Increased virus load in vivo Altered cellular activation pathways	Incorporated at low levels in virions

MHC, major histocompatibility complex; HIV, human immunodeficiency virus; SIV, simian immunodeficiency complex.

CHAPTER 60 Pathogenesis and Medical Aspects of HIV-1 Infection

Oren J. Cohen and Anthony S. Fauci

HISTORY

In June, 1981, the highly unusual occurrence of *Pneumocystis carinii* pneumonia (PCP) in five young homosexual men from Los Angeles was reported to the Centers for Disease Control (CDC) (14). Other unusual cases of diseases indicative of cellular immunodeficiency that occurred in young, previously healthy homosexual men were described soon thereafter (15,205,343,505). Initially, more than 90% of these cases occurred in homosexual or bisexual men, and the term “gay-related immunodeficiency” (GRID) was coined. However, by 1982, hundreds of similar cases of an acquired immunodeficiency syndrome (AIDS) had been reported, not only in homosexual and bisexual men, but also in intravenous drug users, hemophiliacs, blood-transfusion recipients, heterosexual adults from the Caribbean and Central Africa, sex partners of affected patients, and infants born to mothers with the syndrome.

The increase in the incidence of Kaposi's sarcoma (KS) in young gay men after 1979 argued that AIDS was an emerging new syndrome. In addition, sharp increases in the number of requests to the CDC for pentamidine isethionate (a second-line agent for the treatment of PCP) after 1979 further suggested that AIDS was an emerging, new disease entity (501).

An infectious etiology as the cause of AIDS was suggested by geographic clustering of cases, links among cases by sexual contact, mother-to-infant transmission, and transmission by blood transfusion. The depletion in numbers and function of T-helper cells (11) suggested that a lymphotropic agent might be responsible. The prominent immunosuppression that characterized AIDS recalled certain retroviral infections in animals. Human T-cell leukemia virus type 1 (HTLV-I) was known to be tropic for T-helper cells, and was an early candidate in the search for the cause of AIDS (147,179,186). A human T-lymphotropic retrovirus that was immunologically related to HTLV-I was detected in lymph node tissue from a French patient who was at risk for AIDS (32). This virus, later named “lymphadenopathy-associated virus,” or LAV, proved identical or highly related to the virus subsequently isolated at the National Cancer Institute, termed HTLV-III (177,448), and in San Francisco, termed AIDS-associated retrovirus (ARV) (316). These viruses were subsequently cloned and characterized (5,503), and are now known as human immunodeficiency virus type 1 (HIV-1). Molecular and seroepidemiologic studies have consistently demonstrated a near-perfect correlation between infection with HIV-1 and subsequent development of AIDS (194,195 and 196,222). All known HIV-1 sequences are closely related to simian immunodeficiency virus (SIV) sequences harbored by the *Pan troglodytes troglodytes* subspecies of

chimpanzees (182). In fact, zoonotic transmission of retroviruses from chimpanzees to humans is the most plausible explanation for the genesis of the HIV epidemic (182).

Scientific advances in understanding the pathogenesis of HIV infection have proceeded with unprecedented speed. Identification of HIV-1 as the cause of AIDS immediately implicated the viral reverse transcriptase (RT) as a therapeutic target. Azidothymidine (zidovudine), a nucleoside analog RT inhibitor, was shown to delay the onset of AIDS and prolong life in HIV-infected patients with advanced immunodeficiency. Zidovudine was licensed for use in HIV-1 infection in 1987; since that time, 17 additional antiretroviral agents have been approved by the United States Food and Drug Administration.

The discovery of the crystal structure of the HIV-1 protease (393,585) led to the rational design of protease inhibitors, which have revolutionized antiretroviral therapy. The early recognition that the HIV envelope binds CD4 with high affinity and uses this molecule for cell entry (118,287,349) was followed years later by the discovery of coreceptors that are necessary in addition to CD4 for HIV entry and fusion (reviewed in reference 324). Antiretroviral strategies that target this important stage of the viral replicative cycle are currently in clinical trials and appear promising. Many key HIV pathogenesis–related discoveries have elucidated the immunologic mechanisms that regulate HIV replication (158). Manipulation of the immune system as an adjunct to antiretroviral therapy in the long-term suppression of viral replication is in the early stages of development and will likely be an increasingly important tool in efforts to regenerate immune competence.

In spite of the rapid scientific advances that have been made, the brisk pace of the HIV/AIDS epidemic has continued largely unchecked in most parts of the world. Prevention efforts and the availability of antiretroviral therapies have blunted the expansion of the epidemic in the United States and Western Europe; however, expansion of the epidemic continues in sub-Saharan Africa and Southeast Asia, and is now burgeoning in India and in the former Soviet republics. Approximately 300 cases of AIDS had been reported by the end of 1982; by the end of 2000, nearly 22 million individuals had died of AIDS, and 36 million were living with HIV-1 infection worldwide.

INFECTIOUS AGENT

HIV is a member of the *Retroviridae* family, which is characterized by a unique enzyme, RT, which allows the virus to copy its RNA into double-stranded DNA to replicate. Within the *Retroviridae* family, HIV is classified as a lentivirus. The three major coding regions for HIV and all retroviruses encode core (*gag*), polymerase (*pol*), and envelope (*env*) gene products (Fig. 1). The HIV genome additionally encodes several other proteins, initially termed “accessory” proteins (i.e., Tat, Rev, Nef, Vif, Vpr, and Vpu), that may play key roles in the pathogenesis of HIV infection (see Chapter 59); compared with most retroviruses, the HIV-1 genome encodes a large number of proteins (Fig. 2).

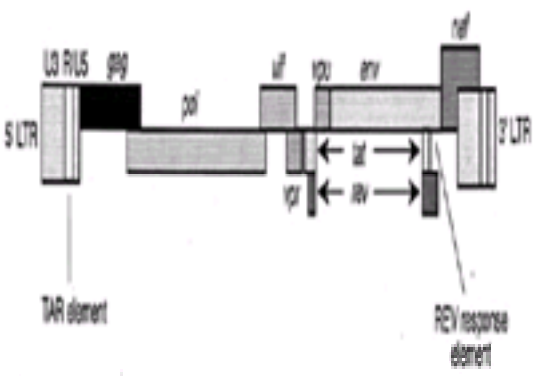

FIG. 1. Genomic organization of human immunodeficiency virus (HIV)-1. Characteristic retroviral elements include the long terminal repeats (LTRs) as well as genes encoding the core proteins (*gag*), reverse transcriptase (*pol*), and the envelope glycoproteins (*env*). Also indicated are genes encoding accessory proteins that are multifunctional and important in the pathogenesis of HIV infection.

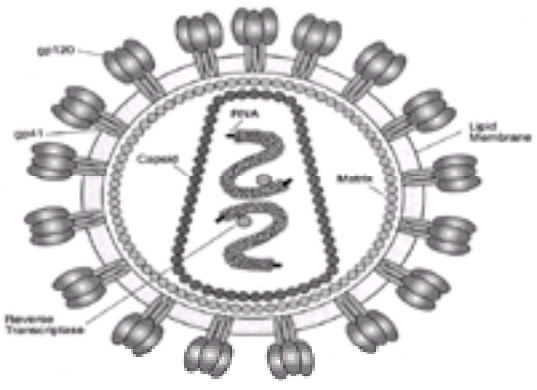

FIG. 2. Organization of a mature human immunodeficiency virus (HIV)-1 virion. Envelope glycoproteins project from the outer lipid membrane. Two copies of the HIV genome are contained within the core.

PROPAGATION AND ASSAY IN CELL CULTURE

A variety of suitable target cells are used for the propagation of HIV-1, including phytohemagglutinin (PHA) or anti-CD3 stimulated primary peripheral blood mononuclear cells (PBMCs), and CD4+ T-cell lines such as CEM, MT-2, HUT78, Jurkat, SupT1, and U937. The kinetics of viral replication vary depending on the input strain of virus and the characteristics of the target cells. Many methods are available to detect virus replication. The most common methods include detection of the viral core p24 antigen in culture supernatants by enzyme immunoassay (EIA) and detection of RT activity in supernatants. Both of these methods detect viral particle production and do not yield information regarding viral infectivity. The RT assay is less sensitive and more labor intensive than the p24 assay; however, the RT assay is considerably less expensive. Assessment of the median tissue culture infectious dose ($TCID_{50}$) is highly labor intensive, but yields quantitative information on infectious virus. Syncytium formation in a cell line such as MT-2 indicates the presence of a syncytium-inducing (SI) strain of HIV; however, this assay is not quantitative and cannot detect non-SI (NSI) strains. The polymerase chain reaction (PCR) is the most sensitive technique available for the detection of HIV. PCR assay for proviral DNA can detect one infected cell per million. Detection of as few as several hundred copies of intracellular HIV RNA can be detected from millions of cells by RT-PCR, and this technique can also detect tens of copies of viral RNA in culture supernatants. Disadvantages of PCR include its expense and labor intensiveness; in addition, because the technique is so sensitive, a great deal of caution must be exercised to avoid contamination.

CYTOPATHIC EFFECTS

The first biologic characteristics ascribed to HIV were its SI and cytopathic effects *in vitro* (Fig. 3) (177, 316,448,503). Multiple mechanisms of cell death appear to be operative after infection of a CD4+ T cell with HIV. A number of different lines of evidence suggest that single-cell killing due to direct infection with HIV is not the predominant mechanism of CD4+ T-cell depletion *in vivo* (see later). In fact, it is uncertain whether HIV has any cytopathic properties *in vivo.* Syncytium formation has been observed only rarely *in vivo* (167,452), and some target cells of HIV infection (i.e., cells of the monocyte/macrophage lineage) appear to be highly resistant to virus-induced cytopathic effects (441).

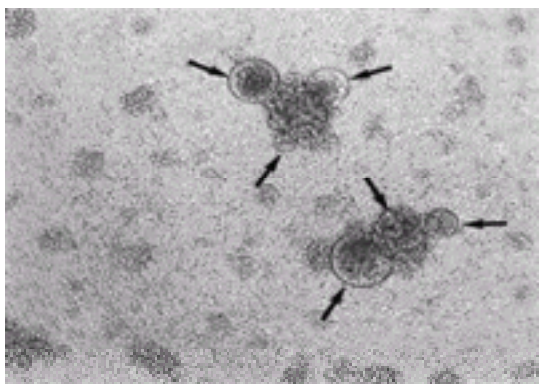

FIG. 3. Typical cytopathic effect of human immunodeficiency virus (HIV)-1 in cell culture; syncytium formation with multinucleated giant cells is shown in a culture of CD4+ T cells.

ACUTE INFECTION

HIV is transmitted either by exposure of the oral, rectal, or vaginal mucosa during sex or breast feeding, or by intravascular inoculation (i.e., through transfusion of contaminated blood products, use of contaminated equipment during injection drug use, or maternal–fetal circulation). Although the earliest events during primary infection may vary depending on the route of exposure, there are no obvious differences in disease manifestations in individuals infected by mucosal versus blood-borne routes. This suggests that the earliest phase of acute infection leads to a common pathophysiologic pathway that is independent of the route of transmission.

Virus that enters directly into the bloodstream is probably cleared from the circulation and is delivered to lymphoid tissue in the spleen, liver, and lungs. Atraumatic application of SIV to tonsils of macaques results in rapid infection of oral mucosa–associated lymphoid tissue, and subsequent dissemination to other lymphoid organs (518). In an animal model of sexual transmission, macaques were exposed to SIV intravaginally; bone marrow–derived dendritic cells (DCs) in the vaginal mucosa were the first cells to contain SIV DNA, which became detectable 2 days after exposure. In subsequent examinations of lymphoid organs, the pattern of appearance and spread of SIV mirrored the course taken by DC on migrating from peripheral tissues to lymphoid organs (516). In addition to serving as direct targets of HIV infection, DCs also are capable of retaining infectious virions on their surface for extended periods (572). Thus their role in the initiation of HIV infection likely includes capturing virions at sites of entry, carrying HIV to the paracortical regions of lymphoid organs, and delivering virus to CD4+ T cells that become activated through their interaction with DCs (Fig. 4). Active viral replication occurs in DC–CD4+ T cell conjugates that are formed *in vitro* (446); similar conjugates of DC and CD4+ T cells containing HIV antigen have been identified *in vivo* in tonsil biopsy specimens from individuals infected with HIV (167), in the peripheral blood in low quantities (572), and in the submucosal tissue after vaginal exposure to SIV (516). Further data from the SIV model suggest that one of the earliest steps of the acute infection process that is necessary for viral dissemination is amplification of infection in macrophages (248).

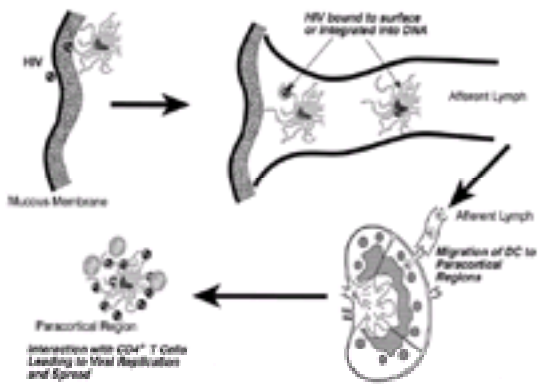

FIG. 4. Role of dendritic cells (DCs) in the initial stages of human immunodeficiency virus (HIV) infection. DCs at the site of HIV exposure transport the virus to paracortical regions of draining lymph nodes, where CD4+ T cells become infected. Reprinted from Weissman D, Fauci AS. Role of dendritic cells in immunopathogenesis of human immunodeficiency virus infection. *Clin Microbiol Rev* 1997;10:358, with permission.

CD4+ T cells and macrophages are key targets of HIV infection. HIV cellular tropism is described in terms of the ability of viral isolates to grow in macrophages or transformed T-cell lines *in vitro.* Isolates that can grow well in macrophages and PBMCs but much less efficiently in T-cell lines are classified as macrophage (M)-tropic, whereas isolates that can grow well in PBMCs and T-cell lines but much less efficiently in macrophages are called T-tropic (185); isolates that can grow well in both macrophages and T-cell lines are referred to as dual tropic. In addition, certain HIV isolates are termed SI, because of their ability to induce giant cell, or syncytium formation in certain T-cell lines *in vitro,* whereas others that lack this ability are referred to as NSI. Considerable but incomplete overlap exists between T-tropism and the SI phenotype and between M-tropism and the NSI phenotype. The viral determinant of cellular tropism maps to the gp120 envelope protein of HIV-1, mostly to the third variable region (V3 loop) (79,262,532,598) that is also the major determinant for coreceptor use (105); most M-tropic strains of HIV use CCR5 as a coreceptor (i.e., R5 strains), whereas most T-tropic strains use CXCR4 (i.e., X4 strains).

Changes in viral phenotype have been observed at different stages of HIV infection. CCR5-using viruses are preferentially transmitted during primary infection and predominate at most stages of infection (612,616). In approximately 50% of HIV-infected individuals, the appearance of CXCR4-using isolates late in the course of disease heralds accelerated $CD4^+$ T-cell decline and clinical disease progression (78,298,538,539). This transition may occur by mutation of only a few amino acid residues, predominantly in the envelope V3 loop (40,79,164,532). Given the high error rate of RT and the rapid kinetics of HIV replication, the surprising failure of such mutants to emerge until late in the course of the disease process indicates a selective advantage of such a mutation during the course of disease progression. The nature of such a selective advantage is currently unknown; however, it may relate to the ability of X4 viruses to gain cellular entry through an expanded repertoire of coreceptor molecules.

The mechanisms responsible for the restriction of R5 viruses during primary infection is the subject of intense investigation. Freshly isolated Langerhans cells (resembling mucosal DCs) express CCR5, but not CXCR4, on their surfaces (604); this finding suggests that infection of DCs may be a necessary first step in acute infection, and that this step is restricted by the expression pattern of HIV coreceptors on DCs. However, HIV-pulsed DCs from individuals lacking a functional CCR5 gene are capable of transmitting infection to CD4+ T cells *in vitro* (140). Thus, although infection of DCs may be dependent on specific HIV coreceptor expression, the ability of DCs to trap virions on their surfaces and infect CD4+ T cells that they encounter is, at least in part, a coreceptor-independent phenomenon.

In animal models of SIV infection, virus can be detected in peripheral lymph nodes within 1 week of infection (73,457,516). Most of the SIV RNA at this time is associated with individual productively infected cells in lymph nodes. This production of virus by individually infected cells in lymphoid tissue precedes and likely is responsible for the peak of antigenemia. Coincident with the appearance of SIV-specific immune responses, a decrease in the frequency of productively infected cells is seen during the second week after infection. By 4 weeks after infection, antigenemia decreases as a result of further elimination of productively infected cells by SIV-specific cell-mediated immune responses and clearance of circulating virions by the formation of immune complexes consisting of virus, antibody, and complement that are trapped within lymphoid germinal centers (73,457).

Cross-sectional studies in patients evaluated soon after acute HIV infection are similar to the findings in the SIV model (Fig. 5). The kinetics of HIV viremia and HIV-specific immune responses in peripheral blood parallel those in the SIV model (45,97,117,301). Preliminary data from a limited number of lymph node biopsies obtained from acutely infected individuals suggest that the SIV model is valid in depicting the early events associated with HIV infection in lymphoid tissue as well (415). In the weeks to months after acute HIV infection, a sharp decline in the frequency of productively infected cells is evident in lymphoid tissue. Germinal center formation within lymphoid follicles becomes pronounced, and viral RNA corresponding to extracellular virions complexed with antibody and complement is detected in the network of follicular dendritic cell (FDC) processes (165,269,419,515). Although the immune system is capable of efficient elimination of a substantial number of productively infected cells in lymphoid tissue, the very earliest interactions between virus and host virtually ensure viral persistence. In this regard, massive numbers of virions trapped within the germinal center FDC network as well as latently infected cells, which harbor proviral DNA but do not express viral proteins (and thus elude the immune response), represent potentially continuous sources of virus for *de novo* infection of CD4+ T lymphocytes that are resident in or migrating through lymphoid tissue (241,261).

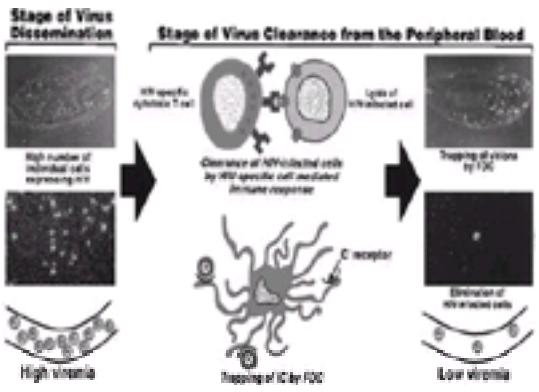

FIG. 5. Cell-mediated and humoral immune mechanisms involved in the down-regulation of viremia after primary human immunodeficiency virus (HIV) infection. Before the emergence of HIV-specific immune responses, large numbers of individual productively infected cells are found in lymph nodes (**left**; low- and high-power photomicrographs of an *in situ* hybridization assay for HIV RNA in a lymph node), associated with high levels of plasma viremia. Emergence of cytotoxic T-cell responses against HIV leads to elimination of a large number of productively infected cells (photomicrograph, **lower right**). In addition, HIV-specific antibodies combine with virions to form immune complexes (*IC*); complement (*C'*) binds to the immune complexes, which are then trapped in the follicular dendritic cell (*FDC*) network of expanding germinal centers by complement receptors (photomicrograph, **upper right**). Adapted from ref. 420, with permission.

VIRAL DYNAMICS

Measures of viral load, including plasma viremia, remain relatively constant in a given patient over a long period (111,432). This steady state is due to an equilibrium between production and clearance of virus. Perturbation of the viral load steady state with highly active antiretroviral therapy allows estimation of the *in vivo* dynamics of HIV infection. Because antiretroviral agents block *de novo* infection of cells, frequent measurement of plasma viremia after administration of these agents yields a decay curve that reflects the clearance rate of virions from plasma as well as the elimination rate of HIV-producing cells. Using different drugs, studies from two groups found the half-life of plasma virus to be approximately 2 days (251,568). In a follow-up study that included more frequent measurements of plasma viremia after drug administration, Perelson et al. (429) estimated the half-life of plasma virus to be 5.8 hours. Rates of virion clearance can also be estimated by acutely removing plasma virions by apheresis and measuring the return of plasma HIV RNA back to baseline. With this approach, the half-life of plasma virus was estimated to be 28 to 110 minutes. Because virus production is proportional to the number of productively infected cells and the number of virions produced per cell, these data imply that the steady-state level of plasma viremia is fueled by rapid and continuous infection of target cells. The average production of HIV virions was estimated to be nearly 10^{10} to 10^{11} virions per day, the average generation time of HIV *in vivo* (i.e., the time from virion release from an infected cell to the time of virus production from a cell infected by the first virion) was approximately 2.6 days, and the half-life of productively infected cells was about 1.6 days (429,453). Although a substantial number of assumptions are built into the mathematical formulae used to derive these estimates, the clear conclusion of these data is that the steady-state level of plasma viremia is dependent on viral replication from a pool of newly infected cells that is rapidly turning over.

VIRAL DISSEMINATION

Like many other invading microorganisms, HIV is transported by antigen-presenting cells to lymphoid tissue. However, in the case of HIV, the host immune system is never able to control and eradicate the infection completely. In an impressive example of subversion of the immune system, HIV uses the activated milieu of lymphoid tissue to its own replicative advantage. Close contact between immune effector cells and high levels of proinflammatory cytokines are characteristic of the lymphoid tissue microenvironment; these conditions favor viral replication in several ways. Activated CD4+ T lymphocytes migrating through lymphoid tissue serve as ideal targets for *de novo* infection with HIV (261,328,339). Activation signals such as those delivered by proinflammatory cytokines, found in abundance within activated lymph nodes, are potent inducers of HIV replication in latently infected cells (53,162,390,527,599) and also are able to increase the pool of activated cells that are susceptible to HIV infection (399,521,523,571). Another example of the ability of HIV to subvert the immune system for its own replicative advantage is the immune hyperactivation induced by the virus itself (408,493). Sequestration of HIV-infected cells within lymphoid tissue due to histopathologic abnormalities and cytokine imbalances (468,579) may further contribute to the high levels of viral replication that occur in lymphoid tissue. Viral replication that occurs in lymphoid tissue before the development of a host immune response is responsible for wide dissemination of virus by lymphatic and hematogenous routes.

Viral dissemination throughout lymphoid tissue is a fundamental pathogenic event during the early phase of HIV infection, and lymphoid tissue remains the most important reservoir of infection throughout the entire course of the disease. In this regard, the frequency of infected cells in lymph nodes exceeds that in peripheral blood by fivefold to 10-fold; differences in levels of viral replication are generally 10- to 100-fold (109,418,419). Up to 25% of CD4+ T lymphocytes present in lymph node germinal centers harbor HIV DNA, further emphasizing the role of lymphoid tissue as a critical reservoir for HIV *in vivo* (142). The continuous state of rapid high-level turnover of plasma viremia derives in large measure from viral replication in lymphoid tissue (67,111,305).

The high concentration of virus in lymphoid tissue is due in part to the normal process of follicular hyperplasia within lymphoid germinal centers after antigenic challenge (41,165,452). The expansion of the FDC network within hyperplastic lymphoid follicles is an efficient mechanism for viral trapping through interactions between antibody and complement-coated virions with the complement receptor molecules C3b and C3d on the surface of FDCs. In addition to this mechanical process, immunologic mechanisms may play a major role in maintaining the viral reservoir in lymphoid

tissue.

During the course of HIV disease progression, there is a shift in the lymphoid histopathologic pattern from follicular hyperplasia to follicular involution (Fig. 6) (419,452). This shift in histopathology is associated with important changes in viral distribution. Disruption of the FDC network is characteristic during this period, leading to reduced trapping of virus in germinal centers and a consequent increase in plasma viremia (419,420). Sequestration of infected cells within lymphoid tissue also becomes less efficient during follicular involution, leading to increased numbers of infected cells in the peripheral blood; as the CD4+ T lymphocyte count decreases to less than 200 cells/μL, there is a tendency for viral load to increase more rapidly in the peripheral blood compartment, leading to equilibration between lymph node and peripheral blood.

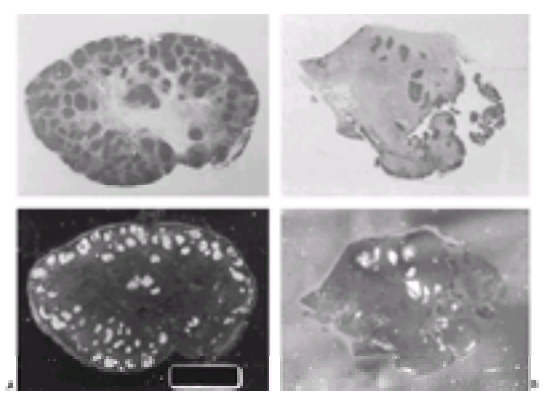

FIG. 6. Changes in lymphoid tissue histopathology and patterns of viral distribution associated with human immunodeficiency virus (HIV) disease progression. In early-stage disease **(A)**, hematoxylin and eosin staining **(top)** reveals florid follicular hyperplasia; *in situ* hybridization for HIV RNA **(bottom)** reveals heavy deposition of HIV in the hyperplastic germinal centers. In intermediate- to late-stage disease **(B)**, loss of normal lymphoid architecture results in follicular involution **(top)**, with consequent loss of HIV trapping capacity **(bottom)**. Reprinted from Cohen O, Pantaleo G, Lam G, Fauci AS. Studies on lymphoid tissue from HIV-infected individuals: implications for the design of therapeutic strategies. *Springer Semin Immunopathol* 1997;18:305, with permission.

Destruction of lymphoid tissue certainly is a major mechanism responsible for the severe immune dysfunction and loss of the ability to inhibit viral replication observed in advanced-stage HIV disease. The ability to maintain an effective immune response to HIV is severely impaired in the absence of intact lymphoid tissue architecture. As a consequence, increased cell-associated viral RNA becomes evident in the paracortical regions of lymph nodes, reflecting increased viral replication. Thus, during progression of HIV disease, there is a reversal in the predominant forms of virus in lymph nodes, with progressive diminution of the extracellular form (i.e., trapped virus) and an increase in cell-associated virus (i.e., cells expressing HIV RNA) (419,420). In the advanced stage of disease, there is almost total dissolution of lymphoid architecture. Follicular involution, fibrosis, frank lymphocyte depletion, and fatty infiltration herald complete loss of functional lymphoid tissue, contributing to the state of immunodeficiency and the dramatically enhanced susceptibility to opportunistic infections.

Disruption of the lymphoid microenvironment during the course of HIV infection remains an enigmatic process with considerable implications for future therapeutic interventions. Productive infection of FDCs by HIV may occur, particularly in the late stages of HIV infection (517); however, the majority of data suggest that productive infection of FDCs is rare during the intermediate stage of disease when dissolution of the FDC network begins (170,486). Direct toxicity of viral gene products and/or factors such as tumor necrosis factor (TNF)-a, nitric oxide, and matrix metalloproteinases may contribute to loss of FDC network integrity (433,567). Several viral gene products can disrupt normal intracellular signaling events (see later), although these effects have been studied largely in CD4+ T cells, and little is known regarding the normal physiology of FDCs and their interactions with HIV proteins. Down-regulation of major histocompatibility complex (MHC) class I expression by viral gene products (254,279,496) may interfere with normal cell–cell interactions in the lymphoid microenvironment. Depletion of CD4+ T cells during the course of HIV disease could also lead to withdrawal of a trophic factor necessary for FDC survival. Of note, some of the HIV-related pathologic changes that occur in lymphoid tissue may be at least partly reversible during potent antiretroviral therapy (614).

Lymphoid tissue is not the exclusive site of HIV infection. Virtually any cell that expresses the CD4 molecule together with an appropriate coreceptor molecule can potentially be infected with HIV. In addition, HIV has been reported to infect *in vitro* a wide range of primary cells and cell lines that may or may not express CD4 or HIV coreceptors (315). These include FDCs, microglial cells, megakaryocytes, eosinophils, CD8+ T cells, B cells, natural killer (NK) cells, thymus and bone marrow stromal cells, astrocytes, oligodendrocytes, renal epithelial cells, cervical cells, trophoblastic cells, rectal and bowel mucosal cells, and parenchymal cells from a variety of organs such as heart, muscle, liver, lung, salivary gland, eye, testis, prostate, and adrenal gland. Infection of at least some of these cell types likely occurs *in vivo.* The consequences of infection of various organs may include pathologic sequelae, such as dilated cardiomyopathy (29) and gastroenteritis (300); in addition, some sites of tissue infection may represent important reservoirs of HIV infection, including not only lymphoid tissue (420), but also the central nervous system (CNS), genital tract, and other sites (495).

IMMUNE RESPONSES

Similar to most pathogens, HIV induces a broad array of host immune responses in an infected individual (Fig. 7). How HIV is able to replicate continuously and cause the inexorable decline in immune system function in the presence of these immune responses is a central question of pathogenesis that has profound implications for the development of effective immunotherapies and vaccines. Some evidence suggests that particular immune responses to HIV may actually

be harmful to the host (20,464,590). A larger body of evidence, however, supports a salutary role for most HIV-specific immune responses. The profound decrease in plasma viremia after acute HIV infection is associated with the appearance of HIV-specific cellular (45,301) and humoral (97) immune responses. The correlation of slow progression with vigorous HIV-specific immune responses also argues strongly in favor of a salutary role for these responses (108).

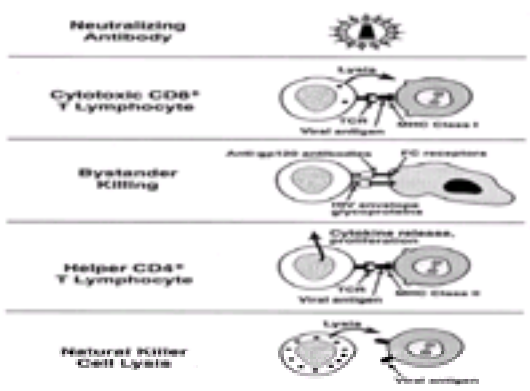

FIG. 7. Immune responses against human immunodeficiency virus (HIV). Neutralizing antibodies bind to virion components and prevent attachment to target cells. CD8+ cytotoxic T lymphocytes recognize viral antigens on the surface of infected cells in the context of major histocompatibility complex (MHC) class I presentation, and are able to lyse these cells directly. Antibody-dependent cell-mediated cytotoxicity (ADCC) results in Fc receptor–mediated elimination of infected cells as well as uninfected cells that are coated with HIV antigen–antibody complexes. CD4+ T cells may recognize viral antigens in the context of MHC class II presentation, resulting in the release of cytokines and cellular proliferation. Natural killer (NK) cells may also directly lyse HIV-infected cells. Adapted from Fauci AS, Lane HC. Human immunodeficiency virus (HIV) disease: AIDS and related disorders. In: Fauci A, Braunwald E, Isselbacher KJ, et al., eds. *Harrison's principles of internal medicine.* 14th ed. New York: McGraw-Hill, 1998:1791, with permission.

Humoral Immune Responses

Antibodies against the viral core protein p24 develop within weeks of acute HIV infection and may play a role in the decline of plasma viremia associated with primary infection. Loss of anti-p24 antibodies is associated with progression of HIV disease (566).

Antibodies that neutralize HIV infectivity may be responsible for at least partial control of viral replication *in vivo* (499,566). eutralizing antibodies may be type specific (i.e., specific for one viral isolate) or group specific (i.e., specific for a broad range of viral isolates). Most type-specific neutralizing antibodies recognize the V3 region of the HIV envelope gp120 protein (206). Neutralizing anti-V3 loop antibodies may prevent conformational changes within gp120 necessary for HIV entry or for cell–cell fusion (168). Group-specific neutralizing antibodies recognize epitopes within the HIV envelope gp41 protein (389), discontinuous conformational epitopes around the CD4 binding site of gp120 (525), or carbohydrate determinants (232). Both type- and group-specific neutralizing antibodies are more efficient in neutralizing laboratory strains of HIV grown in T-cell lines compared with primary isolates grown in PBMCs; this is likely due to differential exposure of the V3 loop and CD4-binding domain epitopes among these isolates (48,529). Some neutralizing antibodies interfere with the interaction between the HIV envelope and CCR5, thereby inhibiting cellular entry of M-tropic strains of HIV (542,591).

Neutralizing antibodies appear to be prognostically relevant to the course of HIV infection (377,434,500). The regularity with which viral variants emerge that resist neutralization suggests that such antibodies are potent impediments to viral replication (3). In nonhuman primate models, neutralizing antibodies are associated with slow rates of disease progression (153) and accelerate clearance of both infectious and noninfectious virions (263); furthermore, passive transfer of SHIV-neutralizing antibodies can protect macaques against a subsequent viral challenge (504).

Some anti-HIV antibodies bind to immunoglobulin G (IgG) Fc receptor–positive cells and sensitize them to mediate antibody-dependent cell-mediated cytotoxicity (ADCC) against HIV-infected or HIV-coated cells (329,403). Most of these antibodies are directed against HIV envelope gp120 or gp41 proteins. $CD16^{+}$ NK cells are important mediators of ADCC (543), and monocytes also may mediate this activity (267). Anti-HIV ADCC antibodies develop soon after primary infection and are detectable throughout the course of HIV disease, with some decrease in titers with the onset of AIDS (323). ADCC also may represent an immunopathogenic immune response that may be responsible for CD4+ T-cell depletion during the course of HIV infection. In this regard, a combination of high levels of plasma viremia with high HIV envelope-specific ADCC activity is correlated with rapid CD4+ T-cell depletion; this correlation may reflect ADCC-mediated “innocent bystander” killing of gp120-coated, but uninfected, CD4+ T cells (508).

Cellular Immune Responses

In HIV-infected individuals, classic MHC class I–restricted, HIV-specific, CD8+ cytotoxic T lymphocyte (CTL) responses have been demonstrated (437,559) against a variety of HIV target proteins including core proteins, RT, envelope proteins, and regulatory proteins. With standard cell-culture methods, a high frequency of HIV-specific CTLs and CTL precursors (up to 1% of peripheral blood T cells) has been observed in asymptomatic HIV-infected patients (252,381); with HLA–peptide tetramers, the frequency of HIV-specific CTLs may be up to an order of magnitude greater than that detected by standard methods (6,401).

A critical role for CTLs in the suppression of viral replication in HIV-infected individuals is suggested by the close correlation between emergence of an HIV-specific CTL response and down-regulation of viremia after acute infection

(45,301,388), the association of vigorous HIV-specific CTL responses with slow progression of HIV disease (289,401,422,461), and the decline in HIV-specific CTL activity with disease progression (252,559). Quantitative studies have revealed an inverse correlation between the frequency of HIV-specific CTLs and levels of plasma viral load (388,401), and between the CTL frequency and the rate of CD4+ T-cell decline (388). A beneficial role for HIV-specific CTLs also is suggested by their presence in the peripheral blood of individuals who are frequently exposed to HIV yet remain uninfected (470,471), and the depletion of HIV-specific CTLs from lymph nodes of patients with advanced HIV disease (536). Finally, studies in nonhuman primates have demonstrated that monkeys subjected to CD8+ T-cell depletion manifest diminished control of plasma viremia during primary SIV infection (487); in addition, CD8+ T-cell depletion during the chronic phase of SIV infection leads to a prompt and profound increase in levels of viral replication (268,345,487).

The quality of HIV-specific CTL response also is an important determinant of the efficacy of these responses in controlling viral replication. The specificity of CTL responses may in part determine their salutary role; in this regard, CTL responses against viral core proteins in particular have been associated with a decreased risk of disease progression (289,401,463). CTL recognition of immunodominant HIV epitopes presented by certain MHC class I alleles may result in potent anti-HIV activity (208) and may in part explain the association of certain MHC class I alleles with slower progression of HIV disease (63,275,276,288). Furthermore, the ability to recruit an HIV-specific CTL response comprising a diverse group of T cell–receptor Vb families that recognize multiple epitopes is associated with better control of viral replication and an improved prognosis compared with a narrow CTL response (238,416).

The loss of HIV-specific CTL activity in patients with progressive disease is likely a result of several factors. Viral proteins such as Tat, Nef, and Vpu can down-regulate cellular expression of MHC class I molecules that are necessary for CTL recognition of infected cells (254,279,496). Increased expression of killer inhibitory receptors also may inhibit CTL activity (131). Another mechanism responsible for the loss of CTL activity is the selective accumulation of CD8+DR $^{+}$ HIV-specific CTLs that lack the interleukin (IL)-2 receptor and are defective in clonogenic potential (421). Finally, the ability of HIV to escape CTL responses by viral mutation or by exhaustion of CTL clones due to high concentration of antigen may explain the loss of CTL-mediated control over viral replication (352,423).

The host CTL response against HIV is constrained by the ability of the MHC class I alleles to bind to various viral epitopes, while the virus is constrained by the degree to which an escape mutation impairs viral fitness (227,271,586). These host–virus dynamics are extraordinarily complex, given the large number of permutations of viral epitopes and MHC class I alleles. Viral mutations within CTL recognition epitopes (i.e., “escape mutants”) are associated with increased levels of viral replication and progression of HIV disease (46,209,293,431). Viral escape mutants may thrive because of the release of CTL control over their replication, and also may inhibit CTL responses against the preescape viral epitope (291,292). A mathematical model of CTL–virus dynamics was provided by Nowak et al. (398), who described disease progression as a result of viral sequence variation that escapes an immunodominant CTL response and shifts the host response toward a weaker epitope. In this scenario, disease progression may be the result of fitness of viral escape mutants outpacing the plasticity of the host CTL response, with slow progression resulting from CTL plasticity overpowering viral escape mutants with limited fitness.

A further mechanism for loss of CTL control over viral replication may be clonal exhaustion. This appears to be a strategy for viral persistence used by other viruses, such as certain strains of lymphocytic choriomeningitis virus, that rapidly and completely mobilize the host CTL response, resulting in CTL exhaustion (i.e., high zone tolerance) (380). CTL exhaustion also may occur to some degree in HIV infection: the disappearance of some CTL clonotypes can be demonstrated in the absence of viral escape mutations that might otherwise explain the phenomenon (352,423).

CD8 Soluble Suppressor Factors

A variety of soluble antiviral factors are elaborated by CD8+ T cells. CD8 antiviral factor (CAF) (560) is noncytolytic, inhibits viral replication at the level of HIV long terminal repeat (LTR) transcription (76), and lacks identity to known cytokines (334). Although CAF activity is non-MHC restricted, its activity is maximal in a syngeneic system (333). CAF activity decreases with disease progression, but remains potent in long-term nonprogressors (31,335).

The combinations of RANTES, MIP-1a, and MIP-1b (the natural ligands for CCR5, a major coreceptor for M-tropic strains of HIV) also are important soluble antiviral factors, and are secreted by CD8+ T cells and other cell types (104,284). These CC-chemokines inhibit viral replication primarily at the level of cell entry. Emerging data support a role for CC-chemokines in protecting against HIV infection and disease progression (171,475,546,601); interestingly, the source of these chemokines does not appear to be exclusively CD8+ T cells, and likely includes CD4+ T cells (171,284,475) and NK cells (404). Macrophage-derived chemokine (MDC) can potently suppress replication of M- as well as T-tropic strains of HIV *in vitro* (412); the role of MDC in controlling HIV replication *in vivo* is uncertain. Finally, IL-16 has been reported to be a soluble antiviral factor (27). IL-16 inhibits HIV transcription and can potently suppress HIV replication when it is expressed in HIV-infected T cells (332,553); furthermore, IL-16 production has been correlated with protection against disease progression in HIV-infected individuals (10,480).

CD4+ T-Cell Responses

HIV proteins contain helper T-cell epitopes that may be presented by MHC class II alleles (68,102). Recognition of these epitopes by CD4+ T cells results in secretion of cytokines and cellular proliferation. These responses may be associated with abortive infection in individuals who are exposed to HIV but who remain uninfected (99), and they decrease with HIV disease progression (68,102).

Studies of other viral infections indicate a central role for T-helper responses in the maintenance of CTL responses. CTLs that persist in the absence of adequate CD4+ T-cell help may be ineffective *in vivo,* as has been demonstrated in the lymphocytic choriomeningitis virus (LCMV) system (605); a similar scenario may occur in HIV infection as well (238).

CD4+ T-helper responses also may be quite important in HIV-specific immunity. In this regard, an inverse correlation has been found between the magnitude of HIV-specific CD4+ T-cell response and levels of plasma viremia (466); these data are consistent with the observed inverse correlation between CTL activity and plasma viremia as well (401). The fate of HIV-specific CD4+ T cells during the course of HIV infection is controversial. Some evidence suggests that these cells are usually depleted in the early stages of disease, and that initiation of potent antiretroviral therapy during acute HIV infection may prevent this loss and lead to more effective control of viral replication (466). Other data suggest that HIV-specific CD4+ T cells are present throughout the course of HIV disease, and that their frequency actually declines during HAART-induced viral suppression (435). Therapeutic strategies currently under consideration include the use of soluble factors that bypass the need for CD4+ T-cell help in maintaining CTL responses.

CYTOKINES AND HIV DISEASE: DYSREGULATION OF CYTOKINE PRODUCTION

Cytokines that are generated during the host immune response to an infection play an important role in determining the outcome of the infectious process; in mice that are susceptible to *Leishmania major* infection, production of the TH2 cytokine IL-4 predominates, whereas the TH1 cytokine interferon (IFN)-g is produced by mice that are resistant to progressive infection (242). Dysregulation of the host cytokine network is characteristic during all phases of HIV infection. Many of the observed alterations in cytokine production contribute to HIV pathogenesis by further stimulating viral replication, suppressing the ability of the immune system to mount an efficient antiviral response, and inducing cytokine-mediated cytopathic effects (108, 150, 152).

HIV infection is associated with increased expression of proinflammatory cytokines; high levels of TNF-a, IL-1b, and IL-6 are secreted by PBMCs and macrophages from HIV-infected subjects, and are found at elevated levels in serum, cerebrospinal fluid, and tissues (reviewed in references 108, 440). High levels of expression of these cytokines, as well as IFN-g (50) and IL-10 (216), are particularly evident in lymphoid tissue, a major site of HIV replication throughout the course of disease (142, 165, 418, 419). Chronically activated CD8+ T cells (266) and HIV-infected macrophages (373) are thought to be major contributors to the elevated cytokine levels observed in HIV-infected subjects.

Another major disruption in the cytokine pattern observed in HIV disease is a progressive loss in the ability to produce immunoregulatory cytokines, such as IL-2 and IL-12 (100, 306). IL-2 and IL-12 are critical for effective cell-mediated immune responses, as they stimulate proliferation and lytic activity of CTLs and NK cells. In addition, IL-12 is essential for stimulating the production of T helper (TH)-1 type cytokines, including IL-2 and IFN-g, that favor the development of cell-mediated immune responses (338, 256). The TH1 limb of cellular immune responses is impaired during the course of HIV infection; this is especially true with regard to defects in IL-2 production and IL-2 receptor expression (98, 121, 336, 362). Although the cause of this TH1 defect in HIV infection is multifactorial, it may derive in part from the ability of the HIV envelope to induce IL-10 production in monocytes, and thereby inhibit IL-2 secretion (30). Some investigators have proposed that a dominance of TH2-like responses (i.e., secretion of IL-4, IL-5, and IL-10) characterizes progression of HIV disease (101, 290). Most studies, however, suggest that cytokine dysregulation during the course of HIV infection is complex and cannot easily be classified in terms of TH1 and TH2 polarity (216, 336, 362).

Effect of Cytokines on HIV Replication

Soluble factors produced by activated PBMCs (162), macrophages (103), and B cells (459) can dramatically up-regulate HIV expression in acutely and chronically infected cells of the lymphocytic and macrophage lineages (Fig. 8). Cytokines that have been reported to up-regulate HIV replication *in vitro* include IL-1b, IL-2, IL-3, IL-6, IL-7, IL-12, IL-15, IL-18, TNF-a, TNF-b, and the colony-stimulating factors (CSF) macrophage (M)-CSF and granulocyte-macrophage (GM)-CSF (reviewed in reference 108; see also 7, 34, 285, 327, 502, and 511). IFN-a, IFN-b, and IL-16 (10, 235) are primarily suppressors of HIV production, whereas other cytokines, such as IL-4 (391, 550), IL-10 (573, 574), IL-13 (391), IFN-g (42, 229), and transforming growth factor (TGF)-b, reduce or enhance viral replication depending on the infected cell type and the culture conditions. The effects of a particular cytokine are often greatly influenced by the activity of other cytokines present in the lymphoid tissue microenvironment (439, 442, 574).

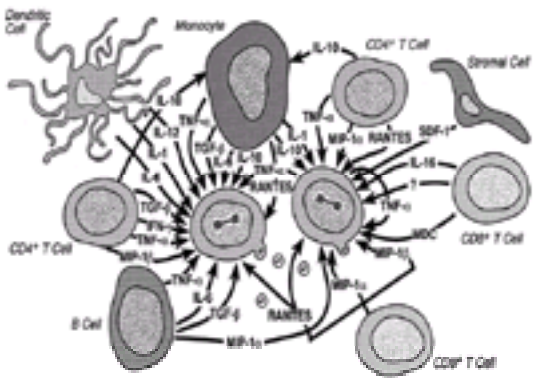

FIG. 8. Cytokine networks that regulate human immunodeficiency virus (HIV) replication. The proinflammatory cytokines tumor necrosis factor (TNF)-a, interleukin (IL)-1b, and IL-6 strongly enhance viral replication. Transforming growth factor (TGF)-b and IL-10 down-regulate viral replication; in the case of IL-10, this occurs at least in part because of down-regulation of the proinflammatory cytokines. The CC-chemokines inhibit R5 strains of HIV, SDF-1 inhibits X4 strains, and MDC-1 inhibits both R5 and X4 strains. Adapted from ref. 152, with permission.

Proinflammatory cytokines, particularly TNF-a, are considered the most potent HIV-inducing cytokines, and their mechanism of action is relatively well understood. Both TNF-a and IL-1b activate the cellular transcription factor nuclear

factor (NF)kB (137,406), a strong inducer of HIV LTR-mediated transcription. IL-6 increases HIV expression primarily by a posttranscriptional mechanism; however, IL-6 can synergize with NFkB-inducing cytokines to enhance HIV transcription (439). The production of HIV by macrophages or PBMCs stimulated with physiologic inducers of proinflammatory cytokine production, such as bacterial endotoxin or IL-2, can be partially or nearly completely abrogated by the addition of antiproinflammatory cytokines (200,573), neutralizing antibodies to the cytokines (285), or receptor antagonists (ra), such as IL-1ra (285). In cultures of HIV-infected macrophages, the viral-suppressive activity of several cytokines, such as IL-10 and TGF-b, is attributable largely to their ability to inhibit the secretion or activity of HIV-inducing proinflammatory cytokines (200,443,573). HIV production by infected T cells is sensitive to both the antiproinflammatory and the antiproliferative activity of such cytokines (202).

Administration of agents that block the action of HIV-inducing proinflammatory cytokines has met with limited therapeutic success. However, the use of cytokine-based therapies aimed at immune reconstitution in HIV disease has expanded over the past several years, particularly with the development of potent antiretroviral therapies that limit the potential for cytokine-mediated increases in viral replication. In this regard, administration of IL-2 to asymptomatic HIV-infected subjects simultaneously receiving effective antiretroviral therapy results in significant and sustained increases in $CD4^+$ T-cell numbers with no concomitant sustained increases in viremia (302). Ongoing studies are continuing to expand the list of cytokines for use as potential immunotherapeutic agents; IL-12, IL-13, IL-15, and IL-16 are all candidates (376,497,615).

Chemokines, or chemoattractant cytokines, are produced by numerous cell types, and may influence HIV replication by binding to chemokine receptors that also serve as HIV coreceptors (Fig. 9) (324). Chemokine production, induced during inflammation, is enhanced by CD40 ligand stimulation (299,350), and by several cytokines including TNF-a, IL-1b, IL-2, and IL-15 (483). Chemokines that bind to CCR5 suppress HIV replication *in vitro* in PBMCs from asymptomatic HIV-infected individuals harboring predominantly R5 strains of HIV (284), but not in PBMCs from individuals with more advanced disease harboring predominantly X4 strains of HIV (265,284). Similarly, HIV isolates obtained longitudinally from individuals with rapid disease progression exhibit reduced sensitivity to inhibition by CCR5 ligands *in vitro* over time (114,265). Ligation of chemokine receptors in different cell types may have different effects on HIV replication; CC-chemokines inhibit replication of R5 strains of HIV in $CD4^+$ T cells, but may actually enhance replication of these strains in monocyte/macrophages (277,485). Unanticipated effects of manipulating the chemokine–chemokine receptor axis have also been observed, including CC-chemokine–mediated up-regulation of CXCR4 expression and enhancement of replication of X4 strains of HIV *in vitro* that is dependent on intracellular signal transduction (135,283).

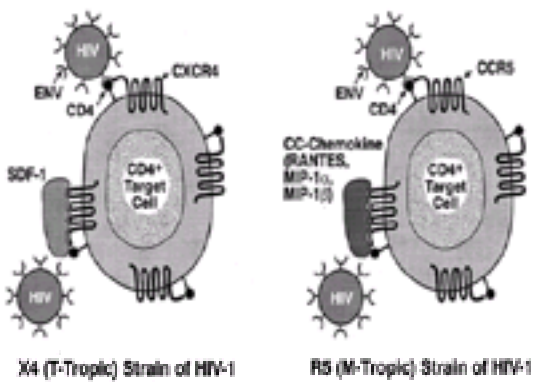

FIG. 9. Model of human immunodeficiency virus (HIV) coreceptor (CCR5 and CXCR4) use and inhibition of HIV entry by coreceptor ligands. Entry of R5 (i.e., predominantly macrophage tropic) strains of HIV is blocked by the CCR5 ligands macrophage inflammatory protein (MIP)-1a, MIP-1b, and RANTES. Entry of X4 (i.e., predominantly T-cell tropic) strains of HIV is blocked by the CXCR4 ligand SDF-1. Adapted from ref. 152, with permission.

Immunologic signals, cytokines, and chemokines influence chemokine receptor expression, which may also exert variable strain-dependent effects on HIV replication and spread (44,283). In this regard, differential regulatory patterns clearly distinguish the major HIV coreceptors, CCR5 and CXCR4 (44,548). CCR5 expression is predominantly seen in previously activated, memory T cells (i.e., $CD26^{high}CD45RO^+$ cells), whereas CXCR4 expression is seen in naive, unactivated cells (i.e., $CD26^{low}CD45RA^+$ cells). Cytokines that are characteristic of TH1-type responses, such as IL-2, IL-12, TNF-a, and IFN-g up-regulate CCR5 expression (44,233,531), whereas TH2-associated cytokines, such as IL-4 and IL-10, tend to up-regulate CXCR4 expression and down-regulate CCR5 expression (176,531,550). Stimulation of CD4+ T cells through CD3 and CD28 protects cells from HIV infection and potently down-regulates HIV replication in infected cells (314,460,465); this effect appears to be due in part to down-regulation of CCR5 (64). Finally, various components of pathogens, including HIV-1 itself, can induce expression of CXCR4 and favor replication of X4 strains of virus that use this coreceptor (258,378,379).

IMMUNE DYSFUNCTION DURING HIV INFECTION

The pathogenesis of HIV disease is a complex, multifactorial process (108,151). A wide array of immune system defects is associated with HIV infection; abnormalities in the function of all limbs of the immune system, including T and B lymphocytes, APCs, NK cells, and neutrophils, have been described.

CD4+ T Cells

CD4+ T-cell dysfunction and depletion are hallmarks of HIV disease. The proximate cause of the susceptibility to opportunistic infections observed with advancing disease is the defects in T-cell number and function that result directly or indirectly from HIV infection. In addition to the decrease in IL-2 production and IL-2 receptor expression, the

percentage of CD4+ T cells expressing CD28 (i.e., the major costimulatory receptor that is necessary for normal activation of T cells) is reduced during HIV infection compared with cells from uninfected individuals (87). $CD28^-$ cells do not respond to activation signals, and express markers of terminal activation, including HLA-DR, CD38, and CD45RO (587). CD4+ T cells from HIV-infected individuals express abnormally low levels of CD40 ligand (47), and this may in part explain the dysregulation of B-cell function that is observed during the course of disease.

A variety of mechanisms, both directly and indirectly related to HIV infection of CD4+ T cells, are likely responsible for the observed defects in T-cell function. Interference with CD4 expression by HIV gp120 (255), Nef (184), and Vpu (581) may impair the ability of the infected CD4+ T cell to interact with appropriate MHC class II molecules. Preferential infection by HIV of CD4+ memory cells and/or the preferential susceptibility of these cells to the cytopathic effects of HIV infection may in part explain the loss of memory responses to soluble antigens and consequent increase in the risk of infection with opportunistic organisms (92,306,490).

The relatively small fraction of T cells that is infected with HIV (i.e., generally <1% even in the late stages of disease) in seropositive subjects at any given time militates against direct infection as the sole mediator of the immunopathogenesis of HIV infection (see later) (418). In addition, CD4+ T-cell dysfunction is evident even in the early stages of HIV infection, before quantitative depletion of this key cellular subset (306). A role for HIV envelope in the immunopathogenesis of HIV disease has been suggested by a number of studies (reviewed in reference 83). The presence of measurable levels of circulating soluble gp120 in HIV-infected subjects (402) and accumulation of high concentrations of virions (both infectious and defective) in lymphoid tissue (165,419,530) underscore the potential for envelope to contribute to T-cell dysfunction in a process distinct from infection of CD4+ T cells.

HIV envelope glycoproteins bind with high affinity to the CD4 molecule and to a number of chemokine coreceptors. Evidence of aberrant intracellular signaling induced by HIV has been available for a number of years (226). Intracellular signals transduced by HIV-1 envelope have been implicated in several immunopathogenic processes, including anergy (409), syncytium formation (106), apoptosis (28,578), and inappropriate cell trafficking (369,575). The molecular mechanisms responsible for these abnormalities include dysregulation of the T cell–receptor phosphoinositide pathway (69), p56lck activation (199,249), phosphorylation of focal adhesion kinase (95), down-regulation of the costimulatory molecules CD40 ligand and CD80 (82), and activation of the MAP kinase and ras signaling pathways (533). Most of these aberrant signals were presumed to result from interactions between HIV envelope glycoproteins and CD4; however, more recently it has become clear that HIV envelope also may transduce intracellular signals through coreceptor molecules such as CCR5 (95,122,575) and CXCR4 (369).

CD4+ T-Cell Depletion

The frequent appearance of X4 strains of HIV late in the course of disease heralds accelerated CD4+ T-cell decline and clinical disease progression (78,298,539). Because the transition from an R5 to an X4 strain of virus may occur by mutation of only a few amino acid residues, predominantly in the envelope V3 loop (79,262,532,598), it is uncertain why such mutants fail to emerge until late in the disease process. The accelerated decline in CD4+ T-cell numbers associated with the emergence of X4 strains of HIV suggests that viral determinants are important with regard to pathogenicity. Because the viral determinant of cellular tropism maps to the gp120 envelope protein of HIV-1 (see earlier, and 105), this observation implicates the viral envelope as a significant mediator of HIV-induced CD4+ T-cell depletion. In an *ex vivo* model system of HIV infection of lymphoid tissue, the viral envelope does indeed appear to be responsible for CD4+ T-cell depletion; although both R5 and X4 strains of virus were capable of depleting CD4+ T cells in this system, R5 viruses depleted only $CD4+CCR5^+$ cells, whereas X4 viruses depleted all CD4+ cells (221). In an SHIV animal model, the viral envelope ectodomains determined the extent of CD4+ T-cell depletion (274). Interestingly, the avidity of the viral envelope for its chemokine coreceptor correlated well with its ability to induce CD4+ T-cell depletion (274) .

Direct Infection as a Cause of CD4+ T-Cell Depletion

The observations that CD4+ T cells are the principal targets of HIV infection *in vivo* and that HIV infection of CD4+ T cells *in vitro* causes cytopathicity led to a reasonable assumption that direct infection of CD4+ T cells *in vivo* results in their depletion. However, quantitative studies of the frequency of HIV-infected cells *in vivo* suggest that single-cell killing by direct infection with HIV may not be the predominant mechanism of CD4+ T-cell depletion (418,489). Although it increases with disease progression, the frequency of HIV-infected peripheral blood CD4+ T cells rarely exceeds 1 in 100, even in patients with AIDS (489). Viral burden and levels of virus expression are far greater in lymphoid tissue compared with peripheral blood (142,418,419); however, these levels even in lymphoid tissue do not appear to be sufficiently high to account for CD4+ T-cell depletion solely by direct mechanisms.

Multiple mechanisms of cell death appear to be operative after infection of a CD4+ T cell with HIV (Table 1). Early events in the viral life cycle, such as accumulation of reverse-transcribed viral DNA in the cytoplasm, may contribute to cell killing in HIV infection (503); however, this is clearly not the sole mechanism responsible for single-cell killing by HIV (38). High levels of viral RNA and aberrant RNA molecules also are present in the cytoplasm of infected cells, and possibly interfere with normal cellular RNA processing (295,513).

Direct mechanisms
• Accumulation of unintegrated viral DNA
• Interference with cellular RNA processing
• Intracellular gp120-CD4 autofusion events
• Loss of plasma membrane integrity due to viral budding
• Elimination of HIV-infected cells by virus-specific immune responses
Indirect mechanisms
• Aberrant intracellular signaling events
• Syncytium formation
• Autoimmunity
• Innocent bystander killing of viral antigen–coated cells
• Apoptosis
• Inhibition of lymphopoiesis

TABLE 1. *Mechanisms of CD4+ T-cell dysfunction and depletion*

The intracellular concentration of envelope gp120 molecules is high during the process of virion assembly in an HIV-infected cell. Several studies have suggested that intracellular gp120 may interact with intracellular CD4 molecules, and that this interaction may induce cell death (133,296). The mechanism of cell death as a consequence of this intracellular gp120–CD4 interaction may be autofusion events that disrupt the integrity of the cell membrane (57). Cell-membrane integrity also may be compromised by the budding of virions from an infected cell (313) and by HIV-induced increases in the concentration of intracellular monovalent cations (558).

HIV-infected cells also may die as a consequence of virus-specific immune responses that occur before the cell succumbs directly to viral infection. Multiple effector mechanisms may be involved in the killing of HIV-infected cells, including CTL responses, ADCC, and NK cell responses.

Indirect Mechanisms of CD4+ T-Cell Depletion

Syncytium formation. HIV envelope glycoprotein molecules are inserted into the host cell membrane during virion assembly, and also are shed by infected cells into the surrounding milieu. Interaction of these HIV envelope glycoprotein molecules with uninfected cells may be an important immunopathogenic mechanism of HIV infection.

The molecular events associated with viral entry that lead to fusion between the viral coat and cell membrane involve the interaction of the HIV envelope glycoprotein, CD4, and a coreceptor molecule. Similar events may occur when an infected cell bearing HIV envelope glycoprotein molecules on its surface encounters an uninfected CD4+ cell with an appropriate coreceptor. Fusion between infected and uninfected cells, resulting in multinucleated giant cells or syncytia, has long been observed *in vitro* (320,512). Other molecules implicated in syncytium formation include LFA-1 (248), CD7 (476), and HLA class I molecules (134). Syncytia have been observed only rarely in tissues obtained from HIV-infected individuals (167,452); thus it is unlikely that syncytium formation is a major pathogenic mechanism of CD4+ T-cell depletion *in vivo.*

Autoimmunity. Autoimmunity may occur during the course of HIV infection as a result of molecular mimicry by viral components. Highly homologous regions exist in the carboxy terminus of the HIV-1 envelope glycoprotein and the amino-terminal domains of different HLA-DR and DQ alleles (197). Sera from a substantial number of HIV-infected individuals react with the shared determinant of gp41 and MHC class II: these sera can inhibit normal antigen-specific proliferative responses and also eliminate class II–bearing cells by ADCC (198). Similar instances of molecular mimicry between HIV-1 envelope constituents and host proteins, which may result in pathogenic autoimmune responses, include the collagen-like region of complement component C1q-A (360), MHC class I heavy chains (215), HLA-DR4 and DR2 alleles (506), variable regions of the T-cell receptor a, b, and g chains (506), Fas (382,602), functional domains of IgG and IgA (506), denatured collagen (213), and a number of nuclear antigens (66). Finally, immune recognition of normal cellular components may be induced by their association with HIV; such phenomena may be responsible for the emergence of CTLs that are specific for autologous CD4+ T cells (212).

Innocent bystander phenomena. Immune responses that target HIV determinants on infected cells also may contribute to elimination of uninfected cells bearing HIV proteins (e.g., gp120) on their surface. Targeting of such “innocent bystander” cells by antibody and cellular immune responses has been described (329,570,606).

HIV-mediated inhibition of hematopoiesis. Failure of normal hematopoiesis is an obvious candidate mechanism to account for depletion of CD4+ T cells during HIV infection. A subset of CD34+ progenitor cells express CD4 and are infectable *in vitro* with HIV-1 (75,163). It is controversial whether CD34+ progenitor cells represent a substantial *in vivo* reservoir for HIV. A number of studies have failed to detect HIV-infected CD34+ progenitor cells in most HIV-infected individuals; however, a large study by Stanley et al. (522) showed that a substantial minority of HIV-infected patients with severe CD4+ T-cell depletion have a reservoir of HIV-infected CD34+ progenitor cells. Recent reports demonstrating expression of HIV coreceptors on CD34+ progenitor cells (62,128,473) suggest that the CD4+ subset of these cells may be infectable with HIV, further substantiating the earlier findings of Stanley et al.

Although the role of direct infection of CD34+ progenitor cells in HIV pathogenesis remains controversial, a large body of evidence suggests that viral proteins and HIV-induced cytokines can impair the survival and clonogenic potential of these cells (130,325,608).

Disruption of the thymic microenvironment (520) and HIV-induced thymocyte depletion also may contribute to the failure of CD4+ T-cell regeneration. Thymic epithelial cells normally secrete IL-6, which can in turn increase HIV replication in infected cells (492). Subpopulations of thymic CD3–CD4–CD8– cells (i.e., “triple negative” cells) are susceptible to infection with HIV *in vitro* (551), and thymic CD3–CD4+CD8– progenitor cells from HIV-infected patients are infected *in*

vivo. Finally, uninfected thymocytes from HIV-infected individuals are primed for apoptotic death, suggesting that indirect mechanisms of defective thymopoiesis are operative as well (528).

Apoptosis. Aberrant intracellular signals transduced by HIV may prime CD4+ T cells for apoptosis, resulting in depletion of these cells during the course of HIV infection (9). Acute infection of T cells with HIV *in vitro* can induce apoptosis (537), and T cells from HIV-infected patients undergo enhanced rates of apoptosis *in vitro* compared with normal T cells, particularly after activation (224,361). Cross-linking of CD4 followed by ligation of the T-cell receptor is sufficient to induce apoptosis, suggesting that uninfected CD4+ T cells can be depleted inappropriately on encountering antigen if CD4 has been cross-linked by gp120 (28).

Fas-dependent and Fas-independent pathways of apoptosis may be triggered by HIV. HIV-mediated Fas-independent apoptosis of CD4+ T cells has been shown *in vitro* by several groups (180); enhanced susceptibility of CD4+ T cells to Fas-dependent apoptosis has been reported as well. Mechanisms that may contribute to this susceptibility include up-regulation of Fas and Fas ligand (24,578); up-regulation and activation of caspase-1 (509), caspase-3 (94), and caspase-8 (33); activation of cyclin-dependent kinases (317); and down-regulation of the antiapoptotic Bcl-2 protein (456). Viral gene products that have been associated with enhanced susceptibility to apoptosis include the viral envelope (28,578), Nef (595,607), Tat (33,578), and Vpu (65).

The susceptibility of uninfected bystander cells to apoptosis is a possible mechanism by which large number of cells may be eliminated during HIV infection. Studies in lymphoid tissue from HIV-infected individuals suggest that the majority of apoptosis occurs in uninfected bystander cells (155,387). Macrophages are efficient mediators of CD4+ T-cell bystander apoptosis. HIV-induced up-regulation of Fas ligand expression on macrophages and enhanced secretion of TNF-a from these cells appear to be responsible in part for this phenomenon (23,24). Another mechanism of bystander apoptosis may involve up-regulation of CD62L on lymphocytes by HIV (564). These HIV-exposed lymphocytes home to lymph nodes, and undergo apoptosis on signaling through homing receptors such as CD62L, CD44, and CD11a (563).

It remains uncertain whether HIV-induced apoptosis plays an important role *in vivo* in CD4+ T-cell depletion. The frequency of apoptotic CD4+ and CD8+ T cells as well as B cells is significantly higher in lymphoid tissue from HIV-infected individuals compared with that from uninfected controls (387,469). The relationship between the frequency of apoptotic cells and the stage of HIV infection remains controversial. Some data indicate a positive correlation between the stage of HIV disease and susceptibility of peripheral blood T cells to apoptosis (207), and another study demonstrated very low frequencies of apoptotic cells in HIV-infected long-term nonprogressors (319). However, other studies found no correlation between apoptosis and stage of disease (363,387). Compelling evidence that apoptosis may play a role in HIV pathogenesis comes from animal models wherein an increased frequency of apoptosis in CD4+ T cells is seen in primates infected with pathogenic strains of SIV, but not in primates infected with nonpathogenic strains of SIV (148).

CD8+ T cells

Dysregulation of CD8+ T-cell numbers and function is evident throughout the course of HIV disease. After an initial decline associated with acute primary infection, CD8+ T-cell counts usually rebound to supranormal levels and may remain elevated for prolonged periods. Increases in CD8+ T cells during all but the late stages of disease may, in part, reflect the expansion of HIV-specific CD8+ CTLs.

During HIV disease progression, CD8+ T cells acquire an abnormal phenotype characterized by the expression of certain activation markers and the absence of expression of the CD25 IL-2 receptor. Alterations in the phenotype of CD8+ T cells in HIV-infected individuals may have prognostic significance. In this regard, individuals whose CD8+ T cells express HLA-DR but not CD38 after seroconversion experience a stabilization of their CD4+ T-cell counts and a less fulminant disease course, whereas individuals whose CD8+ T cells express both HLA-DR and CD38 experience a more aggressive course with rapid CD4+ T-cell depletion and a poorer prognosis (189). CD8+ T cells lacking CD28 expression also are increased in HIV disease (479), possibly reflecting the expansion of the $CD8+CD28^{-}CD57^{+}$ T-cell subset containing *in vivo* activated CTLs (554). The loss of CTL activity with disease progression is not restricted to HIV-specific CTLs; a loss of cytotoxic activity to other common antigens including Epstein–Barr virus (EBV) and *Mycobacterium tuberculosis* also has been observed. In addition to CTL activity, other CD8+ T-cell functions are impaired during HIV disease progression, including loss of noncytolytic non-MHC–restricted CD8+ T cell–derived suppressor activity against HIV (335).

Oligoclonal expansions of CD8+ T cells are characteristic of HIV infection. These expansions are composed largely of HIV-specific CTLs (417,582). The disappearance of CTLs with particular specificity can be due to a number of factors, including mutation of the virus within the CTL recognition epitope. Another cause for the disappearance of some CTLs, however, is clonal exhaustion. This phenomenon, wherein high concentrations of antigen completely mobilize a CTL response, occurs in lymphocyte choriomeningitis virus infection (380); depletion of the CTLs results in persistence of antigen. CTL exhaustion may occur to some extent during HIV infection, where disappearance of some CTLs is observed in the absence of viral escape mutations that would otherwise explain the phenomenon (352,423). Finally, CD8+ T cells may be depleted by apoptosis as innocent bystanders. This phenomenon may be mediated by macrophages in which CXCR4 has been triggered by HIV envelope; membrane-bound TNF-a is up-regulated by HIV in these cells, as is TNF receptor II on CD8+ T cells (245).

Monocytes/Macrophages

Cells of the monocyte/macrophage lineage play key roles in the immunopathogenesis of HIV disease. These cells serve as reservoirs of viral infection and are responsible for a variety of tissue-specific pathologic processes. Dysfunction of these cells contributes to CD4+ T-cell dysfunction, and also to impaired host defense against intracellular pathogens (150,151).

Monocytic cells express CD4 and numerous HIV coreceptors including CCR5, CXCR4, and CCR3 on their surfaces

(77,454,552), and serve as targets of HIV infection. Unlike infection of CD4+ T cells, HIV is relatively noncytopathic for cells of the monocyte/macrophage lineage, and HIV can replicate extensively in these cells in intracellular compartments (187). Chronically infected macrophages may be long-lived, and currently available antiretroviral agents are generally not capable of targeting chronically infected cells; these cells therefore represent a formidable challenge to eradication of HIV (428,495). Circulating monocytes are rarely found to be infected *in vivo* and are difficult to infect *in vitro* (491,549,569); however, infection can readily be demonstrated in tissue macrophages, including resident microglial cells in the brain, pulmonary alveolar macrophages, and mature macrophages derived from blood monocytes *in vitro* (187,294,437). Infection of monocytic precursors in bone marrow may be directly or indirectly responsible for certain of the hematologic abnormalities observed in HIV-infected individuals. Lymphoid tissue macrophages can be prolific producers of HIV in the setting of opportunistic infections, during which the cytokine milieu in the tissue favors a highly productive state of HIV infection (405).

Infection of monocyte/macrophages with HIV or exposure of these cells to viral proteins, including envelope glycoproteins and Tat, leads to a number of functional abnormalities. Impaired accessory cell function (143,597) may result from decreased MHC class II expression, decreased IL-12 secretion, and increased IL-10 secretion (445,597); this HIV-induced dysregulation of antigen presentation may in turn be a significant cause of hyporesponsiveness of CD4+ T cells (143). Defects in ADCC function of monocyte/macrophages, possibly related to low levels of expression of Fc and complement receptors, also have been observed in HIV infection (36,278). Finally, HIV-associated abnormalities in antigen uptake, oxidative burst, and chemotaxis have been described in monocyte/macrophages (383,438,445).

Cells of the monocyte/macrophage lineage are central to the pathogenesis of HIV-induced CNS disease. HIV infection of brain microglial cells, derived from the monocytic lineage, may lead to encephalopathy and neuropathy (51), astrocytosis (395), and cerebral vasculitis (174). Levels of the chemokine monocyte chemotactic protein (MCP)-1 are markedly elevated in the CSF of AIDS patients with HIV encephalitis (96); a major source of these high levels of MCP-1 is likely HIV-infected macrophages (96). MCP-1 in turn recruits and activates monocytes, which elaborate proinflammatory cytokines and thereby enhance HIV replication and induce neuropathologic disease (544). Other mediators of neuropathology that are elaborated by monocyte/macrophages include neurotoxic amines (191), and quinolinic acid (498). These substances may induce neuronal injury by triggering apoptosis (430).

Dendritic Cells

DCs are among the first cells to encounter HIV after mucosal exposure and likely are responsible for transporting the virus to lymphoid organs, thus facilitating infection of CD4+ T cells and viral dissemination. DCs express several different chemokine receptors that can be used as HIV coreceptors for entry (211,472,604). Studies of DCs from HIV-infected individuals have yielded conflicting results; however, productive infection of tissue DCs with HIV appears to be rare (272,351).

It has been reported that infectability of DCs may be dependent on viral subtype (514). This finding could in part explain the differences in the global epidemiology of HIV infection; an HIV subtype that can replicate well in Langerhans cells, likely a major cell type involved in the initiation of viral infection through mucosal contact (516), may be more efficiently transmitted heterosexually. It should be pointed out that these findings are controversial (447), although data do suggest a role for DCs in selecting the strain of HIV that can be transmitted across a mucosal barrier (455).

The degree of DC dysfunction and depletion that occurs during HIV infection remains controversial (56). Emerging data suggest that a subset of DCs expressing CD11c are depleted during the course of HIV infection; interestingly, these cells were not restored during highly active antiretroviral therapy (214). Further studies are needed to clarify the possible role of DC depletion and dysfunction in the pathogenesis of HIV disease.

B Lymphocytes

HIV infection is almost invariably associated with hypergammaglobulinemia and B-lymphocyte hyperactivation. A large component of the immunoglobulin specificity, at least in early-stage disease, is directed against HIV antigens. It has been suggested that a majority of activated B cells produce antibodies directed against HIV during this stage of infection (reviewed in reference 8). In spite of the observed B-cell hyperactivation, the ability of B cells to respond specifically to antigens is reduced. B cells from HIV-infected individuals express abnormally low levels of HLA-DR on their surfaces (188), and also fail to up-regulate CD70 normally after stimulation with activated T cells (587); this latter defect is associated with impaired CD70-dependent immunoglobulin synthesis (587). In patients with advanced-stage HIV infection, B cells fail to proliferate and differentiate in response to ligation of the B-cell antigen receptor and CD40, suggesting a defect in signal transduction (113). Further evidence of HIV-related B-cell dysfunction comes from an *in vitro* lymphoid tissue-culture model of HIV infection. In this model, infection of lymphoid tissue with strains of HIV that use CCR5 as an entry coreceptor results in enhanced antibody responses to recall antigens on challenge; in contrast, HIV strains that use CXCR4 result in profound suppression of these antibody responses (192). This effect appears to be dependent on signal transduction through CXCR4 and may be irreversible (192).

B cells from HIV-infected individuals secrete increased amounts of TNF-a and IL-6, cytokines known to enhance HIV replication (458,459), and express surface-bound TNF-a that can induce the production of HIV from infected CD4+ T cells (330). The secretion of proinflammatory cytokines and the expression of surface-bound TNF-a by B cells in the lymphoid microenvironment may contribute to T-cell activation and HIV replication in these tissues.

HIV gp120 has been observed to bind directly to an immunoglobulin variable chain (VH3) and activate these B cells in much the same manner as a superantigen (37). This antigen-independent polyclonal activation leads in part to the hypergammaglobulinemia and B-lymphocyte hyperactivation of HIV infection. Other portions of HIV, including gp41, directly activate B cells in a non–superantigen-mediated manner (81). Correlates of B-cell dysfunction observed in HIV-infected individuals include an increase in spontaneous EBV transformation *in vitro* and may contribute to the observed increased frequency of EBV-induced lymphomas (374). In addition, the increased susceptibility to bacterial

infections during the course of HIV infection likely results in part from B-cell dysregulation (494).

B cells also may serve as a viral reservoir during the course of HIV infection. In this regard, stimulation of B cells with CD40L and IL-4 up-regulates expression of activation and costimulatory molecules, as well as CD4 and CXCR4. B cells stimulated in this manner are susceptible to infection with dual- and T-tropic strains of HIV (372).

Neutrophils

Neutrophils appear to be hyperactivated during the course of HIV infection, and many functional defects have been observed in these cells (359). Neutrophils from HIV-infected individuals produce more TNF-a and IL-6 in response to lipopolysaccharide (LPS) or *Candida* antigen compared with neutrophils from normal donors (541). These cells also undergo apoptosis at an increased rate compared with those from normal controls (436). When stimulated through Fc receptors or protein kinase C, neutrophils from HIV-infected individuals produced less superoxide compared with controls; this defect could be recapitulated by treatment of normal neutrophils with HIV envelope protein (386).

Dysfunction of neutrophils in HIV-infected individuals has several clinical implications. HIV infection, especially in women, is characterized by an increase in the incidence and severity of *Candida* infections. Although neutrophils from HIV-infected patients readily phagocytize *Candida* organisms, they have a decreased ability to kill the organisms, suggesting a defect in nonoxidative killing (577). This defect may be mediated in part by elevated levels of IL-10 (534).

Natural Killer Cells

Abnormalities of NK cells are observed throughout the course of HIV disease, and these abnormalities increase with disease progression. Most studies report that NK cells are normal in numbers and phenotype in HIV-infected individuals; however, decreases in numbers of the $CD16^+/CD56^+$ subpopulation of NK cells with an associated increase in activation markers has been reported (257). NK cells from HIV-infected individuals are defective in their ability to kill typical NK target cells as well as gp160-expressing cells. The abnormality in NK cell lysis is thought to occur after binding of the NK cell to its target (2). A possible mechanism for defective NK activity includes a lack of cytokines necessary for optimal function. Addition of either IL-2, IL-12, IL-15, or IFN-a to cultures enhances the defective *in vitro* NK cell function of HIV-infected individuals (74,545). Enhanced expression of cytolytic inhibitory receptors during the course of HIV infection also may be responsible for depressed NK cell function (13,175); in addition, selective HIV-mediated down-regulation of HLA-A and -B, but not HLA-C and -E molecules may allow CTL escape and simultaneously prevent NK cell killing of HIV-infected target cells (107).

NK cells are an important source of HIV-inhibitory CC-chemokines in HIV-infected individuals (404). NK cells isolated from HIV-infected individuals produce high constitutive levels of MIP-1a, MIP-1b, and RANTES; high levels of chemokine production also are seen when these cells are stimulated by IL-2, IL-15, or CD16 cross-linking, or during lytic killing (404). Thus NK cells, like CD8+ T cells, may inhibit HIV replication by cell-mediated killing as well as by secretion of soluble HIV-inhibitory factors.

ROLE OF CELLULAR ACTIVATION IN HIV PATHOGENESIS

The result of HIV infection is profound immunodeficiency; however, paradoxically, HIV infection is associated with hyperactivation of the immune system through most of the course of disease (Table 2). HIV subverts the immune system by inducing immune activation and using this milieu to its own replicative advantage (108,151,158).

- Hyperactivation of B cells
- Hypergammaglobulinemia
- Spontaneous lymphocyte proliferation
- Activation of monocytes with secretion of proinflammatory cytokines
- Increased expression of activation markers on T cells
- Follicular hyperplasia of lymphoid tissue
- Elevated circulating levels of neopterin, β_2-microglobulin, acid-labile interferon, soluble tumor necrosis factor receptors, and soluble interleukin 2 receptors
- Autoimmune phenomena

TABLE 2. *Manifestations of an activated immune system in HIV disease*

The replicative cycle of HIV infection is most efficiently achieved in activated cells (53,527,599). Cytokines that induce T-cell activation can further contribute to viral replication by inducing a state of productive infection in latently infected resting T cells (86). Several lines of evidence suggest that HIV replication *in vivo* is dependent on antigen-driven activation of CD4+ T cells. HIV-infected individuals with intercurrent infections experience transient increases in plasma viremia that correlate with the degree of induced immune activation; similar observations have been made in HIV-infected individuals who received immunizations against various pathogens (399,521,523). The amount of viral replication observed after vaccination with influenza vaccine or tetanus toxoid, or during active infection with *Mycobacterium tuberculosis,* correlated inversely with the stage of HIV disease. Individuals with late-stage HIV disease had a moderate increase in viral replication, whereas individuals with early-stage disease had a much greater increase in plasma viremia over baseline, suggesting a correlation between the ability of the immune system to respond to antigen and the magnitude of induction of virus replication. Furthermore, when PBMCs from tetanus toxoid–immunized, HIV-infected individuals were stimulated *in vitro* with tetanus antigen, or when PBMCs from purified protein derivative (PPD)-positive,

HIV-infected individuals were stimulated *in vitro* with PPD or live *M. tuberculosis,* subjects with early-stage disease manifested a much stronger proliferative response to the respective antigens with a larger increase in viral replication *in vitro* than did individuals with advanced-stage disease (201,407,521,523). These studies suggest that the level of viral replication correlates with the level of immune system activation in response to an antigen.

Analysis of viral quasispecies and immune responses within lymphoid tissue from HIV-infected individuals reveals that within individual splenic white pulps, a restricted number of individual antigen-specific immune responses occurs (defined by the analysis of T cell–receptor Vb gene use), and each of the immune responses contains a single or limited number of HIV quasispecies (80). These data support the theory that in the context of individual antigen-specific immune responses, a single quasispecies of HIV, which was present at the initiation of the reaction, spread among the newly activated T cells. Thus it is likely that the continuous daily production of HIV occurs in newly activated CD4+ T cells that are being driven by antigen-specific activation (80,223).

EPIDEMIOLOGY

The Global Pandemic

The global HIV pandemic ranks among the greatest infectious disease scourges in human history. Morbidity and mortality due to HIV infection are staggering; by the beginning of 2001, more than 36 million people worldwide were living with HIV (Fig. 10), and 21.8 million deaths due to HIV infection had occurred since the beginning of the epidemic (547). During 2000 alone, nearly 6 million individuals worldwide acquired HIV infection, and 3 million deaths due to HIV infection occurred; these statistics highlight the continued expansion of the epidemic on a global scale (547).

FIG. 10. Global distribution of the estimated number of individuals living with human immunodeficiency virus (HIV) infection as of December 2000. From ref. 547, with permission.

Phylogenetic analysis of HIV proviral sequences worldwide reveals three major genetic groups of HIVs, the M (major), N (new), and O (outlier) groups. The three major HIV groups are most closely related to SIV sequences (SIVcpz) harbored by chimpanzees of the subspecies *Pan troglodytes troglodytes* (182). The relatively rare O group viruses are concentrated in western Africa in Cameroon, Gabon, and Equatorial Guinea. Group N viruses were isolated in 1998 in two individuals from Cameroon (507). Within the M group, related HIV variants are classified into clades, or subtypes (currently designated A–J) according to their degree of genetic similarity (Fig. 11) (311). At the nucleotide level, viral subtypes differ from each other by about 14% in their *gag* (viral core) coding sequences, and by about 30% in their envelope coding sequences (311). Subtype C viruses are the most common worldwide; they are prevalent in eastern and southern Africa and India, although such viruses also have been isolated in Europe, Russia, China, and Brazil (146). Subtype A viruses are concentrated in central Africa, and also are found in Europe, Russia, east Asia, and South America (146). Subtype B viruses comprise the overwhelming majority of viruses isolated in the United States, likely as a result of a dominant founder effect. Subtype B viruses also are prevalent in Europe, Australia, and South America; variant subtype B viruses have been isolated in Thailand, China, Malaysia, and Japan. Subtype D viruses circulate primarily in central Africa, whereas subtype E viruses are isolated predominantly in the rapidly expanding epidemic in southeast Asia (146). HIV viral subtypes G, H, and J have been isolated in central Africa; however, all three of these subtypes are uncommon.

FIG. 11. Global distribution of human immunodeficiency virus (HIV)-1 subtypes. Subtype B predominates in the United States and Western Europe; however, subtypes C and A are the most prevalent subtypes in the world, particularly in Africa and Asia. From ref. 547, with permission.

The dynamics of the spread of different subtypes of HIV through populations is likely determined by the genetics of the population as well as by viral properties. Some phenotypic properties may be subtype specific. In this regard, the frequency of subtype C HIV viruses that are syncytium inducing and use CXCR4 as a coreceptor is extremely low (427). Additional data suggest that clinical outcomes may vary according to HIV subtype. In one study, infection with subtype A viruses was associated with a more favorable prognosis (273), and in another, infection with subtype C viruses was associated with a poor prognosis (394).

Zoonotic transmission of a retrovirus from chimpanzees to humans in sub-Saharan Africa is the most plausible explanation for the genesis of the HIV epidemic (182). From central, western, and eastern sub-Saharan Africa, the epidemic spread to North America, Latin America, Western Europe, southeast Asia, and southern Africa. Currently, the heaviest burden of the epidemic is concentrated in southern Africa, India, and southeast Asia. Although only 12% of the world's population lives in sub-Saharan Africa, 70% of individuals worldwide who acquired HIV infection in 2000 live there. Of all AIDS deaths since the beginning of the AIDS epidemic, 78% have occurred in sub-Saharan Africa. In the southern African countries of Botswana, Lesotho, Swaziland, and Zimbabwe, 24% to 36% of the population between the ages of 15 and 49 years are HIV infected. The epidemic also is expanding very rapidly in South Africa; 15% of new infections in the entire African continent in 1998 occurred in South Africa. Complex sociologic factors determine the dynamics of the HIV epidemic in different communities. In South Africa, large numbers of male migrant workers are attracted by employment opportunities afforded by valuable natural resources (i.e., gold and diamond mining); this scenario has in turn spawned a large sex-for-money trade that fuels the spread of HIV infection. A great deal of social stigma is associated with HIV infection in South Africa; this further fuels the epidemic, as it hinders open discussion about the disease and its prevention.

Nearly 1% of the adult population in India is infected with HIV. Although this seroprevalence is lower than that in many affected countries, it makes India the country with the largest number of HIV-infected individuals (approximately 4 million). Most HIV infections in India have occurred during the 1990s. Thus an extraordinary burden of HIV-related morbidity and mortality lies ahead in India, as the epidemic there is in its early stages. Alarmingly, among women attending a sexually transmitted disease clinic in Pune, India, more than 90% were married and monogamous; nearly 14% of these women tested positive for HIV (181).

Societal changes are fueling the spread of HIV in eastern Europe and central Asia. Increasing availability and use of illicit drugs, and a burgeoning sex-worker population in the republics of the former Soviet Union have contributed to a 25-fold increase in rates of syphilis in the 1990s (547). Although the absolute number of HIV infections in the region is small, the rate of increase is very rapid. In this regard, the cumulative number of HIV cases reported in the region increased more than five-fold between 1995 and 1997, from 9,111 to 46,573, with Ukraine, Russia, and Belarus accounting for about 90% of all new cases (127). The Yunnan province of China borders the poppy-rich regions of southeast Asia, and 70% of injection-drug users in this province are HIV infected. A similar situation exists in the Xinjiang province, which borders the poppy-growing regions of Pakistan and Afghanistan. Current estimates place the burden of HIV infections at 500,000 in China, and this number appears to be growing rapidly. Molecular epidemiologic studies indicate that nearly 50% of viral isolates originated from injection-drug users in Thailand, and one third of isolates originated from injection-drug users in India.

In the United States, between 600,000 and 800,000 individuals are infected with HIV (547). Although the incidence of new infections declined substantially in the late 1980s as a result of successful prevention efforts, a plateau of approximately 40,000 new HIV infections per year has persisted through the 1990s (467). The availability of HAART in developed countries has led to substantial reductions in the death rate due to AIDS (371,413). Unfortunately, no such benefit has reached the developing world, where AIDS-related mortality continues to exact a devastating toll. The nine African nations with an HIV seroprevalence of greater than 10% will experience a decline in average life expectancy of 17 years by the year 2015; instead of an average life expectancy that would have been on a trajectory to reach 64 years in the absence of HIV, it will decline to only 47 years (Fig. 12) (547). Infant mortality rates are increasing sharply in these countries as well, largely as a direct result of HIV infections. Finally, most developing countries do not have adequate resources to provide for a growing population of AIDS orphans; 20% to 30% of all children younger than 15 years had been orphaned by the year 2000 in nine sub-Saharan countries (540). Many of these orphans, particularly in urban areas, are at high risk for homelessness, starvation, and violent crime.

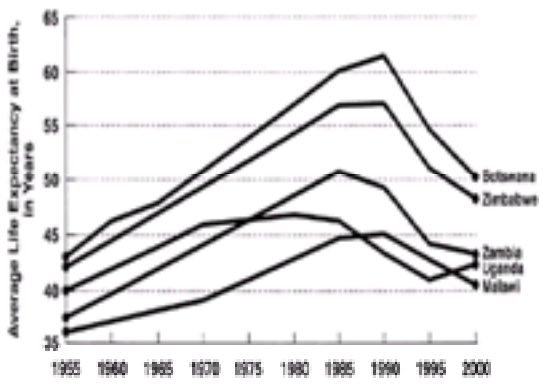

FIG. 12. Projected changes in life expectancy in selected African countries with high human immunodeficiency virus (HIV) prevalence. The extensions in life expectancy realized through improved living conditions and health care from the 1950s through the 1980s are being eroded as a result of HIV-related mortality. From ref. 547, with permission.

Transmission

HIV is transmitted by exposure of the oral, rectal, or vaginal mucosa during sex, by inoculation (i.e., through transfusion of contaminated blood products, use of contaminated equipment during injection-drug use, or maternal–fetal circulation), or by breast feeding. Sexual transmission accounts for more than 90% of HIV infections worldwide. In developing countries, most infections occur as a result of heterosexual contact, with a male-to-female ratio of approximately 1. In the United States and Western Europe, the vast majority of HIV infections that occurred early in the epidemic were associated with homosexual contact. Specifically, unprotected receptive anal intercourse was identified as the strongest risk factor for acquisition of HIV infection in men who reported having sex with men. The demographic characteristics of the epidemic have shifted considerably over the years, with a higher percentage of new infections occurring in injecting drug users and their sex partners. Minority populations are disproportionately affected by HIV; in 2000, AIDS rates per 100,000 population were 84.2 for blacks, 34.6 for Hispanics, and 9.0 for whites (71). Women are also increasingly affected by the HIV epidemic; in the United States, the percentage of AIDS cases occurring in women increased from 7% to 23% between 1985 and 1999 (71). Fewer than 50% of AIDS cases in the United States that occurred in 1999 were in men who have sex with men (71). Behavioral risk factors also have shifted over time. In a cohort of men who have sex with men that was recruited in 1992 through 1994, only 15% of HIV seroconversions that occurred were the result of unprotected anal intercourse; many seroconversions appear to occur after activities previously considered to be of lower risk, including oral sex (555).

Transmission of HIV is dependent on a large number of behavioral and biologic factors. The per-contact probability of male-to-female HIV transmission during vaginal sex is approximately 0.1% to 0.2% (253,410); receptive anal intercourse is associated with a considerably higher (i.e., approximately 0.8%) risk of transmission (555). Not surprisingly, considerable heterogeneity exists in per-contact risk, with some individuals becoming infected after only one or several exposures, and others remaining uninfected despite frequent exposure (18,426,470,555). Some of the many variables that influence the probability of HIV transmission include the genetic background of the potential host (124,322,477), the size and infectiousness of the inoculum, and the local environment in which the exposure occurs. Factors that result in physical disruption of the exposed mucosa, such as the use of vaginal desiccants or the presence of genital ulcer disease, can enhance viral transmission (217,451,519,535).

CLINICAL FEATURES

The clinical features of HIV infection vary depending on the stage of disease. In the acute and early stages of the disease, symptoms resulting from immune hyperactivation predominate; however, with the inexorable depletion of CD4+ T cells that characterizes disease progression, overt cellular immunodeficiency and its many complications develop (Fig. 13). The 1993 CDC classification of HIV infection consists of clinical categories and quantitative CD4+ T-cell categories (Table 3) (70).

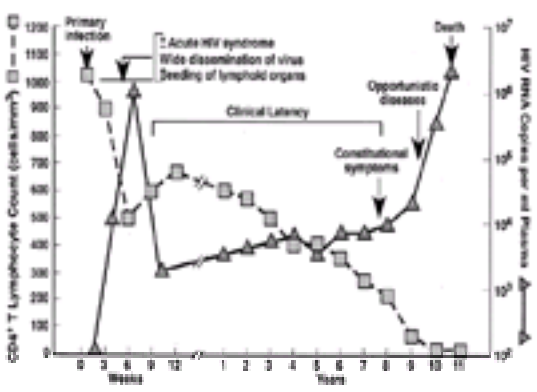

FIG. 13. Natural history of human immunodeficiency virus (HIV) infection. High levels of viremia during acute infection are often HIV associated, with a sharp decline in CD4+ T-cell numbers in the peripheral blood. Emergence of HIV-specific immune responses results in down-regulation of viremia and partial recovery of the CD4+ T-cell count. A long period of clinical latency ensues, during which levels of plasma viremia may remain relatively low, and the CD4+ T-cell count declines slowly. As the CD4+ T-cell count falls below 200 cells/μL, the risk for opportunistic diseases increases. In the late stages of disease, sharp increases in viremia and sharp declines in CD4+ T-cell counts occur. Adapted from Fauci AS, Pantoleo G, Stanley S, et al. Immunopathogenic mechanisms of HIV reproduction. *Ann Intern Med* 1996;124:654.

CD4 cell categories	Clinical categories: A Asymptomatic, lymphadenopathy, or acute infection	B Symptomatic,* not category A or C	C Clinical AIDS†
≥500/μL (≥29%)	A1	B1	C1
200–499/μL (14–28%)	A2	B2	C2
<200/μL (<14%)	A3	B3	C3

Categories A3, B3, and C1–3 are defined as AIDS.

*Examples of these symptoms include bacillary angiomatosis; thrush; vulvovaginal candidiasis that is persistent, frequent, or poorly responsive to therapy; cervical dysplasia or carcinoma in situ; constitutional symptoms such as fever or diarrhea of >1 month duration; oral hairy leukoplakia; multidermatomal or recurrent herpes zoster; immune thrombocytopenic purpura; listeriosis; pelvic inflammatory disease; and peripheral neuropathy.

†Candidiasis of the esophagus or respiratory tract; invasive cervical cancer; extrapulmonary coccidioidomycosis; extrapulmonary cryptococcosis; cryptosporidiosis; extrapyramidal cytomegalovirus infection; herpes simplex with mucocutaneous ulcer >1 month duration, or bronchitis, pneumonitis, or esophagitis; extrapulmonary histoplasmosis; HIV-associated dementia; wasting syndrome; isosporiasis; Kaposi's sarcoma; CNS lymphoma; non-Hodgkin's lymphoma; pulmonary tuberculosis; disseminated *M. tuberculosis*, *M. avium*, or *M. kansasii* infection; nocardiosis; *Pneumocystis carinii* pneumonitis; recurrent bacterial pneumonitis; progressive multifocal leukoencephalopathy; recurrent *Salmonella* septicemia; extrapulmonary toxoplasmosis.

TABLE 3. *AIDS surveillance case definition for adults and adolescents*

The CD4+ T-cell count is an excellent marker of the degree of immunodeficiency and determines the immediate risk of opportunistic infections and other AIDS-related complications (344). The plasma viral load is the most valuable prognosticator of HIV infection that is currently available (Fig. 14). Viral load not only predicts disease progression independent of the CD4+ T-cell count, but also actually predicts the trajectory of the CD4+ T-cell count (356,357). For example, the likelihood of developing AIDS within 3 years, given a plasma HIV RNA level of >30,000 copies/µL is 33% with a CD4+ T-cell count >500 cells/µL, 43% with a CD4+ T-cell count of 351 to 500 cells/µL, 64% with a count of 201 to 350 cells/µL, and 86% with a count of <200 cells/µL (356). Given a CD4+ T-cell count of 351 to 500 cells/mL, the likelihood of developing AIDS within 3 years increases from virtually nil with a plasma viral load of <3,000 copies/mL, to 8% with a viral load of 3,000 to 10,000 copies/mL, to 16% with a viral load of 10,000 to 30,000 copies/mL, and to 43% with a viral load >30,000 copies/mL (356).

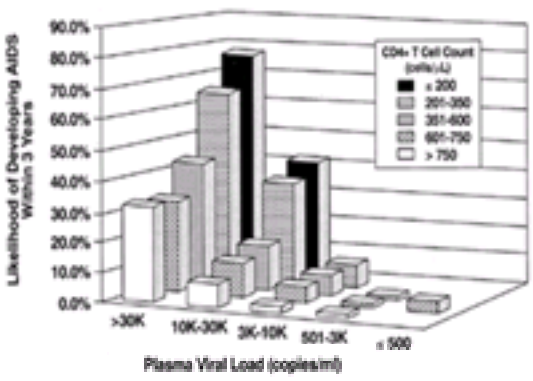

FIG. 14. Likelihood of developing acquired immunodeficiency syndrome (AIDS) within 3 years, given indicated levels of plasma viremia and peripheral blood CD4+ T-cell counts. Adapted from ref. 132, with permission.

Acute Infection

Although more than half of primary HIV infections (and perhaps up to 90%) are accompanied by symptoms, most of these infections are not recognized in the acute setting (481). The differential diagnosis of primary HIV infection is extremely broad, given the variable presentations associated with the syndrome. Fever, rash, pharyngitis, and lymphadenopathy are common during primary HIV infection, as they are in many “flu-like” and “mononucleosis-like” illnesses (397). Myalgias, arthralgias, diarrhea, nausea, vomiting, headache, hepatosplenomegaly, weight loss, thrush, and neurologic symptoms also may occur. Among patients who develop symptoms during primary HIV infection, the mean duration of symptoms is 3 weeks (281).

Plasma HIV RNA levels vary widely in primary HIV infection, from thousands to millions of copies per milliliter (482). After reaching a peak, plasma HIV RNA levels decline by about 6.5% per week over a 4-month period (482). A steep decline of 5.2 cells/µL/week occurs in the peripheral blood CD4+ T-cell count over the 5 months after primary infection (482). The peak level of HIV RNA may have prognostic value (355), and persistently high levels after 4 to 6 months add to the predictive power toward more rapid progression of disease (355,482).

Early-Stage Disease

The natural history of HIV infection includes a long period (i.e., approximately 10 years) of clinical latency between the time of primary infection and the development of symptoms indicative of advanced immunodeficiency. Even during the period of clinical latency, many patients experience fatigue as well as generalized lymphadenopathy. Syndromes indicative of depressed cell-mediated immunity in HIV infection that are not AIDS defining generally begin to appear as the CD4+ T-cell count falls below 500 cells/µL. Examples include oropharyngeal and recurrent vulvovaginal candidiasis, bacillary angiomatosis (usually due to infection with *Bartonella henselae*), recurrent or multidermatomal herpes zoster, listeriosis, infections due to *Rhodococcus equi,* pelvic inflammatory disease, oral hairy leukoplakia associated with EBV, cervical dysplasia (usually associated with human papillomavirus infection), constitutional symptoms such as unexplained fever or diarrhea lasting more than 1 month, idiopathic thrombocytopenic purpura, and peripheral neuropathy (70).

Late-Stage Disease

As the CD4+ T-cell count decreases below the level of approximately 200 cells/µL, the loss of integrity of cell-mediated immune responses allows ubiquitous environmental organisms with limited virulence (e.g., *Pneumocystis carinii* and *Mycobacterium avium*) to become life-threatening pathogens. Conditions indicative of severely depressed cell-mediated immunity due to HIV infection constitute the CDC surveillance case definition of AIDS (see Table 3 and reference 70). HIV-associated diseases indicative of severe impairment of cell-mediated immunity but not included in the current case definition of AIDS include chronic microsporidiosis, gastrointestinal infection with *Cyclospora cayetanensis,* disseminated *Penicillium marneffei* infection (endemic to southeast Asia), cerebral or disseminated *Trypanosoma cruzi* infection (endemic to Latin America), relapsing or chronic visceral leishmaniasis, anal carcinoma, and EBV-positive cases of leiosarcoma, leiomyosarcoma, and Hodgkin's disease (4). Nearly all of these HIV-associated illnesses, including the malignancies, are now known to be caused by infection with or reactivation of opportunistic organisms. In this regard, human papillomaviruses, EBV, and human herpesvirus-8 appear to play causative roles in the AIDS-defining malignancies, cervical cancer, lymphomas, and Kaposi's sarcoma, respectively. The degree to which an infection or reactivation syndrome can be considered opportunistic can be inferred by the CD4+ T-cell counts at which it occurs

(344). Oral candidiasis and tuberculosis tend to occur as the CD4+ T-cell count decreases into the 250 to 500 cells/μL range. Cryptosporidiosis generally does not occur until the CD4+ T-cell count is less than 200 cells/μL. *Pneumocystis carinii pneumonia,* disseminated *Mycobacterium avium* complex infection, cryptococcosis, and toxoplasmosis are indicative of more severe immunodeficiency. At the more extreme end of the opportunistic disease spectrum, cytomegalovirus (CMV) retinitis is usually diagnosed after the CD4+ T-cell count has decreased to less than 50 cells/μL. The steep increase in the risk of developing AIDS-defining illnesses associated with a CD4+ T-cell count of less than 200 cells/μL led to the 1993 revision of the CDC definition of AIDS, which includes a low CD4+ T-cell count (<200 cells/μL) as an AIDS-defining criterion (70).

The incidence of AIDS-defining illnesses in industrialized nations has decreased sharply since 1996. In the United States, the AIDS mortality rate decreased 68% between 1996 and 1999 (Fig. 15) (71,72). These decreases in AIDS-associated mortality can be attributed to a number of factors, including continued progress in prophylaxis against opportunistic infections (Table 4) (17), improved access to health care, and improved antiretroviral therapies (see later).

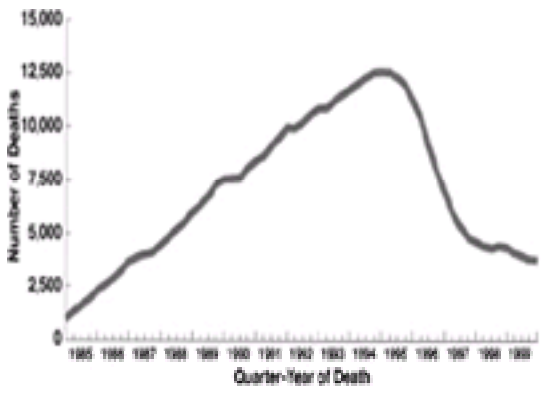

FIG. 15. Numbers of acquired immunodeficiency syndrome (AIDS) deaths in the United States from January 1985 through December 1999. Substantial declines in AIDS-related mortality followed the introduction of potent protease inhibitors in late 1995. From ref. 71, with permission.

Pathogen	Indication	Primary regimen	Alternative
Pneumocystis carinii	CD4+ count <200/μL or thrush	Trimethoprim-sulfamethoxazole	Dapsone; dapsone + pyrimethamine + leucovorin; aerosolized pentamidine; atovaquone
Mycobacterium tuberculosis	Tuberculin skin test reaction ≥5 mm, or prior positive test untreated, or contact with active case	Isoniazid + pyridoxine; rifampin + pyrazinamide	Rifabutin + pyrazinamide; rifampin
Mycobacterium avium complex	CD4+ count <50/μL	Azithromycin; clarithromycin	Rifabutin; rifabutin + azithromycin
Toxoplasma gondii	CD4+ count <100/μL and IgG antibody to *Toxoplasma*	Trimethoprim-sulfamethoxazole	Dapsone + pyrimethamine + leucovorin; atovaquone + pyrimethamine + leucovorin
Varicella zoster virus	Exposure to chickenpox or shingles without historic or serologic evidence of immunity	Varicella zoster immune globulin	—
Streptococcus pneumoniae	All HIV+ patients	Pneumococcal vaccine	—
Hepatitis B virus	All susceptible HIV+ patients (anti-HBc negative)	Hepatitis B vaccine	—
Influenza virus	All HIV+ patients	Influenza vaccine	—
Hepatitis A virus	All anti-HAV negative HIV+ patients with chronic hepatitis C	Hepatitis A vaccine	—

IgG, immunoglobulin G.

TABLE 4. *Prophylaxis recommendations to prevent opportunistic diseases*

Determinants of the Rate of Disease Progression

Myriad host and virologic factors determine the extremely variable rates of disease progression that are observed among HIV-infected individuals. A small percentage of HIV-infected individuals experience no evidence of disease progression over a prolonged period; these long-term nonprogressors provide clues regarding factors associated with disease progression. Although a minority of cases of long-term nonprogressive HIV infection may be associated with attenuated strains of HIV (123,264,286,366), most data suggest that viral attenuation is rare among long-term nonprogressors, and that host factors play a dominant role in determining the state of nonprogression (58,260,365,426).

Host genetic factors strongly influence the rate of disease progression in HIV infection. A number of different mechanisms may be responsible for the observed associations between certain HLA haplotypes and different rates of HIV disease progression (63,275,276,288). The ability of certain HLA molecules to present immunodominant viral epitopes efficiently to generate cell-mediated immune responses may explain an association with slow disease progression. Conversely, other HLA haplotypes may preclude an effective cell-mediated antiviral response and may therefore be associated with more rapid disease progression (63).

Genetic polymorphisms in the HIV coreceptors and their ligands may also significantly affect the course of HIV disease progression. Individuals who are homozygous for a 32-base pair inactivating mutation within the *CCR5* gene (*CCR5-D32*) are afforded a high degree of protection against HIV infection (124,259,477,617), whereas HIV-infected heterozygotes are partially protected against disease progression (110,124,259,364,617). Other mutations that limit the availability of functional coreceptors also are associated with protection against HIV infection and/or partial protection against disease progression. A rare point mutation in the *CCR5* gene (m303) results in a premature stop codon, preventing expression of a functional coreceptor; the *CCR5-D32/m303* genotype confers a high degree of resistance to HIV infection, similar to that afforded by homozygosity for *CCR5-D32* (450). A mutation in the *CCR2* gene involving a conservative amino acid change in a transmembrane domain of the receptor results in a significant delay in disease progression among HIV-infected individuals (510). The mechanism responsible for this observation appears to be related

to the ability of the mutant form of the CCR2 protein to form heterodimers with CXCR4 and CCR5, thus limiting the functional availability of these important HIV coreceptors (354).

Polymorphisms in the *CCR5* promoter have complex associations with HIV disease progression. Two groups have demonstrated that a polymorphism in the *CCR5* promoter is associated with disease acceleration (341,348). Another group has demonstrated that *CCR5* alleles that are partially defined by promoter polymorphisms have variable race-specific effects on disease progression (203,385).

A mutation in the 3' untranslated region of the *SDF-1* gene, *SDF1-3'A,* may be associated with high levels of expression of SDF-1, thereby protecting against disease progression in HIV-infected individuals harboring X4 strains of virus (583). Similarly, a polymorphism in the *RANTES* promoter is associated with enhanced transcription of the *RANTES* gene and retards the rate of HIV disease progression (321).

Genetic polymorphisms in the chemokine–chemokine receptor axis genes represent only one of a number of possible mechanisms responsible for resistance to HIV infection or delayed disease progression. In this regard, down-regulation of coreceptor expression and/or up-regulation of chemokines may recapitulate phenotypes similar to those created by the genetic polymorphisms described earlier. Levels of CCR5 expression exhibit considerable interindividual variability, and these levels correlate with infectability of cells with R5 strains of HIV *in vitro* (592). CCR5 expression occurs predominantly in previously activated, memory T cells (44); treatment of cells with IL-2 slowly up-regulates CCR5 expression (44), whereas stimulation of cells through CD3 and CD28 abrogates CCR5 expression (64). In contrast to CCR5, CXCR4 is expressed on naive, resting T cells (44), and its regulation is reciprocal to that of CCR5 in many respects (44,64). Whether constitutive low-level expression of these coreceptors is associated with a favorable prognosis in HIV infection remains to be determined; in this regard, the more favorable prognosis of *CCR5-D32* heterozygotes should be relevant. A role for high-level expression of HIV coreceptor ligands, such as the CC-chemokines, in protecting against disease progression has been suggested by a number of studies (171,475,480,546,601).

Quantitative as well as qualitative aspects of the host immune response that is mobilized against HIV are important determinants of the rate of disease progression as well. Studies of long-term nonprogressors and exposed-uninfected individuals indicate important roles for CTL, CD8+ T-cell suppressor factors, CD4+ T-helper responses, ADCC, neutralizing antibody responses, and mucosal humoral immune responses in protecting against HIV infection or disease progression (see earlier: Immune Responses).

The morphologic abnormalities of lymphoid tissue associated with HIV disease progression are important determinants of immunodeficiency (420). Despite the long period of HIV infection in long-term nonprogressors, histopathologic examination of lymph node biopsies from these individuals revealed only mild HIV-related abnormalities such as follicular hyperplasia (422). Follicular involution, fibrosis, and lymphocyte depletion, associated with progressive HIV disease, were lacking in lymph nodes from nonprogressors. The degree of follicular hyperplasia, and thus lymphoid tissue activation, seen in nonprogressors is significantly lower compared with that seen in progressors and qualitatively distinct as well, without evidence of large geographic germinal centers extending into the nodal medulla (422). It is likely that preservation of lymphoid architecture in nonprogressors is a reflection of the lower levels of viral replication over time in these individuals. Regardless of the mechanisms responsible for lower levels of viral replication in nonprogressors, preservation of lymphoid tissue architecture is a critical component of the immunocompetence observed. This further highlights the need to understand the mechanisms reponsible for the destruction of lymphoid tissue architecture during progression of HIV disease. If immunorestorative strategies in advanced HIV infection are to be successful, a substrate for the generation of immune responses (i.e., intact lymphoid tissue) must be present, necessitating the prevention or reversal of the histopathologic abnormalities of lymphoid tissue associated with HIV disease progression.

DIAGNOSIS AND LABORATORY MONITORING

Serologic tests for antibodies to HIV form the mainstay of laboratory diagnosis of HIV infection. A solid-phase EIA containing most HIV antigens has a sensitivity of more than 99.5% for the detection of antibodies to HIV. Although the EIA is extremely sensitive, false positives are not uncommon in a number of underlying conditions; therefore, a positive EIA test must always be followed by a confirmatory test. A Western blot assay is the most reliable confirmatory serologic test for the diagnosis of HIV infection. In this assay, HIV antigens are separated by electrophoresis on the basis of their molecular weight and then transferred to a nitrocellulose membrane; after incubation with test serum, antibody reactivity to individual HIV components can be assessed. A negative Western blot demonstrates the absence of any reactivity against HIV components. A positive test demonstrates reactivity to at least two of the following HIV proteins: p24, gp41, gp120, and gp160 (16). Indeterminate tests may be the result of reactivity to antigens that cross-react with HIV determinants; however, indeterminate results also may be a reflection of recently acquired infection and an evolving antibody response. Therefore, clinical follow-up and repeated serologic testing is essential in these cases.

The ideal laboratory marker of HIV disease activity should be easily and reproducibly measurable in all individuals with the disease. Furthermore, it should worsen with progression of disease and improve with positive responses to therapy. Although no ideal marker currently exists, several have been of critical importance in the clinical management of patients, especially with regard to establishing standards of care for initiation of antiretroviral therapy and prophylaxis against opportunistic infections.

Markers of Immune Depletion and Immune Dysregulation

Because CD4+ T cells are the primary targets of HIV infection and because depletion of CD4+ T cells is the immunologic hallmark of HIV disease progression, measurement of CD4+ T cells should be an excellent marker of disease progression. Indeed, studies of the natural history of HIV infection demonstrate that the CD4+ T-cell count is a powerful predictor of the short-term risk of developing an AIDS-defining illness (344). CD4+ T-cell counts frequently increase in response to antiretroviral therapy, and this salutary response has been used as a criterion in the licensing of new

anti-HIV drugs.

Markers of generalized immune activation such as serum levels of b $_2$-microglobulin and neopterin also are valid markers of HIV disease progression. b $_2$-Microglobulin is an 11-kd protein that associates with MHC class I molecules on the surface of most nucleated cells in the body. Serum levels of free b $_2$-microglobulin derive mainly from lymphocytes and are elevated in conditions associated with lymphocyte activation or destruction such as lymphoproliferative syndromes, autoimmune diseases, and viral infections. A direct correlation exists between serum levels of b $_2$-microglobulin and the risk of progression to AIDS (12). Neopterin is a metabolite of guanosine triphosphate, which is produced largely by lymphocytes and by cells of the monocyte/macrophage lineage during tetrahydrobiopterin synthesis. Elevated levels of serum neopterin are seen in patients with autoimmune diseases and viral infections. Like b $_2$-microglobulin, an elevated serum neopterin level is a predictor of progression to AIDS independent of the CD4+ T-cell count (303,358). The combination of a CD4+ T-cell count plus either a b $_2$-microglobulin or neopterin level has more predictive value for disease progression than does any of the three measurements taken individually (149).

The extracellular domains of the receptors for TNF-a are released from the cell membrane by proteolytic cleavage and are detectable in soluble form in serum. Levels of these soluble TNF receptors may reflect levels of TNF-a activity. Insofar as TNF-a has a critical role in up-regulating HIV replication, it is not surprising that levels of soluble TNF receptors serve as a valid surrogate marker of HIV disease progression. In separate studies, levels of soluble TNF receptor type II were found to correlate strongly with plasma viremia and with progression to AIDS (193); however, levels of soluble TNF receptors do not appear to serve as reliable markers of therapeutic efficacy during antiretroviral therapy (169).

A number of other indicators of immune dysregulation correlate with HIV disease progression. The diminished proliferative response of T cells to anti-CD3 antibodies *in vitro* serves as an indicator of immunodeficiency (368), as does diminished delayed-type hypersensitivity response to recall antigens *in vivo* (43). The percentage of peripheral blood CD8+ T cells bearing the activation marker CD38 is positively correlated with disease progression (190). CD8+CD38$^+$ cells mediate cytolytic activity, and increased numbers of these cells in the chronic phase of HIV infection likely reflect a high viral load. Additional markers of HIV disease activity include hematocrit, and serum levels of immunoglobulin A, TNF-b, Fas, and 1,25-vitamin D (237,353,444).

Markers of Viral Load

Before the development of currently available sensitive molecular techniques for the quantitation of HIV RNA molecules, direct culture of HIV from plasma or mononuclear cells was found to correlate with stage of disease (116,250). Changes in levels of culturable plasma viremia further serve as reliable indicators of activity of antiretroviral agents (120); however, these assays are extremely labor intensive and less sensitive than currently available molecular diagnostic tests.

During viral replication, the viral core protein p24 is shed into plasma and can be measured by enzyme-linked immunosorbent assay (ELISA). Measurement of p24 antigenemia is relatively insensitive; however, positivity of a p24 antigen test does herald accelerated decline in CD4+ T-cell counts and the likelihood of progression to AIDS (331). Although a positive test for p24 antigenemia has prognostic value with regard to progression of disease, changes in levels of p24 antigenemia during antiretroviral therapy do not serve as an accurate surrogate for therapeutic efficacy during antiretroviral therapy (126).

The frequency of HIV-infected cells can be quantified by using PCR for detection of HIV-1 DNA, and this measurement has some predictive value with regard to HIV disease progression. Increases of approximately one to two orders of magnitude in the frequency of HIV-infected cells in peripheral blood typically occur among patients who progress to AIDS (489).

Measurement of cell-associated HIV mRNA in peripheral blood, although technically demanding, has been shown by several groups to serve as an independent predictor of disease progression. Particularly impressive is the ability of this marker to predict disease progression in patients with early-stage HIV disease and relatively high CD4+ T-cell counts (476). Determination of the splicing pattern of HIV mRNA in PBMCs can add further predictive value with regard to disease progression. Thus although levels of multiply spliced and unspliced HIV mRNAs increase with disease progression, a disproportionate increase in unspliced HIV mRNA is most predictive of accelerated loss of CD4+ T cells and clinical disease progression (367). Studies of the effect of antiretroviral therapy on the frequency of infected cells in lymphoid tissue, a major *in vivo* reservoir and site of HIV replication, demonstrated that decreases in levels of unspliced HIV mRNA correlated well with decreases in plasma viremia during therapy (111). This finding, combined with the fact that HIV mRNAs are orders of magnitude more abundant in lymph node mononuclear cells compared with peripheral blood mononuclear cells, supports the concept that changes in plasma viremia during antiretroviral therapy are reflective of changes in cell-associated viral mRNA production in lymphoid tissue (111).

The ability to assess the level of viral replication with quantitative assays of HIV RNA in plasma (i.e., plasma viremia) has revolutionized the use of laboratory markers for HIV disease. Measurement of the CD4+ T-cell count yields information regarding the degree of immunodeficiency and short-term risk of opportunistic disease (i.e., a reflection of the damage already sustained by the immune system). In contrast, quantitation of HIV RNA in plasma yields information that predicts the rate and severity of immune deficiency. Technology currently available for reproducible measurement of plasma viremia in clinical specimens includes PCR, nucleic acid sequence–based amplification (NASBA), and branched DNA (b-DNA) assays. PCR and NASBA are both cycle-based target-amplification systems, whereas b-DNA is a single-step signal-amplification system that uses multiple HIV-specific nucleic acid target probes, each of which can be bound to an amplifier molecule containing multiple oligonucleotides. Each oligonucleotide in this array can in turn hybridize to an enzyme-labeled complementary probe, and detection is accomplished by addition of substrate. Each of these assays (PCR, NASBA, and b-DNA) is able to detect as few as approximately 20 to 50 molecules of HIV RNA per milliliter of

plasma, and each has a dynamic range of several orders of magnitude.

The recognition that high levels of HIV replication are sustained throughout the course of infection resulted from a convergence of several lines of data. The enhanced sensitivity of molecular-amplification assays compared with conventional viral detection techniques, and applications of these assays to lymphoid tissue were important developments in this regard (26,142,419,432). The predictive value of plasma viremia as a marker for disease progression was demonstrated in the Multicenter AIDS Cohort Study, in which individuals were stratified by quartiles according to baseline plasma viremia levels. The proportion of patients who progressed to AIDS within 5 years after entry into the study with plasma viremia levels in the lowest through highest quartiles was 8%, 26%, 49%, and 62%, respectively (see Fig. 14) (357). Plasma viremia also was shown to predict progression of disease independent of CD4+ T-cell counts; this measurement was superior to the predictive value of CD4+ T-cell counts (357). Further validation of the use of plasma viremia measurement as a predictor of disease progression was provided by the AIDS Clinical Trials Group, which found that baseline measurements of plasma viremia as well as changes in viremia over time were predictive of disease progression (115,576).

Plasma viral load serves as a valid marker not only for predicting disease progression but also for monitoring therapy in HIV-infected individuals. The link between decreased plasma viremia in individuals receiving therapy and improved clinical outcome was established by the Veteran's Affairs Cooperative Study Group on AIDS (400). Data indicating that decreases in plasma viremia during therapy are reflective of decreases in viral replication in lymphoid tissue further validate the use of plasma viremia as a laboratory marker of a critical aspect of HIV pathogenesis (111).

Levels of plasma viremia become predictive of disease progression after stabilization of viremia (i.e., achievement of a viral load “setpoint”) in the months after primary HIV infection. Mellors et al. (355) found that the level of plasma viremia at 6 months after seroconversion was significantly higher in patients who developed AIDS within approximately 5 years of follow-up compared with levels in those who did not develop AIDS during the same period. A plasma viremia level of >100,000 HIV RNA copies/mL at 6 months after seroconversion was associated with an odds ratio of 10.8 for the development of AIDS. Schacker et al. (482) found that levels of plasma viremia stabilize at a later time than did that reported by Mellors et al. Plasma viremia levels obtained 0 to 6 months after seroconversion did not correlate with subsequent clinical outcome; however, the level of plasma viremia at 7 to 12 months after seroconversion was a strong predictor of CD4+ T-cell depletion during follow-up.

The development of sensitive, quantitative assays for plasma viremia, and the ability of this marker to predict progression of disease and to serve as an indicator of therapeutic efficacy has added an important dimension to decisions regarding initiation and maintenance of antiretroviral therapy in HIV-infected individuals. The variation in plasma viremia by several orders of magnitude in patients with early-stage HIV disease with similar CD4+ T-cell counts allows for the initiation of early therapeutic intervention in those who are most likely to progress. Current recommendations regarding the initiation and maintenance of antiretroviral therapy rely heavily on the two best laboratory markers for HIV disease progression, the CD4+ T-cell count and the level of plasma viremia (59,132).

ANTIRETROVIRAL THERAPY

Recent progress in understanding the pathogenesis of HIV disease and the development of potent antiretroviral agents have resulted in an abundance of treatment options for HIV-infected individuals. The recognition that virus continuously replicates in lymphoid tissue throughout the course of HIV infection, even during the clinically latent stage, strengthened the rationale for early intervention (142,419). Quantitative estimates of the extraordinary rate of viral replication *in vivo* have further strengthened the rationale for early therapy with combination antiretroviral regimens (251,429,568). Combinations of antiretroviral agents that are capable of profoundly suppressing levels of plasma viral load for prolonged periods are referred to as HAART. Significant declines in AIDS-related morbidity and mortality are due in large measure to the wide use of HAART (371,413). However, the optimal use of antiretroviral agents remains a rapidly evolving field, with many obstacles that must be addressed.

Viral Replication Cycle and Antiretroviral Agents

A number of steps in the viral replication cycle can be targeted by agents that are either currently available or under investigation (Fig. 16). Previous disappointment with the use of soluble CD4 as a means of inhibiting viral attachment and entry has yielded to optimism that interference with viral coreceptors may represent an effective therapeutic modality targeted to the earliest stage of the viral life cycle (25). Another promising strategy targets the conformational changes in gp41 that are necessary for fusion of HIV with the target cell membrane (280).

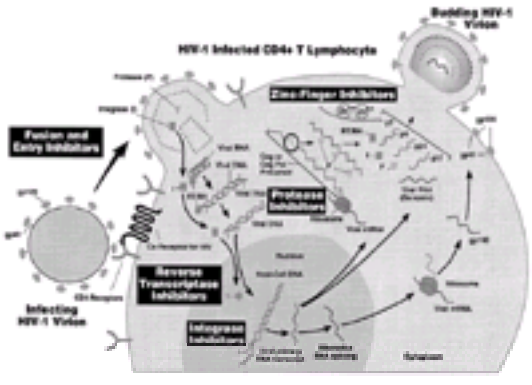

FIG. 16. Targets of antiretroviral therapy. Drugs that are currently licensed for use in human immunodeficiency virus (HIV) infection include reverse transcriptase inhibitors and protease inhibitors. In development are inhibitors of HIV entry and fusion, inhibitors of HIV integrase, and zinc-finger inhibitors.

Inhibitors of viral RT were the first agents to be developed for the treatment of HIV infection; they remain important components of the anti-HIV therapeutic armamentarium. Most RT inhibitors are nucleoside analogs; these agents act as DNA chain terminators by virtue of their structures that lack the 3' hydroxyl moiety necessary for chain elongation. Nonnucleoside RT inhibitors also are used clinically. RT inhibitors as a group have several disadvantages, including their association with multiple neurologic and hematologic side effects, the rapidity with which they select for resistant viral variants when used alone, and their lack of effect on cells already infected with HIV, which no longer require RT to complete the viral replication cycle.

HIV-1 protease cleaves the Gag precursor polyprotein into the p24 and p17 virion components necessary for viral infectivity. Development of HIV-1 protease inhibitors based on the crystal structure of the protease was a triumph for rational and targeted drug design (393,585). The combination of agents that can inhibit *de novo* infection of cells (i.e., RT inhibitors) with agents that lead to the release of defective, noninfectious virions from cells already infected by HIV (i.e., protease inhibitors) results in potent antiviral activity. Protease inhibitors have rapidly become drugs of choice for the treatment of HIV infection in combination with RT inhibitors.

Integration of reverse-transcribed viral DNA (provirus) into the host DNA is facilitated by the viral enzyme integrase. The determination of the crystal structure of integrase (141) has stimulated a search for inhibitors of this enzyme, which we hope will lead to the availability of clinically useful agents.

Targeting the “accessory” proteins of HIV has been hampered by the difficulty in delineating the precise biochemical activities of these proteins. A clinical trial of the Tat antagonist Ro24-7429 failed to demonstrate antiviral activity for this agent (236); however, agents targeting the HIV-1 Rev and Nef proteins are being developed.

Treatment of Primary HIV Infection

Treatment of HIV infection before its wide dissemination to lymphoid tissue and hence before establishment of the viral load setpoint is an approach supported by current understanding of the pathogenesis of early events in HIV infection (270). Unfortunately, the pool of resting, latently infected CD4+ T cells appears to be established during the very earliest stages of acute infection; this process is not abrogated even by initiation of therapy during the symptomatic phase of acute infection (85). Although these data militate strongly against the possibility of eradicating HIV before its wide dissemination during primary infection, the window of opportunity for treatment of primary HIV infection may actually extend to 12 to 18 months after acute infection; this possibility is based on the persistence of high numbers of productively infected cells in lymphoid tissue during this period, despite attainment of the apparent setpoint of plasma viremia (415).

A trial of zidovudine therapy versus placebo given for 6 months after primary HIV infection revealed that those patients assigned to active treatment maintained higher CD4+ T-cell counts, lower levels of plasma viremia, and slower progression to minor clinical end points (e.g., oral candidiasis, herpes zoster, and oral hairy leukoplakia) over a mean follow-up period of 15 months (282). Treatment of patients with recent (i.e., within 90 days) HIV infection with a combination of zidovudine, lamivudine, and a protease inhibitor can suppress plasma viremia to <20 HIV RNA copies/mL for a prolonged period (>2 years) (340); initiation of HAART during acute HIV infection also may prevent the loss of HIV-specific CD4+ T-cell proliferative responses (466). Emerging data suggest that initiation of HAART during acute HIV infection affords significant protection against the development of opportunistic infections and rapid progression to AIDS during a 1.5-year follow-up period (39).

Treatment of Chronic HIV Infection

Early studies of zidovudine monotherapy demonstrated improvements in laboratory markers of HIV disease activity and delayed progression of disease in symptomatic individuals, as well as in asymptomatic individuals with relatively low CD4+ T-cell counts (158,159,556,557,596). Subsequent studies demonstrated that combination therapy with two nucleoside analogs was generally superior to monotherapy (112,129,210,230).

More potent combination antiretroviral drug regimens, such as zidovudine plus lamivudine, which are capable of prolonged suppression of viral replication, became available in 1995 (144). The addition of protease inhibitors to the antiretroviral armamentarium in 1996 resulted in a dramatic enhancement of the ability to suppress viral replication (Fig. 17). The protease inhibitors saquinavir, ritonavir, indinavir, nelfinavir, amprenavir, and lopinavir are all potent antiretrovirals, particularly when used in combination with nucleoside analog RT inhibitors (NRTIs). Such combination therapy is now considered the treatment of choice for HIV infection (132). When used in combination with NRTIs, protease inhibitors typically suppress plasma viral load to undetectable levels in the majority of patients for >48 weeks. In addition, significant reductions in the rate of progression to AIDS or death have been demonstrated for combination regimens including indinavir or ritonavir (55,228).

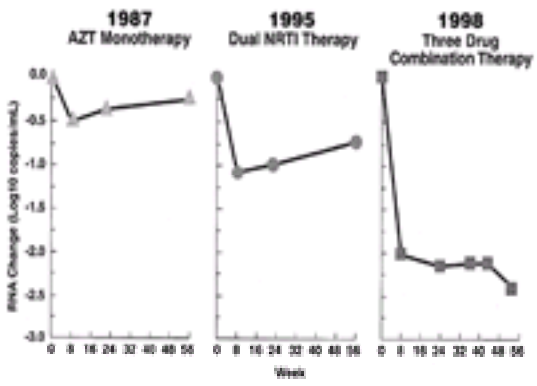

FIG. 17. Representative declines in plasma viral load achieved with zidovudine monotherapy (**left**), dual nucleoside analog reverse transcriptase inhibitor (NRTI) therapy (**middle**), and three-drug combination therapy (**right**).

The decision to initiate antiretroviral therapy should be made jointly by patient and physician. The decision should be driven in part by data regarding the natural history of disease progression at various levels of CD4+ T-cell counts and plasma viral loads (356,357). Treatment is indicated for patients with symptomatic HIV disease regardless of CD4+ T-cell count and viral load (132). Treatment for asymptomatic patients is generally indicated when the CD4+ T-cell count is <350 cells/μL or the plasma viral load is >30,000 copies/mL (132). Some physicians and patients choose to initiate antiretroviral therapy earlier than recommended in official guidelines. Risks and benefits of early initiation of antiretroviral therapy are presented in Table 5; however, unfortunately, no data are yet available regarding the effects of early initiation of HAART on delaying disease progression or survival.

Potential benefits
• Control of viral replication and mutation; reduction of viral burden
• Prevention of progressive immunodeficiency; potential maintenance or reconstruction of a normal immune system
• Delayed progression to AIDS and prolongation of life
• Decreased risk of selection of resistant virus
• Decreased risk of drug toxicity
• Possible decreased risk of viral transmission
Potential risks
• Reduction in quality of life from adverse drug effects and inconvenience of current maximally suppressive regimens
• Earlier development of drug resistance
• Transmission of drug-resistant virus
• Limitation in future choices of antiretroviral agents due to development of resistance
• Unknown long-term toxicity of antiretroviral drugs
• Unknown duration of effectiveness of current antiretroviral therapies

TABLE 5. *Risks and benefits of early initiation of antiretroviral therapy in the asymptomatic HIV-infected patient*

Many treatment options now exist for the HIV-infected patient. A regimen should be selected that will afford a high likelihood of long-term profound suppression of plasma viral load and a significant increase in the CD4+ T-cell count. Many other factors deserve consideration, including the pill burden associated with a particular regimen, dosing frequency, food requirements, convenience, toxicity, and drug-interaction profile. Recommendations regarding specific regimens can be found in Table 6 and in the Department of Health and Human Services/Henry J. Kaiser Foundation Guidelines for the Use of Antiretroviral Agents in HIV-Infected Adults and Adolescents on the worldwide web at http://www.hivatis.org/.

TABLE 6. *Recommended antiretroviral agents for the treatment of established HIV infection*

A change in the antiretroviral regimen may be indicated when a suboptimal reduction in viremia occurs after initiation of therapy, when viremia reappears after suppression to undetectable levels or increases from a nadir of suppression, or when the CD4+ T-cell count declines significantly. When any of these events occurs, it is important to determine whether the underlying cause may be drug intolerance or difficulty with adherence to the drug regimen, suboptimal drug levels due to malabsorption, or drug–drug or drug–food interactions, or development of drug resistance. If drug resistance is suspected, it is appropriate to change the regimen entirely to drugs that have not been used previously and to which cross-resistance is not anticipated. More targeted changes within a drug regimen may be guided by the use of resistance

assays (see later); however, this approach requires further clinical validation. If a regimen is changed because of intolerance or toxicity, it is appropriate to substitute one or more alternative drugs of the same potency and from the same class of agents as the agent suspected to be causing the problem.

Although sustained suppression of viral load is achievable in a high proportion of patients treated with HAART regimens in the clinical trials setting (i.e., nearly 80% at 2 years) (225), only 50% or fewer respond adequately in urban clinic settings (125,326). Predictors of success include lower baseline viral load, higher baseline CD4+ T-cell count, initiation of therapy with multiple drugs simultaneously, and adherence to the drug regimen (125,225,310,326,370,375,524).

Although the use of HAART regimens has greatly improved the prognosis for HIV-infected individuals (371,413), a large number of challenges to the optimal treatment of HIV infection remain to be addressed.

Adherence

Adherence to an antiretroviral regimen is essential to the success of the regimen. The challenges to adherence are considerable. Antiretroviral regimens are complex, consist of multiple agents, and must be taken indefinitely in most cases. Many of the drugs have significant side effects and toxicities (see later). The sheer number of pills required in many regimens (i.e., >20 pills per day) poses a significant challenge to adherence for even the most committed individuals. In addition, many antiretroviral agents, particularly protease inhibitors, have complex dosing requirements in relation to food intake.

Lapses in adherence provide windows of opportunity for virus replication, and enhance the probability of the emergence of drug-resistant virus. In the INCAS drug trial of nevirapine, zidovudine, and didanosine, missed doses of antiretroviral drugs on 28 or more days during the 52-week study significantly predicted a lower likelihood of achieving durable viral suppression (375). In a study of antiretroviral therapy in an urban clinic setting, missed clinic appointments were significantly associated with failure to suppress viral load over a 1-year period (326).

Side Effects and Toxicities

Gastrointestinal disturbances, such as nausea, vomiting, and/or diarrhea, are commonly induced by several of the NRTIs, and by all of the protease inhibitors. Peripheral neuropathy may be caused by most of the NRTIs, and rash and Stevens–Johnson syndrome may occur with use of any of the NNRTIs. Protease inhibitors have a number of drug-specific toxicities, such as the association of nephrolithiasis and indirect hyperbilirubinemia with indinavir; nausea, vomiting, and diarrhea and paresthesias with ritonavir; nausea and diarrhea with saquinavir; and diarrhea with nelfinavir. In addition, several class-specific adverse effects are associated with the use of protease inhibitors. In this regard, a number of metabolic derangements involving lipid metabolism are of serious concern with the use of protease inhibitors. Triglyceride and cholesterol levels may become elevated to dangerously high levels (61,384). Insulin resistance, hyperglycemia, and even frank diabetes mellitus may occur (61,384,562). Additionally, peripheral fat wasting in the setting of central fat accumulation, as well as “buffalo humps” reminiscent of Cushing's disease may occur (61,562). These metabolic derangements may be related to homology between HIV protease and two proteins, cytoplasmic retinoic-acid binding protein type 1 and low-density lipoprotein receptor–related protein that regulate lipid metabolism (60). Finally, a large number of drug interactions may occur with the use of NNRTIs and protease inhibitors, all of which alter cytochrome P-450 metabolism.

Resistance

Failure or loss of suppression of plasma viremia in the setting of good adherence and adequate drug absorption may be due to the emergence of drug-resistant virus. A single nucleotide substitution at position 103 of the reverse transcriptase gene can significantly reduce the activity of the NNRTIs against HIV replication. Similarly, a single nucleotide substitution at position 184 of the reverse transcriptase gene confers resistance to lamivudine. Resistance to some of the NRTIs, such as zidovudine, follows a relatively orderly sequential path whereby accumulation of serial mutations in the reverse transcriptase gene confers increasing levels of resistance to the agent (307); for other drugs in this class, the pathways to resistance are less clear (346).

Resistance to protease inhibitors is a complex phenomenon that has important implications for drug therapy. The HIV protease is a 99-amino-acid protein; that over half of these residues have been reported to be associated with drug resistance is testimony to the genetic plasticity of HIV. Some of these mutations are strongly selected under the pressure of protease inhibitor therapy; however, even when drugs select for unique mutations associated with drug resistance, a great deal of *in vitro* and clinical cross-resistance may still be observed between drugs (484,584). Other mutations are compensatory in nature, and are able to restore partially the replicative fitness that is lost with primary mutations. Distant mutations in the protease cleavage site in the HIV p7/p1 core components create a more optimal substrate for a protease enzyme that is compromised by protease inhibitors (613).

Genotypic and phenotypic resistance assays are now available from commercial sources (247). Genotypic assays generally provide information about the presence of mutations in HIV genes (i.e., reverse transcriptase and protease) that may have been selected for during drug therapy. Phenotypic assays evaluate the replication of virus or of a viral construct containing genes from the patient's virus in the presence of antiretroviral drugs. Interpretation of these assays is fraught with difficulty (247). The tests are insensitive to minor viral variants that may be important *in vivo.* In this regard, viral variants harboring resistance mutations to drugs given in the past may be present at frequencies well below the limits of detectability using these assays. Thus although a positive resistance assay argues strongly that a particular drug will be ineffective, a negative test by no means assures the drug's utility (247).

Preliminary data suggest that resistance testing can be used to optimize the design of antiretroviral regimens. In this regard, one study demonstrated that viral load suppression over a 3- to 6-month period was superior when genotypic resistance assays were used in helping to formulate antiretroviral regimens (138). Another study showed that phenotypic

drug resistance may be detectable before viral load rebound becomes evident during drug treatment (425). These data suggest that drug-resistance assays will likely be an important adjunct in the formulation of antiretroviral regimens in the future.

Persistent Viral Replication

The beginning of the HAART era saw a great deal of optimism that with prolonged suppression of viral load, eradication of HIV infection might be possible. However, Chun et al. (90) reported the presence of unintegrated HIV DNA in lymphocytes from HAART-treated patients who had experienced sustained suppression of plasma viral load for an average of 10 months; because of the short half-life of unintegrated viral DNA, this finding argued strongly that ongoing low-level HIV replication was occurring in spite of undetectable levels of plasma viral load. Support for this same conclusion came from studies showing persistence of HIV transcription in PBMCs from patients with sustained suppression of plasma HIV viral load (173,392). In addition, two other studies demonstrated evolution of proviral DNA in patients receiving HAART with undetectable viral loads, again indicating ongoing viral replication (342,611). Finally, the rapid rebound of plasma viral load that occurs after cessation of HAART after prolonged suppression of plasma viremia also likely indicates ongoing replication during HAART (183,234).

Persistent viral replication in the setting of apparently effective HAART may be due to intermittently suboptimal drug levels (1,526), poor penetration of drugs into various tissue compartments such as genital secretions (145,609), or suboptimal potency of the drug regimen. Clearly, more potent antiretroviral agents that are capable of inhibiting a broader array of HIV target gene products would be welcome additions to the antiretroviral armamentarium. In this regard, inhibitors of the viral entry and fusion process are in clinical trials (280), and inhibitors of the HIV integrase are in development.

Immune Reconstitution

Ultimately, the success of long-term antiretroviral therapy depends not only on suppression of viral replication, but also on at least partial restoration of immune function. Immune competence prevents the onset of HIV-related opportunistic diseases, and also may synergize with antiviral agents to control viral replication. The degree of immune reconstitution that occurs during HAART and the theoretic limits of such reconstitution are matters of intense investigation.

The increases in CD4+ T-cell counts that occur during potent antiretroviral therapy can be modeled to obtain an estimate of CD4+ T-cell turnover at steady state. Initial studies estimated that approximately 2×10^{9} CD4+ T cells turn over each day (251,568). However, the relative contributions of thymic output of new cells, peripheral expansion of preexisting cells, and redistribution between tissue and peripheral blood compartments remain uncertain.

One assay of CD4+ T-cell turnover measures telomeric terminal restriction fragment (TRF) length, a marker of cellular replicative history. After each round of cell division, telomeric sequence is lost, eventually leading to replicative senescence. Data obtained by analysis of telomere lengths do not suggest increased turnover of CD4+ T cells during HIV infection (414,588).

Cell turnover also can be assessed by analysis of incorporation of bromodeoxyuridine *ex vivo* into cellular DNA, quantification of cells expressing Ki67 antigen (a marker associated with cell proliferation), or by analysis of incorporation of infused deuterium into cellular DNA. Studies measuring incorporation of bromodeoxyuridine into lymphocytes *ex vivo* suggest that CD4+ T-cell proliferation is abnormally high in HIV-infected individuals, and is directly proportional to viral load (312). Initiation of HAART resulted in substantial decreases in rates of CD4+ T-cell proliferation measured in this manner (312). In contrast, dichotomous results have been obtained in studies using Ki67 as a marker of cell turnover. In patients with relatively high CD4+ T-cell counts and low levels of viral load, low percentages of CD4+Ki67+ cells are observed, with estimated total body CD4+ T-cell turnover estimated to be normal or moderately increased (161,474). In later stages of HIV disease, in the setting of low CD4+ T-cell counts and high viral load, substantial increases in the percentage of CD4+Ki67+ cells are seen in conjunction with estimated subnormal levels of total CD4+ T-cell production (474). Similar results have been obtained in deuterium infusion studies (243). Thus turnover data obtained by using bromodeoxyuridine suggest that CD4+ T-cell depletion is due not to inadequate T-cell production but to excessive destruction of CD4+ T cells. Turnover data obtained using Ki67 and deuterium suggest that CD4+ T-cell loss is partially compensated for in early-stage disease by a modest increase in production of these cells; however, in late-stage disease, CD4+ T-cell loss appears to result in part from inadequate lymphopoiesis.

Analysis of the phenotype of CD4+ T cells that increase after initiation of HAART reveals that most of the sharp increase in CD4+ T-cell count that is seen in the first weeks of therapy is due to an increase in the memory CD4+ T-cell pool, likely as a result of redistribution from tissue compartments (19,52,411). These findings are consistent with turnover studies using genetically marked cells, in which maintenance of CD4+ T-cell numbers was dependent on peripheral expansion of preexisting mature cells (561).

In many cases of successful HAART, slow increases in CD4+ T-cell numbers follow the sharp increase that occurs within the first weeks of therapy. This later slow increase is largely the result of appearance of naive cells (19,411). Partial normalization of perturbed T-cell receptor Vb repertoires during HAART suggested that some of these cells might be thymically derived cells, and that qualitative as well as quantitative immune reconstitution might be possible (204). Indeed, evidence from several groups suggests the presence of thymic function in HIV-infected adults. In this regard, the radiographic presence of thymic tissue in HIV-infected individuals was associated with higher CD4+ T-cell counts and higher percentages of naive cells compared with those in individuals who did not have detectable thymic tissue (347). Thymic function also can be probed by quantification of cells harboring T cell–receptor rearrangement excision circles (TRECs) that are created during thymocyte development. This type of analysis revealed that HIV-infected individuals have a significantly lower frequency of $TREC^{+}$ cells compared with normal controls, and that this frequency increases significantly during HAART; these increases in $TREC^{+}$ cells correlated with the decrease in viral load and increase in the

number of naive CD4+ T cells (136).

The degree of immune reconstitution that is possible during HAART is unknown. Some data cast doubt on any significant role for the thymus in HAART-related immune reconstitution (240), and one study found that the increased number of thymic emigrants that appear during HAART is insufficient to account for the increased number of naive cells (610). Although some HIV-induced immune damage may be reversible during HAART (614), clearly improvements are more robust in individuals who begin therapy before end-stage disease with near total destruction of the immune system. In this regard, the increase in naive CD4+ T cells during HAART is proportional to their presence at baseline (244). As more is learned about the characteristics of immune reconstitution that occurs during HAART, the fact that *in vitro* responses to antigens associated with opportunistic infections (i.e., cytomegalovirus) are frequently restored during HAART (297,318,462), and that prophylaxis against *Pneumocystis carinii* pneumonia can be safely discontinued as the CD4+ T-cell count increases to >200 cells/μL during HAART (172,488,580) serve as dramatic evidence of the salutary effects of HAART.

Overall, T-cell turnover studies suggest that an important, although not exclusive cause for CD4+ T-cell lymphopenia in HIV infection may be inadequate lymphopoiesis. This is consistent with the known inhibitory effects of HIV infection and HIV proteins on hematopoiesis (see earlier, HIV-Mediated Inhibition of Hematopoiesis). Such a scenario fortifies the rationale for adjuvant immunotherapy in conjunction with HAART that would boost thymic or extrathymic lymphopoiesis and/or peripheral expansion of T cells (139,302).

Latent Reservoirs of HIV Infection

On initiation of HAART, plasma viral load declines in several phases (251,429,568). The first phase of rapid exponential decay reflects the short half-life of free virions and of recently infected virus-producing cells. After the first several weeks of therapy, a slower second phase of viral load decay occurs with a half-life of approximately 14 days. This phase of decay is thought to reflect attrition of longer-lived, chronically infected cells (428). Extrapolation of this decay suggested that treatment of HIV infection with a potent combination drug regimen that completely suppresses viral replication for approximately 3 years may eradicate infection (428). A practical limitation of this estimate is the assumption of complete suppression of viral replication, which is beyond the capability of currently available HAART regimens (90,173,342,392,611).

Another major limitation of the time-to-eradication estimate is the presence of a reservoir of latently infected resting CD4+ memory T cells that persists during HAART. HIV may enter resting CD4+ T cells, and a limited degree of reverse transcription of the viral genome may occur in these cells. This period of preintegration latency may last hours to days; in the absence of an activation signal, the viral nucleic acid loses its capacity to initiate a productive infection. If these cells become activated, however, RT may proceed to completion, followed by nuclear import, and by integration of proviral DNA into cellular DNA (53,527,599). In the majority of CD4+ T cells that become infected with HIV in the *in vitro* setting of a sufficient degree of activation, integration and productive infection occur, followed by cell death. However, a small fraction of productively infected CD4+ T cells may escape cell death and revert to a resting state in which HIV infection is latent (i.e., postintegration latency; Fig. 18). Chun et al. (89,91) estimated the size of this latent reservoir of HIV *in vivo* by examining highly purified resting CD4+ T cells from both blood and lymph nodes of HIV-infected individuals. Using a PCR assay specific for integrated proviral DNA, they estimated that the frequency of latently infected resting CD4+ T cells was approximately 0.05%; interestingly, this frequency was quite similar in the peripheral blood and lymph node compartments, reflecting the fact that resting memory CD4+ T cells may continuously circulate between various lymphoid tissue compartments. Subsequent micro-coculture analysis revealed that approximately one tenth of latently infected resting CD4+ T cells harboring integrated HIV DNA carried replication-competent HIV (91).

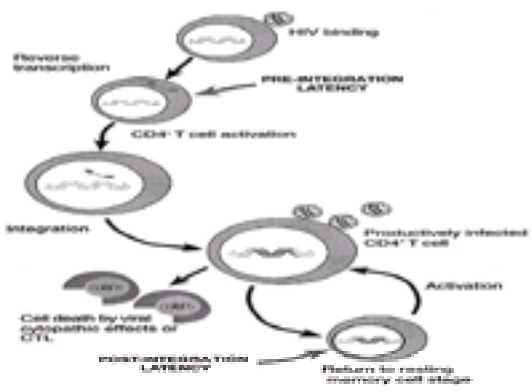

FIG. 18. Human immunodeficiency virus (HIV) entry into the cell may be followed by a state of preintegration latency, productive infection, or postintegration latency. In resting CD4+ T cells, HIV entry may be followed by a limited degree of reverse transcription of the viral genome, resulting in a labile state of preintegration latency. If these cells become activated, reverse transcription may proceed to completion, followed by nuclear import, and by integration of proviral DNA into cellular DNA. Productive infection usually follows integration of HIV DNA, resulting in cell death. However, a small fraction of productively infected CD4+ T cells may escape cell death and revert to a resting state in which HIV infection is latent (i.e., postintegration latency).

Although the size of the pool of latently infected resting CD4+ T cells *in vivo* harboring replication-competent HIV appears to be quite small, it may nevertheless constitute an important obstacle to eradication of HIV infection. Latently infected cells are not subject to elimination by the host immune response because of the absence of expression of viral antigens on the cell surface. Furthermore, integrated proviral DNA cannot be targeted by currently available antiretroviral agents. Therefore the natural half-life of latently infected resting CD4+ T cells may be the rate-limiting step in eradicating HIV

infection. These suppositions are substantiated by several independent studies that attempted to recover replication-competent HIV from cells of patients receiving HAART for prolonged periods. In these studies, virus was recovered from CD4+ T cells in essentially all patients receiving HAART, with levels of plasma viremia that were below the limit of detectability for up to 94 weeks (90,157,589). To estimate the half-life of this pool of latently infected resting memory CD4+ T cells, Finzi et al. (156) performed longitudinal analyses of the number of these cells harboring replication-competent HIV in 20 patients receiving HAART whose plasma viral load remained suppressed to <200 copies/mL over a mean of 14.4 months. The decay of the latent pool of CD4+ T cells was extremely slow, with an estimated half-life of 44 months; given a conservative estimate of the size of the latent pool, this leads to an estimated time-to-eradication of 60 years in patients receiving HAART (156). It is possible, however, that the half-life of the latent pool was overestimated if transient low-level viral replication were reseeding the reservoir over the course of the study. As more potent HAART regimens become available, more accurate assessments of the decay of the reservoir of latently infected cells should be possible.

Strategies aimed at long-term control of HIV infection will need to focus on the pool of latently infected cells that represent a long-lived reservoir capable of “reigniting” viral replication during periods of suboptimal antiretroviral therapy. Antiretroviral regimens that are highly potent and more easily administered should be part of such a successful strategy; however, this approach could be combined with interventions, such as IL-2 therapy, aimed at activating latently infected cells in the setting of HAART as well as enhancing HIV-specific immune responses (86). In this situation, latently infected cells might be driven to a state of productive infection and die; infectious virus released from these cells would be unable to infect new cells under the cover of HAART. Chun et al. (87) found that patients who received IL-2 in addition to HAART had a significantly lower frequency of latently infected CD4+ T cells harboring replication-competent virus compared with patients who received HAART alone. The mechanism of this effect is under investigation; however, unfortunately, even patients who harbored a frequency of latently infected cells that was below the limits of detection experienced prompt viral rebound when HAART was discontinued (93). These data highlight the importance of other reservoirs of smoldering virus replication and/or latently infected cells in the body (88,495).

PREVENTION AND VACCINES

Approaches to HIV prevention must be individualized to the settings in which transmission occurs. In the United States, safer-sex education campaigns within the homosexual community were instrumental in substantially reducing the incidence of new infections in the mid- and late 1980s. Multisector approaches in Uganda and Thailand, including input from governmental and nongovernmental organizations, have resulted in high levels of awareness regarding transmission of HIV; changes in sexual practices, including higher rates of condom use; and commensurate substantial reductions in the incidence of new HIV infections (337,396). Vaginal microbicides that are safe, effective, and acceptable will be welcome additions to prevention efforts in many parts of the world (449).

The most effective weapon in preventing further spread of the HIV epidemic will be a safe and effective vaccine (Table 7). A number of different vaccine approaches might be useful, including those that elicit sterilizing immunity as well as those that may not protect against infection *per se* but protect against development of disease after infection; in addition, others may alter the course of disease in those who had already been infected before vaccination. Vaccine development for many microbes has been aided by the knowledge of the immunologic correlates of protective immunity; however, in the case of HIV infection, correlates of protective immunity are largely unknown (239). Evidence exists supporting salutary roles for neutralizing antibodies, mucosal humoral responses, CD4+ T-helper responses, CD8+ CTL responses, and other immune responses (see earlier); however, none of these responses has been conclusively shown to protect individuals from HIV infection. Therefore HIV vaccine development is a highly empiric endeavor in which stimulation of humoral and cellular immune responses seems to be a reasonable approach. Another major obstacle to developing an effective HIV vaccine is the high degree of genetic heterogeneity of HIV strains within and between clades; protection against one strain by no means guarantees protection against a distantly related strain.

- Peptides (e.g., V3 region of gp120)
- Recombinant proteins (e.g., gp120, gp160, p24)
- Viral vectors (e.g., vaccinia, canarypox, or adenovirus vectors engineered to express HIV proteins)
- Bacterial vectors (e.g., *Salmonella typhi* engineered to express HIV proteins)
- DNA (i.e., plasmid DNA containing HIV genes that are expressed)
- Whole killed virus
- Live-attenuated virus (e.g., viruses harboring mutations in *nef*)

TABLE 7. *Approaches to the development of an HIV-1 vaccine*

Many successful vaccines have been developed that are live-attenuated or killed forms of the relevant microbe. Attenuation of SIV by deletion of portions of the *nef* gene has proven to be an effective vaccine approach in SIV-challenged, immunized monkeys (119,594). However, a number of safety concerns are relevant to further testing in this area. First, *nef*-deleted SIVs do have pathogenic potential in monkeys (21,22). In addition, HIV-infected recipients of transfusions from a single source in Australia were found to be long-term nonprogressors and harbored HIV with deletions in the *nef* gene (308). However, long-term follow-up of this unique cohort has revealed that several of the individuals experienced disease progression characterized by increasing viral load and decreasing CD4+ T-cell counts (309). Finally, another long-term nonprogressor who was infected with a *nef*-defective virus (286) subsequently

experienced HIV disease progression (218).

Neutralizing antibodies are associated with slow rates of SIV disease progression in nonhuman primate models (153), and accelerated clearance of both noninfectious and infectious virions (263). In addition, passive transfer of SHIV-neutralizing antibodies can protect macaques against a subsequent viral challenge (504). More encouraging data regarding a possible role for neutralizing antibodies come from studies by La Casse et al. In these studies, cells expressing HIV envelope were mixed with cells expressing CD4 and a relevant coreceptor and subjected to formaldehyde fixation to capture the transient envelope–CD4–coreceptor structures that arise during HIV binding and fusion. These transient “fusion-competent” epitopes elicited antibodies in a transgenic mouse system and were capable of neutralizing infectivity of 23 of 24 diverse primary HIV isolates from genetic clades A–E (304). Isolation of the fusion-competent epitopes and formulation into a more conventional vaccine is a promising approach.

Viral components, particularly envelope subunits such as gp120, represent the safest vaccine candidates; however, these components tend to be poor immunogens. The only HIV vaccine candidate to enter human efficacy trials to date is a bivalent form of gp120; two monomeric clade B gp120s are being tested in the United States, and a clade B plus clade E formulation is being tested in Thailand (166). It is possible that the immunogenicity of subunit vaccines might be improved by using new adjuvants, using oligomeric as opposed to monomeric envelopes, and by removing some of the envelope carbohydrate that masks HIV from the immune system.

Vaccination with the HIV Tat protein or a detoxified derivative (i.e., Tat toxoid) may prove useful as a preventive and/or therapeutic approach. The rationale for this approach derives from the ability of Tat to be secreted and to act as an immunosuppressant directly and indirectly by inducing interferon-a production from monocyte/macrophages (600). Furthermore, antibodies to Tat correlate with nonprogression of HIV disease (603). Tat toxoid is immunogenic and appears to be safe in HIV-infected and uninfected humans (219,220). Remarkably, immunization of monkeys with Tat protected them from challenge with a pathogenic SHIV (54). Although the mechanism of this protection is not currently known, it is possible that abortive infection occurred, and that neutralization of Tat activity prevented necessary pathogenic events that would otherwise lead to a spreading infection (54,178).

Recombinant microbes that are engineered to express HIV proteins are able to present antigens to the immune system in a physiologic manner. Vaccinia virus vectors have the disadvantage of being potentially pathogenic themselves in immunocompromised hosts. Canarypox vectors and modified vaccinia Ankara (MVA) are nonpathogenic, and are being used to express HIV proteins in clinical trials (231,424). Prime-boost, or combination strategies, in which the vector immunization is followed by or given simultaneous with subunit immunizations, appear promising in their ability to elicit both humoral and cell-mediated immune responses (35,160,618). In addition, cross-clade CTL responses can be elicited by using this approach (154). Recombinant bacterial vectors, such as attenuated strains of *Salmonella typhi,* also are being explored; advantages to this approach include induction of strong mucosal immune responses (593).

Naked DNA, encoding genes of interest, can be readily taken up by mammalian cells. This approach is particularly suited to eliciting cell-mediated immune responses, and shows promise in the search for a malaria vaccine (565). Chimpanzees immunized with an HIV DNA construct encoding *env, rev,* and *gag/*pol developed humoral and cellular HIV-specific immune responses and were protected against a high-titered challenge with a heterologous viral strain (49).

SUMMARY AND CONCLUSIONS

The pathogenesis of HIV infection is a complex, multifactorial process involving viral and host factors. The net degree of virus replication *in vivo* reflects a balance of factors that positively or negatively regulate virus expression; in turn, the amount of virus replication appears to be intimately related to the rate of CD4+ T-cell depletion that occurs, and thus to the rate of disease progression.

HIV is a formidable opportunist of the human immune system, as illustrated by its ability to use activation of the immune system for its own replicative advantage. The virus is able to disarm most components of the host immune response by a variety of direct and indirect mechanisms. A more complete understanding of these mechanisms should aid the rational development of more effective preventive and therapeutic strategies.

Although therapeutic advances for the treatment of HIV infection have been made at a pace that is unparalleled in the study of human viral diseases, a number of sobering obstacles remain in the path of controlling this pandemic. More than 90% of HIV-infected individuals live in the developing world, where expensive combinations of antiretroviral agents are far beyond the capacities of economic and health care infrastructure realities. HIV prevention, including a safe and effective vaccine, remains the best hope in controlling the spread of disease worldwide. Even in the developed world, it is clear that although HAART regimens have vastly improved the prognosis of HIV-infected patients, they are not curative, and their use is fraught with difficulties including numerous toxicities and drug interactions. To truly gain the upper hand against HIV infection, new antiretroviral agents that target different stages of the viral replicative cycle will be needed, as well as immunorestorative strategies that will allow more complete reconstitution of the immune system in the setting of effective antiretroviral therapy.

CHAPTER 61 Nonhuman Lentiviruses

Ronald C. Desrosiers

HISTORY

Use of the term “slow virus infections” and identification of the first lentivirus is generally credited to Sigurdsson et al. (169,170 and 171) in Iceland. Twenty karakul sheep that were imported from Germany into Iceland in 1933 were responsible for the transmission of a chronic disease and death in massive numbers of Icelandic sheep over the subsequent years. More than 100,000 Icelandic sheep died in the decades that followed. Sigurdsson et al. (169,170 and 171) not only described the disease but also demonstrated that it was due to a transmissible agent. They used the term slow virus infections to refer to this disease and also to what is now known as scrapie (168). The term slow virus infection has subsequently been used to describe a wide variety of nonacute, persisting viral infections. In 1960, Sigurdsson et al. (172) described the cultivation of the transmissible agent in tissue culture, and Gudnadottir and Palsson (70) were able to reproduce the disease with the culture-grown virus. The diseases in the sheep were called *maedi* (Icelandic for dyspnea; i.e., a lung disease resulting in difficulty in breathing) and *visna* (Icelandic for a state of progressive apathy, a “fading away,” resulting from brain disease). Both disease states result from the same virus, now referred to as maedi/visna virus (MVV). MVV and related viruses are called lentiviruses, which is derived from the Latin *lentus* for slow. Approximately 600,000 sheep were slaughtered in Iceland in 1965 to eradicate MVV from the island.

The maedi/visna disease in Icelandic sheep, although the first to be specifically shown to be caused by a defined lentivirus, is probably not, however, the first description of a lentiviral disease in the literature. Vallée and Carré described in 1904 the infectious nature of the disease equine infectious anemia (186), which is now known to be caused by a lentivirus (EIAV). Even for maedi/visna, a chronic, progressive interstitial pneumonia had been described in South African sheep in 1915 and in Montana sheep in 1923 (123). Work with EIAV disease was largely on a parallel track with that of MVV, and the first description of EIAV cultivation appeared in 1961 (104). Only subsequently were EIAV and MVV shown to belong to the same lentivirus subgrouping of retroviruses.

The scenario of disease outbreak in a susceptible population leading to the identification of a new lentivirus has repeated itself dramatically on several occasions in more recent history. In 1964, an emerging infectious disease was first detected in Bali cattle in the Jembrana district of Bali (151,173). Bali cattle are the domesticated form of the wild barteng (*Bos javanicus*). Within 12 months, 26,000 of the 300,000 cattle on the island died of the disease. The cause of the disease was subsequently traced to a bovine lentivirus now called Jembrana disease virus (JDV), a distinct variant of bovine immunodeficiency virus (BIV) (20,96). Bali cattle are particularly sensitive to disease caused by this virus, whereas other species are resistant (174,175,195). Outbreaks of immunodeficiency disease and lymphoma in captive colonies of macaque monkeys (Asian Old World primates) were subsequently traced to the introduction of a simian lentivirus or lentiviruses from African monkeys (11,34,117,120). Simian immunodeficiency viruses (SIVs) naturally infect African nonhuman primates without apparent disease, but Asian macaques appear to harbor no such virus naturally. Even the origins of human immunodeficiency virus (HIV) in people have followed a similar pattern. HIV-2 in people in western Africa quite clearly originated from SIV of sooty mangabey monkeys (22,38,61,78). The natural habitat of sooty mangabey monkeys is the same geographic region in western Africa where HIV-2 is endemic, and SIV from sooty mangabey monkeys is indistinguishable at a genetic level from HIV-2. Sooty mangabey monkeys are naturally infected with SIV at high frequency without apparent disease. More recently, the origins of HIV-1 in central Africa have been traced to the chimpanzee *Pan troglodytes* (29,59). These examples illustrate the importance of studying animal viruses even when they are not apparently associated with any disease.

The earliest descriptions of the isolation of HIV and its association with acquired immunodeficiency syndrome (AIDS) did not appreciate that the virus was a lentivirus (8,150). Only subsequently through more careful examination of electron micrographs and through sequence analysis did it become clear that the virus was a lentivirus (68,128). At the time, study of lentiviruses was a rather obscure discipline with which many scientists were not familiar.

From a historical perspective, MVV (172) and EIAV (104) were discovered, isolated, and characterized long before the discovery of HIV; these viruses have retained use of their original designations. Lentivirus groupings identified after the

discovery of HIV have used a nomenclature similar to that for HIV (i.e., “immunodeficiency virus”). A lentivirus that was originally isolated from a cow with a chronic disease by Van Der Maaten et al. in 1972 (187) received little attention until after the discovery of HIV; the cow lentivirus is now called bovine immunodeficiency virus (BIV) (67). Subsequent to the discovery of HIV, lentiviruses were isolated from monkeys and cats (Table 1). Although discovery of MVV, EIAV, and BIV predates that of HIV, research with HIV has far surpassed that of all other lentiviruses in terms of the level of detailed knowledge. New information on other lentiviruses is thus usually compared with what is known for HIV.

Species	Virus	Year that cultivation was first published
Sheep/goats	Maedi/Visna virus; caprine arthritis encephalitis virus	1960[a]
Horses	Equine infectious anemia virus	1961[b]
Cattle	Bovine immunodeficiency virus; Jembrana disease virus	1972[c]
Humans	Human immunodeficiency virus	1983[d]
Monkeys	Simian immunodeficiency virus	1985[e]
Cats	Feline immunodeficiency virus	1987[f]

TABLE 1. *Known lentiviruses*

INFECTIOUS AGENT

Overview of General Properties

Related lentiviruses have been isolated from sheep, goats, horses, cattle, cats, monkeys, and humans (see Table 1). Genetic analysis of the virus from goats (caprine arthritis–encephalitis virus; CAEV) indicates that it clusters closely with MVV (185) and is thus placed in a single grouping with MVV. Thus, based on host species and the genetic analyses described in more detail later, six discrete evolutionary groupings of lentiviruses are generally recognized (Fig. 1A). It is likely that more remain to be identified. It is important to realize that even within a single grouping, discrete subgroupings based on host species, geography, and genetic distance can be defined. For example, within the SIV grouping, distinctly different subgroupings exist for the SIVs from African green monkeys, sooty mangabey monkeys, Sykes' monkeys, and L'hoesti monkeys (see Fig. 1B). Even among African green monkeys, which inhabit virtually all of sub-Saharan Africa, discrete genetic subgroupings of SIVagm can be defined that correlate with subspecies and natural geographic habitat (Table 2).

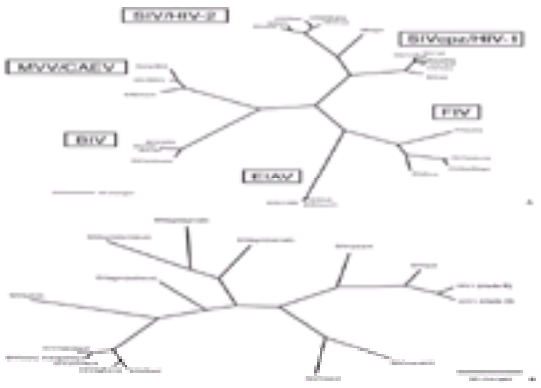

FIG. 1. Phylogeny of the lentiviruses. **A:** Six discrete evolutionary groupings of lentiviruses. Unrooted tree depicts the phylogenetic relationships among the six recognized groups of lentiviruses. The tree is based on a 470-amino-acid alignment of reverse transcriptase sequences from representative members of each group, including the bovine (BIV, Jembrana), equine (EIAV), feline (FIV), ovine/caprine (visna, CAEV) and primate (SIV, HIV) lentiviruses. Maximum parsimony (shown) and neighbor-joining (not shown) analyses give trees of nearly identical topology. Branch lengths are proportional to the number of amino acid replacements. **B:** Phylogeny of primate lentiviruses. Unrooted tree is based on the same amino acid alignment used in **A**. In addition to the viruses shown, SIVs have also been isolated from red-capped mangabeys (SIVrcm) and drill monkeys (SIVdr), but these have not been completely characterized. [a]Sufficient sequence information is not presently available to place these isolates relative to the five known groupings of primate lentiviruses.

In addition to the primate lentiviruses listed, serologic surveys for the detection of antibodies to SIV have suggested SIV infection of a variety of other species. These include but are not limited to talapoin monkeys, Delhbrazza monkeys, guenons, Dent's monkeys, Allen's swamp monkeys, and colobus monkeys (118, 139, 177).

TABLE 2. *Detailed listing of primate lentiviruses*[a]

All lentiviruses have a common morphogenesis and morphology that distinguish them from other subgroups of retroviruses (see Chapter 57). Lentiviruses bud from the plasma membrane without a preformed nucleoid, and mature particles typically have a cylindrical or rod-shaped nucleoid (Fig. 2). Classification into the lentivirus subgroup by morphologic criteria alone is entirely consistent with phylogenetic analysis of *pol* gene sequences. Viruses classified as lentiviruses have *pol* gene sequences more closely related to one another than to other retroviruses, and all have the characteristic morphogenesis/morphology. All lentiviruses have a propensity to replicate in macrophages, and all are associated with a chronic disease course in susceptible hosts. The primate lentiviruses have acquired use of CD4 as one of at least two receptors used by virus for entry into cells (Table 3). Lentiviruses from nonprimates do not use CD4 as a receptor for entry. The chronic disease induced by the primate lentiviruses in susceptible hosts has an immunodeficiency component, presumably because of the targeting of $CD4^+$ lymphocytes by use of CD4 as a receptor. All lentiviruses have a number of auxiliary genes (i.e., genes in addition to *gag, pol,* and *env,* not found in other, simpler retroviruses). Major distinguishing properties are summarized in Table 3.

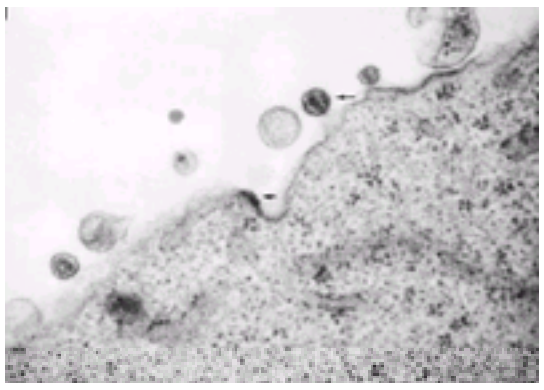

FIG. 2. Lentivirus morphogenesis and morphology. This electron micrograph of a cell infected with simian immunodeficiency virus shows virus budding from the cell in the absence of preformed particles (*lower arrow*) and a mature particle with a cylindrical or rod-shaped nucleoid (*upper arrow*). Genome Organization and Composition

Widespread availability of DNA sequencing capabilities has greatly facilitated our understanding of phylogenetic relationships and the gene products of lentiviruses. Based on sequence analysis, six discrete groupings of lentiviruses are now recognized (see Fig. 1A). It is likely that other groupings remain to be discovered. Extensive diversity exists even within a grouping. For example, among the SIVs, distinct subgroups have been defined from African green monkey, sooty mangabey monkey, L'hoesti monkey, and Sykes' monkey (see Fig. 1B and Table 2). Similar diversity has been observed for FIV in wild and captive cat species (18). Even among four subspecies of African green monkeys (vervet, grivet, tantalus, and sabeus), discrete sub-subgroupings of SIVagm have been defined (see Table 2). These four subspecies naturally inhabit distinct or sometimes partially overlapping habitats that cover almost all of sub-Saharan Africa.

The *pol* gene generally exhibits the greatest degree of sequence conservation. *Pol* gene sequences thus are often used for the comparison of lentiviruses from different groups, subgroups, or sub-subgroups. Sequences from one subgroup of SIV (e.g., SIVsm) will typically exhibit only 55% to 60% identity in *pol* at the amino acid level when compared with sequences from another SIV subgroup (e.g., SIVagm). Diverse members within a subgroup may exhibit as little as 75% to 80% amino acid identity in *pol,* but the number is typically quite higher. When different groups of lentiviruses are compared, for example, MVV with SIV, amino acid identity in *pol* is typically 35% or less. Relatedness in other genes is even less. Nonetheless, these lentiviral sequences are clearly more closely related to one another than to other retroviruses, justifying their classification as lentiviruses on the basis of morphogenesis/morphology and biologic properties.

All known lentiviruses have at least three genes in addition to the standard *gag, pol,* and *env* genes that all replication-competent retroviruses possess (Table 3, Table 4 and Table 5 and Fig. 3). These extra genes likely contribute to a more complicated life cycle for the lentiviruses, which includes persistent viral replication and strategies for immune evasion discussed in more detail later. Genes for *tat* and *rev* are consistently found in all six lentivirus groupings. A *vif* gene is consistently present in five of the six lentivirus groupings; EIAV, however, stands alone in apparently lacking a *vif* gene. Whether another protein may perhaps contribute *vif* function for EIAV remains to be determined. A *nef* gene is found at the 3' end of all primate lentiviruses (see Table 5). None of the more primitive lentiviruses contains a *nef* gene. However, cells infected with EIAV and BIV have been found to make spliced RNAs that predict protein products called Ttm and Tmx that correspond to the carboxy-terminal portion of TM (10,68). Whether these may represent evolutionary precursors to *nef* or perform functions similar to those of *nef* is yet to be determined. All lentiviruses contain an unusually long (>150 amino acids) cytoplasmic domain of TM. In the intergenic region between *vif* and *env,* a number of other genes can be present, particularly in the primate lentiviruses. A *vpr* gene is present in this region in all primate lentiviruses that have been examined. The SIVsm/ SIVmac/HIV-2 subgroup of viruses contains an additional homolog of *vpr* called *vpx,* not found in viruses outside this grouping. HIV-1/SIVcpz contains a gene called *vpu* not found in other lentiviruses.

TABLE 5. *Auxiliary genes of of primate lentiviruses*

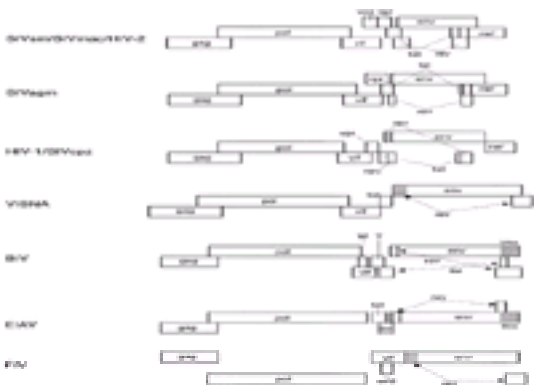

FIG. 3. Genome organizations of representative lentiviruses.

The nonprimate lentiviruses encode a deoxyuridine triphosphatase (dUTPase) activity from a distinct open reading frame located within the *pol* gene (50). Curiously, these dUTPase coding sequences are absent in the primate lentiviruses but present in the type D retroviruses. The explanation for this variable presence of dUTPase is not entirely clear. The type D retroviruses and lentiviruses may possibly have diverged from a common ancestor that possessed such a dUTPase reading frame, and this reading frame may have been lost in the evolution of primate lentiviruses from the more primitive ones. The type D retroviruses and lentiviruses do share a common morphology of the mature particles (i.e., a cylindrical or rod-shaped nucleoid), which also may suggest some commonality. Alternatively, the presence of a dUTPase reading frame in nonprimate lentiviruses and in type D retroviruses could be an example of convergent evolution, with two distinct lineages acquiring these sequences independently by gene capture or by sequence duplication and point mutation.

Another possibility is that one viral lineage may have acquired dUTPase sequences from the other viral lineage by a recombination or capture event (7). The loss of dUTPase in the evolution from nonprimate to primate lentiviruses could relate at least in part to the predominant replication of nonprimate lentiviruses in cells with little potential to divide (macrophages) versus the predominant replication of primate lentiviruses in cells with much greater potential to divide (lymphocytes). Primate lentiviruses incorporate uracil DNA glycosylase into virions through its binding to *vpr* (121). The presence of the dUTPase or uracil DNA glycosylase in virions serves to reduce the mutation frequency in reverse transcription products.

Propagation and Assay in Cell Culture

Primary isolates from all lentivirus groupings can be grown in normal macrophage cultures of the host species. Other types of cells may be more typically used for replicating the individual viruses in routine cell culture. The types of cells that can be used vary with the virus (Table 6) and almost certainly relate to the kinds of receptor that can be used, at least in most cases. Isolates also can be adapted to growth on particular cell substrates. Examples of the latter include growth of FIV on Crandell feline kidney cells and growth of SIVs and HIVs on human tumor T-cell lines (see Table 6).

Lentivirus group	Growth on macrophages	Other cell types	Adaptation to growth
HIV-1	Yes	Stimulated, primary, human CD4+ lymphocytes	Human tumor T-cell lines
SIV	Yes	Stimulated, primary, monkey CD4+ lymphocytes	Human tumor T-cell lines
MVV/CAEV	Yes	Choroid plexus cells; primary synovial cells; endothelial cells	–
FIV	Yes	Primary, stimulated feline lymphocytes	Crandell feline kidney cells
EIAV	Yes	–	Fetal equine kidney; equine dermal
BIV	Yes	–	Bovine, rabbit, canine fibroblasts

TABLE 6. *Cell substrates for growing lentiviruses*

Host Range

The lentiviruses are typically rather restricted in their host range, but both natural and experimental cross-species infections have been documented. SIVs naturally infect a variety of African nonhuman primates, but a single example of natural infection of Asian Old World monkeys has never been documented. The SIVs from sooty mangabey monkeys and African green monkeys, when introduced into macaque monkeys, Asian Old World primates, can infect them and cause an AIDS-like disease (57,75,133). In fact, the SIV of sooty mangabey monkeys was accidentally introduced into macaque monkeys in captive United States colonies on at least one occasion and disseminated unknowingly into other macaques for more than a decade before it was discovered and eliminated (32,120). At least one clear case of laboratory-acquired infection of a human with SIVmac has been documented (100).

Cross-species transmission of SIV to baboons in the wild has been documented. Baboons do not appear to harbor their own SIV naturally. Of 279 baboon sera taken from native habitats in Tanzania and Ethiopia, 277 were negative for the presence of antibodies to SIV. However, two gave strong reactivity to SIVagm antigens (105). One of these two was subsequently shown to harbor SIVagm sequences in stored plasma. The SIVagm sequences clustered with the vervet subtype, consistent with the known cohabitation of vervet monkeys in the same region where the baboon samples were taken (91). An SIVagm variant has similarly been detected in a chacma baboon of southern African (188). Baboons also can be infected experimentally with HIV-2 (116). Evidence for cross-species transmission of SIV from west African green monkeys (*Cercopithecus aethiops sabeus*) to patas monkeys (*Erythrocebus patas*) and to white-crowned mangabeys (*Cercocebus torquatus lumulatus*) has also been presented (12,177). Transmission of SIV or HIV to nonprimates has not been documented.

The origins of both HIV-2 and HIV-1 in humans are now generally believed to be from cross-species transmission. HIV-2 is endemic in western Africa and is only now beginning to be seen detectably in some other regions of the world. The SIV from sooty mangabey monkeys is closely related to HIV-2 and basically cannot be distinguished from HIV-2 on the basis of genetic analysis. The native habitat of the sooty mangabey monkey is the coastal forest regions of western African, the same region where HIV-2 is endemic. Thus strong circumstantial evidence involving both viral sequences and geographic colocalization link the monkey and human lentiviruses in western Africa (23,38,61,78). Similarly, of the four subspecies of chimpanzees, one (*Pan troglodytes troglodytes*) appears to harbor naturally a lentivirus (SIVcpz) that is closely related to group M, N, and O isolates of HIV-1 (29,59). Although more work should be done on the lentiviruses naturally harbored by the four subspecies of chimpanzees, the work to date provides strong support for the introduction of a lentivirus from *P. troglodytes* into the human population on one occasion or more for the origin of HIV-1.

Attempts to transmit HIV-1 experimentally to a variety of animal species have shown a very restricted host range. HIV-1 is infectious for chimpanzees, and a recent chimpanzee-passaged HIV-1 has shown pathogenic potential (137). An early report described HIV-1 infection of pig-tail macaques (*Macaca nemestrina*) (1), but this model has not proven sufficiently robust to date for general use. Attempts to increase the usefulness of this system by serial-passage adaptation of HIV-1 in this macaque species are ongoing.

The more primitive lentiviruses also appear rather restricted in their host range, limited to the same or closely related genera. BIV has been reported to infect New Zealand white rabbits.

Receptor Use

HIV-1 uses a two-receptor system that includes both CD4 and a seven-membrane-spanning chemokine receptor for entry into target cells (see Chapter 59 for details). The SIVs that have been examined to date appear to be similar to HIV in their use of both CD4 and chemokine receptor for entry. Like HIV-1, the SIVsm/SIVmac/HIV-2 and SIVagm groups of viruses appear to use CCR5 as the principal second receptor. However, as with HIV-1, a variety of other chemokine receptors may be used, depending on the virus and the isolate. In addition to CCR5, assorted SIVs have been shown to use CCR2b, CCR3, STRL33 (Bonzo), GPR15 (Bob), and GPR1. The SIVsm/SIVmac/HIV-2 group of viruses in general appears to show less dependence on CD4 for a larger percentage of isolates than does HIV-1 (49). Use of CXCR4 as second receptor also appears to occur much less frequently with SIVsm/SIVmac than with HIV-1. SIV isolates from red-capped mangabeys (*Cercocebus torquatus torquatus*) appear to be unusual in their predominant reliance on CCR2b for use as second receptor (21).

Our understanding of the evolution of receptor-mediated entry among the lentiviruses has been greatly advanced by the discovery that FIV uses CXCR4 as receptor for entry (196). Both primary isolates and laboratory-adapted strains of FIV have been shown to use CXCR4, and the observations have been independently reproduced in several laboratories around the world (147,154). Infection with FIV can be modulated by soluble stromal cell–derived factor, which is believed to be the natural ligand for CXCR4 (81). Little information is currently available on the receptors used by other nonprimate lentiviruses.

The immediate questions regarding receptor use by lentiviruses are obvious ones, but the answers will be instrumental in our understanding of the evolution and logic of receptor use. Do other nonprimate lentiviruses in addition to FIV use seven-membrane-spanning chemokine receptors for entry into host cells? If so, use of chemokine receptors will be a theme common to all lentiviruses. Do the nonprimate lentiviruses also use a two-receptor system for entry into target cells? If so, what is the nature of the other component in the two-receptor system? It is certainly not CD4. In the evolution from the nonprimate to primate lentiviruses, it is possible to envision a switch from a one-receptor system (chemokine receptor) to a two-receptor system (CD4+ chemokine receptor) or a switch from one two-receptor system (X+ chemokine receptor) to another (CD4+ chemokine receptor).

PATHOGENESIS AND PATHOLOGY

Portals of Entry

The primary mode of natural transmission of the nonhuman lentiviruses varies considerably with the virus. EIAV may be the most interesting because it is the only lentivirus for which there is good evidence for vector-borne transmission. During disease episodes, levels of infectious virus in the plasma of horses can exceed 10^4/mL. Transmission via blood can be mediated by inappropriate veterinary practices with needles, scalpels, or by insect vectors. The horse fly appears to be more efficient than mosquitoes, fleas, or other insects for being able to transmit EIAV. Transmission has been documented by following a single horse fly that had taken a blood meal on an infected pony during an acute clinical period (89).

Work on natural modes of infection has demonstrated the capability of both vertical and horizontal transmission for FIV, MVV/CAEV, and EIAV (17). Vertical transmission can occur *in utero,* during parturition, and postnatally via milk. This vertical transmission by these viruses parallels that observed with HIV in humans. Contact transmission also is common, particularly for MVV/CAEV and EIAV when animals are herded closely together in barns or stables. These viruses can be found in semen, lung excretions, and saliva. For cats, bite wounds are believed to be the most important route of transmission (199). FIV infection is much more common in males than in females, consistent with increased fighting and biting among male cats. Cats allowed to roam free in areas with high cat density are at greatest risk of becoming infected.

Information on natural modes of SIV transmission has been harder to come by. One study of wild grivet monkeys in Awash National Park in Ethiopia analyzed SIVagm serologic status with age, sex, and risk (146). Infection was nearly universal in females of reproductive age and nearly absent in younger females. In males, infection was observed in only those that were fully adult. The findings support a predominantly sexual mode of transmission among SIVagm-infected grivets. Maternal–infant transmission of SIV has been documented in captive animals (103).

Experimental infection of laboratory animals has been most commonly achieved by direct needle inoculation. However, mucosal exposure is now being used more frequently, particularly for vaccine studies, as a model for the most common routes of HIV transmission.

Cell and Tissue Tropism

Despite the varied modes of transmission, all lentiviruses are disseminated to an assortment of tissue sites by the blood. Virus can be disseminated as free virus, or more likely by infected blood monocytes or lymphocytes. Differences in the cell tropism of primate versus nonprimate lentiviruses relate largely to receptor use discussed earlier. Infection by the primate lentiviruses SIV and HIV is seen in $CD4^+$ lymphocytes and macrophages, with $CD4^+$ lymphocytes vastly predominating in terms of numbers of infected cells. For the nonprimate lentiviruses, infection of macrophages typically predominates, but infection can be seen in a greater diversity of cell types. Replication in tissue macrophages is a unifying feature of all lentiviruses.

The principal anatomic sites for localization of MVV and CAEV have varied with the study and the strain of virus used. Because many studies of virus localization have used experimental infection, the origin of the infecting strain and the type of cell in which it was grown must be taken into account when interpreting the results of these studies. Various reports have localized MVV principally to lungs, mammary glands, joints, lymph nodes, spleen, and brain. The principal target cell in which MVV and CAEV sequences can be found *in vivo* is quite consistently the tissue macrophage.

However, consistent with the broad range of cell types that can support replication in culture, evidence has been presented for MVV/CAEV replication in other cell types in a less prominent fashion, including epithelial and fibroblast cells in choroid plexus, intestine, and kidneys. An important observation first made with MVV is that although virus may reside in the relatively undifferentiated monocytes in peripheral blood, MVV expression is greatest in the differentiated tissue macro-phages (63,144). This led to the concept of the “Trojan horse” for MVV and other lentiviral infections, whereby undifferential monocytes in the peripheral blood may carry the viral genome without sustaining viral replication until transported to tissues and differentiated into their mature form, the tissue macrophage.

The anemia caused by EIAV is hemolytic and results from the formation of antigen–antibody complexes that can associate with the surface of erythrocytes. The kidney also is affected by this complex formation. A variety of studies, both old and new, have shown the tissue macrophage to be the major cell type producing EIAV (127,138,164). Virus production has been noted in spleen, liver, kidney, lymph nodes, lung, heart, brain, stomach, bone marrow, thymus, adrenals, and intestine. Although EIAV can be adapted to replicate on fibroblasts, virus that comes out of horses during viremic episodes is derived principally from macrophages.

FIV appears to be unusual among the nonprimate lentiviruses in that virus has been more consistently found in a broader range of cell types, particularly lymphocytes, in addition to macrophages. Analysis of tissue and cellular localization of FIV have principally used experimentally infected cats and FIV originally grown in lectin-stimulated peripheral blood mononuclear cell (PBMC) cultures in the presence of interleukin-2. The extent to which cellular and tissue distribution studies represent the situation with natural infection may therefore not be entirely clear. Nonetheless, FIV has been found in a variety of cell types including B cells, $CD8^+$ T cells, $CD4^+$ T cells, macrophages, and cells of the central nervous system (CNS). Macrophages, microglia, and astrocytes, but not neurons, in the brains of cats have been found to be targets of FIV infection (46).

The major sites of pathogenic SIV replication early after infection have been localized to thymus, spleen, gastrointestinal tract, and other lymphoid tissue (107,190). SIV was localized at these early time points primarily within periarteriolar lymphoid sheaths in spleen, paracortex of lymph nodes, and medulla of the thymus. Many early studies have overlooked the fact that the gastrointestinal tract contains most of the lymphoid tissue in the body. SIV infection of rhesus monkeys results in profound and selective depletion of $CD4^+$ T cells in the intestine within days of infection, before any such changes are evident in peripheral lymphoid tissues. The loss of $CD4^+$ T cells in the intestine is coincident with productive infection of large numbers of mononuclear cells at this site. Thus the gastrotintestinal tract appears to be a major target for SIV replication and the major site of $CD4^+$ T cell loss early in SIV infection (190). Within thymus, marked depletion of thymic progenitors has been noted by 21 days; this depletion is followed temporally by increased levels of cell proliferation in the thymus and a marked rebound in thymocyte progenitors (198). The distribution of virus within lymphoid organs varies with the innoculum. SIV also can be found in the central nervous system early after infection. The infected cells in the brain, whether early after infection or late in SIV-induced encephalitis, are primarily cells of monocyte/macrophage lineage (160). These may include perivascular monocyte/macrophages that have migrated from the blood or the resident microglial cells.

Immune Responses and Persistence

Monkeys infected with SIV and animals infected with other lentiviruses typically make strong antibody and cytotoxic T-lymphocyte (CTL) responses to the virus. These immune responses persist at high levels for the lifetime of the infected host, whether infection is by natural or experimental means. Approximately 20% to 30% of macaque monkeys infected with some AIDS-causing strains of SIV develop a more rapid disease course, make few or no antibodies to the virus, and die with AIDS in 3 to 7 months. The deficiency in anti-SIV antibodies in such animals does not appear to be a matter of antigen excess, because B cells from these rapidly progressing monkeys make few or no anti-SIV antibodies (48). The strength of anti-SIV antibody responses also varies with the virulence of the infecting strain (Fig. 4). Deletion mutants of SIV that are progressively more attenuated on the basis of viral load measurements elicit progressively weaker anti-SIV antibody responses (40). CTL responses have been shown to be major histocompatibility complex (MHC) restricted for both SIV and animal lentiviruses. Detailed work on CTL responses has been hindered by limited knowledge of MHC types in these animal species, although a considerable amount of new information is now emerging on MHC alleles in rhesus monkeys and the peptides that they present.

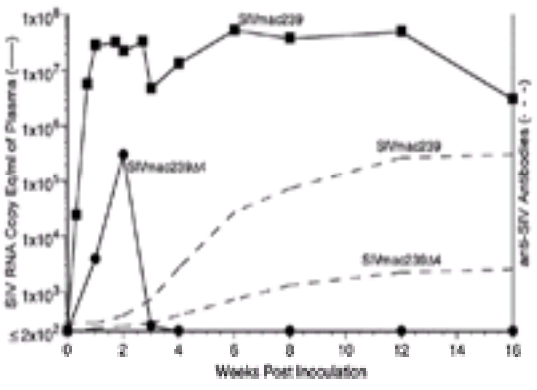

FIG. 4. Attenuation by auxiliary gene deletion lowers viral load and reduces the strength of the antiviral antibody response. SIVmac239D4 has inactivating deletions in *vpr, vpx,* and two in *nef.* From ref. 40, with permission.

The importance of $CD8^+$ lymphocytes in limiting the extent of replication of SIV or SIV/HIV recombinant (SHIV) has been definitively demonstrated by using the approach of CD8 cell depletion (125,161). Extensive or near-total depletion of $CD8^+$ cells was achieved by intravenous administration of large doses of specific anti-CD8 monoclonal antibodies.

Depletion was not permanent because $CD8^+$ lymphocytes returned in the absence of continuous monoclonal antibody. When $CD8^+$ cells were depleted during primary infection, virus replication proceeded unabated after peak loads 10 to 14 days after infection; this contrasts with nondepleted animals, in which immune responses typically result in reductions in viral load beyond 14 days (125,161). Elimination of $CD8^+$ lymphocytes from monkeys during chronic SIV infection resulted in a rapid and marked increase in viremia that was again suppressed coincident with the reappearance of SIV-specific $CD8^+$ T cells (161). Depletion of $CD8^+$ T cells in SHIV-infected animals facilitated the appearance of more highly pathogenic variants (84).

In SIV-induced disease in macaque monkeys with wild-type strains of SIV, viral-specific, proliferative responses of CD4 cells are typically weak or absent. However, infection by attenuated SIV mutants deleted in *nef* results in strong, SIV-specific, CD4 helper cell proliferative responses (62). This situation appears analogous to HIV infection of humans, in which HIV-specific CD4 responses are usually weak or absent in typical progressors but are often very strong in unusual nonprogressors that are controlling their infection (155,156). The picture that emerges with these primate CD4 receptor–using viruses is one of a battle during the early stages of infection. CD4 helper cells try to respond to sites of infection, but these activated CD4 cells at the sites of infection are the ideal targets for replicating virus. In pathogenic infections, the virus wins this early battle and eventually wins the remainder of the war. The status of CD4 helper cell responses in nonpathogenic infection of the natural hosts of SIV (e.g., SIVagm in African green monkeys or SIVsm in sooty mangabeys) has not been investigated.

The lentiviruses persist through chronic active viral replication. The clearest demonstrations of this are with HIV in humans and SIV in macaque monkeys, in which during months and years of chronic infection, millions of viral particles and millions of infected cells are produced and turned over every day (80,193). This does not mean, however, that no cells are infected in a quiescent or latent fashion; some certainly are. The degree of chronic active replication also varies with the strain of virus and the host. The long-term persistence of antibody and CTL responses at high levels is consistent with the prolonged antigen expression of chronic active replication. Even nonpathogenic derivatives of SIV continue to replicate at low levels over prolonged periods, as evidenced by the evolution of sequence changes, persistence of antibody, and other criteria.

EIAV is unusual among the lentiviruses for the episodic nature of the persistent viral replication. Infection of horses with EIAV is associated with recurring episodes of fever, anemia, and thrombocytopenia. These episodic occurrences of clinical disease coincide with bursts of new virus replication, which may be weeks or months apart. Episodes of new virus replication yield EIAV variants that are not neutralized by the horse's own serum; however, the same serum is capable of neutralizing the EIAV variants from earlier episodes (reviewed in ref. 129).

The dilemma of lentiviruses is their ability to replicate persistently in the face of apparently strong immune responses. The levels of anti-HIV antibody and CTLs have been precisely measured and are enormously high. The strategies used by lentiviruses to allow persistent viral replication in the face of these apparently strong immune responses have been recently reviewed (39). These are summarized in Fig. 5 and in points 1 through 5 below.

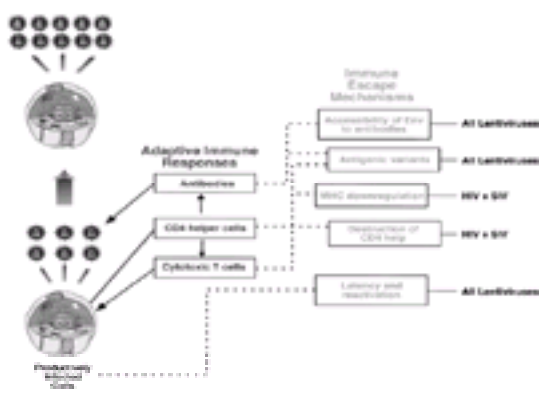

FIG. 5. Human immunodeficiency virus (HIV), simian immunodeficiency virus (SIV), and other lentiviruses use a variety of strategies to avoid both humoral and cellular responses.

1. Differentiation- or activation-dependent expression
   Like all retroviruses, the lentiviruses integrate a proviral DNA copy of their genetic information into the host cell DNA. This proviral DNA may lie dormant for prolonged periods and can be reactivated at a later date when conditions may be more suitable. Triggering events for activation of lentivirus expression can include cellular activation of lymphocytes or macrophages by natural stimuli (antigen, cytokines) and differentiation of monocytes into tissue macrophages, as originally promulgated in the Trojan horse concept.
2. Emergence of antigenic variants
   As RNA viruses, the lentiviruses have an error-prone reverse transcriptase for replicating their genetic information. The emergence of mutant forms of virus (within a single infected individual) that are antigenic variants that escape ongoing neutralizing antibody responses was first described with EIAV, MVV, and CAEV. Subsequent work has provided exquisite detail on the emergence of SIV and HIV variants that escape both neutralizing antibody and CTL responses (14,15 and 16,52).
3. Shielded nature of external surface glycoprotein
   The surface proteins of all lentiviruses are heavily glycosylated, and the external surface glycoproteins of lentiviruses are among the most heavily glycosylated proteins known. The carbohydrate groups help to serve as a barrier that limits the neutralizing antibody response to virus. Strains of SIV lacking specific carbohydrate attachment sites are much more effective targets for antibody-mediated neutralization and are able to elicit considerably higher titers of neutralizing antibodies (19,24,152).

The only lentiviral surface glycoprotein for which three-dimensional data are available is HIV-1 (106). Although the structure lacks loops of variable sequences and lacks carbohydrate, a compilation of antibody mapping and structural and functional data has revealed interesting features that reflect on the replication strategy of HIV. The CD4-binding site is contained within a difficult-to-access pocket, and the variable loops and carbohydrate appear to act largely as a shield to protect regions of the protein that would otherwise make virus sensitive to antibody attack. Although infected people develop high-titer antibody responses reactive with monomeric HIV-1 envelope protein, these antibodies apparently react poorly or not at all to envelope protein as it exists on the surface of virons. These antibodies certainly have very poor neutralizing activites.

4. Destruction of CD4 help
   This immune evasion strategy appears to be applicable only to the primate lentiviruses, which use CD4 as primary receptor. The early destruction of virus-specific CD4 helper cell activity leaves the host without appropriate help for its B-cell and CD8-cell responses.
5. MHC down-regulation
   The primate lentiviruses encode an early gene product, Nef, that down-regulates MHC class I molecules from the surface of cells, making them less-sensitive targets for CTL attack (27,163).

Other RNA viruses with error-prone polymerases, such as poliovirus, seem nowhere near so difficult to neutralize and nowhere near so malleable as HIV. The basis for these differences may lie in the inherent strategies used by persisting versus nonpersisting viruses. The survival of any virus depends on its ability to spread through the population. For a nonpersisting virus such as poliovirus, transmission is limited to the several weeks after the time of primary infection. Resistance to antibodies, once they appear, may not be so important to such a virus. Instead, it is important to replicate maximally for the brief period to maximize the likelihood for transmission. HIV, SIV, and other lentiviruses, in contrast, help ensure their transmission by greatly lengthening the period during which transmission can occur. Thus these viruses may sacrifice inherent replicative capacity in the short term to allow persistent viral replication over the long term.

Virulence

Not all lentiviral infections are uniformly pathogenic. The various forms of SIV are not associated with any disease in their natural hosts. Life-long subclinical infections also have been documented for EIAV and MVV. Various breeds of horses and sheep vary in their general susceptibility to EIAV and MVV, and these may even vary in the degree of susceptibility to specific disease manifestations. For example, the classic CNS form of visna infection originally observed in Iceland is only rarely seen elsewhere. Some strains of SIV are much less pathogenic than others in susceptible macaque monkeys, and some derivatives that have been specifically attenuated by deletion mutations appear to be nonpathogenic.

The diseases associated with lentiviral infections are typically chronic and manifest over a prolonged period. However, there are some prominent exceptions to the classic, prolonged course of lentiviral disease. A particular strain of SIV called SIVsmPbj14 is acutely lethal in rhesus monkeys. Monkeys infected with SIVsmPBj14 typically die within 14 days with very high viral loads, severe gastrointestinal disease, cytokine dysregulation, lymphoproliferative disease, and organ system failure (42,56,58,136). The unusual properties of this strain have been attributed in large part to the unusual positioning of a tyrosine at residue 17 of the nef protein (47). The occurrence of tyrosine at this position of nef creates an immune-receptor tyrosine-based activation motif (ITAM) of the type YXXLX7YXXL that imparts on virus the unusual ability to cause lymphocyte activation and to replicate to high titers in lymphocytes of PBMC cultures without any prior stimulation (47). The BIV variant that is the cause of Jembrana disease in Bali cattle also is acutely pathogenic. About 17% of Bali cattle infected either naturally or experimentally with JDV die with an acute disease within the first few weeks (43,44,195). During acute disease, infectious titers of virus reach 10^{8}/mL of plasma. Jembrana disease has remarkable similarities to the disease induced by the tyrosine- *nef* variant of SIV, SIVsmPbJ. In Jembrana disease, there is marked enlargement of lymph nodes and spleen, which feature proliferating lymphoblastoid cells. Proliferating lymphoid infiltrates are also found in many other tissues. The disease in horses induced by EIAV also is often considered more acute than that occurring with other lentiviruses. The first episode of EIA disease usually occurs 2 to 6 weeks after the initial infection. Subsequent disease cycles are irregular, appearing weeks to months apart, and usually last 3 to 5 days. The frequency and severity of disease episodes usually decline with time. Episodes of clinical disease usually end within the first year after an average of six to eight episodes.

Clinical and Pathologic Features

Good reviews are available on the clinical and pathologic features of nonhuman lentiviral infections (17,94). Some of the most prominent features are highlighted here.

Equine Infectious Anemia Virus

Equines are the only species susceptible to natural or experimental infection with EIAV. Clinical disease is usually divided into acute, subacute, and chronic phases. Acute disease typically results in fever as high as 108°F 1 to 4 weeks after infection. Anemia is not a prominent feature at the outset. Excessive thirst, loss of appetite, weakness, depression, and hemorrhage are seen in the acute phase. The acute disease may result in death. The subacute form is characterized by relapsing fever and recurrence of other signs. Recurrence of episodes may be brought on by hard work or malnutrition. In its chronic form, animals may remain thin despite adequate availability of food, and red cell counts are typically well below normal. Clinical signs in late disease and pathology findings appear to result principally from the hemolytic anemia. Erythrocytes of infected horses are coated with antibodies and complement factor 3, and destruction of red cells is immunologically mediated. Osmotic fragility, shortened half-life, and phagocytosis contribute to the destruction. Bone marrow may also be depressed, but this seems less important than the immune-mediated destruction. Hemorrhage, jaundice, and edema are most commonly found at necropsy. The nature and severity of the lesions will vary with course of disease and duration of the illness.

Maedi/Visna Virus and Caprine Arthritis–Encephalitis Virus

Although maedi (pneumonia) and visna (wasting, depression, paralysis) were once thought to be separate diseases, it is now clear that they are both caused by the same virus. Both systems can be affected in the same animal. Maedi disease in the Netherlands has been called *zwoegerziekte.* Polyarthritis and mastitis also are seen as a result of viral infection. Disease is usually seen only in adult sheep because of the lengthy incubation period, typically 3 to 8 years. The lungs of affected sheep may be 2 to 5 times the normal size, and they exhibit a rubbery loss of elasticity. These abnormalities result from a gross thickening of the alveolar walls from infiltration and proliferation of reticuloendothelial or mesenchymal cells that invade the septa everywhere (Fig. 6A and Fig. 6B). Lymph nodules occur along the bronchi and bronchioles. There is progressive weight loss. Dyspnea is initially apparent only after exercise, but this becomes progressively more severe. Severely dyspneic sheep spend much time lying down. Lesions in the brain consist of demyelination and lymphocytic infiltration (see Fig. 6C and Fig. 6D). Trembling of facial muscles and lips may occur. The onset of clinical signs of visna usually begins with weakness of the hind legs, and this eventually leads to paraplegia. Diseases caused by CAEV in goats are similar to those of MVV in sheep, except that arthritis is usually most prominent, and the pneumonia is usually of lesser severity. Joints are swollen and painful, and this is exacerbated by cold weather. The basic lesion is a proliferative synovitis of joints, tendon sheaths, and bursae.

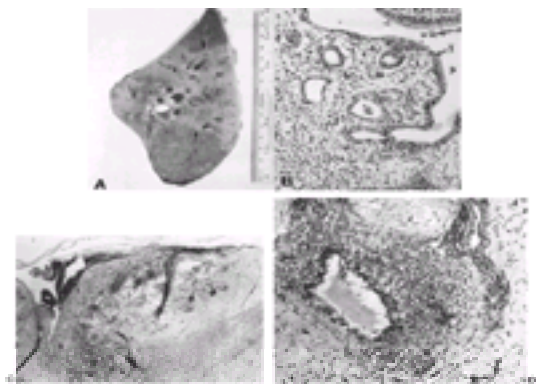

FIG. 6. Pathology of maeid/visna virus (MVV) in sheep. **A, B:** Pneumonia. **C, D:** Encephalitis. **A** and **B** are Fig. 8-69, and **C** and **D** are Fig. 8-68 from ref. 94, with permission.

Feline Immunodeficiency Virus

Primary infection by FIV may lead to low-grade fever, generalized lymphadenopathy, and sometimes diarrhea. During the ensuing months and years, progressing disease is associated with lymphopenia, recurrent fever, lymphadenopathy, anemia, diarrhea, and weight loss of protracted duration. CD4 counts and other cell subsets may be depressed. The final stages of disease are associated with chronic secondary infections, particularly gingivitis, dermatitis, and infections of the upper respiratory tract. Opportunistic infections that have been observed include calcivirus, herpesviruses, toxoplasma, and cryptococcus. Neurologic abnormalities also have been noted, including dementia, twitching tremors, and convulsions. Pathologic lesions primarily reflect those of opportunistic infection.

Simian Immunodeficiency Virus

SIV infection of rhesus monkeys is generally considered the closest model of AIDS in humans. SIV infection of the natural host (e.g., SIVagm in green monkeys or SIVsmm in sooty mangabey monkeys) is not associated with any disease. When SIVsmm was inadvertantly introduced into captive macaque monkey species (Asian Old World primates), AIDS-like disease and lymphomas did ensue (see earlier). AIDS-like disease is generally induced experimentally in macaque monkeys with SIVmac, SIVsmm, or less frequently, SIVagm. As with other lentiviruses, SIV establishes a chronic active infection with a prodromal period of months to years before clinical signs appear. Immunodeficiency is usually but not always associated with marked declines in $CD4^+$ lymphocyte concentrations. Macrophages also are infected. Pathologically, generalized lymphadenopathy is characterized by hyperplasia and is followed by lymphoid depletion in terminal stages (Fig. 7A and Fig. 7B). The gastrointestinal tract, where activated T lymphocytes predominate, appears to be the major site of early viral replication and early loss of $CD4^+$ T cells (see Fig. 7C) (190). However, CXCR4-using viruses may cause a profound loss of T cells in the periphery that is not paralleled in the intestine (72). Marked depletion of progenitor cells occurs in the thymus by 21 days; although a rebound occurs subsequently, thymic dysinvolution is typically seen at terminal stages (see Fig. 7D and Fig. 7E) (198). Nodular lymphocytic infiltrates in a variety of tissues (Fig. 7C), interstitial pneumonia with syncytial cells ("giant cell pneumonia") (Fig. 7H and Fig. 7I), and granulomatous encephalitis (Fig. 7F and Fig. 7G) are variably present. Opportunistic infections are usually present, and these can influence the specific nature of the clinical signs. Common opportunistic infections include *Pneumocystis carinii* pneumonia, generalized CMV, cryptosporidiosis, and *Mycobacterium avium.*

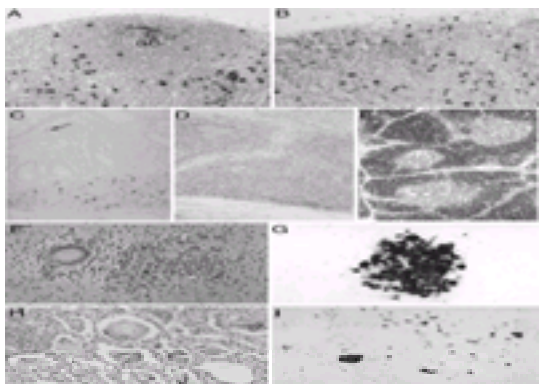

FIG. 7. Acquired immunodeficiency syndrome (AIDS) in monkeys: histopathologic lesions and simian immunodeficiency virus (SIV) localization. **A–C**: *In situ* hybridization for SIV RNA in lymph nodes (**A, B**) and intestine (**C**). In **A**, numerous individual positive cells can be seen in the paracortex of the lymph node of an animal 8 weeks after infection. In addition, diffuse staining of the germinal center (*GC*) of a lymphoid follicle consistent with trapping of virus on follicular dendritic cells can be seen. Note that the lymphoid architecture is relatively intact at this early time point, in contrast to a lymph node from an animal with terminal AIDS in **B**. Although the lymph node in **B** shows severe lymphoid depletion with no evidence of lymphoid follicles, numerous SIV-infected cells can be seen. In **C**, numerous infected cells in intestine can be seen in a submucosal lymphoid nodule with a rare positive cell (*arrow*) in the overlying lamina propria of this animal 2 months after infection. **D, E:** Thymic atrophy. Infection with SIV is associated with profound dysinvolution of the thymus (**D**), as opposed to a normal thymus (**E**) with discrete cortex and medulla. **F, G:** SIV encephalitis. Infection with SIV results in inflammation of the brain in 25% to 50% of the animals that are infected. The brain lesions are characterized by aggregates of mononuclear cells and multinucleated giant cells (**F**). Cells in the lesions contain abundant SIV nucleic acid by *in situ* hybridization (**G**). **H, I:** Giant cell pneumonia. Multinucleated giant cells in this pneumonia (**H**) as well as numerous mononuclear cells contain abundant SIV nucleic acid by *in situ* hybridization (**I**). Figure and legend courtesy of Dr. Andrew Lackner.

Contributions of Individual Genes and Genetic Elements

Because lentiviruses, like other retroviruses, replicate through a proviral DNA intermediate, cloned proviral DNA representing the full-length lentiviral genome can be infectious. Infectious lentiviral DNAs have been used to study the contributions to replication of open reading frames not found in other retroviruses. The unusual, persistent nature of lentiviral replication has raised speculation as to the role of auxiliary genes in the persistent replication and chronic disease of the lentiviruses. Infectious, cloned, lentiviral DNAs also have thus been used to gauge the relative importance and functional role of auxiliary genes in the context of experimental animal infection. The first cloned lentiviral DNA shown to be not only infectious but also pathogenic was one for SIV (97). Infectious clones that are also pathogenic are now available for EIAV, CAEV, and a number of other SIV isolates (28,73,141).

Deoxyuridine Triphosphatase

A dUTPase reading frame is located within the *pol* gene of the nonprimate lentiviruses and the type D retroviruses. dUTPase catalyzes the conversion of dUTP to dUMP and inorganic pyrophosphate (PPi). dUMP is an important precursor for dTTP, used for incorporation into DNA. dUTPase activity in the cell is believed to minimize misincorporation of dUTP into DNA, which can be mutagenic. The effects of eliminating the dUTPase gene (DU) have been studied in EIAV, FIV, CAEV, and visna. In all cases, DU^- virus was still replication competent in cultured cells. Loss of DU in EIAV and FIV had little or no effect on virus replication in permissive fibroblast cell lines that continuously divide. However, loss of DU in these viruses had dramatic effects on virus replication in macrophages (176,192). Macrophages are not a dividing cell and in general have low deoxynucleotide pool sizes. DU^- EIAV exhibited five-fold to 10-fold lower viral loads in plasma at peak compared with the parental virus, and both EIAV and CAEV missing DU were attenuated for pathogenicity (114,183). DU^- FIV and CAEV were found to accumulate increased levels of mutations, particularly G-to-A substitutions (110,183). Visna virus lacking DU also showed decreased viral loads in experimentally infected sheep but still produced neuropathogenic effects on direct intracerebral inoculation (145).

Tat *and* Rev

Tat and *rev* are essential for the replication of SIV and HIV. The *rev* genes of MVV and CAEV have been found to be essential for replication (162,178). *Tat* appears to be essential for replication of BIV and EIAV as well, but in CAEV, where *tat* is only a weak transactivator, *tat* was found to be dispensable for efficient viral replication both in culture and in goats (71). *Tat* is also a weak transactivator in FIV and MVV. Although *rev* is essential for SIV replication, von Gegerfelt et al. (191) have described a rev^- RRE^- strain of SIV that has been rendered replication competent by the addition of a constitutive transport element (CTE). The attenuating effects of loss of *rev* dependence in the rev^- RRE^- CTE^+ SIV are difficult to evaluate because the virus was also nef^-, and no comparison with otherwise isogenic viruses was made. However, based on comparison with published values from other laboratories for nef^- SIV, the loss of *rev* and RRE and the addition of the CTE appeared to have a significant attenuating effect (191). Because antibodies persisted for more than a year without decline, the rev^- RRE^- nef^- CTE^+ SIV appeared to have established a persistent infection but at very low levels.

The tat proteins of lentiviruses can be clearly divided into two groups with respect to whether their transactivating activities are dependent on binding to an RNA sequence element (13,36,130). HIV, SIV, EIAV, and BIV all have long terminal repeats (LTRs) with low basal activity that is strongly induced by their respective tat proteins in a cyclin T1–dependent and RNA sequence–dependent fashion. The LTRs of visna and FIV are strongly active in the absence of any viral proteins, and their tat homologs transactivate via upstream DNA sequence elements. BIV *tat* is unusual in that it is able to bind to the RNA sequence element independent of cyclin T1, but transactivation is nonetheless dependent on the participation of cyclin T1 (13).

S2

An EIAV derivative lacking S2 replicated normally in fetal equine kidney cells, monocyte-derived macrophages, and differentiated macrophages (112). The S2 deletion mutant displayed slightly decreased viral loads and thrombocytopenia-inducing potential when compared with the parental cloned EIAV (111). Infected horses consistently

make antibodies to S2, confirming that S2 is a *bona fide* virus-encoded product.

Vif

Mutations that knocked out the *vif* reading frame of FIV drastically reduced viral replication (165). *Vif*⁻ SIV could be grown significantly only in a *vif*-complementing cell line (40). Thus *vif* is very important for the replication of FIV, SIV, and HIV in most cultured cells. SIVmac239, with a deletion in the *vif* gene, was produced in a *vif*-complementing cell line and inoculated into monkeys (40). Inoculated animals showed no plasma antigenemia, no recoverable virus, and no polymerase chain reaction (PCR)-amplifiable SIV sequences in peripheral blood. However, inoculated monkeys did develop a low-level persisting antibody response. Thus Dvif SIV does appear to be infectious for rhesus monkeys, but it is the most highly attenuated strain yet studied. Little work has been done on the functional activities of nonprimate lentiviral *vif*s, so similarities and differences in their activities compared with HIV-1 *vif* are not known.

Nef

The properties of SIV strains with mutations in *nef* have been extensively studied. SIVmac239 with an in-frame stop at codon 93 of *nef* uniformly reverted to an open *nef* reading frame by 2 weeks after monkey infection (99). Even a form of SIV with a four-amino-acid deletion in *nef* has reverted in about 10% of infected monkeys (194). Thus there is strong selective pressure to maintain an open *nef* reading frame. SIV with deletions in the *nef* gene are markedly attenuated compared with parental virus. Viral loads are typically reduced by 1 to 2 logs at peak 2 weeks after infection and 33–4 logs at set point. Most monkeys infected with SIVmac239Dnef have survived without disease and with undetectable viral loads for as long as they have been studied. Despite the marked attenuation, infection with SIVmac239Dnef is clearly long term and persistent, only at much lower levels. From 10% to 20% of monkeys infected with SIVmac239Dnef have gone on to develop moderate viral loads and to develop AIDS despite the absence of the *nef* gene. Serially passaged Dnef SIV has shown a consistently pathogenic phenotype, and compensatory changes elsewhere in the genome appear to be responsible. *Nef*⁻ SIV replicates similar to wild-type SIV in a variety of standard cell-culture systems, including lectin-stimulated PBMC cultures in IL-2, although conflicting reports have appeared.

The attenuated properties of *nef*⁻ SIV in monkeys appear to be similar to what has been observed in unusual cases of *nef*⁻ HIV-1 infection in humans. One human in the U.S. has been consistently infected with an HIV-1 with large deletions in *nef* since 1983 (101). In Australia, a blood donor with nef-deleted HIV-1 was responsible for infecting eight recipients; the donor and recipients are all slow or nonprogressors with low or undetectable viral loads (37). *Nef*-deleted HIV-1 is clearly an attenuated virus with a similar level of attenuation as Dnef SIVmac. However, as with monkeys infected with SIVmacDnef, some of the humans infected with HIV-1Dnef are showing signs of disease progression (69,109).

The functional properties of SIVmac *nef* appear to parallel those of HIV-1 *nef* in many respects, but there probably are differences in detailed aspects of their function. The amino terminus of SIVmac *nef* consistently overlaps the env reading frame; no such overlap exists for HIV-1. Although there is correspondence in sequence along most of the lengths of SIVmac *nef* and HIV-1 *nef,* SIVmac *nef* is about 40 to 50 amino acids larger because of these extra amino-terminal sequences; these extra sequences appear to have no homologs in HIV-1 *nef.* Most or all of the functional activities that have been reported for HIV-1 *nef* also are seen for SIVmac *nef.* These include CD4 down-regulation, MHC down-regulation, lymphocyte activation, and infectivity enhancement. *Nef* alleles from SIVmac and HIV-2 are able to bind to the zeta chain of the T-cell receptor and activate tyrosine kinase activity (82); HIV-1 *nef* alleles do not do this. Through the use of recombinant viruses, HIV-1 *nef* alleles were shown to be able to substitute for SIVmac *nef* in monkey infections (2). An unusual *nef* allele (Y *nef*; PbJ14 *nef*) has an immunoreceptor tyrosine-based activation motif (ITAM) that results in unusual ability to stimulate lymphocyte activation and to cause an unusually acute disease (47); no analogous HIV-1 *nef* allele has been found.

Vpr *and* Vpx

Two functional activities have been found for *vpr* of HIV-1: facilitation of nuclear import of the preintegration complex in nondividing cells and G_2 cell-cycle arrest (see Chapter 59). HIV-2, SIVmac, and other primate lentiviruses contain two genes related to HIV-1 *vpr*; these have been called *vpx* and *vpr.* The nuclear import function associates with the *vpx* gene, and G_2 cell-cycle arrest associates with the *vpr* gene (53). Two lines of evidence indicate that *vpr* is not a major contributor to the replication of SIVmac in experimentally infected rhesus monkeys. SIVmac239 with a stop signal in the initiating ATG codon of *vpr* was very slow to revert (108). SIVmac239 with *vpr* deleted replicated only slightly less efficiently than did parental virus in rhesus monkeys, and all *vpr*⁻-infected animals have progressed to AIDS (65). The effects of deleting *vpx* from SIVmac239 on levels of replicating virus in rhesus monkeys were more significant, but nonetheless, more than half of the infected animals went on to progress to AIDS (65). A *vpx* deletion of SIVsmPBJ14 was strongly outcompeted when coinoculated with parental virus (79), consistent with these results. Deletion of both *vpr* and *vpx* markedly attenuated the virus, resulting in a virus that was about as attenuated as SIVmac239Dnef (65).

Env

Env is essential for virus replication. The protein products of the *env* gene are responsible for binding receptor(s) on the cell surface and mediating virus entry into cells. The products of *env* are the major or only targets of antibodies that can neutralize infectivity. Determinants of the differences in tropism of related viruses thus often map to the *env* gene. Whereas SIVmac replicates well in stimulated PBMCs from macaques, HIV-1 replicates not at all or only very poorly in macaque cells. Somewhat surprisingly, the block to replication of HIV-1 in macaque cells maps outside of the envelope gene (167). Derivatives of SIVmac in which the envelope gene has been replaced by envelope of HIV-1 are replication competent in macaque cells and capable of infecting macaque monkeys (85,113,119). Such recombinant viruses are called SHIVs. Serial passage of several first-generation SHIVs has resulted in strains that are consistently pathogenic in macaques. A characteristic feature of the first three pathogenic SHIVs that have been derived is that they cause acute,

severe declines in $CD4^+$ lymphocyte concentrations within the first few months of infection.

U3

The U3 regions of the primate lentiviruses are unusually long compared with their counterparts in the nonprimate lentiviruses (86). Most of this unusual length can be accounted for by the overlap of *nef* coding sequences with the LTR. In fact, several lines of evidence suggest that about 300 base pairs (bp) of U3 sequence in SIV and HIV may be nothing other than *nef* coding sequence.

1. In monkeys infected with SIV missing 182 bp in the region that is uniquely *nef,* the SIV progressively and consistently loses about 300 bp of sequence in the region of U3–*nef* overlap (102). The 12 terminal nucleotides of U3 are consistently retained because these are needed for integration. About 50 bp at the C-terminus of *nef* coding sequence, immediately upstream of the nuclear factor kB (NFKB) site, are consistently retained; this region is known to contain a poorly characterized enhancer element (87,122,148).
2. In the human infected with a *nef*-deleted variant of HIV-1, sequences in the U3–*nef* region also were progressively lost over time (101). Again, the U3 terminal nucleotides and 50 bp upstream of the NFKB site were consistently retained.
3. The 300-bp region of *nef*–U3 overlap has been grossly altered in SIVmac239 by 102 point mutations without changing the predicted amino acid sequence of the encoded nef protein (86). This virus replicated like wild-type in rhesus monkeys without evidence of specific reversional events through at least 20 weeks of infection.

These results are most easily explained whereby these 300 bp of U3 sequence serve predominantly or exclusively as *nef* coding sequence. However, it also is possible that this region contains transcriptional control elements that respond to factors induced by *nef* or that in the absence of *nef,* any transcriptional control elements in this region provide less selective advantage than does a shorter genome.

NFKB and Sp1

Sequence elements in U3 for binding NFKB and Sp1 transcription factors have been defined as major enhancer elements of HIV-1, HIV-2, and SIV. SIVmac is still able to replicate well in a variety of cell types, however, in the complete absence of NFKB and Sp1 elements (87). This is due predominantly or exclusively to an enhancer element present within the 50 bp immediately upstream of the NFKB element within sequences that are also *nef* coding sequences (87,122,148). SIVmac239 derivatives with the NFKB sites removed from both LTRs or with all Sp1 sites removed from both LTRs were not detectably attenuated in rhesus monkeys (88). SIVmac239 with NFKB and Sp1 sites removed was detectably attenuated, but not markedly so (88). HIV-1 replication appears more heavily dependent on the presence of the NFKB and Sp1 sites (158), but circumstantial evidence suggests an enhancer element within the 50 bp upstream of the NFKB binding sequence in HIV-1 as well (101). This enhancer element remains poorly characterized.

Multiply-deleted Derivatives

Work in the SIV system has shown that virtually any level of attenuation can be achieved simply by varying the number and locations of deletion mutations (40). Attenuation has been scored by measure of viral load at peak, viral load at set point, strength of the antibody response, and propensity to induce declines in the numbers of $CD4^+$ lymphocytes. Lack of persistence is a phenotype that has never been consistently associated with any mutant strain.

Genetic Resistance

Although individual examples of resistance to disease occur throughout the lentivirus subfamily, the clearest documentations of mechanisms by which it can occur come from studies with humans. In humans, decreased susceptibility to HIV-1 disease is associated with genetic polymorphisms relating to second-receptor use and with MHC diversity (see Chapter 60). In humans, disease progression is quite uniformly related to virus load, with high loads being of poorer prognosis and low loads being of better prognosis.

A very prominent place to look for mechanisms of disease resistance other than in humans is in sooty mangabey monkeys and in African green monkeys. These species are naturally infected with their own SIV without disease, and there is clearly no problem with the SIV that they carry because their SIVs are capable of causing AIDS when transmitted to Asian macaques. Based on experience with HIV-1 in humans, one would expect viral loads in sooty mangabeys and green monkeys to be low. Surprisingly, this is not the case. Many sooty mangabey monkeys harbor SIV RNA loads in plasma in a range (10^5–10^7 copies/mL) in which disease progression uniformly occurs with HIV-1 in humans and SIV in macaque monkeys (95,153). The rates of sequence evolution also are consistent with a high level of continuous virus replication in mangabeys. Data from green monkeys are only beginning to emerge. Thus, the mechanisms of disease resistance in these species remain to be elucidated, but they promise to provide fundamental insights into pathogenesis and immunologic control that have eluded us to date.

A striking example of a genetic polymorphism with analogies to the human situation has been documented in red-capped mangabeys. A 24-bp deletion (D24) was noted in the *CCR5* gene of red-capped mangabeys with an allelic frequency of 86.6% (21). Eleven of 15 red-capped mangabeys were found to be homozygous for this polymorphism. Interestingly, the SIV from red-capped mangabeys does not use *CCR5* as coreceptor but is unusual in its predominant use of CCR2b as coreceptor.

A particular MHC allele in the rhesus monkey has been associated with rapid progression after experimental SIVmac infection. More thorough characterization of MHC types in rhesus monkeys and definition of the SIV peptides that they present may allow testing of how the MHC type of the host and the sequence of the incoming virus influence the extent of

immunologic control that can occur.

DIAGNOSIS

Because lentiviral infections are persistent, antiviral antibodies are present throughout the lifetime of the infected host. Detection of antiviral antibodies is thus the most widely used method for determining the presence of viral infection. A variety of methods are commonly used for antibody detection that vary with the individual virus. These include enzyme-linked immunosorbent assay (ELISA), Western blot, gel diffusion, indirect immunofluorescence, hemagglutination, complement fixation, and neutralization assays. The commonly used Coggins test for the detection of EIAV infection is a gel-diffusion assay for the detection of antiviral antibodies. Attempts are being made to develop simpler ELISAs for EIAV and other nonprimate lentiviruses. ELISAs developed for the detection of antibodies to FIV give a high rate of false positives that is likely due to use of a variety of vaccines containing cellular or serum antigens from production in cell culture. ELISA is most commonly used for the detection of antibodies to SIV; detection by ELISA is usually routine but can be complicated by the history of the monkey, whether the antibodies are to the same or a different type of SIV (i.e., cross-reactive), and in an experimental setting the presence of antibodies at low levels due to attenuation or intervention. Positivity can be confirmed by virus isolation or by identification of viral antigens in plasma or cells. The presence of specific clinical signs and clear demonstration of the presence of antilentiviral antibodies is usually sufficient for a definitive diagnosis.

PREVENTION AND CONTROL

MVV was eradicated from Iceland by a drastic slaughter policy before the availability of diagnostic tests. Test and removal programs have since been and continue to be used as an effective means of control. Test and removal programs may be voluntary or mandated. Buyers of horses have increasingly sought negative test certification for EIAV, and negative test certification is required as a condition for entry into many racetracks, saleyards, and shows. Horses imported into the U.S. and some other countries are required to have a negative test certificate. Testing within a state is not always compulsory, nor is it compulsory for an owner to destroy a positive horse. For FIV, appropriate test and removal programs and certification at the point of sale have been sparingly applied.

The only lentivirus for which a vaccine has been used in the field is EIAV. The vaccine is a live attenuated strain developed by researchers in China by repeated passage in donkey cells (166). The vaccine has been extensively used in China and in Cuba. The vaccine has been administered to millions of horses in China with apparent safety and efficacy. Unfortunately, very little is known by the western world about the properties of this live attenuated vaccine, its genetic composition, or details regarding its performance in the field.

RESEARCH ON VACCINE DEVELOPMENT

One important application of research with nonprimate lentiviruses is in the area of vaccine development. Certainly, development of a safe, effective, affordable vaccine for AIDS is one of the greatest challenges of our times. Most experimental studies have used SIV in rhesus monkeys. Use of SHIV in rhesus monkeys is coming into more frequent use because it allows analysis of HIV-1 env-containing vaccine products in a system in which challenge and meaningful viral load and disease readouts are readily possible. Other studies have used FIV and EIAV.

Expectations were raised when inactivated whole SIV was found to provide protection against pathogenic strains of SIV (41,132). Hope was quickly dashed, however, when it was found that protection occurred only when the vaccine and challenge stocks were grown in human cells (30,31). When the vaccine was grown in human cells and the challenge virus was grown in monkey cells, protection was not observed. Xenoantigens present in virus preparations were able to confer protection when challenge virus was grown in the same xenogeneic cells. MHC class II was found to be at least one of the xenoantigens capable of conferring protection (6). Class II antigens are actually present in greater abundance in virus particles than the virus-encoded envelope proteins (5). The mechanisms by which antibodies to class II present on the surface of virus particles can block viral infection have not been defined, but it could be as simple as steric hindrance. Improved methods for purifying, inactivating, and delivering whole particles justify continued investigation of this vaccine approach (159). Whether the abundance of class II antigens on virus particles has significance for pathogenesis remains to be determined.

Vaccine studies in animal models can provide useful information in several different ways. Head-to-head comparisons of different vaccine approaches can shed light on which approaches perform more effectively, at least under the defined conditions of the experiments. In-depth analyses of individual vaccine approaches also may provide fundamental insights into immunologic control and what is needed for protective immunity. With theses goals in mind, vaccine approaches that have been tried in animal models include a variety of envelope subunit approaches; poxvirus recombinants; DNA; inactivated whole particles; adenovirus recombinants; and prime and boost protocols that use combinations of these approaches. Several themes arising from the studies done to date are worth noting.

1. The particular virus that is used for challenge is one of the single most important determinants of whether an individual vaccine challenge study will be successful. Easy-to-neutralize, nonpathogenic strains of virus have proven relatively easy to protect against. Difficult-to-neutralize pathogenic strains of virus, which could be considered representative of field strains of HIV-1, have proven very difficult to protect against. Homologous cloned virus challenge is less stringent than closely matched uncloned virus challenge, which in turn is much less stringent than challenge by virus with natural, representative levels of sequence divergence.
2. Timing of the challenge is crucial. The vaccine approaches discussed earlier induce transient immune responses; they decay dramatically after the peak of vaccine-induced immune responses, which occurs within the first few weeks after the last vaccine boost. Most challenge experiments have been performed 2 to 4 weeks after the last vaccine boost.
3. It is easier to achieve protection against mucosal challenge than against intravenous challenge. Most early studies used intravenous challenge because of the ability to achieve infection reproducibly in control monkeys with

carefully controlled doses of challenge virus. Many current studies are now using vaginal mucosal or rectal mucosal challenge because these routes represent major modes of HIV transmission around the world.

4. Antibody responses to envelope protein and cellular responses to core *gag–pol* antigens can contribute to protection. Which type of immune response can be most responsible for protection varies with the vaccine approach and with the characteristics of the challenge virus. Inclusion of *gag–pol* and *env* in poxvirus–SIV recombinants results in improved protection in a vaccine/challenge format compared with when either *gag–pol* or *env* was used alone (149).
5. When pathogenic, difficult-to-neutralize strains have been used for challenge, protection has proven very difficult to achieve with the vaccine approaches described. Even using challenge virus identical or highly homologous in sequence and challenge 2 to 4 weeks after the last vaccine boost, the levels of solid long-term protection have seldom reached even 50%.

Live attenuated strains of SIV have performed more impressively as vaccines in experimental monkey studies (33). Although serious hurdles face practical development of live attenuated vaccine approaches for AIDS, continued studies hope to identify critical components of a protective immune response and critical variables that may influence whether a protective immune response is attained. In studies to date, it has been learned that a wide range of attenuation can be achieved by variation of the number and location of deletion mutations (40). Some strains, for example SIVmacD4 (missing *vpr, vpx, nef,* and U3 sequences) and SIVDkRXN (missing NFKB, *vpr, vpx,* and *nef*) are very highly attenuated but still persistent. SIVDvif is so highly attenuated that infection is negative by standard criteria. The ability to achieve protection varies inversely with the degree of protection. Thus more highly attenuated strains are safer but less protective as vaccines (93). Protection is also time dependent; the longer one waits, the better the protection. A protective state can take 6 months or longer to become established. An understanding of protective immunity by live attenuated strains will require an explanation of why it takes so long to develop. Even the live attenuated vaccine strain SIVmac239D3 (missing *vpr, nef,* and U3 sequences) provides only minimal protection against heterologous challenge with SIVsmE660, which contains a level of sequence divergence that one would expect to encounter with a field strain of virus (197). Although this difficulty could conceivably be addressed by using mixtures of sequences in the vaccine strain, the results illustrate the severe difficulties in achieving protection against pathogenic, difficult-to-neutralize strains of SIV. It remains to be seen whether alternate means of attenuation or alternate means of using live attenuated strains (for example, priming with very highly attenuated live virus and subsequent boosting by a different means) can result in improved safety/efficacy profiles.

RESEARCH ON THERAPEUTIC REGIMENS

Antiviral drugs useful against HIV-1 in people have been developed with little or no input from animal models of lentiviral infection. This trend will likely continue. However, there is a growing realization that therapy studies in model systems can provide certain types of valuable information. Cytokines, immunoadjuncts, immune stimulants, immune suppressants, or other highly experimental treatments that could possibly be harmful in the setting of a lentiviral infection can be examined for possible benefit in animal models. Faced with several possible lead compounds, some companies have chosen head-to-head comparisons in an animal model to help select the most promising compound to move forward. Comparisons of experimental regimens during primary infection, analysis of ways to boost virus-specific $CD4^+$ T-helper cell responses during therapy, and analysis of ways to minimize maternal–infant transmission are also areas in which ongoing work in animal models may provide useful information to help guide trials of therapeutic regimens in people.

Some of the antiviral drugs useful against HIV-1 have reduced or marginal activity against SIV. Überla et al. (184) have generated an RT-SHIV in which the reverse transcriptase reading frame of SIVmac239 has been replaced by that of HIV-1. This RT-SHIV is replication competent and capable of inducing disease in monkeys.

PMPA (*R*-9-2-phosphonylmethoxypropyl adenine) is one compound with strong antiviral activity against both HIV-1 and SIV that has been used extensively in monkey studies. Tsai et al. (180) were the first to show that treatment of monkeys with PMPA by 24 hours after SIV inoculation and continuing treatment for 4 weeks prevented the establishment of a persistent infection. Delaying the initiation of therapy to 48 or 72 hours or shortening the duration of treatment significantly reduced efficacy (179). Nonetheless, even when the establishment of persistent infection was not prevented, early treatment significantly reduced viral loads and prolonged AIDS-free survival (179,189).

In a more recent study (115), monkeys were started in PMPA therapy 24 hours after inoculation of SIVsm E660 and kept on drug for 28 days, similar to the studies of Tsai et al. (179) and van Rompay et al. (189). Establishment of a detectable, traditional, persistent infection was prevented, confirming the results of Tsai et al. Interestingly, when three such animals off drug for 6 weeks were subsequently challenged intravenously with SIVsm E660, one animal was completely protected, and the other two showed dramatic reductions in viral load (115). What is most startling and difficult to understand is that protection was achieved in these animals in the absence of detectable SIV-specific antibody or CD4-helper responses (CTLs were not measured) at the time of challenge. Continuation of this line of investigation promises important new insights into immune-mediated control outside the bounds of our current level of understanding.

Hematopoietic stem cell gene therapy is an attractive, futuristic approach for the prevention of HIV-induced disease, but it is clear that many developmental hurdles must be cleared. Research with SIV in monkeys is proving useful toward this goal. Transduction of $CD34^+$ hematopoietic progenitor cells with an anti-tat gene protected T-cell and macrophage progeny from SIV infection (157). Infusion of lymphocytes with antisense tat/rev genes into macaques may have reduced SIV replication on subsequent SIV inoculation (45).

PERSPECTIVE

The worldwide crisis brought on by HIV and AIDS has focused attention on the nonhuman lentiviruses as a source for information that will shed light on the human condition. Lentiviral infections of domesticated animals are economically important in their own right and have been studied historically in this context. The lack of a reliable, usable animal model that uses HIV-1 itself and that recapitulates the features of human infection has resulted in extensive study of nonhuman

lentiviruses as analog models in which susceptible hosts are infected with nonhuman lentiviruses either naturally or experimentally. The most critical issues for future progress include better understanding of pathogenesis; improvements in therapy; improved availability of therapy; and, perhaps most important, development of a safe, effective, affordable vaccine. The most remarkable feature of these viruses, and perhaps most critical for the eventual control of HIV, is their ability to replicate continuously and unrelentingly despite apparently strong immune responses. Further advancement of therapeutic regimens and development of effective vaccines against HIV will have to deal with the strategies of immune evasion used by this group of viruses.

CHAPTER 62 Other Human and Primate Retroviruses

Maxine Linial and Robin A. Weiss

The preceding five chapters have dealt in some detail with retrovirus replication, with the important human retroviral pathogens, human T-lymphotropic viruses (HTLV-I and HTLV-II) and human immunodeficiency viruses (HIV-1 and HIV-2), and with nonhuman lentiviruses (nomenclature from 54). In this chapter, other retroviruses in humans and in simian species are described. Of perhaps greatest scientific interest are the foamy viruses, which is a group of complex retroviruses that stand distinct from all other retroviruses in their genome organization and mode of replication. Foamy viruses are found in most species of primates studied, although humans zoonotic infections are rare. Foamy viruses can be highly cytopathic in cell culture, but they have not been definitively associated with disease.

The other retroviruses of primates discussed here belong to the *Betaretrovirus* and *Gammaretrovirus* genera. Figure 1 depicts a phylogenetic tree of selected retroviruses, including those discussed in this chapter. Betaretroviruses are B-type and D-type retroviruses that form core particles in the cytoplasm of the host cell before budding from the plasma membrane (see Chapter 57). Simian retroviruses 1 to 5 are D-type viruses that cause immunodeficiency in macaques. The recently discovered human retrovirus 5 (HRV-5) genome is also a distantly related betaretrovirus, as is a major group of noninfectious human endogenous retroviral genomes known as HERV-K. Gammaretroviruses are C-type retroviruses related to murine leukemia virus (MLV). Primate gammaretroviruses include those that can replicate in human cells, such as the infectiously transmitted gibbon ape leukemia virus (GALV), an endogenous baboon gammaretrovirus (79), and the baboon endogenous virus, which is a recombinant genome with a betaretroviral *env* gene (127). There is concern that nonhuman gammaretroviruses might infect people through xenotransplantation of animal tissues and organs; hence, cross-species infection or zoonosis by retroviruses is briefly discussed.

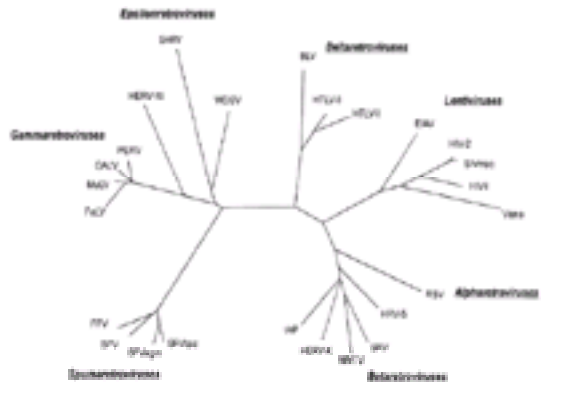

FIG. 1. Phylogenetic relationships of the viruses discussed in this chapter. Alignments were done using the RT domain of Pol. SnRV, snake retrovirus; WDSV, walleye dermal sarcoma virus; BLV, bovine leukemia virus; EIAV, equine infectious anemia virus; RSV, Rous sarcoma virus; IAP, intracisternal A type particles; FeLV, feline leukemia virus; other viruses described in text. (Compilation by D. Griffiths, University College London.)

FOAMY VIRUSES

Description and Prevalence

Despite having been isolated almost 30 years ago, only since the 1990s has there been a large number of reports about foamy virus molecular biology and biology. It was widely assumed for many years that the replication pathway of these complex retroviruses would be very similar to those of the well-characterized gammaretroviruses and lentiviruses. Recent work has, however, belied this idea. The foamy viruses are in the most divergent branch of the retroviral family (the genus *Spumavirus*), and many of the well-accepted paradigms of retroviral replication do not apply to them. In some aspects of their life cycle, the foamy viruses are more similar to the hepadnaviruses, such as human hepatitis B virus (HBV), than to retroviruses.

The highly vacuolating, foamy-appearing cytoplasm of some infected cells and the presence of multinucleated syncytia have given rise to the name of the genus. It is thus surprising that a distinguishing feature of the foamy virus group is a lack of documented pathology in either naturally or accidentally infected hosts. Foamy viruses have been found to be widespread among domestic and feral cats, cattle, and horses and are in most, if not all, primate species other than humans (reviewed in 52). There are also reports of foamy virus detection in sheep, hamsters, and sea lions, but viral isolates from these species are not available for further study. Individual humans have been shown to have acquired foamy viruses as zoonotic infections. Although there is no evidence for viral spread between humans, it is possible that foamy virus may become more prevalent in human populations in the future, especially in populations that have close contact with subhuman primates.

Foamy viruses have been isolated from a number of species. Most research has concentrated on the primate foamy virus, which is the focus of this chapter. The available viral isolates are listed in Table 1. The names given to the primate viruses have resulted in some confusion, especially because cross-species infections occur readily, and similar viruses have been recovered from more than one primate species (115). Additionally, in some cases, the same viruses have been given different names. The phylogenetic relationship of foamy virus to the other retroviral genera is shown in Figure 1. A great deal of work has gone into comparing the genomes of the primate foamy viruses. These viruses appear to have coevolved along with their primate hosts (17). Figure 2 gives the evolutionary relationship among the primate foamy viruses, showing that the sequence similarity among the viruses mirrors that of the host species.

Species	Virus isolates (other designations)	Reference
Feline	FFV (FeFV)	102
Bovine	BFV (BSV)	78
Equine	EFV	125a
Rhesus macaque (*Macaca mulatta*)	SFVmac (SFV-1, SFV-2)	57
African green monkey (*Cercopithecus* species)	SFVagm (SFV-3)	120
Squirrel monkey (*Saimiri sciureus*)	SFVsqu (SFV-4)	58
Galago (*Galago crassicaudatus panganiensis*)	SFVgal (SFV-5)	58
Chimpanzee (*Pan troglodytes* species)	SFVcpz (SFV-6, SFV-7)	103
Spider monkey (*Ateles* species)	SFVspm (SFV-8)	53
Capuchin (*Cebus* species)	SFVcap (SFV-9)	52
Baboon (*Papio cynocephalus*)	SFVbab (SFV-10)	101
Orangutan (*Pongo pygmaeus*)	SFVora (SFV-11)	83
Gorilla (*Gorilla gorilla* species)	SFVgor (SFVgg)	10
Marmoset (*Callithrix jacchus*)	SFVmar	80
Human	SFVcpz(hu) (HFV, HFVhu, CFVhu)	1

Note: The table lists only those foamy viruses whose existence is well documented. In some cases, several different viral types have been given the same isolate number. Infectious clones exist for SFV, FFV, SFV-1, and SFVcpz(hu), which is the prototype for the group and is generally referred to as HFV in the literature. The designations that can be found in the literature are given in parentheses.

TABLE 1. *Foamy virus isolates*

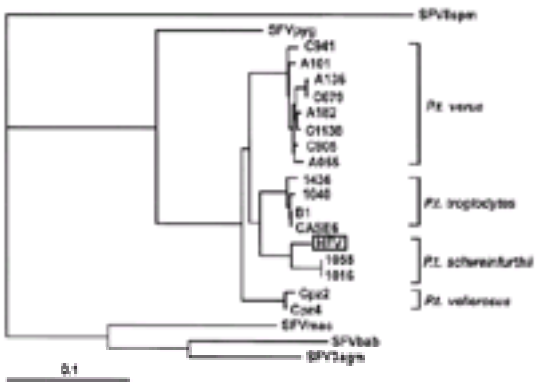

FIG. 2. Phylogenetic relationships of primate foamy viruses. The neighbor-joining method was used to compare integrase sequences from simian foamy virus (SFV), the foamy virus called human foamy virus (HFV) isolated by Achong and associates (1) boxed, and a foamy virus from a human (case 6) infected with a chimpanzee-like SFV. SFV sequences were obtained from chimpanzee subspecies *Pan troglodytes verus* (C941, C679, C1138, A055, A101, A136, A182); *Pan troglodytes troglodytes* (C905, 1040, 1436, B1); *Pan troglodytes schweinfurthii* (1016, 1058); *Pan troglodytes vellerosus* (SFVcpz2, SFVcpz4). SFVpyg, sequence obtained from a pygmy chimpanzee (*Pan paniscus*); other SFVs are described in Table 1. The scale bar represents an evolutionary distance of 0.10 nucleotides per site. (Adapted from ref. 47, with permission).

Origin and Prevalence of Human Foamy Virus

The first description of what was presumably a simian foamy virus in cultures of monkey kidney cells was reported in 1954 (23). However, a primate foamy virus was not isolated until 1971. A virus, with what has proved to be the characteristic foamy virus morphology, was isolated from lymphoblastoid cells released into the supernatant from a human nasopharyngeal carcinoma tissue culture obtained from a Kenyan patient (1). This virus is called human foamy virus (HFV), and is the *Spumavirus*-type species. This so-called HFV was the first foamy virus to be molecularly cloned and sequenced, with an infectious DNA clone derived (31,66,82,100). Later, when a foamy virus was isolated from chimpanzees, it became apparent that the chimpanzee simian foamy virus (SFVcpz) is highly homologous to the laboratory strain of HFV (48). More recently, sequence comparisons of the integrase gene between the HFV isolate of Achong and associates (1), and those of SFVcpz obtained from the four chimpanzee subspecies shows that HFV is most closely related to the foamy virus from *Pantroglodytes schweinfurthii*, which is the species present in Kenya (47) (see Fig. 2). It is therefore possible that the donor from whom the cell culture was derived had acquired foamy virus as a zoonotic infection through chimpanzee contact.

Many papers have been published since the isolation of HFV that purport to demonstrate prevalence of HFV in human populations and to link HFV to different human autoimmune diseases. However, the published data are for the most part based either on a single serologic assay or on polymerase chain reaction (PCR) analysis, rather than both techniques. More recently, two groups have analyzed serum samples taken from large numbers of healthy and diseased individuals for HFV antibodies, including many samples from human populations previously suggested to harbor HFV. In these more recent studies, all samples that were initially positive in one serologic assay were retested with at least one additional assay, or by PCR if DNA was available. Screening of more than 8,000 serum samples revealed no positive cases. Only individuals who acquired foamy virus through zoonotic infection, generally by severe monkey bites, were shown to be infected (3,117). These two studies convincingly demonstrated that HFV is currently not prevalent in the human population. For the purpose of this review, the primate foamy viruses are collectively referred to as PFV. It should be noted that most work has been done with HFV, more correctly called SFVcpz(hu).

Virion Structure

Foamy viruses have a morphology that is distinct from that of the other retroviruses; most noticeably, foamy virus particles have an immature-appearing core and highly prominent surface spikes, composed of the envelope glycoproteins. Virions are seen to bud from both the cell membrane and the endoplasmic reticulum (ER) membrane, where they acquire glycoproteins (Fig. 3A and Fig. 3B). A highly schematized drawing of a foamy virus particle is shown in Figure 4. Very recent structural studies have revealed details of the foamy virus Env protein structure on the surface of released PFV and feline foamy virus (FFV) particles. Electron microscopy of negatively stained particles shows that FV Env proteins are arranged in trimeric complexes, a structural organization considered to be a common feature of retroviral Env surface proteins (see Fig. 3C). The XFV Env trimers are arranged in regular hexameric ringlike strictures, in which two Env glycoprotein trimers are fully integrated into adjacent rings (137).

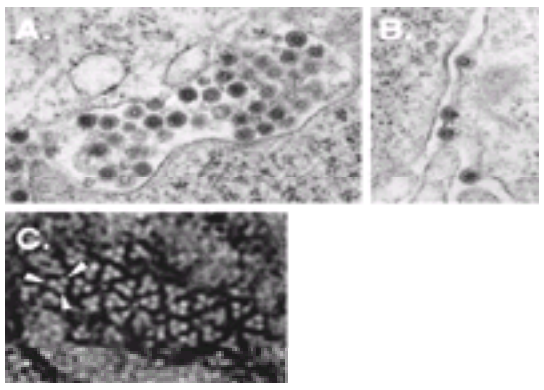

FIG. 3. Electron micrographs of SFVcpz(hu) replicating in human diploid embryonic lung fibroblasts, using negative staining. **A:** Virus budding through the endoplasmic reticulum (ER) membrane. Enveloped particles are seen within the ER. **B:** Virus budding through the plasma membrane. **C:** Electron micrograph of negative-stained SFVcpz(hu). The particles often show a network of trimeric viral spike proteins on the particle surface (*arrowheads*). The 14-nm long glycoprotein complex is predominantly arranged into rings of six subunits. Adjacent hexameric rings always share two completely integrated subunits. (Adapted from ref. 142, with permission.)

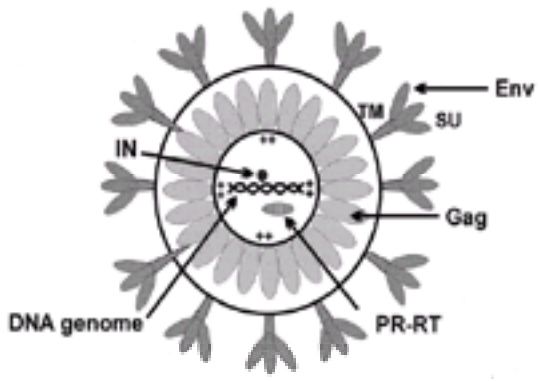

FIG. 4. The foamy virus virion. This highly schematic figure shows the relative locations of the structures and proteins. It does not accurately depict the viral organization. Plus signs (++) indicate the positively charged residues at the carboxyl terminus of Gag in the GR boxes thought to interact with nucleic acid.

As discussed later, efficient cleavage of the Gag precursor protein to the usual retroviral matrix (MA), capsid (CA), and nucleocapsid (NC) proteins does not occur in extracellular, infectious virions. Thus, FV particles appear similar to those of immature gammaretroviruses such as MLV, which are unable to undergo maturation by virtue of mutations in the protease protein. It is likely that the Gag protein is arranged as is the core protein of hepadnaviruses (see Chapter 86), with the amino terminus toward the outside surface of the particle and with the carboxyl terminus, containing positive charged amino acids that are part of the nucleic acid binding domain (143), to the inside of the particle in contact with the genome. However, little is known about other functional domains of FV Gag.

Most extracellular SFVcpz(hu) particles contain RNA; however, a surprisingly large fraction (about 20%) contain apparently full-length double-stranded DNA copies of the RNA (146). Several studies with the reverse transcriptase (RT)

inhibitor 3'-azido-3'-deoxythymidine (AZT) strongly suggest that the infectious genome of SFVcpz(hu) is DNA. In these experiments (88,146), it was shown that treatment of cells with AZT before infection has very little effect on viral infectivity. In contrast, treatment of cells after infection greatly decreased the infectivity of the extracellular particles when assayed on untreated cells, without affecting the amount of virus released. Although the data for SFVcpz(hu) isolate are convincing, similar experiments have not been done using other members of the genus. Additionally, details of the structure of the foamy virus DNA genome have not been reported. Thus, the foamy viruses should be only provisionally considered retroviruses with DNA genomes.

Genome Organization

The general organization of the foamy virus genome is similar to that of the other complex retroviruses, which encode nonstructural proteins as well as Gag, Pol, and Env. The size of the proviral genome is at the upper end of retroviral genomes, about 11.6 kb. As shown in Figure 5A, which diagrams the genome of PFV, the provirus has the requisite retroviral long terminal repeats (LTRs) and a primer binding site, which is complementary to tRNA $_{lys1,2}$. The genome encodes the three characteristic retroviral genes, *gag, pol* and *env,* although as detailed later, the modes of expression and roles of these gene products in viral replication are somewhat unexpected. In addition, there are at least two nonstructural proteins encoded by the primate foamy virus, Tas (previously called Bel-1 for PFV) and Bet. Bet is encoded from both the *tas* and *bel2* open reading frames (ORF). There is no strong evidence for a protein encoded only within the *bel2* ORF, and the *bel3* ORF is not conserved in other primate foamy viruses. The same genomic organization has been found for BFV and FFV, which have also been fully sequenced. These lack the *bel3* ORF. Although the simian, bovine, and feline viruses all encode a Bet protein from the *tas* and *bel2* ORFs, sequence conservation at the amino acid level is low. Thus, although its function may be conserved, it can be provided by highly divergent proteins.

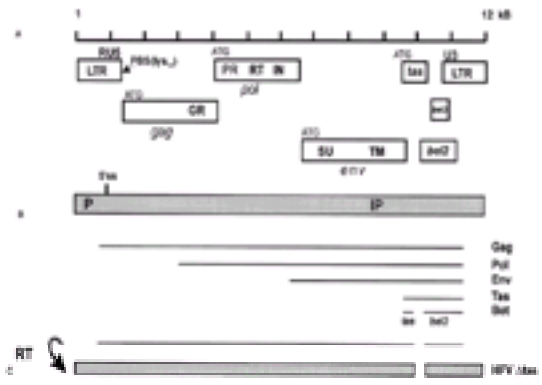

FIG. 5. Foamy virus genome and RNAs. **A:** Organization of the viral genome and coding region of SFVcpz(hu). Open reading frames (ORFs) are shown relative to the proviral structure. Sites of translational initiation are indicated by an ATG initiator codon. ORF names are italicized. *Gag GR* indicates the glycine-arginine boxes, which are the only defined feature of this protein. **B:** Location of the long terminal repeat (LTR) promoter (*P*) and the internal promoter (*IP*) in the provirus. The mRNAs for the five known gene products are indicated below. **C:** Structure of the RNA initiating at the long terminal repeat (LTR) promoter but containing the *tas/bel2* splice, which is thought to lead to the human foamy virus (HFV) D *Tas* genome by reverse transcription. (Adapted from ref. 72, with permission.)

A unique characteristic of the foamy viruses is the presence of a second transcriptional promoter in addition to the normal promoter in the U3 region of the LTR (65). This internal promoter (IP) is in the coding region for the Env protein (see Fig. 5B) and appears to be used for synthesis of the nonstructural protein transcripts, encoding Tas and Bet (64). Bet is synthesized from a transcript in which a portion of *tas* encoding 88 amino acids is fused to the *bel2* ORF. Both the LTR promoter and the IP require the transactivator protein Tas for transcription. As discussed later, these promoters play different roles in viral replication. Additional details about regulation of viral gene expression can be found in recent reviews (72,99).

Another surprising finding about foamy virus gene expression is the method of synthesis of the Pol protein. All viruses in the six other retroviral genera encode Gag-Pol fusion proteins by use of either a suppressor tRNA or ribosomal frame shifting (see Chapter 57). In contrast, the foamy viruses encode Pol from a unique spliced mRNA, using a splice acceptor site at the 3' end of the *gag* ORF (142) (see Fig. 5B). Thus, foamy virus Pol is assembled into virions in a manner different from that of the retroviruses, wherein Pol is assembled by means of the Gag assembly domains in the Gag-Pol polyprotein. The hepadnaviruses also assemble their reverse transcriptase (P) protein into particles independently of the structural proteins (described in detail in Chapter 86). Hepadnaviral P protein binds in *cis* to its own mRNA (which is equivalent to genomic RNA), to initiate the assembly process in conjunction with core protein. Because foamy virus Pol is synthesized from a subgenomic mRNA, a hepadnavirus-like mechanism for Pol assembly can be excluded. Like other retroviruses, the foamy virus Gag protein is encoded from genomic length RNA, and Env protein is encoded from a spliced mRNA. A secreted Env-Bet fusion protein has also been reported in some tissue culture cells, synthesized from an alternatively spliced RNA, which removes a portion of Env (37,71). The function, if any, of this gene product is unknown.

Virion-Associated Proteins

Each of the three virion-associated gene products, Gag, Pol, and Env, has features unique to the foamy virus. Both Gag and Env have features that are shared with human HBV and the other hepadnaviruses. The organization of the viral proteins is shown in Figure 6.

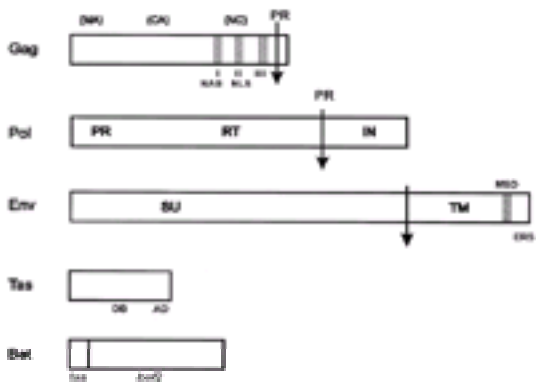

FIG. 6. Viral proteins encoded by SFVcpz(hu). The *arrows* show the most efficient protease cleavage sites. The location of the MA, CA, and NC protein domains in other retroviruses are shown in *parentheses.* The three Gag GR boxes are indicated by *shaded boxes.* The membrane spanning domain (MSD) in *Env* is indicated by a *shaded box*. For *Tas,* the DNA binding domain (*DB*) and activation domain (*AD*) are indicated. NAB, nucleic acid binding; NLS, nuclear localization signal; ERS, endoplasmic reticulum retrieval signal. (Adapted from ref. 72, with permission.)

The foamy virus Gag protein has a calculated molecular weight of 70.6 kd, although this protein migrates on polyacrylamide gels with an apparent molecular weight of 74 to 78 kd. It is phosphorylated on serine residues (24). Unlike other retroviral Gag proteins, it is not efficiently cleaved into matrix, capsid, and nucleocapsid domains in infectious virions. Only one Gag proteolytic cleavage occurs efficiently, in which about 3 kd is removed from the carboxyl terminus. This cleavage occurs about half the time, such that particles contain equal amounts of two large Gag proteins. Gag cleavage is required for production of infectious virus (24). Inefficient processing of the large Gag proteins into smaller components is also seen in infected cells. These secondary cleavages may occur as an early step in infection and may be important for uncoating (95). Foamy virus Gag lacks the two hallmarks of retroviral Gag proteins, a major homology region in capsid, and one or two cystidine-histidine motifs in nucleocapsid. Although it is assumed that the amino terminus of foamy virus Gag has matrix-like functions and that the middle of the protein has capsid-like functions, this has not been directly shown. The carboxyl terminus of PFV Gag has three glycine-arginine–rich regions called *GR boxes.* The first of these binds both RNA and DNA (143), and the second contains a nuclear localization signal. Transient nuclear localization of newly synthesized Gag proteins is a distinct feature of infection of fibroblasts by PFV (111). However, the role of nuclear localization in the viral replication pathway is not clear because a mutant virus lacking a nuclear localization signal (NLS) can still replicate (143). Interestingly, FFV Gag lacks an NLS, and the Gag proteins do not localize to the nucleus (15).

The foamy virus Pol precursor protein, of about 127 kd, encodes the same four enzymatic domains as other retroviruses: protease (PR), RT, RNAase H (RH), and integrase (IN). Unlike, other retroviral Pol proteins, however, cleavage of the protein to PR, RT/RH, and IN moieties does not occur. Instead, only IN is cleaved from the Pol precursor, leaving a PR-RT/RH protein (see Fig. 6), which is a multifunctional enzyme. Active protease is required for viral replication (63). The catalytic domain of the foamy virus RT is not YMDD as in most retroviruses, but YVDD, the same residues as in MLV. Although PFV RT is sensitive to AZT (88,146), it is resistant to most other RT inhibitors developed for HIV (M. Linial and associates, unpublished observations). The IN protein contains the conserved DD35E motif, which is required for integrase function in all retroviruses; mutation of this motif prevents foamy virus replication (25,85). Integrated proviruses contain a 4-nucleotide cellular repeat at each junction (89).

The foamy virus Env precursor protein of about 130 kd is cleaved by a cellular protease into the surface (SU) and transmembrane (TM) moieties, as in other retroviruses. However, there are features unique to the foamy virus *env* gene. Most prominently, extracellular virions are not produced unless Env is present (6,30), reminiscent of hepadnaviruses, rather than retroviruses. The domains in Gag and Env required for budding have not as yet been identified. Foamy virus particles formed by Gag-Gag interactions assemble intracellularly, predominantly in the cytoplasm, probably in a manner similar to that of the betaretroviruses (see Chapter 57). Budding occurs predominantly through intracellular membranes, probably those of the ER, although some particles can be seen budding from the plasma membrane. The foamy virus Env protein contains a dilysine motif at the carboxyl end of the TM protein adjacent to the membrane-spanning domain (see Fig. 6), which has been shown to be a classic ER retrieval signal (39), similar to that of the hepadnaviruses surface protein. The cognate foamy virus envelope glycoproteins are required for foamy virus assembly, release, and infectivity. Unlike with other retroviruses, foamy virus cannot be pseudotyped with other retroviral glycoproteins or the vesicular stomatitis virus G glycoprotein (96). However, MLV can be pseudotyped with a chimeric protein containing the extracellular and transmembrane domains of PFV and the cytoplasmic domain of MLV (70). It is likely that preformed foamy virus capsids must interact with the viral glycoproteins at the ER, or with other cellular membranes, in order for egress from the cell. Mutation of the ER retrieval signal leads to more frequent budding from the plasma membrane but neither increases the amount of extracellular viruses nor decreases the infectivity of the viral particles (38). In general, budding is a highly inefficient process in tissue culture cells; most particles are cell associated rather than released into culture supernatants. Only 1% to 10% of the infectious particles are released from cells, and in order to prepare high-titer stocks of virus, it is necessary to combine free-thawed cell lysates to culture supernatants.

Nonstructural Proteins

Tas is a potent transcriptional transactivator protein with no known nonfoamy virus homologs. It contains a central domain that interacts with DNA, and a carboxyl-terminal activation domain (44). Unlike the transactivator proteins of other complex retroviruses, such as HIV and HTLV, Tas is a sequence-specific DNA-binding protein, which probably requires interaction with cellular DNA binding proteins (43). Tas-binding sites of about 25 nucleotides in length have been mapped to both the LTR and IPs. Interestingly, the binding sites have different primary sequences, and the IP-binding site has a higher affinity for Tas (59). It is likely that early in infection, the IP synthesizes the Tas and Bet transcripts, and after sufficient levels of Tas accumulate, the LTR promoter is used to synthesize Gag, Pol, and Env mRNAs. Such temporal

regulation of transcription is a property more commonly seen in DNA viruses than in RNA viruses and has not been found in any other retrovirus group.

The role of the Bet protein in viral replication is poorly understood. It is not a posttranscriptional transactivator analogous to HIV Rev or HTLV Rex (69). Virus lacking Bet protein can infect tissue culture cells and replicate fairly efficiently (8,69,144). However, conservation of the *bet* ORF from a *tas-bel2*–spliced mRNA in all the diverse foamy viruses suggests that Bet has an important function, perhaps manifested only *in vivo.* There is a suggestion that, at least in fibroblast cultures in which Bet has been overexpressed, Bet can block viral superinfection at an early step (14). Because Bet protein can be taken up by uninfected cells (37), it is possible that Bet could have a physiologic role in modulating infection. It is also interesting that infected cells rapidly accumulate DNA molecules lacking the portion of Tas removed by the Bet splice. This D Tas DNA appears to arise by reverse transcription of a RNA, initiating at the LTR promoter but using the *tas/bel2* splice sites (107) (see Fig. 5**C**). Tas DNA has been proposed to play an important role in establishment of persistent infections by behaving as a defective interfering genome (106). It is not clear that such defective proviruses play a role in *in vivo* infections (27). The *bel3* ORF of PFV has been proposed to encode a superantigen (134), and although there is a report of a *bel3*-encoded protein of 19 kd (135), this report has not been confirmed. Furthermore, this ORF is not conserved in other foamy virus isolates.

Host Range *in Vitro*

The foamy viruses have a broad host range, best characterized for PFV. This virus infects cells derived from all vertebrate species tested, including primates, hamster, mouse, quail, dolphin, and iguana (49). Thus far, no resistant cells have been identified. Infection of primary cells or cell lines often leads to a lytic infection. Productively infected cells, such as human fibroblast cultures, form large multicellular syncytia and are killed within several days. However, little infectious virus leaves the cell, and at least in tissue culture cells, most infectivity is cell associated. A second response to viral infection is seen with some cell lines in which viral infection is not cytopathic but persistent. Cells continue to grow with normal kinetics and continually produce virus, at titers 100-fold or less than the productively infected cells. No syncytium formation of cell death is seen in persistently infected cultures. Again, most of the virus is cell associated. In general, infection of new cells is more easily achieved by cell–cell contact than by free virus (145).

Foamy viruses have been long known to infect a wide variety of cell types, including those of the fibroblastoid, epitheliod, and lymphocytic lineages. PFV can persistently infect a variety of human hematopoietic cell lines, including those of erythroid, T-cell, and myeloid lineages (145). This virus also been shown to infect primary human CD4+ T cells, monocyte-derived macrophages, and microglial cells, whereas CD8+ T cells were less susceptible. Both the CD4+ cells and the microglial cells were rapidly killed by viral infection (87). The observed lack of infection of CD8+ cells is surprising because other work indicates that this lineage is infected in naturally infected primates (131). In addition, it is difficult, if not impossible, to establish T-cell lines from animals that are naturally infected with SFV (29).

Viral Life Cycle

The foamy virus life cycle, based primarily on *in vitro* experiments with SFVcpz(hu), is depicted in Figure 7. Stages of the life cycle that are tentative are marked with a question mark. Virions infect cells through an as yet unidentified receptor(s). It is not clear whether both RNA- and DNA-containing particles can infect cells. Currently, the strength of the evidence suggests that particles with reverse transcription either completed, or ostensibly completed, are the infectious agents (88,146). After adsorption to the cell, the virions are presumably uncoated. During this process, there may be further processing of the large Gag proteins to smaller products (36,95), although the necessity for this, or the function of any of the resultant Gag domains, is not known. Viral DNA is next transported to the nucleus. It is possible that the virion-associated DNA is incomplete and requires some repair using RT, several enzymes, or both. Viral DNA is then integrated into the genome through the action of IN, and provirus serves as a template for transcription and translation using host factors. Viral gene transcription requires synthesis of the Tas protein, which is encoded by the IP. There appears to be temporal regulation of transcription with synthesis of the “early” mRNAs encoding Tas and Bet, preceding that of the “late” RNAs for the virion-associated proteins. Virion assembly is poorly understood, and most takes place in the cytoplasm, although some assembly at intracellular membranes cannot be excluded. Nothing is known about the domains in Gag required for capsid formation. Preformed capsids are transported to intracellular membranes, presumably the ER, where glycoproteins are added. Some glycoprotein addition also occurs at the plasma membrane. Particle egress appears to occur through both the ER and plasma membrane.

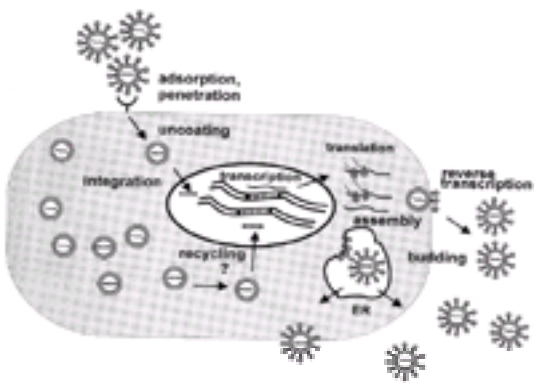

FIG. 7. Foamy virus (FV) life cycle. Viral RNA is indicated by a *wavy line,* viral DNA by a *striped box.* The speculative intracellular recycling pathway is indicated by a *question mark.* Reverse transcription is believed to be a late event for SFVcpz(hu) but has not been shown for other FVs. For SFVcpz(hu), the infectious virion is shown as containing DNA. (Adapted from ref. 72, with permission.)

Foamy virus reverse transcription proceeds presumably using the normal retroviral mechanism (see Chapter 57). Negative-stranded synthesis uses a tRNA primer (in the case of PFV, it is $tRNA_{lys1,2}$). Reverse transcription culminates in production of a cDNA bordered by two LTRs. Reverse transcription appears to occur during viral assembly or shortly thereafter, leading to about 20% of extracellular particles containing DNA (146). The rest of the particles contain RNA, but it is not known how many particles contain dimeric full-length RNA molecules. The RNA in virions is unlikely to be capable of initiating a new round of infection because infectious viral synthesis is sensitive to AZT at a late stage in the life cycle, rather than an early stage (88,146). The temporal regulation of RT/RH activity has not been studied. Perhaps the synthesis of Pol as a free protein instead of a Gag-Pol fusion protein allows RT activity to occur earlier during assembly than with the other retroviruses.

The role of the large numbers of intracellular particles is not known. There is a large reservoir of such particles in persistently infected tissue culture cells. Early in the HBV life cycle, viral nucleocapsids lacking glycoproteins transit back into the nucleus where reverse transcription is completed to produce additional copies of viral covalently closed circular DNA, which is the stable form of the viral genome, akin to the retroviral provirus. It is possible that DNA in these intracellular particles is a source of additional proviruses by a process analogous to this intracellular recycling seen with HBV and other hepadnaviruses. It is attractive to speculate that the NLS in the Gag protein could be involved in such a process. Alternatively, persistently infected cells could provide a reservoir of infected viruses that are budded slowly from cells, or intracellular virus could spread by cell–cell contact.

Overall, the foamy virus life cycle is similar to that of other retroviruses. Notably, reverse transcription is identical to that described for the other six genera of the *Retroviridae* family, and obligate integration (25) is accomplished using an integrase protein with similar features to those of other retroviruses (90). The genomic structure is similar to that of other retroviruses, including the presence of LTRs in proviruses and *gag, pol,* and *env* genes. The LTRs of primary foamy virus isolates range in size from 1.3 to 1.6 kb. However, many of the details of the replication cycle place the foamy virus closer to other RT-encoding viruses (pararetroviruses) with DNA genomes, such as the *Hepadnaviridae* and the less well understood plant *Caulimoviridae* (51), which do not integrate as part of their life cycles.

Viral Transmission and Replication *in Vivo*

Foamy virus infections are extremely widespread in all subhuman primates, including great apes, as well as in cows and cats. Long-term persistent infections ensue, and virus can often be recovered decades after the initial infection. There is no evidence that foamy virus is ever cleared by the host immune system. On the other hand, finding viral expression *in vivo* is extremely difficult, and viral isolation invariably requires cocultivation with highly susceptible cells. Thus, the hallmark of foamy virus infection is a long-term inapparent infection, with a small number of cells that are productively infected and capable of producing new particles.

Although humans are not natural hosts for foamy virus infection, a number of individuals have been identified who have both antibody to a specific SFV and virus that can be recovered by co-cultivation. In each case, transmission can be traced to a severe injury sustained from interaction with primates. In one case, it was shown that an individual was infected with the HFV laboratory strain, perhaps through a laboratory accident (117). In one case of zoonotic transmission, virus highly related to SFVagm was isolated from an animal caretaker who had been bitten repeatedly by African green monkeys, once resulting in a deep injury requiring surgery. Virus could be recovered from primary blood lymphocytes, but not from saliva, from this individual 20 years after transmission; both his wife and daughter were found to be seronegative (114). In recent studies, the results of a screen of individuals with occupational exposures to nonhuman primates were reported (46,47). Of 235 individuals studied, six (about 2.5%) were identified to be infected with various simian foamy viruses. SFVagm, SFVcpz, and SFVbab were all found to be transmitted. All 6 cases were Western blot and PCR positive. Virus could be recovered by co-cultivation of primary blood lymphocytes with canine thymocytes or *Mus dunni* cells from three individuals. No male-to-female sexual transmission of SFV was observed in five spouses who were available for testing (46). In the same study, only one case of simian immunodeficiency virus (SIV) transmission and none of simian T-lymphotropic virus (STLV) transmission was found. SFVbab was also found in humans who had received baboon liver transplants. In a retrospective analysis of tissues from two acquired immunodeficiency patients (AIDS) patients with end-stage hepatic disease who received baboon livers, it was found that baboon cells harboring SFV migrated from the xenografts to peripheral tissues such as lymph node and kidney. In this study, infectious virus could not be isolated (4). This work highlights a potential danger of xenotransplantation using primate tissue (see Cross-Species Retrovirus Infection). It is interesting to note that foamy viruses appear extraordinarily genetically stable compared with the lentiviruses, alpharetroviruses, or gammaretroviruses. For example, comparison of the SFVcpz sequences found in one case where both the recipient and the source chimpanzee were available for samples showed no difference in IN or Gag after at least 15 years of documented infection (47). LTR, IP, ORF-1 (*tas*), and ORF-2 (*bel2/bet*) sequences (see Fig. 5) from one SFVagm-infected person were also compared with those in prototype SFV-3agm. Sequence conservation was seen in all these regions except for ORF-2, which contained premature stop codons (18) that would lead to truncated Bet proteins.

Natural transmission of foamy viruses has been studied in both primates and nonprimate species. In one study, transmission of BFV (previously called bovine syncytial virus, or BSV), which is endemic in domestic cattle, was analyzed. It was found that newborn calves show passive immunity to BFV from ingestion of colostrum but become negative for BFV antibodies by 3 to 5 months of age. No maternal transmission of virus was detected, and even experimental infection of dams with BFV at 5 to 7 months of gestation did not lead to infection of offspring. However, when antibody-negative calves were co-housed with infected adults, by 2 years of age, about 35% of the animals became seropositive within 10 weeks of introduction into the herd, and 85% became seropositive by 2 to 3 years (56). These studies suggest that BFV is transmitted through licking or biting. Similar results were obtained more recently looking at transmission of SFV in baboons. Virtually all adult baboons in a large primate center colony were found to be infected with SFVbab (17). Maternal antibody appears to be protective; most infants have antibodies to SFV, but few have viral sequences. Maternal antibody disappears at about 9 months. Thirteen of 35 young animals from 1.4 to 2.6 years of age were found to be infected with SFV. In contrast, few animals in this age group are infected with sexually transmitted retroviruses. Additionally, SFV antibodies can be detected in juvenile animals, before sexual maturity. These

studies strongly suggest that transmission is not sexual but rather occurs through biting or licking (J. Allan, personal communication).

An important question is how foamy viruses maintain a long-term persistent infection without any disease manifestations, in the presence of neutralizing antibodies (52). Maintenance of persistent infections does not appear to require generation of variant viruses that can escape immune surveillance. Work with SFVagm shows that there is little genetic diversity in the SU portion of Env between isolates from different monkeys or a human animal handler who acquired SFVagm from a monkey bite, although SFVagm isolates could be grouped into four strains. Almost no variation was seen in viruses obtained from a single animal over 13 years (116). In fact, it was found that nonsynonomous mutations were selected against, rather than for, as in the case of lentiviruses. These authors conclude that the absence of viral variation is most likely caused by a low rate of viral replication (116). This conclusion is consistent with results of several studies addressing detection of virus *in vivo,* in both naturally and experimentally infected hosts. One general conclusion is that it is very difficult to detect viral RNA or viral replication *in vivo* using sensitive techniques such as RT-PCR. One possible reason for low viral replication is that replication is suppressed *in vivo* by interferon-g (28). In a recent study of four African green monkeys that had been naturally infected with SFVagm for more than 18 years, viral DNA was easily detected in all organs, including brain, lymph nodes, kidney, and lungs. It was difficult, however, to detect viral RNA, which was found only in the oral mucosa of one of the monkeys (27). This location is consistent with the presence of virus in saliva and the mode of transmission. Whether there are other sites of viral replication, especially earlier in infection, remains to be seen. In another study, lymphocytes, and in particular CD8+ T cells, were shown to be the major reservoir for foamy virus DNA in the peripheral blood, but viral gene expression was not detected (131). Because cell-associated viral particles contain DNA, it is not possible to know whether any of the organs contain integrated proviruses. Also, because at least *in vitro,* infected cells can contain hundreds to thousands of copies of viral DNA, the number of infected cells is hard to determine. Clearly, more studies are required to understand which cells harbor integrated foamy virus proviruses in infected animals and which serve as the major viral reservoir.

Foamy Virus Vectors

The characteristics of foamy virus discussed in this chapter, such as lack of pathogenicity, broad host range, and large genome size, make them attractive agents for development of viral vectors for gene therapy. Recent work that shows that FV DNA can be found in all organs of infected monkeys, including brain (27), provide additional impetus to explore the utility of these agents as vectors. Unfortunately, it is not yet known which cells in brain actually contain foamy virus DNA, and such studies are important for vector development. Unlike lentiviruses, such as human immunodeficiency virus (HIV), foamy viruses cannot replicate with high efficiency in fibroblastoid cells that have been arrested at the G_1/S or G_2 phase of the cell cycle (11). It has been found that foamy virus DNA can enter the nucleus of G_1- or S-phase arrested cells, but no viral replication is observed (108). However, there is evidence that vectors based on SFVcpz(hu) can transfer markers such as alkaline phosphatase to progenitor CD34+ hematopoietic cells more efficiently than MLV-based vectors (50). Thus, integration and expression of the vectors is occurring, and it is possible that foamy virus–based vectors could prove useful for transduction of pluripotent hematopoietic stem cells.

Foamy viruses provide the option of creating replication competent vectors that work with high efficiency in tissue culture cells. Because the *bet* gene is not required for *in vitro* replication, cloning of markers into this region allows introduction of easily selected or assayed marker genes into cells with high efficiency. Such vectors allow infection of all the cells in the culture (112). This could be useful for stable expression of marker genes in cell types that are not killed by foamy virus infection. Vectors that bypass the need for the viral transactivator protein Tas can be made by substitution of the 5' LTR with a strong constitutive promoter (126). Although there are several published vector systems, and a first-generation packaging cell line for SFVmac (140), there is not as yet highly efficient foamy virus packaging cell lines available for foamy virus as there are for MLV and other conventional retroviruses (Chapter 57 includes a detailed discussion of retroviral vectors and packaging cell lines). There have been several reports defining the cis-acting sequences in the foamy virus genome required for transfer of vectors (26,45), but detailed analyses have not yet been done. It is interesting that two regions of the foamy virus genome appear to be required for vector transfer. One is at the 5' end of the viral RNA which does not appear to be involved in RNA packaging (45a). The second is in the *pol* gene and may also be involved in packaging, or perhaps in some posttranscriptional regulation using host factors. Further understanding of the cis-acting elements required for optimal viral replication is important for design of packaging cell lines for nonreplicating vectors.

HUMAN ENDOGENOUS RETROVIRUSES

Most vertebrate species studied contain multiple copies of DNA proviruses integrated in chromosomal DNA, and humans are no exception. Genetic retroelements compose a variety of reverse transcripts, including genuine endogenous retrovirus genomes, human “LINE” elements (retrotransposons lacking LTR sequences but encoding reverse transcriptase), pseudogenes, and “SINE” elements without RT, such as human repetitive *alu* sequences (16). This discussion includes only the HERVs, which are endogenous retroviral sequences representing “fossil” infections and insertion into the germline in the evolutionary past. Primates contain numerous such genomes, including potentially infectious viruses such as baboon endogenous virus, mentioned previously. Many genera of retrovirus have become endogenous in host DNA, although endogenous lentiviruses, spumaviruses, and HTLV-related deltaretroviruses have not been detected; perhaps retroviruses with “complex” genomes containing regulatory and accessory genes do not survive as mendelian elements in host chromosomes.

It is estimated that 0.1% or more of human DNA sequences may be of retroviral origin. With the completion of the human genome sequence, it will become possible to analyze the total distribution, insertion, and expression of HERV elements. Multiple types of HERV exist (Table 2), some as unique copies (e.g., HERV-R) and some as multiple copies (73,74,133). HERVs belong to different retroviral subfamilies and have been classified according to the tRNA thought to associate with the primer binding site; for example, the HERV-K subfamily has tRNA lysine, and the HERV-W subfamily has tRNA tryptophan. HERV genomes proliferated markedly during early Old World primate radiation. Several HERV genera are expressed in the placenta as whole particles (118) or abundant Env protein (86,123), and more selectively in other

human tissues.

Name	Retroviral genus	tRNA primer binding site	Approximate copy number per cell	Reference
HERV-E	Gammaretrovirus	Glutamic acid	50	98
HERV-H (RTVL-H)	?	Histidine	1,000	77
HERV-I	Gammaretrovirus	Isoleucine	10	138
HERV-K	Betaretrovirus	Lysine	100	74
HERV-L	?	Leucine	?	20
HERV-P	Gammaretrovirus	Proline	15	138
HERV-R (ERV-3)	Gammaretrovirus	Arginine	1	128
HERV-W	Gammaretrovirus	Tryptophan	15	12
ERV-9	Gammaretrovirus	Arginine	40	67

Note: Many more HERV genomes that have been partially characterized by *pol* sequences alone are not listed here (138).

TABLE 2. *Human endogenous retroviral genomes*

Ancient proviruses in host DNA tend to be defective, accumulating stop codons and deletions, but some proviruses maintain ORF and functional LTRs. Insertions into new chromosomal sites can be distinguished by comparison with related host species; for example, humans of all ethnic groups possess six HERV-K proviruses not present in chimpanzees (7). HERVs of ancient lineage may maintain an ORF if that retroviral gene has been adopted by its host to perform a function. There is evidence that the HERV Env glycoproteins play a role in the trophoblast development in the human placenta (13,86). HERVs have also been used during primate evolution to modify the expression of cellular genes. An HERV-E insertion 5' to a gene duplication of the pancreatic amylase gene provides a tissue-specific enhancer for salivary gland expression (125), thus allowing humans to enjoy a cereal-rich diet of wheat, corn, or rice. Pleiotrophin expression in the human placenta has been attributed to the insertion of a HERV-E LTR promoter (113), and another placental transcript has a polyadenylation signal provided by a HERV-H LTR (40).

There has been considerable speculation in recent years on the participation of HERV expression in chronic or autoimmune diseases. A HERV-K10 genome was reported to be up-regulated in antigen-presenting cells associated with islets in insulin-dependent diabetes mellitus, and its envelope glycoprotein suggested to have a superantigen effect (19), but these studies could not be confirmed (75). A retroviral genome was detected in multiple sclerosis (94) and designated *multiple sclerosis retrovirus*, but this finding also remains controversial (32). Multiple sclerosis retrovirus is indistinguishable from the newly characterized HERV-W (12,94,130). The most convincing and repeated observation of disease association is of HERV-K sequences in germ cell tumors of the testis, both teratocarcinoma and seminoma (74,109). HERV-K encodes *gag, pol,* and *env* genes and produces both RT activity and retroviral particles. It remains to be determined whether HERV expression plays an etiologic role in the diseases with which HERVs are associated or whether HERV antigens are merely markers of diseased tissues and states (73,121).

Where ORF are maintained in evolution, one might conclude that the HERV element is playing some useful role to the host, but that can be difficult to determine. For example, the evolutionary preservation and high expression of the HERV-3 truncated envelope glycoprotein (128,141) in the syncytiotrophoblast of the human placenta suggested a functional role. However, there is a frequent deletion in HERV-3 in the white population (21). Recently, the HERV-W envelope, which is also highly expressed in the syncytiotrophoblast, was found to be able to induce syncytium formation when transfected into a wide variety of cell types (86) by interacting with the D-type virus receptor (13). This placentally expressed HERV-w *env* gene product may therefore play the role first suggested for HERV-3.

If HERV genomes were highly mobile, one would expect to detect more human genetic diseases caused by insertional disruption of essential genes in the germline, or insertion into somatic cells leading to clonal proliferation and induction of human tumors. However, such events are rare in humans, and where recorded, are more frequently related to retroid LINE or SINE elements rather than HERVs themselves (16). For example, some cases of factor VIII hemophilia in one human lineage are caused by a LINE-1 insertion (61), and Alu insertion into the *NF-1* gene has been correlated with neurofibromatosis (132). Another possible medical concern is the contamination of retroviral vectors to be used in human gene therapy by endogenous retroviral genomes. Although murine packaging cells do incorporate high levels of VL30 murine endogenous retrovirus sequences (110), it is reassuring that human packaging cell lines do not copackage HERV genomes into MLV, and human cells expressing HERV particles do not incorporate and mobilize MLV-based vector genomes (93).

HUMAN RETROVIRUS 5

HRV-5 is a recently identified genome of a retrovirus initially detected by RT-PCR from sucrose gradient concentration of virus-like particles with RT activity (42). However, HRV-5 has not as yet been isolated as replication-competent retrovirus in culture. The HRV-5 genome has not been completely cloned and characterized, but analysis of *gag* and *pol* sequences indicate that it is a betaretrovirus distantly related to SRV-1 to -5 and to murine intracisternal A-particle genomes. Like other betaretroviruses, the protease sequence is in a different reading frame from that of RT and integrase. Southern blot and PCR analysis clearly show that HRV-5 is not endogenous in human DNA. Thus, it appears to represent a novel, infectiously transmitted HRV (42). Its provisional name, HRV-5, denotes that it represents the fifth exogenous HRV, after HTLV-I and -II and HIV-1 and -2.

Although HRV-5 was originally detected in salivary gland biopsies from patients with Sjögren's syndrome, proviral DNA is only rarely detected in such tissue (41). However, a disease association with HRV-5 has become apparent for rheumatoid arthritis (RA) and systemic lupus erythematosus. Some 12% of blood samples from RA patients and 16% of blood samples from lupus patients contain HRV-5 DNA (41). HRV-5 was also detected in about half of synovial biopsies

from arthritic joints, including osteoarthritis and reactive arthritis as well as RA (41). The more frequent detection of HRV-5 by RT-PCR in sucrose gradient fractions of tissue biopsy samples but rarer detection by PCR of proviral DNA indicates that this retrovirus may represent a relatively high prevalence human infection with an exceedingly low viral load in the tissues examined thus far, with less than 1 provirus among 50,000 cells. The higher detection rate in RA and lupus suggests that the virus expression is up-regulated in these conditions, but it would be premature to conclude that it has an etiologic role in disease. Nonetheless, the identification of a novel, presumably infectious retrovirus in humans merits further investigation.

SIMIAN RETROVIRUSES 1 TO 5

The prototype D-type retrovirus is Mason-Pfizer monkey virus (MPMV), also known as SRV-3. SRV strains are associated with a severe, pan-leukopenic immune deficiency in various macaque species (35,104,105). Five serotypes (SRV-1 to -5) are known, of which SRV-1 to -3 have been molecularly cloned and sequenced (104). Although they can be readily distinguished by neutralization in serologic assays, their genomes show 75% sequence similarity. All SRVs use a common cell surface receptor (119), which has recently been identified (97,122). More distantly related D-type retroviruses are endogenous in an Asian leaf monkey (the spectacled langur), in the African yellow baboon, and in the New World squirrel monkey (104,127). These viruses can emerge as infectious retroviruses in culture. The squirrel monkey retrovirus has been detected as a laboratory contaminant of human lymphoblastoid and epithelial cell lines that have a long passage history in various laboratories.

CROSS-SPECIES RETROVIRUS INFECTION

Cross-species infection of retroviruses to new hosts is well known, including potentially infectious endogenous retroviruses with ORFs for all viral genes. The host species harboring the mendelian provirus is often resistant to cell–cell infection and viremia when some host cells become activated to release virions. However, cells of other host species can be experimentally infected, and such retroviruses are called *xenotropic* (16). Sequence analysis of endogenous viruses reveals that some have jumped across broad host phylogenetic taxa. For example, the endogenous viral genome RD114, of the domestic cat, is closely related to baboon endogenous virus but is present only in the tabby species of the genus *Felis* (9). Further, an endogenous genome in the marsupial Koala bear is closely related to GALV (81). GALV itself is possibly a recent cross-species infection from an endogenous virus in Southeast Asian mice such as *Mus caroli.* Certain captive colonies of gibbons are infected with GALV (60), which can cause lymphoid and myeloid leukemia, but its presence in wild gibbons has not been surveyed.

The risk of retroviral zoonosis for human infection is real. HIV-1 probably originated from chimpanzees on at least three separate occasions (33), and it is clear that HIV-2 came from the SIV of sooty mangabey monkeys in West Africa on several occasions (34). Similarly, some strains of HTLV-I closely resemble their simian counterparts in the same geographic area, harbored by baboons and chimpanzees (76,129). As discussed under Foamy Viruses, zoonotic infection also accounts for the few well-documented cases of foamy virus infection in humans by transmission from chimpanzees and monkeys. A replication-competent amphotropic murine gammaretrovirus was derived by recombination from a retroviral vector and caused lymphoma in a macaque recipient of experimental gene therapy (22). Several animal species, such as mice, cats, and pigs, carry endogenous retroviruses capable of infecting human cells in culture. It has been suggested that humans are protected from nonprimate retrovirus infection because human complement (C') inactivates these viruses (136). We now know that C' inactivation is largely mediated through the presence of a_{1-3}-galactose antibodies in human plasma, which bind to a- *gal* xenoantigens on the glycoproteins and glycolipids of enveloped viruses grown in animal cells (124). The mechanism is akin to C'-mediated lysis of ABO-mismatched red blood cells because Old World primates lack the enzyme a_{1-3}-galactosyl transferase and therefore recognize the a- *gal* carbohydrate antigen (e.g., expressed on enteric bacteria) as foreign. It also accounts for hyperacute rejection of xenografts transplanted to primates (5,124). Thus, the generation of transgenic animals expressing human complement-modulating genes (*DAF, CD46,* and *CD59*) could allow enveloped viruses, including retroviruses, which assemble these membrane proteins to transmit more readily to humans in the xenotransplantation setting (133).

There is much debate about the safety of conducting human xenotransplantation. There are several practical, ethical, and safety reasons why simian-to-human xenotransplantation of tissues and organs should not be pursued, including the danger of retrovirus infection (4,5). Pigs are the favored source of tissues, and a number of humans have already been transplanted with fetal porcine brain cells for Parkinson's disease and with pancreatic islet cells for insulin-dependent diabetes mellitus. Extracorporeal perfusion of human circulation through porcine hepatocytes is under trial, and if hyperacute rejection is overcome by using transgenic pigs, kidney and heart xenotransplantation may follow (5,133).

It was therefore timely to demonstrate that porcine endogenous retroviruses (PERV) can infect human cells (92,123,139). Multiple copies of the human tropic PERV strains exist as mendelian proviruses endogenous in all strains of pig examined, and it will not be simple to eliminate them. However, PERVs do not appear to be highly infectious for humans *in vivo,* and there is no evidence of PERV infection in nearly 160 patients after exposure to live porcine cells and tissues (91). It is therefore likely that porcine xenografting to humans will proceed in carefully controlled clinical trials. It is well known that human tumor xenografts in mice can become infected with xenotropic MLV (2). Conversely, graft into host infection by animal retroviruses will need to be closely monitored in human xenotransplantation.

PERSPECTIVES

Less is known about the replication and host interactions of the viruses discussed in this chapter than about the other retroviruses. It has been surprising, given the large numbers of simple replication-competent endogenous retroviruses that have been found in other species, that there have not as yet been any propagated from humans, although some have apparently intact genomes. It is possible that in the future, more cross-species transmission of viruses to humans from primates or other sources may occur, as was the case with HIV. Our current understanding of the role of retroviruses in chronic and autoimmune disease is perfunctory, and this area needs considerable further research and

clarification.

Foamy viral replication has proved to be much more interesting than expected. In some regards, foamy viruses are a link between the *Retroviridae* and *Hepadnaviridae.* There are many open questions about their replication. How is Pol sequestered in particles? What is the role of nuclear localization of Gag? Does an intracellular recycling (retrotransposition) pathway occur? Why is Env required for particle egress from the cell? Does the Bet protein have any role in viral replication? These and other questions should be highly tractable given the ease of work with foamy viruses in tissue culture. An extremely interesting question is why foamy virus are not pathogenic, despite their ability to launch highly cytopathic infections *in vitro.* It appears that they have evolved a lifestyle that permits lifelong maintenance without any gross destruction of tissues, but the role of either viral or cellular factors in this commensal relationship are not known.

CHAPTER 63 *Polyomaviridae:* The Viruses and Their Replication

Charles N. Cole and Suzanne D. Conzen

DISCOVERY AND CLASSIFICATION

The *Polyomaviridae* were previously considered a subfamily of the *Papovaviridae,* a name derived from the names of three prototypical members: rabbit papilloma virus (pa), mouse polyomavirus (po), and simian virus 40 (SV40), originally called vacuolating virus (va). Their genomes are single molecules of covalently closed, superhelical double-stranded DNA that are replicated in the nucleus. Thorough investigations since the 1980s indicate that SV40 and mouse polyomavirus differ from the papillomaviruses in having smaller capsids (diameters of 45 nm versus 55 nm), smaller genomes (about 5,000 base pairs versus about 8,000 base pairs), and a different genomic organization. The *Polyomaviridae* are now considered an independent family of viruses. In this chapter, the term *polyoma* is used to refer to mouse polyomavirus, whereas the family of viruses is referred to as *polyomaviruses.*

Thirteen members of the *Polyomaviridae* family have now been identified. All have capsids that are the same size and are constructed from three viral capsid proteins. All have genomes of about 5,000 base pairs and display a similar genomic organization. Many regions of their genomes are highly conserved, demonstrating that the *Polyomaviridae* are descended from a common ancestor. Different family members infect several species of mammals, including humans, other primates, rodents, rabbits, as well as birds. Table 1 lists the members of the *Polyomaviridae* and their natural hosts. Most of these viruses display a narrow host range and do not productively infect other species. However, infection of cultured cells in which these viruses cannot grow productively often leads to the malignant transformation of these cells. Some of these viruses also induce tumor formation in newborn hamsters.

Virus	Host species
Polyomavirus (PyV)	Mouse
Simian virus 40 (SV40)	Rhesus monkey
BK virus (BKV)	Human
JC virus (JCV)	Human
K papovavirus (KPV)	Mouse
Hamster papovavirus (HaPV)	Hamster
Lymphotropic papovavirus (LPV)	African green monkey
Simian agent 12 (SA12)	Baboon
Rabbit kidney vacuolating virus (RKV)	Rabbit
Stump-tailed macaque virus (STMV)	Stump-tailed macaque
Budgerigar fledgling disease virus	Bird

TABLE 1. *The polyomaviruses*

These small DNA tumor viruses, particularly SV40 and polyoma, have been subjects of intensive studies by virologists and molecular biologists since their discovery in 1953 (143). Polyoma was the first family member to be discovered. In his studies on the transmission of murine leukemia, Ludwig Gross noted that extracts from infected animals could be used to transmit leukemia (143). However, some inoculated animals developed salivary gland tumors rather than leukemia. Gross's further studies showed that the two agents could be separated on the basis of differences in sedimentation or filtration (the murine leukemia virus [MLV] was larger) as well as heat inactivation (the agent that induced salivary gland tumors was insensitive to treatment at 65°C, whereas MLV was completely inac tivated). The virus that caused the salivary gland tumors was subsequently named *mouse polyomavirus* because of its ability to cause a variety of different types of tumors in newborn mice (329). Infection of adult mice with polyomavirus does not usually result in tumorigenesis.

SV40 is one of several viruses identified by screening for viruses in the secondary rhesus monkey kidney cell cultures used for production of poliovirus vaccines. Although SV40 does not induce a visible cytopathic effect in rhesus monkey kidney cells, Sweet and Hilleman (338) noted a pronounced cytopathic effect when African green monkey kidney cells were infected with extracts from the rhesus kidney cell cultures. Soon afterward, it was discovered that tumors were induced by injection of SV40 into newborn hamsters (102,133). Many lots of poliovirus vaccine were contaminated with live SV40 virus, raising the concern that this virus, which is oncogenic for newborn hamsters, might also be oncogenic for humans. Fortunately, studies to determine the risk for cancer in those individuals inadvertently inoculated with SV40 during poliovirus vaccination indicate that exposure to the vaccine is not associated with significantly increased rates of ependymomas and other brain cancers, osteosarcomas, or mesotheliomas (244,332). However, SV40 T-antigen sequences have recently been detected in these cancers in the general population, leading to renewed interest in the role of SV40 infection in contributing to the development of some human tumors (reviewed in 39).

Two polyomaviruses of humans have been described. JC virus (JCV) was isolated in 1971 (254) by inoculating human fetal brain cells with extracts of diseased brain tissue from patients with progressive multifocal leukoencephalopathy (PML). BK virus (BKV) was isolated in the same year from the urine of an immunosuppressed renal transplant recipient (123). The genomes of both of these human viruses show closest homology to SV40. Most people worldwide become infected with and acquire antibodies to these viruses during childhood, with no apparent disease manifestations. These viruses are then thought to lie dormant in cells of a subset of infected people. Once extremely rare, the incidence of PML has increased dramatically in recent years as a consequence of the immunosuppression associated with infection by human immunodeficiency virus (HIV). A related simian papovavirus has been isolated from cynomolgus monkeys under immune suppression (363).

Although most polyomaviruses replicate primarily in epithelial or fibroblastic cells, zur Hausen and Gissmann (402) discovered a B-lymphotropic virus antigenically related to SV40 in a B-lymphoblastoid cell line derived from an African green monkey. Because this virus grows only in B-lymphoblastoid cells, it has been named *lymphotropic papovavirus* (LPV). Serologic studies suggest that humans and most other primates harbor viruses antigenically related to LPV. This virus does not induce tumors in newborn hamsters but will transform cultured hamster and mouse cells.

Hamster polyomavirus (HaPV) was isolated originally from a spontaneously occurring hair follicle epithelioma of a Syrian hamster (139). These tumors resemble papillomavirus-induced tumors in being highly keratinized and having virus particles exclusively in the differentiated cell layer. When injected into newborn hamsters, this virus causes leukemias and lymphomas, a tumor spectrum quite distinct in the polyomavirus subfamily. On the basis of nucleic acid sequence homology and genome organization (83,138), this virus is more closely related to polyoma than to SV40 or the human polyomaviruses. Other mammalian polyomaviruses include bovine polyomavirus (BPV) (293), which is sometimes found in fetal calf serum, a rabbit polyomavirus (RKV) (152), a rat polyomavirus (RPV) (370), and Kilham virus, an additional polyomavirus of mice (231).

The first avian polyomavirus (APV) was identified in 1986 (207). Budgerigar fledgling disease virus (BFDV) is classified as a polyomavirus on the basis of nucleic acid homology to other polyomaviruses as well as on morphologic and serologic criteria. It appears to be more similar to SV40 than to mouse polyomavirus because it lacks a middle T antigen. Several additional APV isolates from a variety of avian species have now been characterized; so far, all belong to one genotype and one serotype within the proposed subgenus *Avipolyomavirus* of the family *Papovaviridae* (258).

POLYOMAVIRUSES AS PARADIGMS

The initial impetus for studies of these viruses was their oncogenic potential. However, these viruses are easy to cultivate in tissue culture and to purify, making them suitable model systems for diverse studies in molecular biology. Because of the small size of their genomes, physical maps of their genomes were generated as soon as restriction endonucleases became available in the 1970s, and they were among the first DNA genomes to be completely sequenced (109,271,310,311). Since the 1970s, these viruses have been used to examine many fundamental questions in eukaryotic molecular biology.

Among the major discoveries resulting from work on these viruses are the structure of supercoiled DNA, the identification of eukaryotic origins of DNA replication, the discovery of enhancers and elucidation of the organization of promoters involved in transcriptional regulation, the discovery of alternative splicing, and detailed understanding of the mechanisms of negative and positive regulation of gene expression. Because viral DNA is organized into chromatin, and because replication of viral DNA involves only a single viral gene product and uses almost all of the proteins used for cellular DNA replication, replication of SV40 origin-containing DNA *in vitro* has served as a model for understanding eukaryotic chromosomal DNA replication. Studies to understand the oncogenic potential of these viruses have provided fundamental insights into cell cycle regulation, oncogenes, and tumor suppressor genes. Much of our understanding of the polyomaviruses derives from studies of SV40 and polyoma, and this chapter focuses primarily on these two viruses.

VIRION STRUCTURE

The capsids of the polyomaviruses contain three virus-encoded proteins, VP1, VP2, and VP3, surrounding a single molecule of viral DNA (Fig. 1A) complexed with cellular histones H2A, H2B, H3, and H4 in the form of chromatin (see Fig. 1B). The sizes of the capsid proteins of SV40 and polyoma are shown in Table 2. These proteins are arranged to form a T=7 icosahedral capsid (see Fig. 1C) containing 360 molecules of the major capsid protein, VP1, organized into 72 pentamers. A single VP2 or VP3 molecule associates with each pentamer. The virus particle is 88% protein and 12% DNA and has a sedimentation coefficient of 240S in sucrose density gradients. Because they lack envelopes, the virus particles are resistant to lipid solvents. They are also relatively resistant to heat inactivation. Virions have a density of 1.34 g/mL in cesium chloride (CsCl) equilibrium density gradients, whereas empty capsids have a density of 1.29 g/mL.

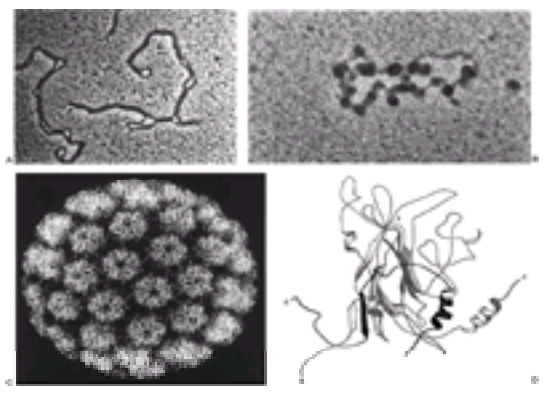

FIG. 1. Viral DNA, minichromosomes, and virions. **A:** Electron micrograph of supercoiled SV40 DNA molecules. **B:** Electron micrograph of an SV40 minichromosome. Note that this particular minichromosome displays a nucleosome-free region. About 20% of minichromosomes have a nucleosome-free region surrounding the regulatory region at the origin of DNA replication. **C:** Computer graphic representation of the structure of the SV40 virion. Note that the shell is made up of 72 pentamers of VP1. Twelve of these lie on icosahedral fivefold axes and are surrounded by five other pentamers. The remaining 60 pentamers, such as the ones near the center of this diagram, are surrounded by six other pentamers. The pentamers are linked together by extended C-terminal arms of VP1 molecules of the subunits. **D:** A ribbon diagram of a VP1 subunit of the mouse polyomavirus virion. *N* refers to the location of residue 15 of the VP1 polypeptide; the first 14 residues are thought to be disordered. *C* is the C-terminus of an invading arm (*darkly shaded*) of another VP1 molecule. At the right of the figure is an *arrow* showing that this VP1 molecule goes off to the right, where it interacts with another VP1 molecule. The interactions of the C-terminal arms of VP1 molecules can be pair-wise with each of two VP1 molecules interacting with the C-terminal arm of the other (as in this figure), or the incoming C-terminal arm of VP1 can come from a third VP1 subunit. (see Chapter 3 for more details on protein–protein interactions in the capsids of the polyomaviruses). *X* is the site of the mouse polyomavirus receptor-binding pocket. TABLE 2. *Capsid proteins of the polyomaviruses*

Although originally thought to contain 60 hexameric (hexons) and 12 pentameric (pentons) capsomeres, it is now clear that these viruses contain 72 pentameric capsomers, which each contain five molecules of VP1 (209,269). In fact, polyoma VP1 produced in *Escherichia coli* will self-assemble into pentameric capsomeres, and under appropriate conditions, these molecules will further assemble into virus-like empty capsids and other structures (280). The same is true of SV40 VP1 synthesized *in vitro* (126). Icosahedral viruses have both sixfold and fivefold axes of symmetry, and the structure of the polyoma capsids presents a puzzle because these capsids contain capsomeres that have only fivefold axes of symmetry. The high-resolution structure of the SV40 capsid (209,324,383) indicates that the C-terminal arm of VP1 does not form part of the capsomere structure itself but instead makes contacts with neighboring pentamers (see Fig. 1D). It is the flexible geometry of these contacts that appears to allow the pentamers to fit together in such a way that an icosahedral capsid is formed. Calcium ions are required for virion stability (32,52) and are thought to stabilize pentamer–pentamer interactions (209). There are no disulfide bonds within the SV40 pentamer subunits, but disulfide bonds may exist between adjacent pentamers because reducing agents are required to disassemble virus particles.

The sequences of the minor capsid proteins, VP2 and VP3, are overlapping; VP2 contains the entire VP3 sequence at its C-terminus and an additional sequence of about 115 amino acids at its N-terminus. The N-terminus of SV40 and polyoma VP2 is myristoylated (331). The VP2 and VP3 proteins of all polyomaviruses are most highly conserved near their C-termini, and it is this region that interacts with VP1 through its N-terminal region (13,50). The disorder seen for VP2/3 in earlier virion structures reflects the fact that VP2/3 interacts differently with different VP1 molecules within each capsomere, but has an equal probability of interacting most directly with any of the five VP1 molecules (50). Only VP1 molecules are exposed on the outside of the virion. VP1 contains a small groove that interacts with specific carbohydrate residues on the cell surface (325,326 and 327). Oligosaccharide chains that terminate with sialic acid serve as the receptor for mouse polyomavirus (327). Some strains bind only straight-chain oligosaccharides, whereas others bind both straight and branched chains. There are wide variations in the response of mice to polyomavirus infection, ranging from persistent infection to tumorigenesis to death. This can be explained on the basis of the differences in receptor–virion interactions (16,17).

Preparations of polyomaviruses contain three kinds of virus particles. Infectious virus particles contain a single molecule of viral DNA in association with four cellular histones. The DNA and histones are arranged as chromatin, and the histone–viral DNA complex is often referred to as the *viral minichromosome.* This minichromosome has been used as a model system to study the effects of chromatin structure on DNA replication and transcription. Most viral DNA molecules

contain a full complement of nucleosomes, but some lack nucleosomes over viral regulatory sequences. Virion minichromosomes lack histone H1, whereas the form of the minichromosome found within infected cells contains it (364). Virion preparations also contain empty capsids as well as pseudovirions, capsids containing cellular rather than viral DNA. Passage of polyomaviruses at high multiplicities of infection leads to the generation of defective viral genomes containing deletions, duplications, and rearrangements of viral genetic information, often with duplications of the viral origin of DNA replication. If within appropriate size limits, these defective viral genomes can be encapsidated.

GENOME ORGANIZATION

The genomes of all polyomaviruses are divided into early and late regions (Fig. 2). The early region is, by definition, that portion of the genome transcribed and expressed early after the virus enters the cells, and it continues to be expressed at late times after infection, after the onset of viral DNA replication. The late region of the genome is expressed efficiently only after viral DNA replication begins, although low levels of transcription of the late region occur early after infection as well. The first maps of the polyoma and SV40 genomes were divided into 100 map units, with the unique Eco RI site in both the SV40 and polyoma genomes defined as 0/100 map units. Because the complete nucleotide sequences of these genomes have been determined, use of nucleotide positions rather than map units permits more precise description of specific sites within the genome. Nucleotide position 1/5243 for SV40 is the center of a 27–base pair palindrome located at the origin of viral DNA replication (*ORI* in Fig. 3). The numbering system used for SV40 is that of Buchman and colleagues (36). The numbering system used for polyomavirus is that of Griffin and associates (141). For polyoma, nucleotide position 1/5295 corresponds to the center of the Hpa II cleavage site at the junction of the fifth and third largest of eight fragments of polyoma DNA produced by cleavage with Hpa II. This site is also close to the polyoma origin of DNA replication.

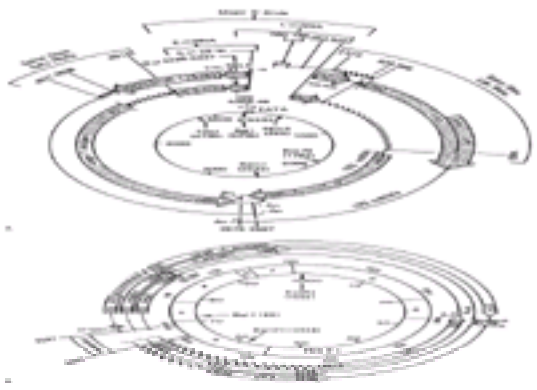

FIG. 2. Genomic organization of SV40 and mouse polyoma virus. **A:** SV40. The origin of replication and transcriptional regulatory region is at the top. The early region extends counterclockwise and the late region clockwise from the top. The regions encoding viral proteins are shaded. Also shown are the nucleotide positions for the 5' and 3' ends of viral mRNAs and the positions of introns. (From ref. 26, with permission). **B:** Mouse polyoma virus. The 0/100 map unit position is at the top and corresponds to the unique Eco RI site. The origin is located counterclockwise about one third the way around the circle. The early region is located in the top half of the figure and the late region in the bottom half. Also shown are the positions where each of the viral gene products are encoded, the nucleotide numbers of the 5' and 3' ends of the viral mRNAs, and the nucleotide positions of the introns. (From ref. 350, with permission.)

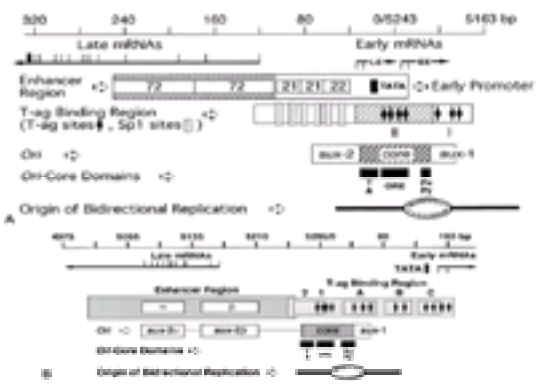

FIG. 3. The regulatory regions of SV40 (**A**) and polyoma (**B**). Shown are the location of the core origin of viral DNA replication and the location of auxiliary sequences (*aux*), which enhance viral DNA replication. Replication of polyoma requires either aux-2a or aux-2b. Within each core origin region are located a TA tract, with a strand bias for Ts and As, the palindromic region that serves as an origin-recognition element (*ORE*), and a region with a purine (*PU*) and pyrimidine (*PY*) strand bias, within which bidirectional DNA replication is initiated. Also shown are sites at which large T antigen binds to viral DNA; pentanucleotides involved directly in binding are indicated by *arrowheads,* which point in the direction of the pentanucleotide, 5'GAGGC3'. Several additional 5'GAGGC3' pentanucleotides are located in the vicinity of the Sp1 sites, to the left of binding site II, but these bind T antigen very weakly and are not thought to play a role in SV40 replication. Sites within this region at which transcription is initiated for production of viral early and late mRNAs are also indicated. The sites marked *EE* for SV40 are those used early after infection; those marked *LE* are used to produce early mRNAs after the onset of viral DNA replication. Additional sites for production of both SV40 and polyoma late mRNAs are located further downstream for both SV40 and Py. For SV40, the locations of the two 72–base pair repeats, which serve as enhancers, and of the 3 nearly perfect 21–base pair GC-rich repeats are also shown. Within these repeats are six sites to which transcription factor Sp1 can bind. (Courtesy of Dr. Mel DePamphilis, National Institutes of Health, Bethesda, MD.)

Two lines of evidence indicate that polyomavirus genomes contain a single unique origin of DNA replication. In one of the earliest uses of restriction endonucleases as tools to address important problems in molecular biology, Danna and Nathans (77) exposed SV40-infected BSC-1 monkey cells to pulses of ^{3}H-thymidine and, at various subsequent times, isolated viral DNA molecules that had completed replication. They then hybridized this labeled DNA to fragments of SV40 DNA generated with restriction endonucleases Hind II + III. In mature viral DNA molecules, label should first appear at sites near the terminus for DNA replication, whereas the origin region should become labeled later because molecules just initiating DNA replication at the time of addition of label require a longer time to be completed. The region of the genome around map position 17 (nucleotide 2622) became labeled first, whereas that near position 67 (nucleotide 0/5243) was labeled last and designated as the origin region.

This location for the origin was also revealed by electron microscopy. Replicating SV40 DNA molecules were cleaved with Eco RI, which cuts SV40 DNA once (nucleotide 1782), and examined by electron microscopy. The unique cleavage site allows mapping of the sites at which replication bubbles are initiated; these studies indicated that replication began one third of the way around the genome from the Eco RI site. By performing similar analyses with viral DNA molecules lacking portions of the early or late region, it was shown that there is no unique site for the termination of DNA replication. Rather, bidirectional replication proceeds away from the origin, with the replication forks meeting at a site about 180 degrees from the initiation site. Detailed mutational analyses to define the origin more precisely are discussed later.

The promoters and enhancers for transcription are located close to the origin of replication (see Fig. 2 and Fig. 3). Together, the promoters, enhancers, and origin are referred to as the *viral regulatory region.* Transcription extends bidirectionally from initiation sites near the origin, with early and late messenger RNAs (mRNAs) being transcribed from opposite strands of the viral genome. Thus, the early region extends from the origin to a site about halfway around the genome. The early region encodes the viral regulatory proteins, the tumor, or T, antigens, so called because they can be detected with antisera derived from animals bearing tumors induced by these viruses or by injection of cells transformed by these viruses. SV40 and the other primate polyomaviruses encode two T antigens—designated large T and small t antigens on the basis of size. Polyoma and closely related viruses encode three T antigens—large T, middle (or medium) T, and small t. All of the T antigens of each virus share N-terminal sequences and contain different C-terminal regions. The mRNAs encoding them are produced by alternative splicing from a common pre-mRNA. Figure 2 shows the common and unique regions of SV40 and polyoma T antigens.

The late regions of these viral genomes encode the three capsid proteins, VP1, VP2, and VP3. As with the early mRNAs, late mRNAs are generated from a common pre-mRNA by alternative splicing. The coding regions of VP2 and VP3 overlap, with VP3 sequences being a subset of VP2 sequences. The coding region for the N-terminus of VP1 overlaps that for the C-termini of VP2 and VP3, with translation of VP1 being from a different reading frame than VP2 and VP3. SV40 and the human polyomaviruses encode a fourth late protein, called the *agnoprotein* (see Table 2). This 62– to 71–amino acid protein is encoded by the leader region of some species of late viral mRNA and accumulates in the perinuclear region during the late phase of the infection cycle (167,253). It was originally named agnoprotein because its function was unknown. It appears to facilitate the localization of the major capsid protein to the nucleus and may also enhance the efficiency with which virus spreads from cell to cell (43,273). Mutants that do not produce the agnoprotein yield fewer progeny virions and produce small plaques (11,238). Pseudorevertants of these mutants map to the major capsid protein, VP1, suggesting a possible interaction between the agnoprotein and VP1. Additional small open reading frames that could encode other proteins are found in other species of late mRNA as well as in some species of early-stranded mRNA present late after infection (186). Thus, many SV40 late mRNA species are bi-cistronic.

VIRAL GENETICS

Genetic analyses have played a central role in our understanding of the biology and replication cycle of the polyomaviruses (reviewed in 351). The first mutants to be isolated were host range mutants of polyoma whose growth was restricted to certain mouse cell lines, and temperature-sensitive (ts) mutants of SV40 and polyoma. The availability of restriction endonucleases led to the construction of a wide variety of deletion and substitution mutants during the 1970s and 1980s. Site-directed mutagenesis and polymerase chain reaction–based approaches have also been used to produce mutants of the polyomaviruses. Today, it is relatively easy to construct any desired point, deletion, or substitution mutant of these viruses.

For SV40, ts mutants were divided into five complementation groups, A, B, C, BC, and D, based on their ability to complement one another to produce plaques at the nonpermissive temperature. We now know that the product of the A gene is large T antigen. VP2 and VP3 are both altered by mutations in gene D, whereas mutants in groups B, BC, and C produce altered VP1. Intracistronic complementation is often seen in genes that encode proteins that assemble into multimers or in multifunctional proteins in which separate domains perform distinct roles. Intracistronic complementation is observed between VP1 mutants in groups B and C but not between those in the BC group and either group B or group C. It has also been observed between mutants of large T antigen that affect the host range of the virus and mutants that affect replicative activities of the protein (352). The ts mutants of polyomavirus have been sorted into similar complementation groups.

By infecting cells at the permissive temperature and shifting them to the nonpermissive temperature at various times after infection, it was shown that the products of genes A and D were required early after infection, whereas the products of genes B and C were required only at late stages of infection. It is not surprising that large T antigen is required early after infection because it is required for viral DNA replication. Studies that suggest a role for VP2 and VP3 in adsorption or uncoating of the virus explain the finding that the D gene product is also required for early events of the infection cycle.

The sites of mutation of representative members of each complementation group were mapped by marker rescue using restriction endonuclease fragments of viral DNA (197). This involved producing partial heteroduplexes containing a circular strand of a particular ts mutant and a linear restriction endonuclease fragment. Successful marker rescue

depends on the wild-type restriction endonuclease fragment containing the information that is mutated in the mutant genome. In this way, the SV40 A gene was mapped to the early region and the SV40 B, C, BC, and D groups to the late region of the genome. Similar mutants of polyoma were mapped to analogous regions of the polyoma genome.

Although these studies were able to identify viral genes and their positions on the physical map of the viral genome, they did not indicate which of the viral gene products were encoded by each gene. Deletion mutants were constructed using restriction endonucleases, and this permitted assignment of some viral proteins to viral genes because it was easy to determine which viral gene product had been shortened by the deletion mutation. Many of these mutants could be propagated only in the presence of wild-type helper virus. Mutants of SV40 with deletions at the unique Eco RI or BamH I sites produce internally deleted or truncated VP1 polypeptides, indicating that the gene for VP1 spans the Eco RI and Bam HI sites (59). This is the region of the genome where marker rescue studies placed mutations in the B, BC, and C complementation groups.

Mutants with deletions at the unique Hae II site affected only VP2 (59). These mutants were able to form very small plaques and hence could be propagated without helper virus. Because these slow-growing mutants could complement tsD mutants at the nonpermissive temperature, they were assigned to a new complementation group E, with VP3 assigned to complementation group D. SV40 mutants with deletions in the early region were also constructed and found to produce large T antigens of reduced size, thus proving that the large T antigen was the product of the A gene rather than a cellular protein induced by SV40 infection (198).

A set of viable mutants with small deletions located randomly around the SV40 genome was produced. Three regions of the viral genome were identified that could accommodate deletions without impairing the plaque-forming ability of the virus (301). These sites are located in the agnogene region, in the region encoding the 3'-untranslated regions of the early and late mRNAs, and in the early region between map positions 54 and 59 (nucleotides 4900 to 4600, approximately).

Normal-sized plaques were produced by the 54/59 region deletion mutants, but these viruses were unable to transform nonpermissive cells as efficiently as wild-type SV40, suggesting that a gene product needed for transformation was encoded in this region. No tsA mutants (affecting large T antigen) had been mapped to this region. Analysis of T antigens encoded by mutants with deletions in the 54/59 region showed that the deletions did not affect large T antigen, although size measurements of large T suggested that most or all of the early region was required to encode it. Studies by a number of investigators subsequently showed that the SV40 early region encodes both small and large T antigens (22,71,256) and that small t antigen was reduced in size by mutations in the 54/59 region. Alternative splicing allows the production of mRNAs that encode these two early gene products; there is not sufficient genetic information in the SV40 early region to encode distinct polypeptides of 84 and 17 kd.

Viable deletion mutants of polyomavirus have also been isolated and characterized. Host range mutants of polyoma were selected that grew poorly or not at all in mouse 3T3 cells but replicated efficiently in primary cells or in cells transformed by retroviruses or by polyoma itself (18). Because these mutants display this host range phenotype and are also defective for transformation, they are called *hrt* mutants. Marker rescue experiments indicated that the hrt mutants map to the analogous region of the polyoma genome as the SV40 54/59 deletion mutants. Complementation is observed between polyoma tsA and hrt mutants to permit cell transformation at a temperature restrictive for tsA mutants. The hrt mutants are known to encode truncated forms of both small and middle T antigens. The role of these proteins in transformation is discussed later.

BIOLOGIC PROPERTIES OF THE POLYOMAVIRUSES

Although SV40 and polyoma are able to infect a wide range of mammalian cell lines and cultures, the response to infection can be productive or nonproductive. In some types of cells, viral DNA replication occurs, followed by the assembly of progeny virions and, ultimately, the death of the cell. This is called a *productive infection,* and cells in which infection is productive are said to be *permissive* for growth of the virus. Monkey cells are permissive for growth of SV40 and mouse cells for growth of polyoma. Some polyomaviruses show an extremely narrow host range for productive infection. For example, JCV replicates only in human fetal glial cells.

Nonproductive infections result when viral DNA replication cannot take place in the infected cell. For viral DNA replication to occur, SV40 or polyoma must produce adequate levels of large T antigen, the only viral protein needed directly for replication, and this protein must interact with cellular replication factors and the viral origin of DNA replication. An inability of SV40 large T antigen to interact productively with host replication factors in rodent cells is the reason that SV40 infection of rodent cells is unproductive. A similar inability of the polyoma large T antigen to interact productively with simian or human host cell factors is responsible for the inability of polyoma to replicate in primate cells.

In nonproductively infected cells, the infection cycle begins normally. The viral early mRNAs are produced, and the viral T antigens can be detected. The early proteins exert a variety of effects on the host cell. Because the polyomaviruses require the host cell DNA replication machinery, they replicate only during S phase, and T antigen stimulates cells to move through the cell cycle into S phase. When expressed in cells that are nonpermissive for viral replication, the viral T antigens also cause cells to acquire the properties of transformed cells. Such cells proliferate in semisolid media or in the absence of a high concentration of fetal calf serum. Usually, these transformed properties are manifested for only a few days. Usually, the viral genome, which does not replicate, is lost from the cells, and they return to normal growth. Such cells are said to have been “abortively” transformed. At a low frequency, the viral DNA becomes integrated into the host cell genome and is subsequently inherited as if it were a cellular gene. Integration appears to occur randomly with respect to sites in both the viral and host cell genomes. If the arrangement of viral DNA sequences after integration permits continued expression of SV40 large T antigen or polyoma middle T antigen, the transformed phenotype is expressed permanently, and the cell is said to have been *transformed* by the virus.

Most studies of transformation by SV40 have been conducted in mouse, rat, and hamster cells, but primate cells can be

transformed by SV40 if replication is prevented by mutation of the viral origin of replication or the viral T antigen gene. The Cos-1 and Cos-7 monkey kidney cell lines express wild-type SV40 large T antigen and contain an integrated copy of SV40 DNA carrying a deletion of sequences within the origin of DNA replication that are essential for DNA replication (135). For polyoma, rat cells are normally used to study viral transformation. Although permissive for replication of polyomavirus, mouse cells can also be transformed by polyoma if the virus carries a mutation affecting large T antigen or its origin of replication or if viral DNA becomes integrated into the mouse cell genome in a way that interrupts the early coding region and prevents continued synthesis of full-length large T antigen. Although multiple regions spanning most of the SV40 large T antigen are required for transformation, the critical protein for transformation by polyoma is the middle T antigen. Although these viral gene products must be present continuously to maintain the transformed phenotype, mutation of cellular genes can eliminate the need for maintenance of the viral transforming region (266,267).

In addition to being able to cause malignant transformation of cultured cells, these viruses can efficiently immortalize primary rodent cells that would normally undergo a limited number of cell doublings. Immortalization is a function of the large T antigens of SV40 and polyoma. Studies of immortalization of primary mouse embryo fibroblasts by mutants of SV40 T antigen suggest that some mutants that can neither immortalize primary cells nor transform established cell lines have the ability to extend the normal lifespan of the primary mouse fibroblasts (64,345). Although the lifespan of human fibroblasts and epithelial cells can also be extended by wild-type SV40 T antigen, their immortalization is a rare event and requires mutations of one or more cellular genes (122,300,362).

THE REPLICATION CYCLES OF SV40 AND POLYOMA

Productive infection of cells by polyomaviruses can be divided into early and late stages. The early stage begins with attachment of virus to cells (Fig. 4) and continues until the beginning of viral DNA replication. Thus, the early stage is marked by adsorption and penetration of the virion and its migration to the nucleus, where the viral genome is uncoated and made available for transcription. During the early phase of infection, the viral early proteins, the T antigens, are produced, and they affect the host cell by stimulating the production of enzymes required for cellular DNA replication, thereby preparing the cell for replication of viral DNA. These viral early proteins also stimulate resting cells to reenter the cell cycle. The late stage of infection extends from the onset of viral DNA replication to the end of the infection cycle and involves the replication of viral DNA, expression of the viral late genes encoding the capsid proteins, assembly of progeny virus particles in the nucleus of the infected cells, and release of virus, possibly at the time of the death of the cell.

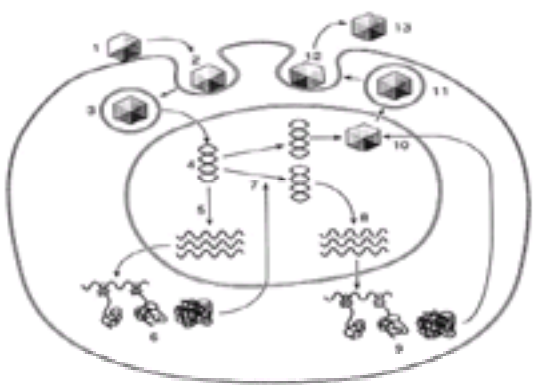

FIG. 4. Replication cycle of polyomaviruses. Steps in the replication cycle are indicated by numbers as follows: *1,* adsorption of virions to the cell surface; *2,* entry by endocytosis; *3,* transport to the cell nucleus (route and mechanism not yet known); *4,* uncoating; *5,* transcription to produce early region mRNAs; *6,* translation to produce early proteins (T antigens); *7,* viral DNA replication; *8,* transcription to produce late region mRNAs; *9,* translation to produce late proteins (capsid proteins); *10,* assembly of progeny virions in the nucleus; *11,* entry of virions into cytoplasmic vesicles (mechanism unknown); *12,* release of virions from the cell by fusion of membrane vesicles with the plasma membrane; *13,* released virion. Virions are most likely also released from cells at cell death when virions have an opportunity to leak out of the nucleus. In nonpermissive cells, the first six steps occur normally, but viral DNA replication cannot occur and subsequent events do not take place.

The time course of infection by SV40 and polyoma depends primarily on two parameters. Infection proceeds more rapidly at higher multiplicities of infection than at lower multiplicities. This most likely reflects the fact that critical levels of the viral early proteins are attained earlier when more viral genomes are available for transcription to produce the viral early mRNAs. The other critical parameter is the growth state of the host cell. At the same multiplicity of infection, viral DNA replication begins sooner, and the production of progeny virions is completed more rapidly when cells are growing exponentially than when cells are confluent and in a G_0 state at the time of infection. Figure 5 illustrates the time course for the expression of polyoma T antigen, induction of cellular enzymes, replication of viral DNA, and production of progeny virions.

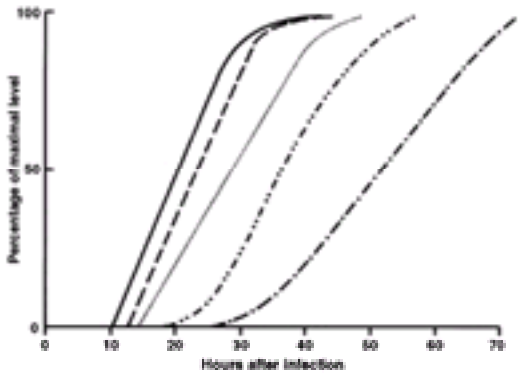

FIG. 5. Idealized time course of central events during productive infection of mouse cells by mouse polyoma virus. Events after infection of monkey cells by simian virus 40 follow a similar course. Parameters shown are expressed as a percentage of maximal level reached. T antigen (——) was measured by percentage of cells showing positive immunofluorescence; the actual rate of accumulation of T antigen may be slower because T-antigen–positive cells continued to synthesize T antigen over a long period. Cellular enzyme production (-----) is expressed as stimulation of enzyme activities compared with activity levels present in uninfected cells. Cellular DNA synthesis (.....), viral DNA and RNA (·····), and infectious virus (-·-·-) are expressed as the percentage of the total final yields of these macromolecules attained at particular times, not the rate of production at any particular time. (From ref. 350, with permission.)

Adsorption and Receptors

Early studies of the initial events of polyomavirus infection were complicated by the fact that virus preparations used contained not only infectious virus particles but also empty capsids and pseudovirions. Less ambiguous results have been obtained using purified virion preparations. Norkin and coworkers found that binding of SV40 virions to LLC-MK2 rhesus monkey kidney cells was inhibited by antibodies to class I major histocompatibility complex (MHC) antigens but not by antibodies to other cell surface proteins (34). Little binding was observed to two human lymphoblastoid cell lines that do not express MHC class I molecules owing to failure to express either b $_2$-microglobulin or HLA class I molecules. Binding occurred when class I expression was restored by transfection of cells with plasmids encoding b $_2$-microglobulin or HLA class I molecules. Different results were obtained by Basak and colleagues, who studied the binding of SV40 virions to polarized monkey kidney cells (Vero C1008) (14). Binding was restricted to the apical surface of these polarized cells, whereas HLA expression was detected at both the apical and basolateral surfaces.

Perhaps class I MHC molecules are required for adsorption of SV40 virions but are not sufficient, with other cell surface molecules also being part of the receptor. In nonpolarized cells, binding sites for SV40 were distributed uniformly over the cell surface. Different subclones of C1008 Vero cells bound different numbers of virions, and the abundance of binding sites was cell cycle regulated. Those cells that bound the greatest number of virions contained about 10 ^{5} receptors per cell.

Competition experiments indicate that SV40 and polyoma receptors are distinct (14). This was also inferred from earlier studies that showed that binding of polyoma was sensitive to treatment of the cells with sialidase, whereas binding of SV40 was not. The polyomavirus receptor is known to contain oligosaccharide chains terminating with sialic acid. Antibodies to VP1 block adsorption of polyoma virions (25). Small and large plaque strains of polyoma produce different VP1 molecules, suggesting that plaque morphology may reflect different efficiencies of interaction of the virus particles with their receptors. When examined by isoelectric focusing (25), polyoma virions are seen to contain six distinct isoforms of VP1 (A to F), which differ in posttranslational modifications. Empty capsids lack one of these species (E) and do not compete with virions for binding to mouse kidney cells, suggesting that species E plays a central role in specific virus adsorption (26). Empty capsids can still bind to guinea pig erythrocytes and are internalized and degraded in lysosomes, rather than being transported to the nucleus for productive infection. Additional evidence for a role for VP1 in virus binding comes from binding studies with capsid-like structures that self-assemble from polyoma VP1 expressed in and purified from bacteria. The fact that the binding of these “capsids” to quiescent cells stimulates modest induction of *c-fos* and *c-myc* (399) suggests that these capsids may be interacting with a growth factor receptor or related protein.

The VP2 polypeptide of polyoma and SV40 is myristoylated at its N-terminus (331), and this modification plays a role in the early events of infection. Deletion mutants of SV40 that produce no VP2 are weakly viable. Plaques formed by these mutants are extremely slow to appear and enlarge slowly, suggesting that these mutants produce a dramatically reduced yield of infectious progeny (59). However, the yield of physical virus particles is nearly normal, suggesting that these progeny are defective in some early event of the infection cycle, perhaps adsorption. Mutation of polyoma VP2 so that it can no longer be myristoylated still permits its incorporation into virions, but infectivity is reduced 15- to 20-fold, and the infection cycle is prolonged by several hours (196,279). Together, these results suggest that the myristic acid moiety of VP2 may interact with cellular membranes, whereas VP1 probably interacts with specific receptor polypeptides. Because VP2 is entirely internal to the virion outer shell, how the N-terminal portion becomes exposed is unknown. There is about a 12.5 Å opening at the top of each pentamer, which may be large enough for the N-terminal portion of VP2 to emerge (50). Weakening of the VP1 contacts in each pentamer could also allow the N-terminal portion of VP2 to be exposed, but no mechanism is known that could explain such a rearrangement. Possibly, initial interactions with the cell (before binding to the true receptor) could trigger such a rearrangement.

Virion Entry and Uncoating

How polyomaviruses gain entry to the nucleus is uncertain. Most particles in a virus preparation do not initiate infection successfully; hence, there is the problem that the particles observed during the early stages of infection are likely to be

primarily those that do not initiate an infectious cycle. After binding to the cell surface, SV40 virions appear to transmit an intracellular signal that in turn facilitates viral entry into caveolae. Class I MHC molecules do not enter cells, indicating that although these molecules mediate binding of virions to cells, they are not required for viral enclosure within the preformed caveolae (2,51). Soon after infection, virus particles can be detected by electron microscopy in small vesicles within the cytoplasm (162,229). These vesicles may ferry virus particles to the nucleus, and the fusion of these vesicles with the nuclear envelope has been observed by electron microscopy (142,250). Virus particles have also been observed within the endoplasmic reticulum (ER) (176); thus, the ER may also provide a pathway to the nuclear envelope.

The nuclear pore complex could serve as an entry portal for virus particles because SV40 virions injected into the cytoplasm enter the nucleus and begin production of SV40 early mRNA (55). This process is blocked by wheat germ agglutinin or by monoclonal antibodies to nuclear pore complex proteins (382), treatments known to block the movement of karyophilic proteins through the nuclear pore complex. Large T antigen is normally not detected until 10 to 12 hours after infection but can be detected within 3 to 4 hours after microinjection of virus particles into the cytoplasm. This time differential may reflect slow steps in penetration and the escape of virions from membrane vesicles into the cytoplasm before entry through the nuclear pore complex. Alternatively, it may mean that the nuclear pore complex is not generally a route of entry into the nucleus for SV40 or polyoma virions, with the pathway to the nucleus involving movement of virus particles within the ER or other membrane-bound structures. Because virus capsid proteins contain nuclear localization signals used to direct the proteins to the nucleus before virion assembly, these same nuclear localization signals may be able to mediate the entry of microinjected virions into the nucleus, even if this route is not normally used.

Most studies indicate that virions are uncoated within the nucleus because intact virions can be detected within the nucleus before expression of the viral T antigen (8,162,219). However, in some studies, partially disassembled virus structures were seen in the cytoplasm and were presumed to be uncoating intermediates (118). Whatever the route of entry, the viral minichromosome is transcribed, replicated, and subsequently encapsidated within the nucleus.

Transcription and Processing of Early Viral Messenger RNAs

Once virions have been uncoated, the viral minichromosome can be used as a template for transcription by RNA polymerase II to produce early viral mRNAs, derived from the early region of the viral genome. Production of mRNAs derived from the late strand of viral DNA is inefficient early after infection. Maximal production of the viral late mRNAs requires both an activity of large T antigen and the onset of viral DNA replication. Viral late mRNAs are discussed later.

For many years, studies on patterns of transcription of polyomavirus genomes were hampered by the very low levels of the viral early mRNAs, which make up only 0.01% to 0.02% of the total cellular RNA synthesized before viral DNA replication. During the initial 10 to 15 hours of an SV40 or polyoma infection, the total production of early mRNA likely represents not more than a few hundred molecules, in comparison to the 300,000 molecules of total mRNA found in a eukaryotic cell (reviewed in 351). From the application of more sophisticated and sensitive mapping techniques, it is now known that transcription initiates within the viral regulatory region and extends at least 180 degrees around the viral genome (188), and may extend further. Functional viral early mRNAs are produced by alternative splicing of this pre-mRNA (22). For SV40, alternative splicing generates two species of early mRNA. Messenger RNAs encoding large T antigen result from excision of an intron that extends from nucleotide 4918 to nucleotide 4571, whereas excision of an intron extending from nucleotide 4638 to the same splice acceptor at 4571 yields mRNAs encoding small t antigen. Thus, the SV40 early pre-mRNA contains two splice donor sites and a common splice acceptor. All of these mRNAs are polyadenylated at the same site at nucleotide 2694. Infected cells may also contain a third alternatively spliced early SV40 mRNA (391).

For polyoma, a similar early pre-mRNA is spliced to generate three polyoma early mRNAs (174,175). These mRNAs share 5' ends located in the viral origin region and 3' ends located at nucleotide 2930, and they differ with respect to sequences excised by splicing. The introns for the mRNAs for the polyoma large, middle, and small T antigens extend from nucleotides 409 to 794, 746 to 808, and 746 to 794, respectively. Thus, there are two splice donors and two splices acceptors. Low levels of polyoma early mRNAs that use a weak polyadenylation site at nucleotide 1525 have also been detected (156,354).

Other polyomaviruses show similar patterns of early transcription. For those that produce two T antigens, including JCV and BKV, two early mRNAs are generated by alternative splicing; for those that produce large, middle, and small T antigens, the three mRNAs are produced by alternative splicing from a common precursor, analogous to the situation with polyoma.

Early Promoters and Enhancers

The sites at which SV40 early mRNAs are initiated have been mapped in three ways—by nuclease S1 protection using end-labeled DNA probes, by primer extension of short labeled oligonucleotides, and by analysis of the nucleotide sequences attached to 5'-capped oligonucleotides produced after enzymatic digestion of purified labeled viral early mRNAs. All three approaches can produce artifactual results, particularly if the RNAs to be analyzed are inabundant (as viral early mRNAs are) or if they have significant secondary structure. Taken together, these experiments suggest that there are multiple clustered start sites for the SV40 early mRNAs, positioned around nucleotides 5237 and 5231 (127,146,348) (see Fig. 3).

Additional species of SV40 early mRNA are also detected that contain 5' ends at nucleotides 34 through 28 (127). Molecules using these upstream starts can be detected relatively early after infection, but these sites become the primary initiation sites after viral DNA replication begins (117). This shift from early-early to late-early start sites requires both T-antigen and viral DNA replication. When all T-antigen–binding sites in the origin region are mutated and a second origin is introduced at another site, the shift from early-early to late-early sites still occurs (37). These 5'-extended early mRNAs have the potential to encode an additional viral polypeptide of 23 amino acids (186) (see Fig. 2), although deletion mutants unable to produce this protein behave like wild-type viruses. Translation from these longer early

mRNAs, in which the initiation codon for the T antigens is not the first one, is inefficient (37).

The promoters that govern the production of the SV40 early mRNAs were among the first to be studied in detail and dissected by exhaustive mutagenesis. The critical features of the SV40 regulatory region are shown in Figure 3. Three sites (I, II, and III) for binding of SV40 large T antigen are located in this region. Upstream from the start sites for transcription is located an AT-rich region that contains a TATA box–like element, TATTTAT. Analysis of deletion and point mutants affecting the SV40 early TATA box and sequences between it and the normal transcriptional start sites demonstrated for the first time that TATA boxes function to direct transcription initiation to a site about 30 nucleotides downstream (65). Detailed point mutagenesis of this region indicates that it actually contains two TATA boxes, which specify initiation at the two clusters, around nucleotides 5237 and 5231 (257).

Upstream from the AT-rich region is a GC-rich cluster that contains two repeats of a 21–base pair sequence and a homologous 22–base pair sequence (often referred to as the *three 21–base pair repeats*). Altogether, this region contains six copies of a GC-rich sequence (CCGCCC) present 40 to 103 nucleotides upstream of the RNA initiation sites. Lying further upstream are two copies of a 72–base pair repeat. A variety of *in vivo* and *in vitro* studies have been performed in many laboratories to determine the importance to viral early transcription of these various regulatory region elements. Together, they indicate that the 21–base pair elements are important promoter elements but are not absolutely essential for early transcription (21,105,117,153). Studies of the SV40 promoter indicate that transcription factor Sp1 binds to these sites *in vitro* and is absolutely required for transcription *in vitro* from the SV40 early promoter (95,96).

The 72–base pair repeat elements function as enhancers for the SV40 early promoter. In fact, it was the study of these repeats that led to the discovery of eukaryotic transcriptional enhancers. These elements act to increase transcription initiation in an orientation-independent mechanism when located either upstream or downstream from transcriptional start sites, with little dependence on distance for their enhancing effects. Many different transcription factor–binding sites are located within the SV40 and polyoma enhancers, but it has not yet been possible to identify which factors actually interact with them *in vivo* (reviewed in 168). The SV40 enhancer is quite strong and functions well in cells of a variety of species and types; it has been widely used as an enhancer to drive expression of heterologous genes. The BKV enhancer consists of three repeats of a 68–base pair sequence, with the middle copy containing an internal 18–base pair deletion, and also includes another sequence element located adjacent to the repeat element closest to the BKV late genes (88). JCV contains two copies of a 98–base pair sequence that functions as an enhancer and that, like SV40 and BKV enhancers, is located on the late side of the origin or replication (183).

The organization of the regulatory region of polyomavirus is similar to that of SV40 (see Fig. 3) but has some important differences. Similar approaches were used to map the major sites of transcription initiation to sequences between nucleotides 147 and 158 (67,173). As in the case of SV40, 5' sites mapping further upstream were detected during the late phase of polyoma infection (67,108,173). In contrast to their production by transcription initiation during SV40 infection, these 5'-extended polyomavirus transcripts appear to arise by processing of long viral pre-mRNAs, which themselves arise by transcription that continues more than once around the complete polyomavirus genome (1). Also in contrast to the late-early SV40 transcripts, these polyoma transcripts are uncapped and primarily nuclear.

The polyomavirus regulatory region contains an enhancer element that has a more complex organization than does the SV40 enhancer. The polyoma enhancer contains a single copy of two different adjacent enhancers, called A and B, or a and b (160), which can function independently and which confer different cell-type specificities. Extensive studies have been conducted of polyomavirus variants selected for efficient growth on either differentiated or undifferentiated embryonal carcinoma cells; these viral variants contain point mutations within the enhancers (76,235,236). Because enhancers contain multiple sites to which transcription factors can bind productively (168), these genetic studies suggest that there has been a selection for mutants that acquire binding sites for transcription factors present in embryonal carcinoma cells.

Regulation of Early Transcription

The early promoters of all polyomaviruses are autoregulated by their large T antigens. This was shown first for SV40 (189,272,344). In cells infected with tsA mutants affecting the large T antigen, early mRNAs are overproduced, and the rate of synthesis of large T antigen is elevated in parallel. A similar result has been obtained for polyoma (57). Autoregulation of viral early transcription has been reproduced *in vitro* and shown to be dependent on T-antigen–binding sites (150,276,277), indicating that large T antigen autoregulates synthesis of its own mRNA. The binding of large T antigen to viral DNA blocks the assembly of a functional transcription complex, thereby repressing early transcription (248). The location of the binding sites that are the target for this repression is different for SV40 and polyoma. The SV40 binding sites I and II (see Fig. 3A) are located downstream of, or overlap, the early mRNA start sites used early after infection, respectively (277), whereas the binding sites critical for autoregulation by polyoma T antigen (see Fig. 3B) are located upstream of the early transcription initiation sites (68,107).

Most studies on autoregulation by large T antigen were performed under conditions in which T-antigen levels were relatively high. Early after infection, when T-antigen levels are much lower, T-antigen–binding sites are unoccupied. Under these conditions, large T antigen stimulates transcription from its own promoter by a mechanism that does not require direct binding of T antigen to viral DNA (375).

Processing of Viral Early Pre-messenger RNAs

Alternative splicing is used to generate multiple species of early mRNA from a single class of mRNA precursor (see Fig. 2). Because of the advantages of working with viral systems, alternative splicing of SV40 pre-mRNA has been extensively analyzed both *in vivo* and *in vitro* as a model system for alternative splicing. The very small size of the intron excised to produce the SV40 small t mRNA (66 nucleotides) helped to define the relationship between minimum intron size and efficiency of excision (119). Splicing to produce large T mRNA uses multiple alternative branch-point sites, whereas splicing to produced small t mRNA uses only the most distal of these sites (251). The use of alternative lariat

branch sites is probably central to alternative splicing in other systems. The ratio of small t to large T mRNA produced varies from cell line to cell line and is 10- to 20-fold higher in human 293 cells than in many other mammalian cell lines (119). Because the ratio of large T to small t splicing *in vitro* in HeLa cell extracts is 100:1 (252), extracts supplemented with fractions from a human 293 cell extract were used to identify and purify a factor from 293 cells that promoted use of the small t intron. This resulted in the discovery of ASF, a protein factor that controls alternative splicing for SV40 (124) and that appears to play an important role in alternative splicing in many cellular gene systems.

For polyoma, the 48-nucleotide intron excised to produce small t mRNA is the smallest known mammalian intron and is below the minimum size thought to be required for excision. Excision of this intron involves two branch-point sites, one only 4 nucleotides upstream of the small t 3' splice acceptor site, and also requires an intact 3' splice site for middle T antigen, located 14 nucleotides downstream of the small t 3' splice acceptor site (125). This indicates that the two 3' splice sites somehow cooperate to permit excision of the tiny small t intron. Such splice-site cooperation could be important for alternative splicing of cellular pre-mRNAs as well.

Synthesis and Functions of the Viral T Antigens

Large T Antigen

The large T antigens of the polyomaviruses are complex multifunctional proteins that have multiple enzymatic activities, interact with several cellular proteins, and perform several different roles during infection. The organization and activities of different large T antigens have been compared and reviewed (260). Considerably more is known about SV40 large T antigen than about the other large T antigens. Although this portion of this chapter focuses on SV40 large T antigen, key differences between SV40 and polyoma are highlighted.

The sizes of the T antigens of several polyomaviridae are listed in Table 2. The functional organization of SV40 and polyoma large T antigens is shown in Figure 6. All of the large T proteins are closely related and contain identical or similar sequences over most of their lengths. Polyoma large T contains a region of 154 amino acids following amino acid 82 with no homology to SV40 large T sequences; the viral DNA encoding this portion of large T is the portion of the polyoma genome that also encodes, in a different reading frame, the unique portion of middle T antigen. Conversely, SV40, JCV, and BKV large T antigen contain about 70 amino acids at their carboxyl termini that have no homology with any sequences in polyoma large T. This carboxyl-terminal domain of large T is involved in host range and adenovirus helper function (see later).

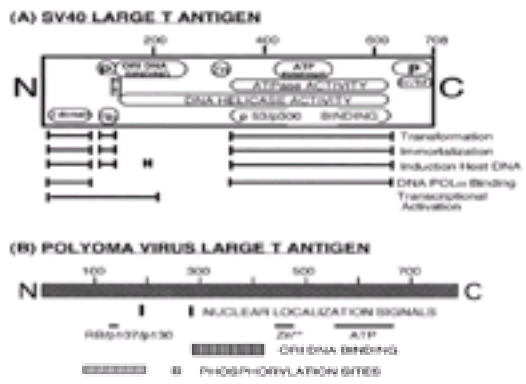

FIG. 6. The domain structures of SV40 large T and mouse polyomavirus large and medium T antigens. **A:** SV40. Shown are the domains of large T antigen required for nuclear localization (*NLS*) and for binding ATP and Zn^{2+} and for binding to the viral origin of DNA replication. The regions of T antigen required for ATPase activity, helicase activity, host range and helper function activity (*hr-hf*), as binding to $p105^{Rb}$/p107/p130 (indicated by *Rb*) and to p53 are shown. The DNA J domain functions like the J domain found in *Escherichia coli* DNA J/hsp40 molecular chaperone proteins and is involved in protein–protein interactions between T antigen and members of the $p105^{Rb}$ family. Also shown are the regions required for transformation of most rodent cell lines, for immortalization of primary mouse fibroblasts, for binding to DNA polymerase a, for induction of host DNA synthesis, and for transcriptional activation of the SV40 late promoter and many simple modular promoters by SV40 large T antigen. **B:** Mouse polyoma virus. Shown are the sequences that serve as nuclear localization signals (*NLS*) and sequences required for binding ATP and Zn^{2+} and for binding to the polyomavirus origin of DNA replication and to $p105^{Rb}$/p107/p130. Sites of phosphorylation are also shown. (**B** courtesy of Dr. Brian Schaffhausen, Tufts University Medical School, Boston, MA.)

The SV40 large T protein is modified posttranslationally in several ways. It contains two clusters of phosphorylation sites (285,343) (see Fig. 6) and is also modified by *O*-glycosylation (165,289), acylation (192), adenylation (30), poly(ADP)-ribosylation (137), and amino-terminal acetylation (237). Little is known about the functions of most of these modifications. However, phosphorylation is known to play a major role in controlling the activities and functions of the protein, and acylation often permits a modified protein to associate with cellular membranes. More than 95% of SV40 large T antigen is located in the nucleus, although a small percentage is found at the plasma membrane. Nuclear T antigen exists both free in the nucleoplasm and associated with chromatin and nuclear matrix (323). It is estimated that lytically infected cells contain between 5×10^5 and 5×10^6 molecules of large T antigen.

Detailed studies of the sequences of SV40 large T antigen required for nuclear localization led to the definition of amino acids 127 to 133 (KKKRKVD) as the first identified nuclear localization signal (170,200). Polyoma large T antigen contains two nuclear localization signals, one at a place analogous to the site of the SV40 nuclear localization signal, the other in a region without homology to SV40 T antigen (275). Phosphorylation sites are located near these nuclear localization signals and may be used to regulate the location of T antigen. For both polyoma and SV40, some of the

phosphorylation sites are substrates for cell cycle–dependent kinases or for isoforms of casein kinase I.

SV40 large T antigen is a DNA-binding protein that interacts specifically with several pentameric sequences (GAGGC) at the SV40 origin of DNA replication. It also binds, but with considerably lower affinity, to both single- and double-stranded DNA in a sequence-independent manner. The organization of these T-antigen–binding sites is shown in Figure 3. Binding of T antigen to site I permits T antigen to autoregulate production of SV40 early mRNAs (91,150,276). Binding at site II plays a central role in initiation of viral DNA replication. Binding site II is the preferred site for binding of SV40 large T antigen in the presence of physiologic levels of adenosine triphosphate (ATP) (27,80), which induces the formation of double hexamers of T antigen bound to site II (225). Individual pentanucleotides within site I are sufficient to direct hexamer formation, whereas certain pairs of these pentanucleotides can direct formation of T-antigen double hexamers (169). These double hexamers are fully able to initiate the structural changes that occur at the origin of replication after T-antigen binding. Because more pentanucleotides than two in site I are required, the others most likely play a role subsequent to the initial formation of double hexamers. In the presence of ATP, binding of polyoma T antigen to the polyoma regulatory region is also stimulated, and binding occurs over an extended portion of the origin (217). Some mutations of phosphorylation sites affect the DNA replication activities of T antigen, and this appears to affect interactions between T antigen hexamers critical for replication (373).

A second activity of large T antigen is DNA helicase activity (78,321). SV40 large T antigen can bind and hydrolyze ATP, and this activity is stimulated by single-stranded DNA (130,350). Helicase activity is crucial for viral DNA replication and requires functional ATPase activity and the ability to bind to SV40 DNA. *In vitro,* T antigen displays helicase activity with substrates lacking specific T-antigen–binding sites. T antigen also possesses RNA helicase activity (284), but the importance of this activity is unknown. There have also been reports that T antigen has (or is tightly associated with) topoisomerase I activity and that T antigen is able to promote strand reannealing and DNA looping (221,224,287). Formation of double hexamers stimulates the helicase activity of T antigen (308,309).

More recently, the N-termini of all known polyomavirus large T antigens have been noted to have sequence homology with the J domain of the DnaJ (Hsp40) family of molecular chaperones (181,261). The T-antigen J domain contains the Hsp70/DnaK family domain histidine-proline-aspartate (HPD) that is conserved within the J domain of all DnaJ homologs (358). T antigen retains its functions when its J domain is replaced by the J domain of two human J-domain proteins (40). *In vitro* studies indicate that this portion of T antigen can stimulate the ATPase activity of hsc70 and also enhance release of an unfolded polypeptide from hsc70 (317). Furthermore, this region has been shown to function as a molecular chaperone mediating phosphorylation of the T-antigen–associated proteins p107 and p130 (333). The domains of T antigen required for these enzymatic activities are shown in Figure 6.

Based on its primary sequence and structural modeling, the DNA-binding domain of large T antigen does not resemble a known DNA-binding domain, and this is confirmed in the solution structure of the DNA-binding domain of SV40 large T antigen, determined using nuclear magnetic resonance spectroscopy (218). Two nearby loops define a continuous surface of T antigen that is altered in the presence of added GAGGC-containing oligonucleotides, suggesting that this surface is the one that directly contacts DNA. The ATP-binding/ATPase domain of large T shows substantial similarity to many known ATP-binding and hydrolyzing proteins. Located between the DNA-binding domain and the ATP binding/ATPase domain is a zinc finger domain important for the overall structure and function of large T antigen (215). Attempts to crystallize T antigen have so far been unsuccessful, perhaps owing to heterogeneity resulting from nonuniform posttranslational modification. High-resolution electron microscopy, image processing, and three-dimensional reconstruction suggest that each T-antigen hexamer at the origin has a propeller-like shape organized around a central channel, similar to what has been seen in other DNA helicases (282).

T antigen forms complexes with several cellular proteins important for DNA replication, including at least two subunits of DNA polymerase a-primase and the single-stranded DNA-binding protein, replication protein A (RPA) (33,63,93,94,161,234,372). T antigen also binds DNA topoisomerase I, and this interaction serves to stimulate initiation of replication at the origin and to prevent the unwinding of nonorigin sites by T antigen (147,303,304 and 305,357).

Complexes are also formed between T antigen and several proteins important for regulation of cell growth. Through conserved sequences located between amino acids 102 and 115, T antigen interacts with the tumor suppressor protein, $p105^{Rb}$, as well as with related cellular proteins, p107 and p130 (82,97,106,149). A sequence very similar to T-antigen amino acids 102 to 115 is found in the adenovirus E1A and the human papillomavirus E7 proteins, which also interact with $p105^{Rb}$ and related proteins. In fact, the adenovirus E1A gene remains functional when its $p105^{Rb}$-binding domain is replaced with the $p105^{Rb}$-binding region of SV40 large T antigen (242). The Dna J domain, in conjunction with an intact $p105^{Rb}$-binding domain, has been shown to perturb p130 and p107 phosphorylation and to target p130 for rapid degradation (334). The mechanism of this effect is thought to require an association between the T-antigen J domain and mammalian hsc70, resulting in activation of the intrinsic ATPase activity associated with hsc70 and alteration of the folding of associated p107 or p130 (81). Small t antigen also contains the J domain and is also able to stimulate the ATPase activity of hsc70 (317).

The tumor suppressor protein p53 forms complexes with SV40 large T antigen (199,213) through portions of a large conformationally sensitive domain located in the carboxyl-terminal half of the protein (190,288,394). Although p53 also interacts with the JCV and BKV T antigens, it does not form complexes with the polyoma large T antigen, and this is one of the most important differences between SV40 and polyoma large T antigens. However, both SV40 (101) and polyoma large T-antigen (249) oncoproteins bind to members of the cap-binding protein (CBP) family of transcriptional adapter proteins (p300 and p400) that contain high histone acetyltransferase activity. The p300 protein, a transcriptional coactivator related to CREB, also binds to the adenovirus E1A protein (374,381), although T antigen and p300 appear to bind to distinct p300 isoforms (5). Furthermore, p300 can also bind directly to and modulate p53 (210), implying the existence of a complex transcriptional regulatory mechanism resulting from the tripartite interaction of large T antigen, p300, and p53.

Small t Antigen

The small t antigens of most polyomaviruses are cysteine-rich proteins of 172 to 195 amino acids (see Table 2) whose amino-terminal 82 amino acids are shared with large T antigen. For those polyomaviruses that encode middle T antigens, almost all of the sequence of small t antigen is contained within the middle T antigen of the same virus. Small t antigen is located in both the nucleus and the cytoplasm (104,398). Studies with mutants of SV40 and polyoma that contain deletions within the region of small t not shared with large T antigen indicate that small t antigen is dispensable for the lytic cycle of these viruses in cultured cells (301,322). SV40 small t antigen promotes G_1 phase progression and increases the efficiency of SV40 transformation of mammalian cells through activation of growth factor–stimulated signaling pathways. Small t antigens (and polyoma middle t antigen) associate with the catalytic (C) and structural (S) subunits of protein phosphatase 2A (PP2A) (255). This interaction displaces the B subunit of PP2A, resulting in inhibition of phosphatase activity (385). Inactivation of PP2A in turn results in the activation of the mitogen-activated protein kinase (314) and stress-activated protein kinase (371) pathways as well as pathways that use nuclear factor-kB (NF-kB), protein kinase C, and phosphatidylinositol-3 kinase (PI-3 kinase) (315). Small t-antigen expression has also been shown to be required to decrease p27 (KIP1) levels during cell cycle reentry of human diploid fibroblasts, perhaps explaining the requirement for small t in cell cycle activation of density-arrested human fibroblasts (263).

In some studies, SV40 small t antigen expressed from plasmids has been shown to be capable of activating transcription from the SV40 late and other viral promoters (23,216). However, when small t was expressed during a viral infection, transcriptional activation was not observed (264), making it uncertain whether small t antigens play a role in regulation of transcription. SV40 small t antigen has been reported to bind zinc ions through its cysteine clusters (361), but the function and importance of this interaction is uncertain because the small t antigens of the bovine and parakeet viruses contain only a single cysteine and would therefore be unable to bind zinc ions. Although the conserved cysteine appears to be required for PP2A binding, interaction with zinc is not required for binding PP2A (226).

There is evidence for yet another t antigen encoded in the SV40 genome, expressed from a third species of SV40 early mRNA that is spliced between nucleotides 4425 and 3679 (391). This alternatively spliced mRNA encodes a 17 kd small t antigen containing the first 131 amino acids of large T antigen and 4 amino acids encoded downstream of the splice junction in an alternate reading frame from that used to produce large T antigen. Whether a similar mRNA and small t antigen is produced by other polyomaviruses is not known.

Middle T Antigen

T antigens of medium size (middle T) are encoded by polyoma and closely related viruses, but not by SV40 or other primate polyomaviruses. The middle T protein is located primarily at the plasma membrane (164,297), where it associates with several cellular proteins important in the signal transduction pathways regulating growth. These include c-src, the cellular homolog of the transforming protein v-src of Rous sarcoma virus (66), and related src family kinase members. This association leads to the activation of the tyrosine kinase activity of c-src. Also complexed with middle T antigen and c-src is PI-3 kinase (4), which in turn leads to activation of the Ser/Thr kinase c-Akt, the cellular homolog of the viral oncogene v-Akt 2A (335). Shc, a two-protein complex that lies upstream of Ras in the signal transduction pathway (41,90) and the A and C subunits of protein phosphatase 2A (255,369), also form complexes with middle T antigen. PP2A binding appears to be required for middle T–src complex formation (134). Mutants of polyomavirus unable to produce middle T antigen are defective for replication, persistence, transformation, and tumor induction in mice (114).

Although formation of complexes with src family kinases and activation of PI-3 kinase signaling pathways are important events for cellular transformation, a role for middle T antigen during lytic infection is not known. Because polyoma large T antigen does not interact with p53, and because the interaction of SV40 large T with p53 is thought to be central to its ability to stimulate cellular S-phase entry and in turn create an optimal environment for viral DNA replication, an interesting possibility is that the polyoma middle T antigen–cellular protein interactions perform a related function for polyoma infection. In this view, middle T antigen plays the role of an activated growth factor receptor through its activation of src family members, PI-3 kinase, and other proteins that mediate signal transduction pathways leading to cell cycle progression and cell division.

Preparation for Viral DNA Replication and Modulation of Cellular Gene Expression

Soon after T antigen is detected within cells, the levels of many cellular enzymes increase (see Fig. 5), and this requires T antigen (reviewed in 351). This probably reflects the ability of T antigen to stimulate expression from a variety of viral and cellular promoters (131,145,274). Diverse mechanisms underlie the ability of T antigen to alter host cell gene expression. For example, when T antigen forms complexes with $p105^{Rb}$ and related proteins, other host cell proteins, including transcription factors of the E2F family, are released and can reach their promoter targets (6,7,48). Many genes involved in growth regulation and cell cycle progression, including *c-fos* and *c-myc*, contain E2F-binding sites.

The regulation of cellular genes is also affected by binding of p53 to T antigen because p53 is a transcription factor (9,184) with both activating (178,390) and repressing activities (132). Binding of p53 to DNA is inhibited by T antigen (10), abrogating the ability of p53 to stimulate gene expression. Among the targets of p53 transcriptional activation is *WAF1/CIP1,* a potent inhibitor of the cell cycle owing to its ability to block the kinase activity of some cyclin dependent kinase (CDK)–cyclin complexes. It is reasonable that *WAF1/CIP1* expression is reduced in the presence of T antigen because this stimulates cell cycle progression by permitting cyclin-dependent kinase–cyclin complexes to function (103,151,380).

Several studies indicate that T antigen can play the role of a TFIID-associated factor (TAF) in transcription initiation by all three RNA polymerases (73,74 and 75,393). T antigen forms a complex with TATA-box binding protein (TBP) and stabilizes the TBP–TFIIA complex on the promoter (74). Direct interactions also occur between T antigen and other cellular transcription factors. Some of these interactions activate, and others repress, transcription of various cellular

genes. T antigen also transactivates transcription by RNA polymerases I and III. Because TBP is involved in transcription by all RNA polymerases, the T antigen–TBP interaction may play a role in activation of multiple classes of genes. In addition, T antigen stimulates the phosphorylation of RNA polymerase I transcription factor, UBF, most likely by recruiting a kinase (392).

T antigen stimulates resting cells to enter the cell cycle and replicate their DNA and, by so doing, creates an optimal environment for viral DNA replication. Multiple distinct subregions of large T are independently able to stimulate cellular DNA replication and probably cooperate to provide maximal stimulation and to activate a broad spectrum of cellular genes (92,316,349). These regions are the Rb-binding domain, the DNA-binding domain, and sequences near the carboxyl terminus of large T (92). Polyoma middle T antigen was also able to stimulate cellular DNA replication. Mutants defective for binding to either SHC or PI-3 kinase were able to stimulate cellular replication, whereas a double mutant (Y250F/Y315F), unable to bind either, was not (245). In some cases, SV40 (226,263) and polyoma small t antigens (292) are required for the support of S-phase induction in concert with the respective T antigens, likely through their ability to stimulate growth factor–signaling pathways. However, in other cases, polyoma small t antigen alone can stimulate cell cycle progression, dependent on its ability to interact with PP2A (245). Because the middle T-antigen double mutant (Y250F/ Y315F) retains PP2A binding, yet cannot stimulate cellular DNA replication, middle T and small t appear to modulate cellular signaling differently when each binds PP2A.

Viral DNA Replication

Replication of viral DNA within infected cells requires a functional origin of DNA replication, large T antigen with its DNA binding and helicase activities intact, and most of cellular proteins involved in replicative DNA synthesis. Viral DNA is in the form of a minichromosome, and its replication occurs in the nucleus during S phase, like cellular DNA replication. By other parameters, including the enzymes used and the geometry of the replication fork, replication of SV40 and polyoma DNA is sufficiently similar to cellular DNA replication that the viral systems have been exploited as powerful tools to understand cellular DNA replication. Excellent *in vitro* systems have been developed (208,330,368,377) that permit accurate and efficient replication of viral DNA using 10 purified cellular proteins, viral DNA containing a functional origin, and purified large T antigen. Viral DNA replication differs from cellular DNA replication in that the SV40 DNA origin can fire multiple times during S phase, whereas cellular DNA replication is tightly controlled to prevent any region of the genome from being replicated more than once in a single cell cycle. This difference reflects the use of the cellular origin-recognition complex (ORC) at cellular origins. T antigen performs ORC's origin-recognition function and is not subject to the cellular mechanism that prevents additional rounds of DNA replication within one cell cycle.

Viral Origin of DNA Replication

The region of DNA required in cis for initiation of viral DNA replication (ORI) has been defined genetically for each of the polyomaviruses by the construction and analysis of detailed sets of deletion and point substitution mutations and by the analysis of evolutionary variants of these viruses, which carry deletions of sequences not required for replication (reviewed in 85 and 86). These studies indicate that both SV40 and polyoma contain a core of sequences absolutely required for viral DNA replication and that auxiliary sequences on either side of the core act to enhance initiation of DNA replication within the viral core (see Fig. 3). For SV40, the core origin of 64 base pairs extends from nucleotides 5209 to 29, whereas the auxiliary sequences extend from nucleotides 5164 to 5208 and 30 to 72.

The major difference between SV40 and polyoma in the organization of their ORI regions is that polyoma replication requires promoter and enhancer sequences on the late side of the ORI core, whereas SV40 replication does not. Critical sequences, shown in Figure 3, include the core, auxiliary sequences on the early side of ORI (aux-1), and enhancer sequences. Replication of DNA-containing polyoma sequences requires core and either aux-2a or aux-2b. The polyoma core covers 66 base pairs. Although quite different in sequence, the auxiliary sequences of polyoma can substitute for those of SV40, and the SV40 72–base pair enhancer can be used in place of the polyoma a and b enhancers. The SV40 21–base pair repeats, which play a role as auxiliary origin elements, cannot substitute for the polyoma enhancer elements. Replication of SV40 in monkey cells and polyomavirus in mouse cells absolutely requires the presence of the appropriate core and large T antigen (19). Interestingly, the SV40 core ORI contains start sites for early mRNA, whereas polyoma early mRNAs are initiated at sites that lie outside of the polyoma core ORI.

The features shared by all polyomaviridae ORI regions are an inverted repeat of 14 base pairs on the early gene side of ORI (see *PU/PY* in Fig. 3), a GC-rich palindrome of 23 to 34 base pairs in the center (see *ORE* in Fig. 3), and an AT sequence of 15 to 20 base pairs on the late side (see *TA* in Fig. 3). That all polyomavirus core origins contain these elements suggests that common structures play a role in binding proteins and in initiation of viral DNA replication. SV40, BKV, and JCV contain a second nearby palindrome of differing size, but it is not required for viral DNA replication and is absent from the polyoma genome.

Initiation of Viral DNA Replication

In the absence of ATP, T antigen binds as a tetramer to binding site II in the origin region and protects about 35 base pairs of DNA from DNAse (278). In the presence of ATP, T antigen undergoes a conformational shift, permitting the assembly of a bi-lobed double hexamer of T antigen at the origin of DNA replication (27,79,80,161,225). Although a single monomer of T antigen can bind to a GAGGC pentanucleotide (see *dark arrowheads* in Fig. 3), clearly not all 12 molecules of T antigen will be bound to a pentanucleotide in the assembled dodecamer–DNA structure. Some of the T antigen subunits can be thought of as playing an allosteric role, modifying the conformation of other subunits to permit proper binding and assembly of the double hexamer (29). Studies of T-antigen mutants indicate that each of the two hexamers interacts with the other. ATP hydrolysis is not required for the assembly of this structure on the DNA.

A variety of physical and chemical analyses indicate that the bound T-antigen double hexamer catalyzes the local unwinding of part of the early palindrome (see *PU/PY* in Fig. 3) and the distortion or untwisting of the TA element (27,299). Once this initial unwinding has occurred, T antigen no longer binds specifically to viral DNA because the ORI

region is no longer double stranded (3). T antigen then associates with RPA, a three-subunit single-stranded DNA-binding protein that keeps unwound regions single stranded, and this permits more extensive unwinding of the DNA using the helicase activity of T antigen (78,378). In its ability to unwind double-stranded DNA from an internal site, T antigen is unusual among DNA helicases (227,321).

The association of the viral ORI, the T-antigen double hexamer, and RPA, is referred to as the *preinitiation complex.* Recruitment of DNA polymerase a-primase into this complex converts it to an initiation complex. It is this step in viral DNA replication that defines the very limited host range for members of the *Polyomaviridae* family. SV40 DNA can be replicated in extracts prepared from murine cells if these are supplemented with DNA polymerase a-primase from monkey cells (247,320). Specific protein contacts form between T antigen, RPA, and DNA polymerase a-primase (62,93,94,121,307), and the nature of these interactions at the viral origin of replication limits productive complex formation with SV40 and polyomavirus T antigens to primate and murine DNA polymerase a-primases, respectively (290). Polymerase a-primase synthesizes short RNA primers, which it then extends into short DNA fragments (38,155,228).

Processive extension of DNA in eukaryotes requires three factors to coordinate their actions. First, DNA polymerase a-primase synthesizes the primed site. Then, replication factor C loads a proliferating cell nuclear antigen (PCNA) clamp onto the primer. Following this, DNA polymerase d assembles with PCNA for processive extension. These proteins each bind the primed site tightly and trade places in a highly coordinated fashion such that the primer terminus is never left free of protein. RPA, the single-stranded DNA-binding protein, forms a common touchpoint for each of these proteins, and they compete with one another for it. Thus, these protein exchanges are driven by competition-based protein switches in which two proteins vie for contact with RPA.

DNA Synthesis at the Replication Fork

After initiation, DNA synthesis moves bidirectionally away from the ORI. Replication fork movement is facilitated by the helicase activity of T antigen, which translocates along the DNA. The cellular replication factor C (RFC) binds the 3' end of elongating DNA strands, displaces polymerase a-primase, and coordinates the switch to DNA polymerase d. RFC, PCNA, and DNA polymerase d can each interact with RFA bound to the growing strand. Multiple subunits of RFC coordinate the assembly of the PCNA sliding clamp and then remain associated with the complex through an RFC–RPA interaction. DNA polymerase d interacts with this complex through its ability to bind to RPA and actually competes with RFC for RPA binding (388). RFC is displaced from the 3' end of the growing strand but remains associated with this complex, which synthesizes both the continuous leading strand (359,360) and the Okazaki fragments on the lagging strand (368). The actions of RNase H, a 5'to 3'; exonuclease (MFI), and DNA ligase I are required for removal of primers and ligation of Okazaki fragments, yielding covalently closed circular form I DNA (367).

Termination of Replication and Separation of Daughter Molecules

Replicative intermediates have been isolated by sucrose gradient centrifugation and analyzed biochemically, electrophoretically, and electron microscopically. Preparations of replicative intermediates are enriched in molecules that are almost completely replicated. Replication moves bidirectionally around the circular chromosome, with both replication forks advancing at about the same rate. These replication intermediates contain three DNA loops—two daughter loops and the unreplicated parental DNA. Molecules that are 85% to 95% complete are enriched in replicative intermediate pools, suggesting that separation of daughter molecules is a slow step in DNA replication (336,337,341). Topoisomerase II is required for this separation (384). There is no specific termination site for viral DNA replication. Deletion analysis indicates that termination can occur within any sequence located about 180 degrees from the origin.

Regulation of Viral DNA Replication by Phosphorylation

The activity of T antigen in viral DNA replication is regulated by phosphorylation of the protein. Both SV40 and polyoma large T antigens carry phosphorylation sites near their DNA-binding domains in the amino-terminal half of each protein. An underphosphorylated population of T antigen isolated from infected cells, or T antigen that is dephosphorylated enzymatically, is more active in DNA binding and viral DNA replication *in vitro* (240). Although phosphorylation of threonine-124 of SV40 T antigen is essential for unwinding of viral origin DNA and replication (239,373), dephosphorylation (240,365,366) or substitution (291) of adjacent serine residues enhances origin unwinding and replication. Interestingly, the phosphorylation site at threonine-124 is a substrate for the cyclin-dependent kinases (233), whereas protein phosphatase 2A is active in dephosphorylation of the nearby serines, whose phosphorylation inhibits viral DNA replication *in vitro* (286). This suggests that the replication activity of T antigen may be regulated during the cell cycle so that T is maximally active for replication during S phase and inactive for replication at earlier stages of the viral infection.

Viral Late Gene Expression

The onset of viral DNA replication brings about a shift in the pattern of viral transcription. The start sites for production of the viral early mRNAs shift to upstream positions (see *LE* in Fig. 3A), and there is a dramatic increase in transcription to produce the viral late mRNAs. Early after infection, late transcription is repressed owing to occupancy of the late promoter by a steroid receptor family heterodimer between RXRa and TRa1, a thyroid hormone receptor (376,400,401).

Infected cells contain up to 200,000 molecules of viral DNA, and more than half of this may be encapsidated into progeny virions. With 360 molecules of VP1 per virus particle, a minimum of 3.6×10^{8} molecules of VP1 must be produced. Assuming a normal loading of ribosomes on viral late mRNA and a normal rate of translation to produce VP1, each molecule of mRNA encoding VP1 could generate 5,000 to 10,000 molecules of VP1 in an infected cell. Thus, more than 30,000 molecules of message encoding VP1 are required. This is several hundred times greater than the abundance of viral early mRNA, making studies of the synthesis and structure of viral late mRNAs relatively easy.

Late transcription of SV40 and polyoma has been studied in the greatest detail. In both systems, two sets of late mRNAs

are produced, originally referred to as 16S and 19S late RNAs based on velocity sedimentation in sucrose gradients. The 16S late mRNAs are considerably more abundant than the 19S late mRNAs. These late mRNAs are all derived by transcription, which begins near the origin and extends around the opposite strand from that transcribed to produce the early mRNAs (see Fig. 2). The start sites for SV40 late mRNAs are heterogeneous and map to many positions (see Fig. 3A) between nucleotides 120 and 482, although the start at nucleotide 325 is the most abundant (128,129,270). All viral late 16S mRNAs contain a leader sequence spliced to a second exon that extends from nucleotide 1464 to a polyadenylation site at nucleotide 2674 (see Fig. 2A). All lack sequences between 527 and 1464. Thus, the 16S late mRNAs differ in the structure of their leader regions, with some containing an additional splice, and a rare group containing a duplication of sequences in the leader region. The 19S late mRNAs are also heterogeneous at both their 5' ends and in the structure of their leader regions. A minor class is unspliced. All of the others contain a leader spliced to sequences extending from nucleotide 558 to the same polyadenylation site used for 16S late mRNAs at nucleotide 2674. All SV40 late mRNAs are derived by processing of precursors that begin at heterogeneous initiation sites and extend most of the way around the viral genome.

Polyomavirus late transcription differs from SV40 in that most viral late pre-mRNAs are extremely large, resulting from transcription completely around the viral genome multiple times (1,206). The mRNAs produced from these giant transcripts contain a single copy of the coding region for late proteins spliced to multiple copies of the leader region by leader-to-leader splicing (172). As with SV40, the start sites for late transcription are heterogeneous (see Fig. 3B); they extend from nucleotides 5075 to 5170, with about 90% of them lying in the region from nucleotides 5077 to 5101 (69,70,110,355). The late promoters of SV40 and polyoma lack TATA boxes, which likely explains the heterogeneity of initiation sites for viral late transcription. Maximal rates of SV40 late transcription depend on sequences within the 21–base pair GC repeats as well as within the 72–base pair enhancers (180,230).

At least three mechanisms are involved in the production of high levels of the viral late mRNAs: amplification of templates for late transcription by viral DNA replication, relief of repression of the viral late promoter, and T-antigen–mediated activation of transcription from the viral late promoter. Studies with origin-defective viral DNA molecules indicate that genome amplification is not required for activation of the late promoter by large T antigen (31,179). The region of large T antigen involved in activation of the late promoter maps to the amino-terminal half of the protein (395). Transcriptional activation of the late promoter by T antigen requires sequences within the 72–base pair enhancer region, including a unique sequence element located at the junction of the two 72–base pair repeats (144). One factor able to bind to these sequences is TEF-1, which is able to form a complex with large T antigen (145,182). Interactions between T antigen and TBP likely also contribute to activation of the late promoter. One mechanism of T-antigen stimulation of transcription involves T antigen functioning as a TAF. In fact, T antigen can complement the ts defect in TAF_{250} in the ts13 cells (73), a baby hamster kidney with a cell cycle defect (340). As a TAF, T antigen acts to stabilize the complex between TBP and TFIIA (74). T antigen appears to be a promiscuous activator, enhancing transcription of both viral and cellular genes in multiple ways. The structure of replicated minichromosomes likely also plays a key role in activation of late transcription (339). Although transcription factors are thought to stimulate DNA replication, complex formation between T antigen and TBP (and perhaps also with other transcription factors) actually inhibits DNA replication *in vitro,* most likely by occupying a binding surface of T antigen required for viral DNA replication (159). SV40 T antigen also interacts with TAF_{110} (232). Overall, T antigen interacts with many cellular proteins as well as with DNA and possibly RNA. This suggests that competition for T-antigen binding can be used to regulate the course of infection.

Synthesis of Late Proteins and Assembly and Release of Progeny Virions

Within the cytoplasm of infected cells, viral 16S late mRNAs are translated to produce VP1, whereas viral 19S late mRNAs are translated to produce VP2 and VP3. Because the sequence of VP3 is contained entirely within that of VP2, VP3 could be derived from VP2 by proteolytic processing. However, deletion mutants lacking the initiation codon for VP2 still produce VP3, indicating that VP3 can be synthesized independently of synthesis of VP2 (59). Because all of the SV40 late mRNAs are polycistronic and contain open reading frames upstream from the capsid protein genes, leaky scanning permits synthesis of capsid proteins from these mRNAs. For some late mRNAs, the upstream ORF encodes the agnoprotein. Studies of translation of SV40 late mRNAs (294,295 and 296) have dramatically increased our understanding of how leaky scanning permits internal AUGs to function efficiently as initiation codons (194,195).

Virion proteins VP1, VP2 and VP3 are synthesized in the cytoplasm of infected cells and transported to the nucleus for assembly into virions. When all three capsid proteins are produced, all three enter the nucleus efficiently. Detailed studies of these proteins indicate that sequences near the amino terminus of VP1 and near the carboxyl termini of VP2 and VP3 are essential for this nuclear accumulation. Within the N-terminus of both SV40 and polyoma VP1 are nuclear localization signals (46,243,379). Sequences required for localization of VP2 and VP3 to the nucleus have also been identified. VP1 is able to cotransport VP2 or VP3, and VP2 or VP3 can cotransport VP1, indicating that these proteins may be imported as a complex as well as separately (13,84,112,163,177). Within the nucleus, these proteins are found in the same ratio as within the viral capsid (212).

Viral chromatin is not required for the assembly of capsids or capsid-like structures. Purified polyoma VP1 self-assembles into pentamers and capsid-like structures (126,280), whereas coexpression of polyoma or SV40 VP1, VP2, and VP3 in insect cells from baculovirus vectors results in the assembly of capsid-like structures containing all three capsid proteins in about the same relative ratio as is found in mature virions (112,283). Sequences within the regulatory region of SV40 have also been shown to facilitate encapsidation (72).

The precise mechanism of encapsidation in polyoma-infected cells remains uncertain. Available data are consistent with two possibilities. Empty capsids can be purified from infected cells and could be precursors to virions. Alternatively, capsomers may condense on viral chromatin to assemble a virus capsid (387). The 75S to 90S chromatin structures containing viral DNA are detected, as are 200S previrions and 240S virions. Although intracellular chromatin contains histone H1, virion chromatin does not, but the precise time or mechanism of removal of histone H1 is not known. Analysis of immunoprecipitates of insect cells expressing one or more polyomavirus capsid proteins indicates that cellular histones associate with capsid proteins and suggest that VP2 or VP3 may be the direct mediator of capsid

protein–histone interactions (112). Polyoma VP1 and SV40 VP2 and VP3 have been shown to bind to DNA in a sequence-independent manner (45,54). The importance of these interactions for virion assembly or stability is uncertain because capsid protein–histone interactions could serve the same roles in assembly or stability as would capsid protein–DNA interactions.

SV40 and other polyomaviruses do not encode a lysozyme that causes cell lysis. It was previously suggested that exit of SV40 virions from infected cells occurs when cells disintegrate or rupture as part of their dying. However, studies of virus-infected epithelial cells lines indicated that SV40 can be released from the cell surface, primarily from the apical surface of polarized epithelial cells and uniformly from the surface of nonpolarized epithelial cells (53). By electron microscopy, SV40 was seen in cytoplasmic smooth membrane vesicles, and release of SV40 was inhibited by monensin, an inhibitor of intracellular vesicular transport. How and where these vesicles form and the fraction of total infectious progeny released in this manner or by leakage from dying cells are not known.

The Host Range and Helper Function of SV40 Large T Antigens

Most monkey cell lines infected by human adenoviruses produce low yields of viral progeny, with the block to productive infection occurring very late in the adenovirus infection cycle (reviewed in 191 and 351). This block can be overcome by the extreme carboxyl terminus of SV40 large T antigen (58,262), which is unrelated to any portions of polyoma large T antigen. Mutants of SV40 whose T antigens lack a normal carboxyl terminus are defective in this helper function and also show a restricted growth range among different African green monkey kidney cell lines (60,61,222,259). Human adenoviruses and host range mutants of SV40 both grow well in some monkey kidney cells lines (e.g., Vero) and poorly in others (e.g., CV-1). This activity of large T antigen is referred to as the *host range and helper function* (hr/hf). It is a distinct and separable activity of large T because a VP1 fusion protein containing the normal carboxyl terminus of large T can provide hr/hf activity (353).

Mutants lacking the hr/hf domain of large T show defects that affect late gene expression. The levels of viral late mRNA and capsid protein are reduced to about one third of their normal levels, but virion production is reduced much more dramatically (319). Agnoprotein is not produced (187,319) because the 5' ends of late viral mRNAs in mutant-infected cells map to normally used minor sites downstream of the agnoprotein initiation codon (319). Provision of agnoprotein in trans permits hr/hf mutants to form plaques but does not increase late mRNA or VP1 production. This suggests that agnoprotein permits more efficient use of the capsid proteins available in mutant-infected cells. This is consistent with studies that suggested a role for the agnoprotein either in transport of VP1 to the nucleus or in assembly of progeny virions (12,43,273).

Evolutionary Variants and Defective Viral Genomes

As with most animal viruses, passage of polyomaviruses at high multiplicities of infection leads to the generation of defective viral genomes and the accumulation of those that have selective growth advantages. These evolutionary variants contain deletions, inversions, and rearrangements, and they often contain multiple origins of DNA replication (140,203). The only sequence retained by all defective viruses is the viral origin region, indicating that it is the only cis-acting sequence required for propagation of the origin-containing DNA. This has led to the development of many eukaryotic expression vectors containing an SV40 origin of replication. These molecules will replicate in monkey kidney cells that provide the SV40 T antigen constitutively (e.g., Cos cells) owing to the integration into the cellular genome of an origin-defective SV40 genome encoding wild-type T antigen.

Those variants with more than one origin replicate more efficiently than wild-type virus and become enriched. Defective viruses require the presence of wild-type virus for their propagation because they often contain no intact viral genes, but nondefective variants have been constructed that contain two functional origins (220). Virus stocks maintained by high multiplicity passage can become contaminated with these evolutionary variants, but this can be prevented by frequent reisolation of wild-type virus through plaque purification.

TRANSFORMATION AND IMMORTALIZATION BY SV40

The polyomaviruses are also known as small DNA tumor viruses. The ability of these viruses to transform established cell lines, to immortalize primary cell cultures, and to induce tumors in animals resulted in the widespread study of these viruses as a window into understanding the molecular basis of oncogenesis and growth regulation. Transformed cells grow readily into tumors when injected into syngeneic or immunocompromised hosts. Transgenic expression of polyomavirus antigens has provided a useful model for studying the development of cell type–specific tumors.

Early studies indicated that genetic information in the viral early region was necessary and sufficient for transformation (reviewed in 116 and 351). One of the first experiments performed after the development of Southern hybridization was an analysis of the patterns of integration of viral DNA in SV40 transformed cells. Although these studies demonstrated that there were no unique or preferred sites of integration in either the viral or host genomes, a functional viral early region were present in all transformed lines analyzed (28,185,281). For SV40, studies using tsA mutants readily demonstrated that T antigen was required for both the initiation and maintenance of the transformed state (35,223,342).

For polyoma, large T antigen is required for transformation (89,99,115), but subsequent studies indicated that T-antigen expression is needed only for initiation but not for the maintenance of the transformed state. The viral DNA in transformed cells is usually integrated to interrupt the early region, blocking continued expression of large T antigen but permitting continued synthesis of both small and middle T antigens (15,201). Studies of polyoma hrt mutants (18), which encode a wild-type large T antigen, demonstrated that other early region gene products besides large T antigen were required for transformation by polyomavirus (100,111). It is now known that a cyclic DNA encoding just middle T antigen is sufficient to transform established cell lines (265,356). The requirement for polyoma large T antigen to initiate transformation after viral infection may reflect modest amplification of the genome by replication. Subsequent integration of the viral DNA often interrupts the large T-antigen–coding region, thereby eliminating the replicative activities of

polyoma large T antigen while leaving the middle T-antigen–coding region intact. Levels of middle T antigen sufficient for transformation may be achieved by transfection, thus eliminating the need for large T antigen. In transformation, polyomavirus middle T antigen activity requires association with the plasma membrane. Here, interaction with many of the same cellular signal transduction proteins mediating growth factor receptor signaling leads to constitutive activation of the cell cycle. Although the interaction between middle T and pp60c-src cannot be essential because middle T antigen can transform cells that contain a disruption of the *c-src* gene, middle T continues to interact with other src family kinases and PI-3 kinase in cells lacking *c-src* (346).

Mutational analyses of transformation by SV40 large T antigen demonstrate that only the amino-terminal portion of large T (amino acids 1 to 121) is required to transform mouse C3H 10T1/2 cells, whereas sequences extending over much of large T antigen are required to transform REF-52 rat embryo fibroblasts and many other established rodent cell lines (318). Transformation by T antigen can be separated from its role in viral DNA replication (136,171) and does not require any of the activities involved in viral DNA replication (e.g., DNA binding, ATP binding, ATPase activity, helicase activity) or host range and helper function. SV40 mutants defective in transformation of REF-52 cells map to three regions of large T antigen: the amino terminus containing the conserved DNA J domain (amino acids 1 to 82), the domain that binds $p105^{Rb}$ and the associated proteins p107 and p130 (amino acids 102 to 114), and the p53/p300 binding domain of the carboxyl half (49,171,396). SV40 small t antigen is clearly required for transformation under many conditions (301,306), but sufficiently high levels of large T antigen (24), growth conditions of the infected cells (298), or contributions to transformation from the cellular genetic background probably account for the lack of a uniform requirement for small t antigen for transformation by SV40. Under circumstances in which SV40 small t antigen is required for transformation, mutants of small t defective for interaction with and inhibition of PP2A are defective for transformation, suggesting that this interaction is central to the effect of small t antigen on cellular growth properties (246).

The requirement for the SV40 large T antigen amino terminus in cellular transformation reflects its DNA J domain activity as a molecular chaperone whereby it disrupts DNA-binding complexes between Rb family proteins and E2F (389). Mutants that express only amino acids 83 to 708 are defective for transformation, as are several deletion, insertion, and point mutations within the first 82 amino acids. Mutants of SV40 that express a T antigen lacking residues 1 to 82 can be complemented for transformation by SV40 small t antigen (241), consistent with the small t-antigen J domain functioning as a molecular chaperone (317). Results of experiments using double knockout mouse embryo fibroblasty (MEFs) (p107–/– and p130–/–) have revealed that the J domain is dispensable for transformation of these cells. This implies that the J domain plays an essential role in SV40 transformation by inactivating p107 and p130 functions (81), even though these proteins do not appear to have tumor suppressor activity.

Binding of T antigen to $p105^{Rb}$, an important tumor suppressor gene product, and the related cellular proteins p107 and p130, contributes to the disruption of the function of these cellular proteins (389). A clue to the mechanism of $p105^{Rb}$ function in cellular growth control suppression is its interaction with the E2F family of transcription factors (6,47). E2F family members bind as heterodimers to sequence-specific sites present in the promoter-enhancer regions of genes known to have important roles in cellular growth control, including *c-myc* and *c-fos* (158). Different E2F family members are thought to associate with different $p105^{Rb}$-related proteins at unique points in the cell cycle (98,205). For example, in G_0 phase, hypophosphorylated $p105^{Rb}$ interacts with E2F, preventing E2F from interacting with target genes (47,157). By binding to the hypophosphorylated form of $p105^{Rb}$, T antigen causes the release of E2F, and this activates E2F-regulated genes, leading to cell cycle progression (48). The related proteins, p107 and p130, complex with different members of the E2F family. The p130 complexes are found predominantly at the G_0–G_1 phase border (56), whereas the p107 complexes are most abundant at the G_1–S phase boundary (98). The concomitant binding of T antigen to p107 and p130 and the amino terminal J domain perturbation of their phosphorylation state result in the release of free and active E2F. Subsequently, genes encoding proteins required for the initiation of DNA synthesis are activated by E2F-dependent mechanisms.

Yet another $p105^{Rb}$, p107, and p130 (“pocket proteins”) mechanism for cell cycle control was identified by the discovery that these proteins, in association with E2Fs, can bind to the cyclins and cdks. The association of pocket protein–E2F complexes with cyclin/cdks appears to be cell cycle regulated and specific for particular cyclin/cdks complexes (42,56,87,204,302). Expression of SV40 large T antigen inhibits the activation of cyclins by cdks, thereby interfering with multiples stages of cell cycle progression (193).

SV40 large T antigen also binds p300 and CBP (5,101) through a common region of T antigen that is required for binding to the tumor suppressor protein p53 (211). The coactivators p300 and CBP form a transcriptional activation complex and can function to promote histone acetylation; binding of p300 and CBP to T antigen disrupts p300-dependent growth control and is likely to contribute to T antigen–induced cell transformation (210). The viral oncoprotein E1A has been shown to repress the normal functions of p300 and CBP by both displacing them from transcriptional coactivating complexes and directly repressing their histone acetyltransferase activity (44). This repression, in turn, leads to p53 deacetylation, thereby disrupting p53 tumor suppressor activities. Whether SV40 large T antigen uses a similar mechanism for direct inhibition of p300 and CBP family histone acetyltransferase activity is not yet known; however, the ability of T antigen to bind directly to p53 (199) is yet another important mechanism through which SV40 can disrupt an important cellular growth checkpoint control protein.

Transgenic mice have been used to study SV40-induced oncogenesis in a broad range of tissues, including mammary gland, salivary gland, pancreas, prostate, liver, lung, kidney, intestine, brain, choroid plexus, lens of the eye, bone, smooth muscle, and cartilage (reviewed in 120). Interestingly, transgenic experiments have suggested that the p300- and p53-binding region may not be required for tumor cell formation in animals. For example, hepatic tumors can be induced by the N-terminal fragment of T antigen (amino acids 1 to 121) encoded by dl1137. This truncated protein retains the ability to bind and inhibit pRb function but cannot bind p53. Surprisingly, these tumors grow significantly faster than those induced by wild-type T antigen (20).

The ability to immortalize primary rodent cells is another property of the large T antigens of polyoma and SV40 that has also been studied in detail. Analysis of the domains of polyoma and SV40 large T antigens required for immortalization

have also been performed, but with conflicting results. Some studies demonstrated that the ability of SV40 large T antigen to bind p53 is required for immortalization of primary mouse cells (347,394), whereas others indicated that the amino-terminal 147 amino acids of large T can immortalize primary mouse or rat cells (312,313). Studies with a ts mutant of SV40 T antigen indicated, however, that T antigen is required continuously to maintain immortalization because cultures shifted to the nonpermissive temperature ceased proliferation (166).

Critical to evaluation of the immortalization potential of these viruses and their individual T antigens are the assays used to measure immortalization. If immortalization of primary cultures requires multiple genetic or epigenetic alterations (e.g., the formation of a complex between SV40 T antigen and p53), mutant viral T antigens may provide some or most of the required functions, and a single additional cellular mutation could result in the full spectrum of genetic changes leading to immortalization. In some assays, no attempts were made to distinguish between extension of normal lifespan, with eventual senescence, and true immortalization. In other assays, populations of cells still proliferating at a time when control cells had senesced were serially subcultured and considered to be immortal if the culture survived for several months. However, the probability is high that cellular mutations will occur that contribute to immortalization of cells expressing mutant T antigens, particularly if mutation of one cellular gene in one cell in the population is sufficient to cause its immortalization and eventual predominance in the culture.

There is solid evidence that mutation of p53 plays a central role in immortalization. Mutation of the p53 gene was seen in all spontaneously immortalized mouse embryo fibroblast cell lines examined (154). It is easy to see that mutation of p53 or its functional inactivation by complex formation with SV40 large T antigen could increase the frequency of cellular mutations because p53 loss of function is known to be associated with gene amplification and genomic instability (214,386). In fact, inactivation of p53 by complex formation with SV40 T antigen is likely to be at least partially responsible for the known genomic instability associated with expression of SV40 T antigen (268,328).

Careful analysis of immortalization by mutant SV40 large T antigens suggests that all three domains required for transformation (J domain, binding region for pRb family proteins, and binding region for p53) are required for immortalization of primary mouse embryo fibroblasts. Substantial lifespan extension was seen in cultures expressing mutant T antigens defective for the amino-terminal transformation function or unable to bind p105 ^{Rb}, but a minority of colonies expressing these mutant T antigens became immortalized after continued subculturing. In contrast, neither lifespan extension nor immortalization was achieved with mutants of T antigen unable to bind p53 and p300. Similar results were shown using amino-terminal (amino acids T1 to T147) or carboxyl-terminal (T251 to T708) fragments of large T antigen: these two regions of T antigen appear to function in the same way as in wild-type T antigen to extend cell lifespan, and together they cooperate to immortalize primary B6MEF cells (345). The fact that immortalization of human cells by SV40 is such an exceedingly rare event may reflect a differential requirement for telomerase activity in human versus rodent cell immortalization because recent evidence demonstrates that introduction of the telomerase catalytic subunit hTRT allows human cells expressing SV40 large T antigen to escape crisis and divide indefinitely (148,397).

Fewer studies have been performed to understand immortalization by polyoma large T antigen, which does not bind p53. An essential role in immortalization for the p105 ^{Rb}-binding activity of polyoma large T antigen has been demonstrated (113,202), and it is likely that additional activities are also required.

CHAPTER 64 Human Polyomavirus

Eugene O. Major

HISTORY

Isolation of the BK virus (BKV) and JC virus (JCV) human polyomaviruses was first described in companion articles in 1971 (61,122) using laboratory cultivation of BKV in African green monkey kidney cells and JCV in human fetal brain cells. BKV was derived from the urine of a renal allograft recipient, whereas JCV was derived from brain tissue of a Hodgkin's lymphoma patient with the demyelinating disease progressive multifocal leukoencephalopathy (PML). The viruses were named from the initials of these patients and later classified in the family of polyomaviruses based on viral particle size, icosahedral architecture (Fig. 1A), and genome structure of its DNA (see Chapter 63). Recently, the International Committee on Taxonomy of Viruses has recognized that viruses with these and similar characteristics form an independent virus family, *Polyomaviridae,* no longer using the previous larger family designation of *Papovaviridae,* which included the papillomaviruses. Although many genomic variants of both BKV and JCV have been reported since then, there have been no new human polyomaviruses isolated. Before its isolation from urine, BKV was not a suspected pathogen in renal transplant recipients. However, a virus was suspected in the etiology of PML as early as 1958. In the initial description of PML, inclusion bodies were seen in damaged oligodendrocytes as part of the pathology of demyelination (133). In 1969, electron micrographs from PML brain tissue showed a crystalline array of assembled viral particles in the nucleus of the infected oligodendrocyte that were structurally identical to polyoma virions (169), as represented in Figure 1B. Since that time, JCV has consistently been found in brain tissue as well as the cerebrospinal fluid (CSF) of PML patients, which has firmly established JCV as the etiologic agent of PML. Although routinely found in urine of renal allograft recipients and patients with other kidney diseases (10), BKV, as well as JCV, is also found in the urine of normal, healthy individuals. To date, there is no direct correlation between BKV infection and renal or other human diseases. However, BKV infection has been associated with hemorrhagic cystitis in bone marrow transplant recipients, ureteric stenosis in renal transplant recipients that could lead to kidney failure which BK himself demonstrated, and pulmonary infection.

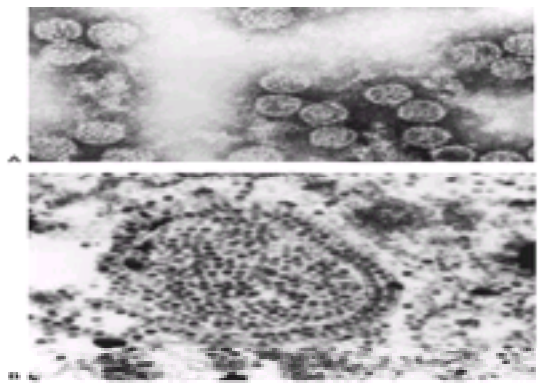

FIG. 1. Electron micrographs of human polyomaviruses. **A:** Negative stain of BK virus in the urine, concentrated by ultracentrifugation. **B:** Transmission electron micrograph of JC virus particles assembled in the nucleus of an infected oligodendrocyte from the brain of a patient with progressive multifocal leukoencephalopathy (×100,000).

Both viruses are associated with diseases affecting immune compromised hosts, suggesting that the human polyomaviruses remain latent in tissues that can be reactivated during times of immune suppression. Because of their presence in urine, BKV and JCV were thought to reside in the kidney as the site of latency (125). More recent work has implicated lymphoid tissues as well as a probable site for latent virus (80). Shortly after their isolation, these viruses were

found to agglutinate erythrocytes similar to the mouse polyomavirus but unlike the simian SV40. This observation helped develop a method to quantitate virus grown in cell cultures for use in seroepidemiologic studies. Such studies demonstrated that nearly 80% of the human population worldwide possessed antibodies to BKV and JCV. Antibodies arise early in life, at juvenile ages, to either or both viruses independently and remain elevated throughout life (65,131). It is still unknown whether the continual presence of antibodies to BKV and JCV results from new or reactivated infection or to what extent circulating antibodies neutralize infection. There is little understanding of the cellular immune response to either virus, mostly because of the immune-suppressed background of individuals in whom these viruses are mostly studied (46,165).

As members of the *Polyomaviridae* family, as shown in Table 1, both viruses were tested for their ability to induce transformation of cells in culture and tumors in experimental animal models. BKV and JCV were able to induce various histotypes of malignant tumors rapidly in rodents depending on route of administration (15). JCV was also shown to cause malignant brain tumors in New World monkeys after long incubation times following intracranial inoculation (102). Considering these results and because of the widespread nature of BKV and JCV infection in the population, there remains a concern about the possible role these viruses may have in initiating oncogenic events in human hosts.

Host	Virus	Characteristics
Human	BK virus (BKV)	Common infection of childhood; persists in kidney epithelium and possibly lymphocytes
	JC virus (JCV)	Common infection of childhood; persists in kidney epithelium, lymphocytes, and bone marrow; produces PML in immunocompromised hosts
Monkey*	Simian virus 40 (SV40)	Natural infection of macaques in Asia; persists in kidney; produces PML-like disease in immunocompromised macaques
	Simian agent 12 (SA 12)	Natural infection of baboons in Africa
	Lymphotropic papovavirus (LPV)	Virus of African green monkey; multiplies in B lymphoblasts
Cattle	Bovine polyoma virus (BPyV)	Common infection of cattle; probably persists in kidney
Rabbit	Rabbit kidney vacuolating virus (RKV)	Infection of cottontail rabbits
Mouse	Mouse polyoma virus	Natural infection of mice in wild; may infect laboratory mouse colonies; persists in kidney
	K virus	Natural infection of mice; infects lung endothelium
Hamster	Hamster papovavirus (HaPV)	Produces cutaneous tumors in hamsters
Athymic rat	Rat polyomavirus	Affects parotid gland
Parakeet	Budgerigar fledgling disease virus (BFDV)	Produces acute fatal illness in fledgling budgerigars

*A virus initially described as originating from squirrel monkeys was subsequently identified as bovine polyomavirus.
PML, progressive multifocal leukoencephalopathy.

TABLE 1. *Host of origin and characteristics of polyomavirus infections*

In the early investigations of BKV and JCV, it was clear that the host range of these viruses reflected the human tissues from their first isolation. BKV multiplies best in kidney epithelial cells of primate origin, whereas JCV multiplies best in glial cells derived from human brain. However, these cell types are not the only cells that support virus multiplication. The current list of cells susceptible to BKV or JCV infection now includes lymphocytes, stromal cells, and numerous cell lines (82). In the three decades since their isolation, experimental emphasis has been on understanding the cellular and molecular mechanisms that control viral host range. Such studies have helped clarify the pathogenesis of virus infection, particularly for JCV and PML, which may lead to the development of new diagnostic tests and therapies against polyomavirus infection.

INFECTIOUS AGENTS

Polyomaviruses are similar in physical virion particle structure and general genome organization. These properties have been discussed in more detail in Chapter 63 and thus are only briefly reviewed here. BKV and JCV particles are about 40 nm icosahedrons, containing a double-stranded, supercoiled DNA of about 5.13 kb. Three virion capsid proteins make up the particle, although the largest capsid protein, VP1, is responsible for virion structure and can self-assemble into icosahedral particles without either VP2 or VP3 (32). The viral genome is organized into coding sequences of about 2.4 kb, which are transcribed before DNA replication, termed *early,* from one strand initiating from the near the DNA replication origin; whereas the *late* coding sequences are transcribed after DNA replication begins from the opposite strand and in the opposite direction (Fig. 2). Both early and late coding regions give rise to multiple proteins from differential splicing events similar to SV40 (see Fig. 2). Early transcripts encode the viral large T and small t proteins, which function similar to the SV40 early proteins (see Chapter 63). There are also several minor transcripts made from the early region sequences that use alternate splicing sites at the carboxyl-terminal end, but no exact functions are known for these proteins (159). Table 2 lists the viral proteins for comparison and the length of their transcripts, mapped to the genomes for both BKV and JCV.

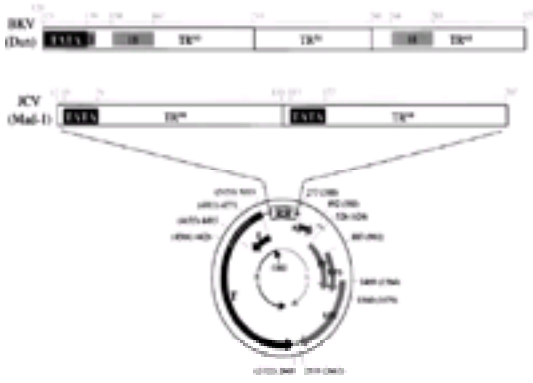

FIG. 2. Graphic representation of the genome organization of the prototype strains of JC virus Mad-1 (55) and BK virus Dunlop (138) human polyomaviruses. Expanded region depicts the regulatory region (*RR*) sequences. Nucleotide numbering has been adopted from references 55 and 138. *Open boxes* represent tandem repeat sequences (TR#) with inclusive base pair length designated by *superscript.* Tandem repeats may include *dark shaded* TATA *boxes* or *light shaded* sequence insertion *boxes* labeled by respective base pair lengths. In the circular genome, the origin of

replication (*ORI*) divides the coding sequences, represented by *broad arrows,* into two expression regions either on the early (*E*) or late (*L*) side of DNA replication. The T and t proteins are expressed E, and the Agno, VP1, VP2, and VP3 proteins are expressed L. *Dots* represent noncoding regions, which include the RR. Numbering of the nucleotides for the proteins surround the genome with JC virus and BK virus numbers in *parentheses*. (Courtesy of Peter Jensen, National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, MD.)

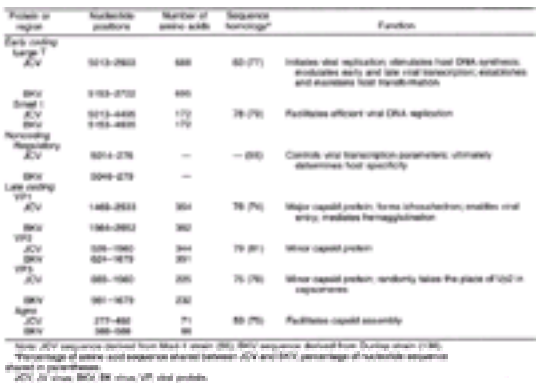

TABLE 2. *Genomic comparison of the human polyomaviruses*

There are, however, significant differences in the genomic organization of the noncoding nucleotide sequences between the human polyomaviruses and the simian polyomavirus, SV40. These sequences function as promoters and enhancers of mRNA transcription and DNA replication and, consequently, make up the regulatory region of the viral genome. Although all polyomaviruses possess noncoding nucleotide sequences located between the early and late coding regions of the viral genome, the arrangement of these sequences differs markedly not only among the primate polyomaviruses but also between BKV and JCV. The prototype strain of the human polyomavirus regulatory region sequences exists as direct tandem repeats, at times occurring in multiple copies as well as demonstrating rearrangements from deletions or insertions of additional regulatory elements. Such *cis* elements may be derived from another structure of the regulatory sequences found frequently in kidney and urine samples. Named the *archetype sequence,* these nucleotides are not arranged in repeats but contain all the elements found in a single repeat along with other sequences, which may function as promoters and enhancers. The regulatory region is widely believed to be the major factor determining host range; therefore, its molecular functions are described in more detail in the discussion of viral biologic properties and pathogenesis. Whether viral genomes with either tandem repeats or archetype arrangements of their regulatory region nucleotides are derived from each other or represent separate strains of BKV or JCV has yet to be firmly established.

Propagation and Assay in Cell Culture

The cell types used for the initial isolation of BKV and JCV have proved the most efficient cell substrates for viral propagation. BKV multiplies well in kidney epithelial cells of primate origin, although progeny virions can be made in human fetal brain cells and, to a lesser extent, in human fibroblasts and lymphocytes (52,128). However, the most productive BKV infection occurs in human embryonic kidney cells (HEK), with more than 70% of epithelial cells yielding virus. The kinetics of infection in HEK cells suggest synthesis of the T and t proteins within 24 hours of infection, but mature, infectious virions cannot be readily detected for several days. During the course of infection, there are marked cytopathic effects typical of polyomavirus infections with rounding of cells, which become translucent in phase microscopy, contain cytoplasmic vacuoles, and detach from cell monolayers in a stringlike appearance (Fig. 3A). BKV forms plaques on HEK monolayers within 2 to 3 weeks. However, HEK cultures do not contain uniform populations of epithelial cells nor are routinely available. Consequently, BKV plaques assays are not usually conducted (137). Because both BKV and JCV agglutinate human type O erythrocytes, hemagglutination remains the routine laboratory assay for quantifying virus.

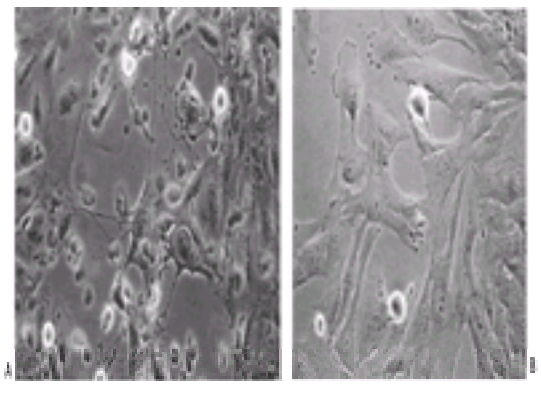

FIG. 3. Cytopathic effects due to polyomavirus lytic infection of susceptible cells in culture. **A:** BK virus infection in human embryonic kidney cells demonstrating cell swelling, pycnotic nuclei, and elongation of cytoplasm before cell lysis. **B:** JC virus infection in human fetal brain cultures, predominantly astrocytes, showing cell enlargement and shrinking of cytoplasmic processes in several cells.

JCV multiplication was originally described in human fetal brain cultures, which are a heterogeneous population of cells, including neural precursors as well as differentiated glial or neuronal cells. Cell type identification in these cultures is usually made through detection of cell type-specific, intermediate filament expression: glial fibrillary acidic protein for astrocytes, neurofilament for neurons, and nestin for progenitors. JCV grows well in astrocytes, which are the predominant cell type in these cultures, and in precursor cells of oligodendrocytes, originally described as spongioblasts, which are not highly represented in these cultures. Therefore, JCV infection occurs predominantly in the glial fibrillary acidic protein–positive cell (11,106) and does not infect neurons. Two glial cell lines established from human fetal brain support JCV multiplication: SVG cells, which were immortalized by insertion of the SV40 T-protein gene; and POJ cells, immortalized by insertion of the JCV T-protein gene (104,109). Although JCV T protein can be detected within 48 hours of infection, the growth of JCV in even highly susceptible cells derived from human fetal brain is slower than BKV. Progeny virions can be detected in several weeks. Typically, JCV T protein is made in about 70% of susceptible cells, but fewer cells actively replicate viral DNA, and even fewer appear able to synthesize capsid proteins and produce infectious progeny. New JCV virions assemble in the nucleus but remain tightly associated in the nucleoplasm, frequently requiring treatment of infected cell cultures with nonionic detergents, such as sodium deoxycholate, to release virus particles (123). Because virions remain in the cell during infection, there is little cell lysis and no easily recognizable cytopathic effects (see Fig. 3B). Because JCV is only gradually released from cells, there is no plaque assay because of the slow kinetics of viral multiplication. Cells that are susceptible to JCV infection do not remain viable for extended periods using agar overlays for plaque assays; 3 to 4 weeks is required for JCV release and cell-to-cell spread of virus. This observation is also true for the progression of the demyelinating plaque lesions seen in the brain in PML patients, which can take months to develop.

Although usually described as strictly neurotropic, JCV can infect many other cell types outside the human nervous system. Table 3 shows the diverse cells types that support JCV multiplication. Most notable are cells of the immune system, discussed under Pathogenesis and Pathology, and tonsillar stromal cells that make up the supporting cellular architecture of tonsil tissue and lymph nodes. JCV can also infect hematopoietic progenitor cells (114), human Schwann's cells (11), and cell lines established from human brain tumors of glial origin (3).

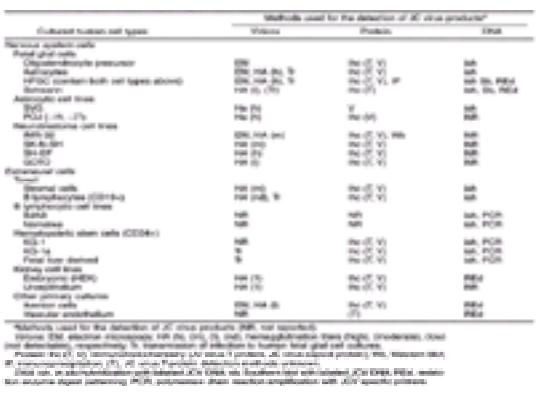

TABLE 3. *Cultured human cell types susceptible to infection with JC virus*

To follow the stages of infection in culture, antibodies to the viral T or capsid proteins are used in immunocytochemistry assays. Both polyclonal and monoclonal antibodies to BKV and JCV have been made, which are cross-reacting or specific to each of the human polyomaviruses (5,87,88,111).

Biologic Characteristics

Typically, DNA-containing viruses cause either permissive or nonpermissive infections, depending on the host cell. For the polyomaviruses, permissive infections occur in the host of origin (see Table 1), whereas nonpermissive infections occur in hosts not related to the species of origin. As described previously for BKV and JCV, cells that are permissive (i.e., all viral genes are expressed) are of primate or human origin. Restriction of viral growth in human cells is cell type specific, controlled at the transcriptional level. For example, virus may attach and enter into human fibroblasts, but early transcripts are not made. Restriction for viral growth in nonpermissive cells is at the level of DNA replication. Cells that allow early transcription of the T protein have DNA polymerases that do not interact with the T protein for initiation of viral DNA replication. Consequently, it is generally thought that cell type specificity is controlled at the transcriptional level, whereas species specificity is controlled at the replication level (50). The viral T proteins of the primate polyomaviruses may substitute for one another but not with the same efficiencies (24,37). This has been demonstrated by construction of hybrid proteins made among BKV, JCV, and SV40, whose T protein substitutes for BKV or JCV T proteins by binding the repeated penta nucleotides near the origin of DNA replication most effectively (30,56,103). Mechanisms of virion uncoating, entry into the nucleus, and assembly have not been studied in detail for the human polyomaviruses but are assumed to be similar to those for SV40. Permissive infection results in progeny virion formation. BKV infection has a higher yield of virus than JCV. Both viruses produce a minority of empty capsid particles along with viral DNA–encapsidated, infectious virions. Both full and empty capsid structures hemagglutinate human erythrocytes. The ratio of hemagglutin titer to infectious particles is about 10^{4} and that to total particles is about 10^{6}, based on plaque assay or TCID 50 doses combined with electron microscopy.

Nonpermissive infection in which only the viral T and t proteins are made commonly results in cell transformation, usually in rodent cells. For example, BKV can readily transform rat, mouse, and hamster fibroblasts, whereas JCV transforms hamster and rat fibroblasts as well as hamster brain cells, but with less efficiency than BKV (54,126,127). The transformed cells can induce tumors in the appropriate animal host and, if explanted, grow in culture and express T protein. Viral DNA is normally integrated in host DNA and can be rescued by polyethylene glycol–mediated fusion with

permissive cells after heterokaryon formation (15,27,35,41,68,107).

BKV and JCV can also initiate clastogenic events in infected cells, causing chromosomal changes during the course of infection. BKV induces high mutation rates in cell lines (155) and chromosomal damage in human fibroblasts expressing T protein (157). JCV-infected cells in culture demonstrate chromosomal abnormalities and damage resembling what is described as “rogue” cells in lymphocytes. Rogue cells show dramatic cytogenetic damage and, probably, do not undergo mitosis. Because of the widespread nature of human infection worldwide with human polyomaviruses and their ability to induce chromosomal damage in cultured cells, a serologic survey was conducted that linked individuals with high antibody titers to JCV, to a lesser extent to BKV, with the presence of such rogue cells (97,117). It is thought that JCV, or possibly BKV as well, may initiate “simple” chromosomal damage, translocations, and unstable multicentric chromosomes, which leads to further DNA damage and ultimately to complex chromosomal abnormalities and cell transformation or cell death (118).

Key Proteins

The human polyomaviruses share a high degree of nucleotide sequence and amino acid protein sequence homology with the primate polyomavirus SV40, as shown in Table 2. Generally, homology exists among all the viral proteins at the amino-terminal end, with divergence not only from SV40 but also between BKV and JCV toward the carboxyl-terminal ends of the proteins. The large T proteins are multifunctional in both lytic and transforming infections, which is required for initiating viral DNA replication (described in detail in Chapter 63) as well as augmenting late gene transcription, binding cell cycle–related proteins, and stimulating cellular gene expression. The small t protein may be dispensable for lytic infection but contributes to transforming infections to establish a fully transformed cell phenotype. The T protein binds the cellular p53 and retinoblastoma proteins in both lytic and transforming infections, which abrogates their cell cycle–regulatory functions. There is also evidence for BKV that inhibition of p53 and pRB protein functions up-regulates transcription factor E2F proteins, which contributes to the release of cells from control of cell cycle pathway or toward apoptosis (73). The JCV T protein also interacts with p53 and pRB cell cycle proteins, which has recently been described in PML brain tissue as well as cultured cells (7,49). JCV T protein may also directly or indirectly interact with cell cycle–dependent kinases, A1 and B1, which disrupts cell cycle movement and induces S-phase synthesis needed for viral multiplication (8).

The viral capsid proteins assemble into naked viral particles 40 nm in diameter according to thermodynamic parameters for icosahedrons. During assembly in lytic infection, replicated viral DNA in its supercoiled form, 5.13 kb, is encapsidated into the particle, which begins to form a crystalline array of virions visualized by electron microscopy. Nonviral DNA, fragmented cellular DNA, may also become encapsidated, which appears limited in size to 5 to 6 kb. The VP1 makes up the major structural protein, is used by the virus for cell attachment, and is the antigen that gives rise to antibody response. Recently, the VP1 of JCV (32,121) and BKV (57) have been cloned into baculovirus vectors and produced in high concentrations in insect cells. VP1 molecules can self-assemble into virus-like particles (VLPs), encapsidate any DNA of appropriate size, and transfer genes into cells in culture. VLPs can be used as a gene delivery vehicle for molecules with therapeutic value (66,121,142). VP1 molecules can also be used as antigens for hemagglutination inhibition or enzyme-liked immunosorbent assays (ELISAs) (71,162).

Infection in Experimental Animals

JCV and BKV infection in experimental animals and in transgenic mice engineered to express the T protein results in tumor formation. The frequency, tumor type, and experimental animal studies have recently been thoroughly reviewed (15). Briefly, BKV induces different types of tumors dependent on the rodent species and route of inoculation. Intracerebral inoculation in hamsters results in ependymomas, neuroblastomas, and pineal gland tumors. Intravenous inoculation causes pancreatic islet cell tumors, fibrosarcomas, and osteosarcomas. Mouse inoculations frequently result in fibrosarcomas, liposarcomas, nephroblastomas, gliomas, and choroid plexus tumors, which are also common in SV40 T-protein–expressing transgenic mice (120). BKV tumor induction shows some viral strain variation with the prototype isolate, BKV Gardner, possessing the greatest oncogenic potential. It is unclear whether trans- or cis-acting factors influence tumor formation frequency, but it is assumed that the regulatory sequence variations have a dominant role (160).

JCV inoculation into hamsters either intracerebrally or subcutaneously also results in multiple tumor types, including medulloblastomas, glioblastomas, and pineocytomas. As reported with BKV, the incidence of tumor formation with JCV showed some viral strain dependence (124). However, unlike BKV or SV40, JCV induces a grade 4 glioblastoma multiforme or malignant astrocytoma upon intracranial inoculation into New World owl and squirrel monkeys. JCV does not induce tumors in Old World macaques or rhesus or African green monkeys. The frequency of tumors is more than 50%, but the time for tumor formation is measured in months (18 to 36 months). Growth of the tumors can be detected by computed tomography (CT) scans and followed by observation of the monkey's abnormal behavior. These tumors progress rapidly, at times metastasizing within the parenchyma of the brain to the noninoculated hemisphere. Tumor cells can occupy nearly one third of the cerebral hemisphere before the animal dies within several months of initial detection of the tumor (79). The astrocytoma cells can be grown in culture, demonstrating the JCV T protein, which binds the monkey p53 protein. In some tumor explants, JCV T protein synthesis gradually diminishes. The cells then quickly enter a senescence period, assumed to be an apoptotic pathway, and die in culture. One owl monkey tumor, however, demonstrated unique properties not only surviving in culture but also in becoming transplantable back into other owl monkeys. JCV DNA in these tumor cells, termed *586,* was both integrated in the cell chromosome and episomal in high copy number. JCV infectious virus was produced continually in culture, resulting in a persistent viral or carrier culture (105). A neuroblastoma cell line has been established that also is a JCV carrier culture (5).

Transgenic mice have also been made that express the JCV T protein. However, it is rare that astrocytomas occur in these animals. There is a hypomyelination that results directly from T-protein disruption of compact myelin formation (143). The T protein affects myelin gene expression by interacting with transcription factors, MEF-1/pura, which may down-regulate myelin basic protein (MBP) synthesis (158). In transgenic mice made using the archetype regulatory region promoters, hypomyelination was not seen. These animals did exhibit primitive neuroectodermal tumors similar in

histology to medulloblastomas with high level of T-protein expression (94). Neural crest–derived tumors in other transgenic mice also showed efficient T-protein synthesis with binding to the p53 and pRB proteins and altered regulation of cyclin-dependent kinases suggesting a mechanism for tumor cell growth (93).

PATHOGENESIS AND PATHOLOGY

Cellular Pathways of Infection and Molecular Regulation of Viral Multiplication

Entry Into Host: Viral Receptors

The simian polyomavirus, SV40, binds the class I major histocompatibility complex (MHC) molecule, which acts to position the viral particle in caveolae for viral entry. However, the efficiency of SV40 infectivity does not completely correlate with the presence or distribution of the class I MHC receptor; consequently, other molecules may act as coreceptors. Antibodies to MHC I do not block human polyomavirus binding to cells, nor does SV40 compete for JCV binding to susceptible cells (100). Because both BKV and JCV agglutinate human type O erythrocytes, as does the mouse polyomavirus, viral attachment was thought to involve sialic acid–containing glycoproteins. In recent studies, treatment of cells with neuraminidase, protease, or phospholipase blocked JCV binding, but only neuraminidase effectively blocked infection. Further competition assays determined that JCV uses an a $_{2–6}$–linked sialic acid residue on glycoproteins for attachment on the cell membrane (101). Little is known about the BKV receptor, although there has been the suggestion that BKV may bind to phospholipids (141). As with many viruses, binding of virus to the cell does not always result in infectivity. There may be multiple binding sites for the polyomaviruses, but only specific molecules function for viral entry, resulting in infection, as suggested by the enzymatic blocking assays. Recently, pseudoreceptors for the mouse polyomavirus were described that selectively blocked binding of several viral strains in various organs, thereby determining spread of virus in the mouse (16). Table 4 lists the currently known cellular receptors for polyomaviruses.

Virus	Receptor	Number/cell	Size (kd)	Tropism	Notes
PyV	N-linked glycoprotein containing α (2–3) linked sialic acid	25,000	1.8×10^{-7} M	Broad	Mutations in VP1 alter sialic acid recognition and tissue tropism
SV40	MHC class 1 proteins, also a possible role for O-linked glycans	90,000	3.75×10^{-9} M	Broad	Only family member that does not interact with sialic acids
LPV	O-linked glycoprotein containing α (2–6) linked sialic acids	1,600	2.9×10^{-7} M	Restricted to B lymphocytes	Presence of a specific receptor correlates with susceptibility to infections
BKV	Glycolipid containing α (2–3) linked sialic acid	Unknown	Unknown	Broad	
JCV	N-linked glycoprotein containing α (2–6)	50,000	Unknown	Oligodendrocytes, astrocytes, and B lymphocytes	Does not share receptor specificity with SV40

PyV, polyomavirus; SV40, simian virus 40; LPV, lymphotropic papovavirus; BKV, BK virus; JCV, JC virus.

TABLE 4. *Polyomavirus receptors*

For the human polyomaviruses, virions are carried to the nucleus, presumably through an endocytotic pathway. Uncoating takes place at the nuclear membrane, although intact virus particles have been described in the nucleus directly after infection. Binding of cellular proteins on the viral regulatory region leads to early transcription and ultimately determines host range or viral tropism (see later).

Site of Primary Infection and Spread in the Host

The widespread nature of both BKV and JCV infection, which occurs at an early age in the human population, strongly suggests a common route for initial infection. Respiratory inhalation had been suggested as a common route of infection, but until recently, there was little evidence for the presence of either JCV or BKV in the respiratory tract. BKV has been reported in lung tissue from one case of interstitial pneumonia (136) in a hematopoietic stem cell transplant recipient; respiratory tract disease and infected tonsil tissue were reported in another case (67). Recently, however, JCV DNA has been identified consistently in human tonsil stromal cells, in the tonsillar tissue itself, and in the B-lymphocyte population contained in the tonsils (115). JCV is also able to infect tonsillar stromal cells productively in culture with an efficiency nearly comparable to human glial cells. BKV has not been shown to infect stromal cells in culture. Because both viruses are not stable under conditions that are consistent with oral ingestion of virus, inhalation of virus or a respiratory pathway for initial infection seems most likely. Whether BKV uses lymphoid tissue for initiation of infection needs further study, but JCV seems able to infect tonsil tissue.

The mechanisms of virus spread throughout the human host remains difficult to ascertain. Using polymerase chain reaction (PCR) analysis, JCV DNA is routinely found in the peripheral circulation in 5% to 40% of normal subjects as well as 70% to 85% of PML patients (164). JCV DNA is also found in a high percentage of patients with immune deficiencies such as allograft recipients treated with immune suppressive drugs, HIV-1 infection, and neoplastic diseases. In the blood, the B lymphocyte appears as the principal cell carrier of virus, but other blood-borne cells, including T cells, may also harbor virus (48). However, if cell tropism is associated with DNA-binding proteins, which function for transcription, only B cells allow viral multiplication (13, 134). There is evidence that BKV can also be found in the peripheral blood from surveys of normal, healthy individuals (R. Frisque, personal communication). Both BKV and JCV have been identified in multiple organs besides kidney and brain (JCV), including heart, spleen, lung, colon, and liver, suggesting a hematogenous route of virus spread (107, 164).

Cell and Tissue Tropism

An early observation of the biologic differences between BKV and JCV was their cell specificity or host range and tissue tropism. BKV could grow in monkey or human epithelial and fibroblast cells in culture with high efficiencies. JCV, on the other hand, was thought to be strictly neurotropic, growing only in glial cells derived from human fetal or adult brain with low viral yields. This pattern of cellular host range was similar whether infection was initiated with virion particles or viral DNA; both BKV and JCV genomic DNA are infectious on transfection into cultured cells (107). Consequently, this observation emphasized that control of host range was at the intracellular, molecular level, which led to investigations on the nature of the viral regulatory region and host factors that recognize these sequences.

Hypervariability of the regulatory region is a typical feature of polyomaviruses, particularly BKV and JCV, which demonstrate multiple arrangements depending on the tissue source of isolation. For example, virus found in the urine contains regulatory region nucleotides, which consistently demonstrate promoter and enhancer sequences in a linear series of 187 base pairs for JCV and 170 base pairs for BKV. JCV isolates from brain or tonsil tissue contain regulatory region variants but consistently demonstrate the promoter and enhancer elements in direct tandem repeats. The prototype strain of JCV, termed Mad-1, named for the location of its isolation Madison, Wisconsin, has direct tandem repeats of 98 nucleotides, including duplication of the TATA sequences. Many other variants of JCV regulatory sequences have been identified in brain, kidney, blood, tonsils, and other tissues that contain multiple forms of this arrangement (reviewed in 82). The linear arrangement found in the urine contains all the elements in the tandem repeat structures plus additional sequences of 23 and 66 base pairs. Figure 4 graphically demonstrates the nucleotide arrangements of these sequences. The linear arrangement of sequences from urine has been termed the *archetype structure* because deletion of the 23 and 66 base pairs and duplication of 25 base pairs, including the TATA sequences as well as 55 and 18 base pair segments, can result in the direct tandem repeats frequently found in tissues outside the kidney (55,167). There have been many isolates of JCV DNA whose regulatory sequences demonstrate variations on either the tandem repeat or archetype arrangement.

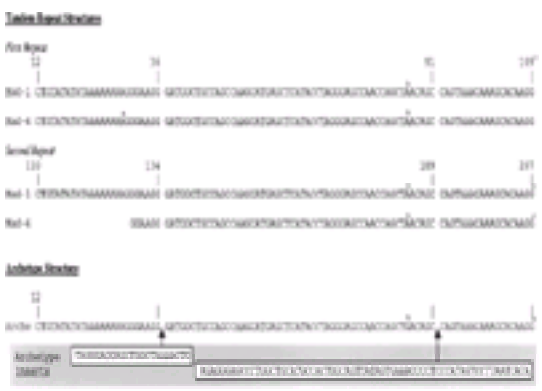

FIG. 4. Nucleotide sequence variations in the regulatory region of JC virus. **a:** This adenine may be deleted in Mad-4 strain. **b:** Variants that have sequence insertions after nucleotides 36 or 91 have a guanine (*G*) at this position. Variants without insertions have an adenine (*A*). **c:** End of the variable portion of the regulatory regions with conserved sequence following GGAAGTGGAAAGCAGCCAAG. . . . **d:** Nucleotide numbering was adopted from Mad-1 (55).

BKV demonstrates a similar phenomenon of archetype sequences found in the urine as well as other repeat structures identified in kidney and other tissues (110). The BKV archetype sequences are composed of blocks of nucleotides directly upstream of the origin of DNA replication and TATA sequences of 68, 39, and 63 nucleotides in length (135). Variations on these nucleotide segments or blocks are found in a number of BKV isolates, which may contain partial duplication of the 68 and 39 segments, the BKV DB strain, minor deletions from the archetype, the BKV AS strain, or triplication of the 68 block of nucleotides, the BKV WT strain (152).

Interestingly, neither BKV nor JCV with archetype regulatory region arrangements are able to grow in cell culture with any degree of efficiency, even though these strains are highly represented in nature. Although it has been suggested that the archetype strains of the human polyomaviruses may be the circulating strain in the human population from which variants are derived by rearrangement of the regulatory sequences, there is no direct evidence that this can occur either by cell culture passage or during the course of active infection in humans (43). It does appear that the archetype sequences cannot be transcribed effectively to produce the viral T protein, but if T protein is already present in the cells, replication of the archetype sequences can occur (72,145). The cell type–specific regulation of JCV, particularly, has been studied in detail because of its limited host range and pathogenicity in humans. Nucleotide sequences that act as transcriptional promoters are principally located in 45 base pairs just upstream from the origin of DNA replication. These sequences include the TATA box and binding sites for transcription factors Sp1, YB1, sup2, pura, NF-1 juxtaposed directly next to AP-1, or c-jun/c-fos (76,129). These sites are all duplicated in the tandem repeat arrangement of JCV, although repeat of the second TATA sequences are routinely not found as seen in the Mad-4 strain, which has greater biologic activity than the Mad-1 strain. The NF-1 proteins exist as a family of proteins expressed in almost all cells but in multiple classes. The NF-1 class D is highly expressed in human brain as well as other cells susceptible to JCV infection, such as stromal cells, and may contribute to the cell-specific regulation of JCV transcription (92,149). Interactions between YB1 and pura also provide cell-specific regulation (34). There is also an NF-kB binding site downstream from the T protein coding sequences that has been shown to be active for late transcription and possible positioning of other DNA-binding proteins, with T protein to initiate efficient transcription (59). Both JCV and BKV contain active AP-1 binding sites, which are necessary for efficient promoter activity (129).

Immune Response

Because of the amino acid homology among the polyomaviruses, many polyclonal or monoclonal antibodies made in rodents to the T or capsid proteins, particularly VP1, are cross-reacting (140). However, there are monoclonal antibodies to the T proteins that discriminate among SV40, BKV, and JCV, which react to epitopes that can be found in the carboxyl-terminal ends of these proteins where amino acid homology is less. Transgenic mice, however, which are tolerant to SV40 T-protein immunization, did make antibody to the amino-terminal end of the JCV T protein upon immunization with JC T protein (153,154). SV40 T-protein transgenic mice can also make antibody to the T protein upon immunization, with the SV40 T protein revealing both major and minor antigenic epitopes in the T-protein molecule. During tumor progression, hamsters develop high-affinity, anti-T antibodies that cross-react with the primate polyomaviruses. Astrocytoma-bearing monkeys develop anti-JCV T antibodies with low affinity and low titer, no doubt owing to the sequestered nature of the tumors in the brain. There are antigenic strain variants of BKV demonstrated by antibody responses raised in rabbits as well as antibodies in the human population (152). Although there are sequence variations in the JCV genome for the VP1 protein, there have not been antigenic strain variants defined as yet by immunologic assays.

BKV inoculation into rabbits also induces antibodies to its own double-stranded DNA as well as eucaryotic double-stranded and single-stranded DNA (131). An anti-DNA antibody response can also be elicited by inoculation with BKV double-stranded DNA, which causes infection.

EPIDEMIOLOGY

Serologic Studies and Amplification of Viral Genome Sequences

Age of Infection and Seroepidemiology

BKV and JCV cause widespread infections throughout the world based on seroepidemiologic studies and identification of viral DNA excreted in the urine. Serologic surveys of populations using hemagglutination inhibition assays for the detection of antibodies indicates that seroconversion takes place early in life, at 5 to 7 years of age (151). Antibodies to either virus remain throughout life but may fluctuate in titer. It is still unclear whether persistence of antibody is the result of reactivation or reinfection. Generally, antibody that is measured by hemagglutination inhibition is immunoglobulin G (IgG), although a number of reports identified an IgM response with onset of clinical symptoms of infection (51). IgM and IgA antibodies have been detected against BKV in bone marrow and renal transplant recipients (47). ELISAs have now been developed using either cloned VP1, viral peptides, or virion particles as antigen (58,71,168). Although there are exceptions, antibody titers show that individuals usually have high titers to one of the human polyomaviruses and low titers to the other. This is an interesting observation because there is such close homology between BKV and JCV in the amino acid sequence of the VP1 molecule against which these antibodies react. Table 5 lists titers of human sera tested for antibodies to BKV and JCV before and after absorption by the heterologous antigen either BKV or JCV. The titers to either virus do not markedly change after absorption with the heterologous virus (71). This observation indicates that antibody made during the course of human infection is selective to unique epitopes on BKV and JCV VP1 capsid proteins, with little or no cross-reaction between viruses. There do not appear to be cross-reacting antibodies to SV40 in human sera (108,146). Whether SV40 independently circulates in the human population as a result of its introduction in contaminated vaccines in the early 1950s or by other means remains a question of considerable concern and debate.

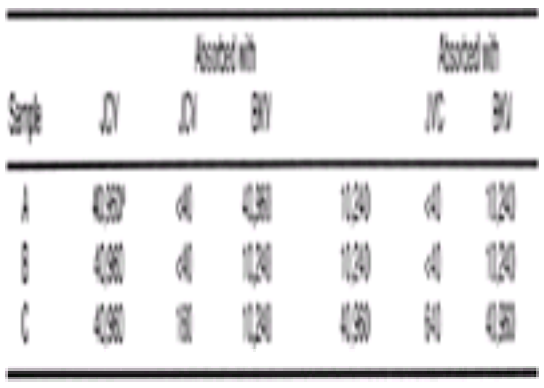

TABLE 5. *Human sera with high antibody titers to either JC virus (JCV) or BK virus (BKV) before and after absorption with either viral antigen*

Spread of Infection

Antibodies to both BKV and JCV are prevalent in populated countries but less prevalent in remote populations. In a recent study analyzing sera from Amerindian tribes from remote regions of South America, a low percentage of samples was positive, demonstrating low titers compared with a collection of Japanese samples of which most were positive with high antibody titers, particularly to JCV (108). It also seemed that introduction of the human polyomaviruses into the Amerindian population occurred at the time of human contact from other countries. However, how the human polyomaviruses are spread among individuals is not clear. Another study collected urine samples from young and older individuals in Japan who would have had contact with American military and their families. The samples were analyzed using PCR to identify JCV DNA and nucleotide sequencing, which ould “type” variants of the DNA; one type was specific to Japan, whereas others were prominent in the United States. The results suggested that none of the JCV DNA types found commonly in the American population were present in any age group in Japan, indicating that virus is not easily

transmitted between populations (84). Other data showed that JCV is readily transmitted from parent to child (95).

New Methods to Track Infection in World Populations

Because urinary excretion of the human polyomaviruses is common, a number of studies have tested urine by PCR for the prevalence of BKV and JCV. As mentioned previously, the nucleotide sequences that compose the regulatory region of both BKV and JCV found in the urine, termed the archetype, rarely contain variants nor tandem repeat sequences, unlike those sequences found frequently in other tissues. In addition to the regulatory region, JCV DNA VP1 sequences from urine samples have also been extensively analyzed. A system for classifying or typing JCV variants has been reported among some groups using nucleotide comparisons and construction of genetic linkages and a phylogenetic tree (83). Genotyping of the JCV VP1 sequences has allowed a geographic distinction of viral variants, particularly from Asia, North America, Europe, and Africa, which has been used to assess migration patterns of human populations of North America Indians (2). Regulatory region sequences have been used as a tool to estimate specific, intercontinental patterns of human population migration (69,148).

In comparison among BKV, JCV, and SV40, it appears that BKV is excreted more frequently than JCV in HIV-1–infected and severely immunosupressed individuals. However, in the population as a whole, JCV is excreted far more commonly—in 40% in the United States and as high as 75% in Japan. The prevalence for BKV is about 15% in the United States and only 2% to 5% in Japan. SV40 has not been found using PCR methods in the urine in the human population.

From the time that JCV was first recognized in lymphoid tissue, it was assumed that JCV or JCV DNA could be identified in the peripheral blood. Many studies have identified JCV DNA using PCR analysis. Reports have also documented BKV in the peripheral circulation, but not with the same frequency (14). There is no consensus yet on the precise percentage of the normal population with JCV in the blood at any time point, but it does appear as a relatively high number. It is clear that at least 5% to 40% of the human population, from predominantly American and European populations with no underlying disease, have JCV in their peripheral blood (48). In the blood, viral DNA is usually associated with lymphocytes, particularly B lymphocytes, with some reports of other cells in the blood or in the plasma (48). Viral mRNA has been reported in blood cells, including B and non-B cells, indicating that some level of infection can take place in these cells. JCV can infect human B lymphocytes as well as human CD34+ hematopoietic cells in culture, but neither T cells nor cells of monocyte origin (31,114).

CLINICAL FEATURES

JC Virus–Induced Demyelination in the Human Central Nervous System

Progressive Multifocal Leukoencephalopathy

PML is a demyelinating disease of immune compromised individuals caused by JCV lytic infection of oligodendrocytes, the myelin-producing cells in the white matter of the human brain. The demyelinated areas form multifocal plaque lesions, which contain enlarged, hyperchromatic oligodendrocytes, macrophages, and bizarre astrocytes, the characteristic features of the histopathology of PML (Fig. 5) described in 1958 (12). Clinically, PML patients demonstrate a typical triad of neurologic symptoms, including muscle weakness and gait disturbance leading to hemiparesis, cognitive abnormalities consistent with a subcortical dementia, and sensory and visual deficits (107). Lesions can be visualized using magnetic resonance imaging (MRI) or CT, most frequently in the cerebral hemispheres in the temporal, frontal, occipital, and parietal regions but also in the posterior fossa in the cerebellum and brain stem (107). Lesions are typically located at the gray matter–white matter junction in areas of highest cerebral blood flow, implicating virus entry by a hematogenous route. Perivascular infiltrates, usually T lymphocytes, have also been described in some PML lesions. In heavily infiltrated regions, few infected oligodendrocytes can be detected. In these lesions, class I MHC has been identified on bizarre astrocytes, whereas class II MHC has been found on macrophages, microglia, and endothelial cells (1). These observations suggest immune clearance of infected cells and JCV antigen presentation in the infected brain in some PML cases. There is a strong correlation between longer-term survival, defined as greater than 12 months, and the levels of CD4 and CD8 cells at the time of diagnosis (17). In these patients, there is also enhancement of lesions on CT scans, suggesting immune reactivity in the brain. Further, intrathecal antibody to JC VP1 protein has been detected in the CSF of PML patients, which again demonstrates both that B cells are present in the PML brain and that an immune response can take place in the brain (162).

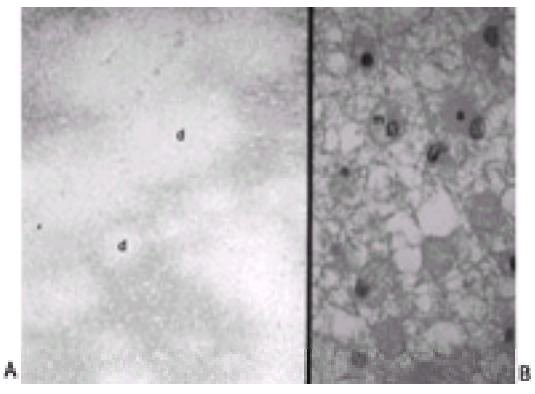

FIG. 5. Histopathology of demyelinated lesion from PML brain tissue. **A:** Luxol fast blue stain of white matter demonstrating demyelinated plaques. **B:** Presence of macrophages (*m*) and astrocytes (*a*) frequently associated with progressive multifocal leukoencephalopathy lesions.

PML can occur at any time during life, even in children (19), although it is usually found in adults with severe immunodeficiencies. Life expectancy ranges from several months to 1 year, depending on the severity of the immune-compromised state, as mentioned previously, and the viral burden in the brain (18). Until the mid-1980s, predisposing immune disorders in PML patients have been lymphoproliferative disorders, neoplastic diseases, granulomatous and inflammatory diseases like sarcoidosis, and allograft transplantation treated with immune-suppressive drugs for graft protection. PML has been recognized more frequently since the mid-1980s and recently in other cases of liver and heart transplantation, Wiskott-Aldrich syndrome in children, Alzheimer's disease, and systemic lupus erythematosus (85). However, the highest number of PML patients occurs in HIV-1–infected patients, reaching as high as 5% to 10% of all acquired immunodeficiency syndrome (AIDS) cases and accounting for nearly nearly 80% of all PML cases. PML has been the presenting AIDS-defining illness in 1% to 3% of HIV-1–infected individuals. Before the AIDS epidemic, PML was considered a rare disease in the United States, with only several hundred reported cases. With the advent of an increased population with severe immune deficiencies, particularly AIDS, the incidence of PML has risen dramatically not only in the United States but also throughout the world.

Pathogenesis

The increased incidence of PML in AIDS patients, particularly, has provided more clinical samples to study virus–cell interactions during the course of disease. Collectively, these cellular events define the stages or pathogenesis of JCV from initial infection, establishment of latency, reactivation, and targeting of glial cells in the brain causing demyelination. The ability of JCV to infect tonsillar stromal cells in culture and the presence of JCV DNA in tonsil tissue have suggested that initial infection can occur in this tissue. The widespread nature of JCV infection in the population also suggests a common route for spread of virus. Infection of tonsil tissue would be consistent with these observations. However, there are no data available as yet on the correlation between the presence of JCV DNA in tonsil tissues and development of antibody. The respiratory tract has also been considered as a potential site. However, there is little evidence for susceptibility of respiratory tract epithelial cells to JCV infection.

JCV causes a subacute or asymptomatic infection that is cleared by immune surveillance or, in some individuals, establishes a latent infection. There is no estimate on the number of individuals who harbor JCV in a latent state. Given the high frequency of urinary excretion of JCV in the population, however, viral latency probably occurs in most infected individuals. Consequently, the kidney has been considered a primary site for establishment of latency. JCV and its DNA have been identified in kidney, in uroepithelial cells, and routinely in urine (see previous discussion). JCV DNA has also been found in lymphoid tissues, such as bone marrow and spleen, particularly in PML patients (80). Viral DNA has also been identified in lymphocytes in the peripheral blood and in B cells isolated from tonsils and PML brain tissues (90,115). It is probable that JCV remains latent in several sites and reactivates at times of immune suppression. Whether JCV DNA integrates into the cellular DNA or remains episomal is not known; nor are there data on the mechanisms for reactivation, although it is assumed that depletion of cell-mediated immunity is a crucial step in release of virus from a latent state.

Because most PML patients have preexisting antibody to JCV, humoral immunity is not considered a factor in viral pathogenesis. It is assumed, however, that an intact cell and humoral immune response to JCV controls infection. Whether virus reactivates from kidney or from lymphoid tissues has been the focus of intense investigations. To address this question, viral nucleotide sequences have been examined from patients with or without PML or AIDS collected from multiple tissues, including kidney, urine, lymphocytes, tonsils, brain, and CSF. As mentioned previously, the regulatory sequences from kidney and urine, the archetype arrangement, do not contain repeats, whereas those sequences from PML brain tissue contain direct tandem repeats (see Fig. 4). Consequently, these sequences have been used as signatures or identifying sequences for tissue origin. One set of data suggests that JCV remains latent in kidney with the archetype arrangement of the regulatory sequences. Viral replication may lead to deletions and rearrangements, resulting in duplication of nucleotide sequences that resemble the tandem repeat arrangement in the brain or the PML type. Virus is carried to the brain through infected cells or through a viremia and initiates a highly productive infection in glial cells. Another set of data suggests that JCV, which resides in a latent state in lymphoid tissues (i.e., bone marrow) and has regulatory sequences in the tandem repeat arrangement and on activation from latency during episodes of immune suppression, is amplified during infection in lymphocytes, which carry the virus to the brain. Examination of the nucleotide sequences from all these tissue compartments provides support for both views. There are many examples of divergence from either principal sequence arrangement—archetype or tandem repeat. There is no clear correlation between strain of virus and the course of the disease or the pathology. There is no animal model as yet available to test this point. However, SV40 latent infection in macaques is associated with a demyelination that pathologically resembles PML (77).

JC Virus and Human Immunodeficiency Virus Type 1 in Acquired Immunodeficiency Syndrome

What mechanisms accounts for the high incidence of PML in AIDS patients is unknown. Whether there is a specific immune control of JCV latency that is deficient in AIDS patients or a direct interaction between the two viruses remains an open question. However, the observation that JCV DNA can be found in lymphocytes in the peripheral blood and brain of PML patients has provided a common host cell for direct interaction between JCV and HIV-1. The JCV T protein can transactivate the HIV-1 LTR in cotransfected cells (64). Conversely, the JCV late promoter is up-regulated through the HIV-1 tat-responsive DNA element in the JCV promoter termed upTAR (36,150). The HIV-1 tat protein complexes with the DNA-binding protein pura at this site (91). Although JCV production in co-infected cells in culture is highly efficient, there has not been identification of co-infected cells *in situ,* either in the brain of PML patients or in lymphocytes.

BK Virus Infection in the Kidney and Other Organs

BKV has been isolated or associated with a limited number of cases of retinitis, nephritis, pneumonia, and encephalitis (74,136,161). Viral DNA or virus was identified in these tissues, suggesting a possible etiological role in these diseases. BKV has also been linked with acute respiratory disease in children in whom an IgM antibody rise was measurable. Viral DNA was found in tonsil tissues in these patients using Southern blot hybridization (67). Virus could not be grown from

tonsil tissue, however, either from transfection of BKV-positive tonsil DNA or from cultivation with human embryonic kidney cells. BKV has been identified in lymphocytes, as mentioned previously, but not in a productive infection. There has been one report of the presence of receptors for BKV on B lymphocytes, which formed rosettes with human erythrocytes (98).

Kidney Infection and Cystitis

BKV has most consistently been identified in kidney diseases and cystitis in renal allograft and bone marrow transplant recipients (6). About 40% of renal allograft recipients shed BKV in the urine (9,10) either transiently or continually over weeks to months. BKV has been implicated in ureteric stenosis and circumstantially associated with kidney failure (25,62). Viral inclusions are present in uroepithelial cells excreted in the urine. Infectious virus can also be isolated from urine of renal or bone marrow transplant recipients. There has been a documented case of BKV transfer from the donor kidney to the recipient patient.

BK Virus in Bone Marrow Transplantation and Hemorrhagic Cystitis

Bone marrow transplant recipients undergo thorough immunosuppressive therapy before transplantation. These patients frequently demonstrate BKV viruria several weeks to several months after transplantation, which ends concurrently with the episodes of cystitis. The frequency of disease is higher in adult allogeneic transplant recipients than in autologous transplant recipients. Both groups have BKV in their peripheral circulation (21). The use of single primed or nested PCR techniques has greatly increased the sensitivity of assays designed to identify BKV in blood and urine of such patient populations. Because of the common occurrence of BKV in the urine in BMT patients compared with BMT patients with cystitis, it has been difficult to identify BKV directly as the cause of cystitis.

In a comprehensive study of children between 7 and 17 years of age followed for nearly 1 year, all the BMT patients who developed hemorrhagic cystitis had antibodies to BKV before transplantation, as did the marrow donors. However, there was a significant increase in hemagglutination inhibition antibodies and presence of IgM antibodies in cystitis patients compared with those with no signs of cystitis, indicating a new or reactivated infection. There was a correlation of the immune status to BKV of the donor and the risk for cystitis in the recipient. Donors of BMT patients without occurrence of cystitis had higher antibody levels compared with donors of BMT patients who did develop hemorrhagic cystitis (22). However, as in the adult patients, there was not a direct correlation between BKV infection and hemorrhagic cystitis.

Polyomaviruses and Human Neoplasia

SV40 in the Human Population

From the mid-1950s to 1963, the simian polyomavirus, SV40, was unknowingly introduced into a large number of individuals receiving contaminated poliovirus vaccines (139). Because SV40 is tumorigenic in rodents and can transform human cells in culture, there has been concern whether SV40 circulates in the human population and consequently is involved in neoplastic diseases. At this time, follow-up studies have concluded that there has not been an increase in neoplasias over three decades in the population that became infected with SV40 compared with matched age, gender, and geographic control populations not exposed to SV40 (140). However, there has been evidence that SV40 DNA and its T protein can be identified in rare human tumors, such as ependymomas, osteosarcomas, mesotheliomas, and choroid plexus papillomas (20,99). A more recent retrospective cohort study of data collected by programs designed to track tumor incidence in specific populations did not find an association between SV40 exposure and increased risk for these rare tumors (146). However, a number of investigations have identified authentic SV40 DNA sequences, T protein, and complexes with p53 and pRb cellular proteins in different human tumors (28,44).

In 1998, the U.S. Food and Drug Administration Office of Vaccine Research and Review convened a meeting of international authorities to discuss the topic of SV40 in the human population and the technical approaches needed to evaluate its presence as an infectious agent and role, if any, in human tumors. A report of this meeting has been published (26) that extensively reviews the available information. As a result of this conference, a study was initiated to standardize the methods for assessing the presence of SV40 in tumor tissues, particularly PCR analysis of tumor tissue, and means of determining antibody in humans to SV40. This study is ongoing.

BK Virus, JC Virus, and Human Tumors

The widespread use of gene amplification methods allows extremely sensitive levels of detection of viral genomes. Levels of detection are now in the range of 1 to 100 copies of viral DNA in 10^4 tumor cells. Consequently, PCR technology has reopened investigations focusing on identification of BKV and JCV DNA sequences in human tumors, particularly in those tumor types that these viruses are known to induce in experimental animals. The role of human polyomavirus infection in initiation of tumors has been thoroughly reviewed recently (15) and is briefly reviewed here.

BK Virus

BKV is highly oncogenic in rodents, as described previously, and can transform human cells in culture if gene expression is limited to the viral T protein. BKV T protein induces chromosomal aberrations, binds the products of tumor suppressor genes, and cooperates with the protein *c-ras* to induce a transformed phenotype (42,156). Many studies have now identified BKV DNA in human tumors, some in the same tumor as SV40 (45,119). Figure 6 shows detection of BKV T protein in a human glioblastoma cell line, which also demonstrates abnormal chromosomal numbers (156). Reports have identified BKV DNA in primary brain tumors, osteogenic sarcomas, and meningiomas. However, BKV DNA has also been described in normal brain, bone, and peripheral blood, so that it is difficult to draw conclusions on the importance of its presence in tumor tissues. However, some of these tumors do not show mutations in *p53* or *RB* genes, as would be expected, and consequently could be targets for BKV T-protein complexes to form, inactivating their normal role in cell cycle regulation. BKV DNA has recently been found in a study of 18 childhood neuroblastomas. Interestingly, p53 in

undifferentiated neuroblastomas becomes sequestered in the cytoplasm. In the tumors in which BKV DNA was found, T protein and p53 were colocalized in the cytoplasm as a complex (53). It is not likely that T-protein binding to p53 contributes to cytoplasmic sequestration because in other tumors, the protein complex does exist in the nucleus. This observation, however, adds to the evidence of possible functions of viral proteins in the phenotype of tumor cells.

P>*JC Virus*

Because JCV induces glial tumors in nonhuman primates, the major focus of interest in the oncogenic potential for JCV in humans has been the brain. There have been several reports of PML patients with multiple astrocytomas or oligodendroglioma along with evidence of anaplastic astrocytes (29,60). However, this occurrence is not common in PML, nor has there been evidence of JCV in these tumors or in bizarre or anaplastic astrocytes. Pathologic description of astrocytes in PML has suggested a preneoplastic morphology. The lack of viral capsid proteins in these cells is consistent with a transforming, not a lytic, infection. However, JCV replicating DNA has been described in JCV-infected astrocytes in PML, which would not be consistent with tumor formation and describe an abortive infection (4). Recently, an unusual oligoastrocytoma was described containing JCV DNA that expressed the T protein (132) and an xantoastrocytoma that contained JCV DNA by nested PCR detection (23). PML was not a consideration in either of these cases, nor was an immunodeficient condition.

Evidence for the presence of JCV DNA in malignancies beyond the nervous system now extends to leukemias and lymphomas (144) and surprisingly to human colon tumors (96). JCV DNA was found in high copy number in colorectal tumor tissue compared with normal, noninvolved colon tissue from the same patient. In leukemias and colon tumors, malignancies initiate by clastogenic events, chromosomal aberrations, and mutations in tumor suppressor genes, which then become inactivated. JCV infection has been associated with these cellular effects in culture and now in some tumor tissues.

DIAGNOSIS

Clinical Tissue Samples and Biopsy Specimens

JC Virus and Progressive Multifocal Leukoencephalopathy

Clinical history and neuroradiologic evidence of white matter lesions alone cannot confirm a diagnosis of PML. For example, white matter lesions identified in AIDS patients may be caused by HIV-1–associated encephalopathy and not JCV-induced demyelination. JCV DNA or antigen should be demonstrated in the patient in order to make an accurate diagnosis. Shortly after PML was described and JCV was isolated, viral protein was detected in biopsy tissue using antibody to the capsid protein, VP1. The initial antibody used was rabbit polyclonal made to SV40 VP1, which cross-reacts with JCV. Now there are monoclonal antibodies that are specific to each of the polyomaviruses.

As the incidence of PML increased because of AIDS, *in situ* DNA hybridization using probes specific to JCV DNA was frequently used because of its increased specificity and sensitivity. Positive hybridization signals also indicate viral DNA replication indicative of active infection. Use of biotin-labeled DNA probes helped identify not only infected oligodendrocytes but also astrocytes and B lymphocytes in biopsy and autopsy brain tissue (4,85,125). However, the need for brain biopsy complicated the decision whether to proceed for a definitive diagnosis, particularly in children.

Gene-amplification–based assays, usually PCR, have advanced quickly, so that detection of viral genomes in tissue samples is not only highly sensitive but also increasingly more specific. PCR detection of JCV DNA in brain tissue demonstrated that this technique could be reliable and can correlate directly with clinical disease. PCR for JCV DNA was then applied to CSF samples of PML patients, which demonstrated a high degree of correlation with biopsy results (38,75). Estimates of specificity are now in the range of 95% to 98%, and sensitivity rates are as high as 90% (163). Although false-positive results are rarely seen in this assay, false-negative results can occur in about 10% of PML cases. Many laboratories and clinical centers have adopted PCR detection of JCV DNA in CSF samples as the laboratory tool for a confirmation of PML in place of biopsy. Several recent studies have further shown that quantitative measurement of JCV DNA can also be used as a prognostic indicator of the progression of disease. Lower copy numbers or the absence of viral genomes predicts longer-term survival of PML patients (89,166). However, longitudinal studies of serial CSF samples collected from biopsy-confirmed PML patients demonstrated that a single sample may be negative, with viral DNA not detectable below 10 copies/mL, but another CSF sample collected 1 or 2 weeks later might be positive. This suggests that a single PCR-negative CSF sample in a patient in whom PML is strongly suspected warrants collection and

testing of another CSF.

BK Virus

BKV is most closely associated with kidney disease or cystitis in kidney transplant and bone marrow transplant recipients. BKV can be readily detected in urine by PCR methods; hence, viral isolation is not necessary. Viral DNA has also been detected by nucleic acid hybridization assays or viral protein using immunocytochemical techniques that demonstrate intracellular viral infection, predominantly in epithelial cells. It is not common practice to screen clinical samples for BKV at this time. Because the population in general already possess antibody titers to both BKV and JCV, serology has not been useful in assessing the importance of BKV in suspected infections.

TREATMENT

Progressive Multifocal Leukoencephalopathy

Treatment of PML patients has typically used nucleoside analogs in attempts to block JCV DNA replication. Cytarabine (cytosine arabinoside, or ARA-C) has been used most frequently but without consistent results. Several reports described remission of PML symptoms and brain lesions upon intrathecal administration of ARA-C. However, other patients treated with combined intravenous and intrathecal ARA-C did not show remarkable neurologic improvement, although in some cases there was a reduction of viral DNA in the CSF (112,116). With laboratory data showing that ARA-C could specifically block JCV DNA replication without toxicity to human glial cells (78), a multicenter phase II treatment trial of PML patients with AIDS was conducted. Sixty-four PML patients were enrolled in the trial based on brain biopsy examination. The trial was conducted by the AIDS Clinical Trial Group (ACTG 243 protocol) and the Neurology AIDS Research Consortium and represents the largest trial conducted for treatment of PML. ARA-C was administered either intravenously or intrathecally in randomized patients who also received antiretroviral drugs and were followed for several months using clinical improvement as the criterion for drug efficacy. When the trial was ended, there was no evidence of clinical improvement in patients receiving intrathecal or intravenous ARA-C compared with those receiving antiretroviral therapy alone (70). However, there was a reduction or loss of JCV DNA in the CSF in several patients treated with intrathecal ARA-C (166). Consequently, the combined experience of ARA-C in PML patients did not support its therapeutic effectiveness.

With the increased incidence of PML in AIDS patients, there has been the opportunity to evaluate the potential effect of high activity antiretroviral therapy (HAART), which was not available in the ACTG 243 trial. Several studies have now reported a correlation between HAART therapy and a number of parameters in PML patients, including increased survival time up to 1 to 2 years, improvement in clinical status, radiologic features, and, importantly, reduction of HIV-1 load in the blood (39,40,113). In some of these patients, there was also a clearance of JCV DNA in the CSF. These observations suggest that eliminating HIV-1 burden may reduce the multiplication and spread of JCV into the brain either by direct viral interactions or increase in immune reactivity to JCV. In many of these patients, there was a rise in CD4 T cells. However, there is neither cell culture data (78) nor clinical data to suggest that zidovudine (AZT) alone is effective against JCV replication or improvement in PML patients (63).

Several other drugs have been used in PML patients, including cidovofir, a drug mostly used against herpesvirus infections such as cytomegalovirus and interferon-a (81), which showed some evidence of effectiveness in delaying the clinical progression of disease. Cell culture experiments have identified topoisomerase inhibitors, camptothecin and topothecan, that block JCV DNA replication (86). JCV replication requires unwinding of genomic DNA for transcription and replication using topoisomerase, which makes this a target for drug treatment. However, there has been only sporadic use of these drugs in PML patients, with too few results to evaluate their effectiveness.

BK Virus

BKV is a common infection in renal allograft recipients, causing interstitial nephritis, and in bone marrow transplant recipients, associated with prolonged episodes of hemorrhagic cystitis. Both patient groups receive immunosuppressive drugs for graft protection, which may allow reactivation of latent BKV from the kidney. Active BKV infection in kidney transplant recipients at times mimics graft rejection, complicating the use of immune suppressive drugs. In a recent study, antirejection therapy led to an increase in graft loss in most patients, probably owing to increase in viral multiplication (130). Consequently, viral infection leading to interstitial nephritis and graft dysfunction may be sufficient reason to decrease immunosuppressive therapy and closely monitor acute rejection. Vidarabine (adenosine arabinoside, or ARA-A) has been tried in a BMT transplant recipient with a good response (33).

PERSPECTIVES

Since the publication of the last edition of this textbook, there has been intense interest in the human polyomaviruses, demonstrated by a four-fold increase in the rate of related publications. Investigators have contributed rapid advances to understanding the virology and pathogenesis of these agents. The growth of this field is due, in part, to refinements in medical and scientific technologies.

The use of gene amplification methods has allowed routine but highly sensitive detection of viral genomes in human tissues, such as urine, blood, and CSF. Identification and analysis of variant viral DNA sequences isolated by PCR are now being used to track the spread of virus between organs. These data have also aided in the diagnosis of PML as well as in the prognosis of disease severity and progression. New information has also led to reassessments of viral epidemiology on a global scale and even to studies of historical migration patterns of human populations. PCR-based studies have also indicated that both BKV and JCV circulate in the peripheral blood in a large proportion of the normal, healthy population worldwide. The implications of this observation on the public health, as numbers of immune-compromised individuals rise, requires further scrutiny.

Because of unique host range restrictions, viral promoter sequences are now used as tools for studies of cell-specific gene regulation, functional nucleotide rearrangements after replication, and molecular differentiation pathways shared between immune and nervous system cells. Capsid proteins of polyomaviruses, on the other hand, recently have been used to probe for cell receptors. Recombinantly produced capsid proteins promise to bring more readily available antigen for antibody screening and even to generate potential new vectors for gene delivery, employing the self-assembly properties of icosahedral virus-like particles that encapsidate nucleic acids.

In addition to the acute diseases associated with BKV and JCV, both viruses are now implicated in human neoplastic events. New data have now firmly established that these viruses induce chromosomal aberrations with either simple or extensive genetic damage, which could lead to mutations as a first step in oncogenesis. Mechanisms that account for this observation implicate the viral T proteins by interfering with cell cycle–regulatory proteins, p53, pRb, and other cyclins, which remove these proteins from their normal role in directing cells away from mitosis or toward apoptosis. Consequently, more studies are focused on the detection and consequences of the presence of BKV and JCV genomes in human tumor tissues.

Finally, with the ability to monitor these viruses in the population or in individual patients, more extensive clinical trials, particularly for PML, have started. In future studies, new drugs or alternative uses of other drugs, like HAART therapy in AIDS patients with PML, should emerge with potential for treatment. In conjunction with new therapies, hurdles associated with drug delivery must be overcome, particularly to target infected cells in the central nervous system.

Because of the ubiquitous presence of these viruses in the population and their potential for involvement with human diseases, a continued growth in interest and investigations on BKV and JCV is expected.

CHAPTER 65 Papillomaviruses and Their Replication

Peter M. Howley and Douglas R. Lowy

GENERAL DEFINITION AND PROPERTIES

The papillomaviruses are a group of small DNA viruses that induce warts (or papillomas) in a variety of higher vertebrates, including humans. Some papillomaviruses also have malignant potential for animals and people. A number of human papillomaviruses (HPVs) have been implicated as the etologic agents for cervical cancer and other epithelial tumors.

The viral nature of human warts was first indicated more than 90 years ago by Ciuffo, who demonstrated transmission of common warts using cell-free filtrates (48). The first papillomavirus was described in 1933 when Richard Shope recognized the cottontail rabbit papillomavirus (CRPV) as the etiologic agent responsible for cutaneous papillomatosis in the cottontail rabbit (269). This group of viruses remained refractory to standard virologic study for many years because tissue culture systems for the propagation of any of the papillomaviruses in the laboratory did not exist. It was not until the late 1970s, when the first papillomavirus genome was successfully cloned in bacteria, that investigators had reagents that were sufficiently standardized to begin a detailed analysis of the molecular biology of this group of viruses. In addition to standardizing reagents, the molecular cloning of the papillomavirus genomes provided adequate viral genetic material to permit the sequencing of the genomes of a number of papillomaviruses and to initiate a systematic mutational analysis and definition of the genes encoded by this group of viruses. The study of the papillomaviruses was spurred during the 1980s by the development of *in vitro* transformation assays that permitted the analysis of the viral functions involved in the induction of cellular proliferation. The bovine papillomavirus type 1 (BPV-1) initially served as the prototype for studies on various aspects of the molecular biology of the papillomaviruses; therefore, a major focus of this chapter will be on BPV-1. The recognition that specific HPVs are closely linked with cervical cancer, as well as other human tumors, has focused interest on the subgroup of HPVs that are associated with genital tract lesions. Consequently, information on the molecular biology of these HPVs will also be highlighted in this chapter.

CLASSIFICATION

Historically, the papillomaviruses were grouped together with the polyomaviruses to form the papovavirus family. The term papovavirus is derived from the first two letters of the virus first grouped together to form this family of viruses: rabbit papillomavirus, mouse polyomavirus, and simian vacuolating virus (SV40). The properties shared by these viruses include small size, a nonenveloped virion, an icosahedral capsid, a double-stranded circular DNA genome, and the nucleus as the site of viral DNA replication and virion assembly. The papillomavirus particles are about 55 nm in diameter, whereas those of polyomavirus and SV40 are slightly smaller, measuring about 45 nm. Based on this difference in size, the papovavirus family was initially divided into two genera: the polyomaviruses (which include polyomavirus and SV40) and the papillomaviruses. However, comparative molecular biologic studies made possible by the molecular cloning of papillomavirus genomes indicated there were fundamental differences in the genomic organization of the papillomaviruses and the polyomaviruses. Recognition of these differences, as well as others, has led to the papillomaviruses and polyomaviruses now being considered distinct virus families. The genomes of papillomaviruses are larger than are those of polyomaviruses (8,000 base pairs [bp] versus 5,000 bp). Papillomaviruses have more open reading frames (ORFs) than polyomaviruses and encode a different number of structural and nonstructural proteins. The genes of papillomaviruses are all transcribed from the same DNA strand, whereas some polyomavirus genes are transcribed from one strand but others are transcribed from the opposite strand. The two families can also be distinguished by the presence of conserved family-specific epitopes in their major capsid protein (139).

The papillomaviruses are widespread in nature and have been recognized primarily in higher vertebrates. Viruses have been characterized from humans, cattle, rabbits, horses, dogs, sheep, elk, deer, nonhuman primates, the harvest mouse, and the multimammate mouse (*Mastomys natalensis*). Papillomavirus antigens have been identified in a variety of other

mammals, including other nonhuman primates (290). Papillomaviruses have also been described in some avian species, namely the parrot and the chafinch. In general, the papillomaviruses are highly species specific, and there are no examples of a papillomavirus from one species causing a productive infection in a second species. Most papillomaviruses have a specific cellular tropism because squamous epithelial cells are associated with purely squamous epithelial proliferative lesions (warts, papillomas). The lesions can be cutaneous or can involve the mucosal squamous epithelium from the oral pharynx, the esophagus, or the genital tract. Expression of the productive functions necessary for virion replication appears to be limited to the terminally differentiating cells of the squamous epithelium.

There is a distinct group of papillomaviruses, found in ungulates, that induce benign fibropapillomas in which there is a proliferative dermal fibroblastic component in addition to the typical proliferative squamous epithelial component. The best studied papillomavirus of this group is BPV-1. Other papillomaviruses that also induce fibropapillomas include BPV-2, the European elk papillomavirus, the deer papillomavirus, and the reindeer papillomavirus. Interest in this subgroup of papillomaviruses stemmed initially from the fact that, in addition to their ability to induce fibropapillomas in their natural host, they have the ability to induce fibroblastic tumors in other species, such as hamsters (90). Members of this group of papillomaviruses can also readily transform a variety of rodent cells in culture. The capacity of BPV-1 to induce morphologic transformation of tissue culture cells was first demonstrated in the early 1960s (23,25,302). Quantitative transformation focus assays were developed for BPV-1 in the late 1970s, which provided a biologic assay to define and study the viral functions involved in the induction of cell proliferation (79). Although most studies have been carried out with BPV-1, it is notable that the European elk papillomavirus and the deer papillomavirus have also been demonstrated to have these transformation properties.

To date, more than 100 different human papillomaviruses have been characterized, and it is estimated that there may be many additional viral types that have not yet been described (64). Because serologic reagents are not generally available to distinguish each of the known HPV types, they are not referred to as serotypes. The classification of viral types is based on the species of origin and the extent and degree of relatedness of the viral genomes. Hence, the HPV types are often referred to as *genotypes.* For most animal species, only a single papillomavirus type has been described, but this is likely because extensive comparative studies have not yet been carried out for most animal species at a molecular level.

The papillomavirus DNA isolates from one species are classified according to their sequence homology. As noted previously, more than 100 HPV types are now recognized. The initial classification of a specific type was based on the extent of homology of the DNA genomes using liquid hybridization techniques under stringent reassociation conditions (51). Classification of types is now carried out by comparison of the nucleotide sequence of specific regions of the genome. Based on criteria adopted by the Papillomavirus Nomenclature Committee, the nucleotide sequences of the *E6, E7,* and *L1* ORFs of a new type should not exceed 90% of the corresponding sequences of the genomes of known HPV types (63). A closer relationship is considered a subtype or variant of the type with the highest degree of homology.

VIRION STRUCTURE

Papillomaviruses are small, nonenveloped, icosahedral DNA viruses that replicate in the nucleus of squamous epithelial cells. The papillomavirus particles have a sedimentation coefficient (S_{20},W) of 300. The papillomavirus particles are 52 to 55 nm in diameter (Fig. 1). The virion particles consist of a single molecule of double-stranded circular DNA about 8,000 bp in size, contained within a spherical protein coat, or capsid, composed of 72 capsomers. The virus particles have a density in cesium chloride of 1.34 g/mL (54). Fine structural analysis by cryoelectron microscopy on three-dimensional image reconstruction techniques have revealed that the viruses consist of 72 pentameric capsomers arranged on a T=7 surface lattice (10). Like the polyomavirus capsids, the capsomers exist in two states: one capable of making contact with six neighbors, as observed in the 60 hexavalent capsomers, and the other with 5 neighbors in the 12 pentavalent capsomers (Fig. 2).

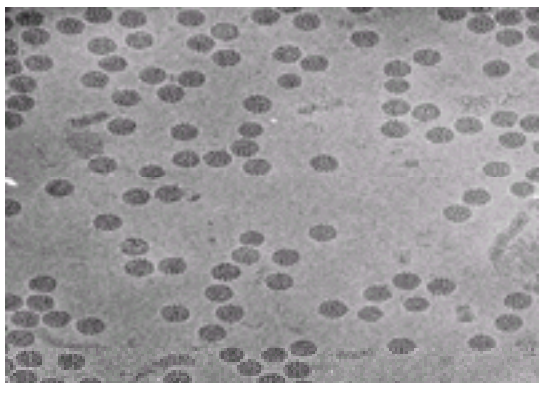

FIG. 1. Electron micrograph of BPV-1 virion particles (55 nm in diameter). (From ref. 10, with permission.)

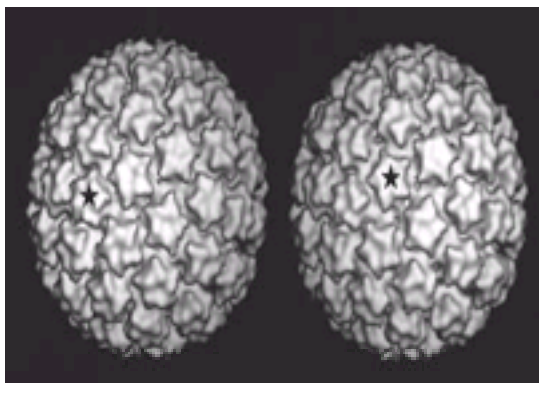

FIG. 2. Surface-shaded displays of papillomavirus three-dimensional image reconstructions of a cryoelectron microscopic analysis of virion particle structures. The individual capsomers exist in either a pentavalent (*starred on left*) or hexavalent (*starred on right*) state. (From ref. 10, with permission.)

The capsid consists of two structural proteins. The major capsid protein (L1) is about 55 kd in size (86,100,222) and represents about 80% of the total viral protein. A minor protein (L2) has a molecular size of about 70 kd. Both of these proteins are virally encoded. In addition, analysis of proteins in the virus particle has shown that the viral DNA is associated with cellular histones to form a chromatin-like complex (86,222). Virus-like particles (VLPs) can be produced from different papillomaviruses by expressing L1 alone or the combination of L1 and L2 using mammalian or nonmammalian expression systems (108,150,243,339). Although not required for assembly, L2 is incorporated into VLPs when coexpressed with L1. The morphology of VLPs containing only L1 appears identical to intact virus particles by cryoelectron microscopy (107). L2 plays a role in the selective encapsidation of papillomavirus DNA in viral capsids and therefore increases the infectivity of papillomavirus virions (338). It colocalizes with the viral E2 transcription and replication factor in PML oncogenic domains (PODs) within the nucleus (60), where it probably fosters virion assembly and perhaps antagonizes some of the activities of E2 (118).

Full papillomavirus particles contain a double-stranded circular DNA viral genome of about 8,000 bp. The guanosine cytosine content of most papillomavirus genomes is about 42%. The DNA constitutes about 12% of the virion by weight, accounting for the density in cesium chloride of about 1.34 g/mL (54).

GENOME STRUCTURE AND ORGANIZATION

The genomes of many of the animal papillomaviruses and human papillomaviruses have been sequenced in their entirety. The genomic organization of each of the papillomaviruses is remarkably similar. The genomic map of BPV-1 DNA is shown in Figure 3. One characteristic of the genomic organization of all of the other papillomaviruses is that all of the ORFs are located on one strand of the viral DNA, indicating that all of the viral genes are located on one strand. Transcriptional studies of the RNAs encoded by the papillomaviruses indicate that only one strand serves as a template for transcription.

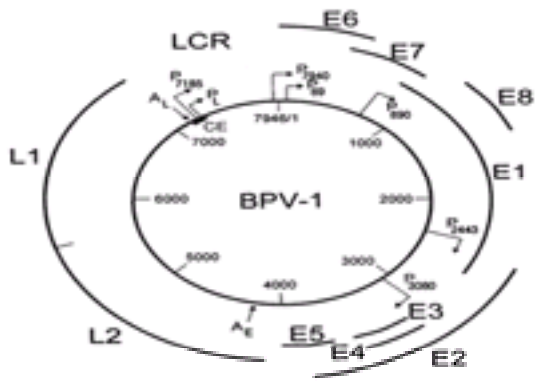

FIG. 3. BPV-1 genomic map. The numbers inside the circle indicate the nucleotide positions. The individual open reading frames of the early (*E*) and late (*L*) regions are depicted as areas outside the double-stranded circular genome. Only one strand is transcribed, and transcription occurs in the clockwise direction. Early promoters are indicated by an arrow labeled P_n, where *n* is the approximate nucleotide position of the RNA initiation site. P_L is the late promoter whose initiation sites map between nucleotides 7214 and 7256. *LCR* designates the long control region, which contains the origin of DNA replication (nucleotides 7911 to 22) (310,328) and the constitutive (*CE*) transcriptional enhancer (nucleotides 7162 to 7275) (312). The early (A_E) and late (A_L) poly(A) sites are located at nucleotides 4203 and 7175, respectively.

The coding strand for each of the papillomaviruses contains about 10 designated translational ORFs that are classified as either early (E) or late (L) ORFs, based on their location in the genome. The early ORFs of the BPV-1 genome are located within the fragment of the BPV-1 genome, which was sufficient for inducing cellular transformation (177). The early region of the viral genome is expressed in nonproductively infected cells and in transformed cells (117). The early region of the papillomavirus genomes encodes viral regulatory proteins, including those viral proteins that are necessary for initiating viral DNA replication. The *L1* and *L2* ORFs encode the viral capsid proteins and are expressed only in productively infected cells (9). The position, size, and function of many of the ORFs are well conserved among the various papillomaviruses that have been sequenced and studied in detail thus far (7,37). The individual ORFs whose functions have been well characterized are described in more detail in the appropriate sections of this chapter.

There is a region in each of the papillomavirus genomes in which there are no ORFs. The region varies slightly in size among the different papillomavirus genomes; in the BPV-1 genome, it is about 1 kb in size. This region has been referred to by several terms, including the *long control region* (LCR), the *upstream regulatory region*, and the *noncoding region.*

VIRUS REPLICATION

As noted earlier, the papillomaviruses are highly species specific, induce squamous epithelial tumors and fibroepithelial

tumors in their natural hosts, and have a specific tropism for squamous epithelial cells. The productive infection of cells by the papillomaviruses can be divided into early and late stages. These stages are linked to the differentiation state of the epithelial cell. Histologically, the lesions induced by papillomaviruses share a number of features. For papillomavirus infections of cutaneous (keratinized) epithelia, there is thickening of the epidermis (acanthosis), usually with some degree of papillomatosis. Keratohyalin granules are often prominent in the granular layer of a keratinized epithelium, and occasionally, basophilic intranuclear inclusions can be detected in the cells of the upper layer of the epidermis. These histologic features reflect the biologic properties of the papillomaviruses; most likely, these morphologic changes are induced by specific viral gene products. The specific tropism of the papillomaviruses for squamous epithelial cells is evidenced by the restriction of the viral replication functions, such as vegetative viral DNA synthesis, the production of viral capsid proteins, and the assembly of virions, to keratinocytes in the process of terminal differentiation. The close link of the papillomavirus life cycle with the differentiation program of the squamous epithelium is depicted in Figure 4.

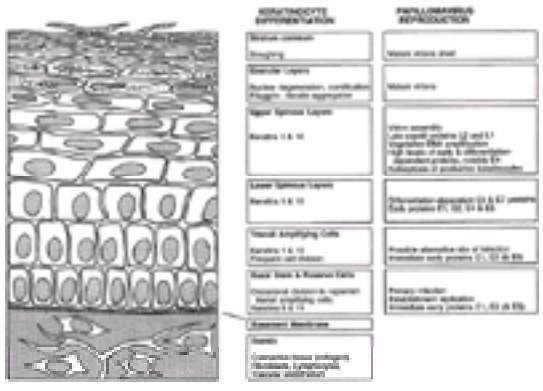

FIG. 4. Differentiation of normal cutaneous squamous epithelium and papillomaviral activities in productively infected benign lesions. The various epithelial strata and the host-differentiation, stage-specific, gene-expression profile are indicated in the *left* and *center* panels. In nonkeratinized squamous epithelia such as cervical or laryngeal, keratins 4 and 13 are expressed in the place of keratins 1 and 10 in the differentiated cells. Although profilaggrin is expressed, there is no granular layer or stratum corneum in nonkeratinized squamous epithelia. The viral activities in the corresponding strata during productive infection shown on the *right* have been determined or inferred from *in situ* hybridization studies. (From ref. 46, with permission.)

Because the basal cell is the only cell in the squamous epithelium capable of dividing, the virus must infect the basal cell to induce a lesion that can persist. By *in situ* hybridization, it has been demonstrated that the viral DNA is indeed present within the basal cells and the parabasal cells of a papilloma (263). Furthermore, using probes to the early gene regions of the papillomaviruses, viral transcripts have been detected in the basal cells of the epidermis (283), and at least some early viral protein is found in basal cells (33).

Late gene expression, synthesis of capsid proteins, vegetative viral DNA synthesis, and assembly of virions occur only in terminally differentiating squamous epithelial cells. The link of viral DNA replication to the state of differentiation of the squamous epithelial cell is illustrated in Figure 5B, which shows an *in situ* hybridization of a BPV-1–induced fibropapilloma. Using a BPV-1 DNA probe, which can hybridize to denatured viral DNA, positive hybridization can readily be detected in the nuclei of cells in the middle and upper layers of the squamous epithelium, but not within the cells of the lower portion of the epithelium or within the fibroblasts in the dermis. This represents a relatively short exposure and is only sensitive enough to detect viral DNA in those cells in which there has been significant amplification of the viral DNA (i.e., vegetative viral DNA replication). Thus, vegetative viral DNA synthesis occurs only in differentiating keratinocytes and is therefore linked to the differentiation program of the squamous epithelial cell. The regulation of expression of the genes encoding the capsid protein is at the level of RNA, as demonstrated in the *in situ* hybridization analysis depicted in Figure 5C, in which a probe complementary to the late viral mRNAs localizes the transcripts to the more terminally differentiated keratinocytes within the wart. Conversely, the major capsid protein (L1) can only be detected in the more superficial cells of the wart (139). The replication cycle for the papillomavirus is depicted in Figure 6 and is discussed in detail below in the appropriate sections.

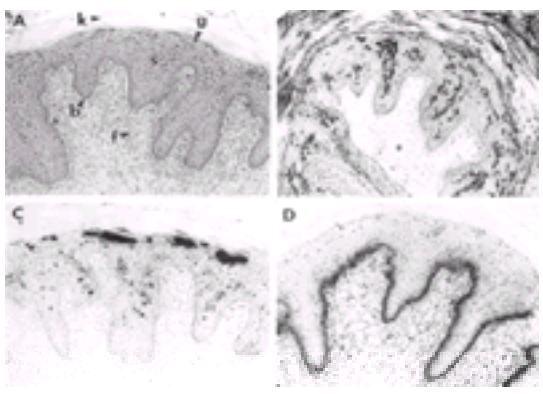

FIG. 5. *In situ* hybridization of a bovine fibropapilloma induced by BPV-1 revealing the linkage of the papillomavirus replication cycle to the squamous epithelial cell differentiation program. **A**: Control section with a sense probe and no denaturation: keratinized horn (*k*), granular layer (*g*), basal layer (*b*), and dermal fibroma (*f*). **B:** Hybridization of a sense probe to a denatured section revealing cells with a high copy number of viral DNA molecules owing to vegetative viral DNA replication. **C:** Hybridization with a probe complementary to the L1 open reading frame indicating late gene expression in the more differentiated epithelial cells of the epithelium. **D:** Hybridization with a probe complementary to a spliced message specific for the E5 transcript revealing maximal expression in the basal cells and some expression in

the dermal fibroblasts. (From ref. 14, with permission.)

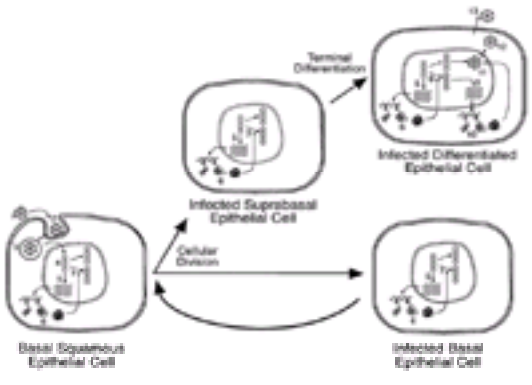

FIG. 6. Replication cycle of a papillomavirus. To establish a wart or papilloma, the virus must infect a basal epithelial cell. Our knowledge is limited about the initial steps in the replication cycle such as attachment (1), uptake (2), endocytosis (3), and transport to the nucleus and uncoating of the viral DNA (4). Early-region transcription (5), translation of the early proteins (6), and steady-state viral DNA replication (7) all occur in the basal cell and in the infected suprabasal epithelial cell. Events in the viral life cycle leading to the production of virion particles occur in the differentiated keratinocyte: vegetative viral DNA replication (8), transcription of the late region (9), production of the capsid proteins L1 and L2 (10), assembly of the virion particles (11), nuclear breakdown (12), and release of virus (13).

Attachment, Entry, and Uncoating

The first step in viral infection is the binding of the virion to the cell. Binding studies with radiolabeled virions have revealed that the papillomaviruses can bind a wide variety of cell types in addition to the normal host cell, the squamous epithelial cell (197,237). Therefore, the specific tropism of these viruses for keratinocytes does not appear to be due to a cell-type–specific receptor. This observation is consistent with studies with the BPV-1, which have shown that this virus can infect and transform a wide variety of cells, including rodent fibroblasts.

The receptors by which papillomaviruses bind and enter cells have not been unequivocally identified. The a_6 integrin was first identified as a candidate receptor for the papillomaviruses based on studies showing that papillomavirus VLPs bound a protein that was identified as a6 and that antibodies to a6 could block binding of VLPs to cells (85). Recent studies have established that the expression of the a6 integrin in a receptor-negative cell line is sufficient to confer papillomavirus binding to the cell, providing functional evidence for the role of a6 as the receptor (189). The a6 integrin partners with a b integrin subunit, either b1 or b4, on the cell surface. The a6b1 integrin is expressed on a wide range of cells, including platelets, lymphocytes, endothelial cells, and so forth, whereas a6b4 is on relatively restricted epithelial cells, mesenchymal cells, and some neuronal cells (189). Papillomaviruses can bind cells expressing either the a6b1 or the a6b4 complex, although the cells with the highest degree of papillomavirus binding match the a6b4 expression profile. The expression of a_6 is widespread, and it is well conserved among species, consistent with the criteria identified for the papillomavirus receptor from the previous binding studies (237). Although evidence suggests that the a6b4 complex is an attractive candidate receptor for papillomaviruses, it is apparently not obligatory because at least some papillomaviruses can infect cells that lack this complex (270). Papillomavirus virions can also bind to heparin and cell surface glycosaminoglycans on human keratinocytes, which may provide an initial binding event that could be followed by receptor binding and internalization (142).

There have been few published studies on the mechanisms by which the papillomavirus enters the cell, gains entry to the nucleus, or uncoats its DNA. It is presumed that these steps proceed similarly to the mechanisms used by the polyomaviruses. In one study using BPV-1, the uptake of the virions was complete by 90 minutes, with most of the capsid antigen localized in the nucleus (337). The virus particles were transported in phagosomes, and their uptake and transport could be inhibited by cytochalasin B and paclitaxel (Taxol), suggesting the possible involvement of microfilaments and microtubules in these processes. Although binding to the plasma membrane and uptake of virions into large cytoplasmic vesicles could be monitored by electron microscopy, no complete virions were observed in the nucleus of infected cells despite a very strong nuclear fluorescent staining for both L1 and L2 proteins (337). This observation suggests that disintegration of the virion occurs in the cytoplasm and that the L1 and L2 proteins may migrate to the nucleus through their nuclear localization signals.

Transcription

The replicative phase of the papillomavirus life cycle has been difficult to study because of its link to the terminal differentiation program of the epithelium. Historically, BPV-1 has served as the prototype for analyzing the papillomavirus transcription program. The studies have been carried out in a variety of systems, including viral RNAs from rodent cells transformed by BPV-1 as well as those from infected wart tissues. Viral transcription studies have been extended to some of the HPVs associated with genital tract lesions, such as HPV-11, HPV-16, HPV-18, and HPV-31, by using HPV-positive clinical lesions, xenograft tissue in nude mice, cervical carcinoma cell lines, and, more recently, organotypic cultures. This section focuses on BPV-1 and on HPV-31, both of which have been extensively analyzed by *in vitro* culture techniques (192).

Viral RNAs and Promoters

Papillomavirus transcription is complex owing to the presence of multiple promoters, to alternate and multiple splice patterns, and to the differential production of messenger RNA (mRNA) species in different cells. Transcription has been most extensively analyzed for BPV-1, for which seven different transcriptional promoters have been identified (1,9,43,281). Their locations are indicated on the circular genomic map of BPV-1 (see Fig. 3). More than 20 different mRNA species have been identified in BPV-1 transformed cells and in the productively infected cells of fibropapillomas (6). The various RNA species and the genes products they might possibly encode are depicted in Figure 7. The known viral RNA species are often present in very low abundance, making it likely that additional RNA species exist. Most RNA species in warts use a polyadenylation site (A_e) at nucleotide 4180, downstream of the early genes. It is the only polyadenylation site used in transformed rodent cells. The mRNAs in transformed cells principally encode viral factors involved in viral plasmid replication, in the regulation of viral transcription, and in cellular transformation. A second set of RNAs, which are expressed in productively infected cells, use the polyadenylation signal (A_l) at nucleotide 7156, positioned downstream of the *L1* and *L2* ORFs. RNAs that use this late polyadenylation site are found only in the terminally differentiating keratinocytes of fibropapillomas and are absent in transformed cells and in the nonproductively infected cells of BPV-1 fibropapillomas. The control of late transcription is complex and involves at least three regulatory mechanisms, as discussed later.

FIG. 7. Transcription map of BPV-1. The genomic map is shown at the *top,* with the *black line* indicating the 69% transforming region containing the long control region (LCR) and the early-region open reading frames (ORFs). The known promoters and poly(A) sites are indicated. The structures of the species A to Q were determined from RNA species in BPV-1 transformed mouse C127 cells by cyclic DNA (cDNA) cloning, electron microscopy, nuclease protection, polymerase chain reaction (PCR), and primer extension. The 5'-most ORF, which is likely to be encoded by the messenger RNA (mRNA) species, is indicated to the *right.* Structures of additional mRNAs that appear to be unique for productively infected BPV-1 fibropapillomas (species R to X) were determined by reverse transcription–PCR and cDNA cloning. Although E2 and E4 are the first significant ORFs for the W and X species, these mRNAs could also encode the L2 capsid protein. (From ref. 6, with permission.)

Six of the transcriptional promoters for BPV-1 are active in transformed cells. These promoters are also active in productively infected fibropapillomas (9). The nomenclature that has been generally adopted for use in the papillomavirus field designates the promoters (P) with a subscript indicating the nucleotide position of the 5' end of the most abundant RNA species expressed from the designated promoter. Thus, for BPV-1, P_{89} is the promoter that has its major transcription start at nucleotide 89. Another promoter, P_{2443}, gives rise to RNA species with 5' ends heterogeneously mapping in the vicinity of nucleotide 2443. The six promoters active in transformed cells that have been mapped to date are P_{89}, P_{890}, P_{2443}, P_{3080}, P_{7185}, and P_{7940} (1,9,43,281,282). One additional promoter, P_{7250}, is referred to as the *major late promoter* (P_L) and is principally active in productively infected keratinocytes, giving rise to the late mRNA species containing the *E4* and *L1* ORFs (9).

A variety of mRNA and promoter mapping studies have also been carried out with the genital tract–associated papillomaviruses, most notably HPV-11, HPV-16, HPV-18, and HPV-31. A transcription map of HPV-31 is shown in Figure 8. As with BPV-1, multiple promoters are involved in generating the various mRNA species for the genital tract HPVs. For HPV-31, P_{97} is the major promoter active in nonterminally differentiated cells. This promoter, which directs the expression of E6 and E7 as well as several other early gene products, is analogous to P_{97} of HPV-16 and P_{105} of HPV-18. Upon differentiation of immortalized keratinocytes harboring episomal HPV-31 DNA, there is activation of the differentiation-dependent late promoter P_{742}, which directs the expression of the late gene products, including E4, L1, and L2, as well as an increase in the level of the E1 mRNA (153,244).

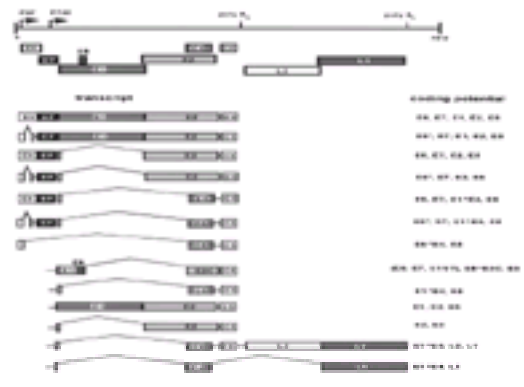

FIG. 8. Transcription map of HPV 31 (134,135,153,213). A linearized version of the genomic map is shown at the *top.*

Transcripts initiated at the early viral promoter, designated P_{97}, are expressed in the nonterminally differentiated cells in the lower portion of the epithelium, whereas those initiating at the late promoter (P_{742}) are expressed upon differentiation in the cells committed to the replication of the progeny virions. (From ref. 289, with permission.)

An important difference in the structures of the E6 and E7 mRNAs and in the manner by which they are expressed distinguishes the high-risk and low-risk HPV types. As discussed in detail in Chapter 66, the HPVs associated with the genital tract lesions can be divided into high-risk (e.g., HPV types 16 and 18) and low-risk (e.g., HPV types 6 and 11) categories based on the risk for malignant progression of the lesions they induce in the cervix. For the high-risk HPVs, such as HPV-16 and HPV-18, a single promoter (P_{97} for HPV-16 and HPV-31, or P_{105} for HPV-18) directs the synthesis of mRNAs with *E6* and *E7* intact or with splices in the *E6* gene (see Fig. 8). The species with *E6* intact could be translated into E6 but not E7 because there is insufficient spacing for translation reinitiation. The mRNAs with the spliced *E6* splice the 5' end of the *E6* ORF (referred to as E6*) to a translation frame with stop codons that provides sufficient spacing for translation reinitiation of the *E7* ORF and are therefore likely to represent the E7 mRNAs. In contrast, the *E6* and *E7* genes of the low-risk HPVs, such as HPV-6 and HPV-11, are expressed from two independent promoters (46).

Regulation of Transcription (cis Elements)

Papillomavirus transcription is tightly regulated by the differentiation state of the infected squamous epithelial cell. This is evident in part through the analysis of the differential expression of viral RNAs in the cells in the different levels of the epithelium in warts (14,47). It is also evident *in vitro* through the analysis of infected keratinocytes using organotypic and suspension tissue culture systems that permit epithelial cell differentiation (72,153,191). Cells transformed by bovine papillomavirus have provided a useful model for examining transcriptional regulation in the nonproductively infected cell, in which transcription is also tightly regulated. The genomes of the papillomaviruses contain multiple cis regulatory elements and encode several transcriptional factors that modulate viral gene expression.

The LCR region of papillomavirus contains enhancer elements that are responsive to cellular factors as well as to virally encoded transcriptional regulatory factors. All of the viral LCRs that have been studied in detail have been found to contain constitutive enhancer elements that have some tissue or cell-type specificity (245). This was first established for HPV-16 and HPV-18 (55,297) and has also been shown for HPV-11 (42) as well as for BPV-1 (312,313). It is thought that these constitutive enhancer elements are essential for the initial expression of the viral genes after virus infection and that they may also be important in the maintenance of viral latency. A number of transcription factor–binding sites have been identified in the LCRs of the various papillomaviruses that have been carefully studied. Included among them are sites that bind AP1, SP1, Oct-1, and YY1, among others (17,36,44,45,123,210,299). The HPV-16 LCR has also recently been shown to contain nuclear matrix attachment sites that may be important for controlling viral gene expression (295).

In addition to the binding sites for cellular transcription factors, the LCR contains binding sites for the virally encoded E2 regulatory proteins and the origin of DNA replication that binds the E1 replication factor, discussed in some detail later.

E2 Regulatory Proteins

The papillomavirus *E2* gene products are important regulators of viral transcription and replication. The *E2* gene product of BPV-1 was first described as a transcriptional activator (278) capable of activating viral transcription through E2-responsive elements located within the viral genome (276). The E2 proteins are relatively well conserved among the papillomaviruses in two domains: a sequence-specific DNA-binding and dimerization domain located in the carboxyl-terminal region of the protein, and a transactivating domain that is located within the amino-terminal half of the protein (99,187). These two domains are separated by an internal hinge region, which is not well conserved in size nor in amino acid composition among different papillomaviruses. The E2 proteins bind the consensus sequence, $ACCN_6GGT$ (2,174), and can regulate transcription from promoters containing E2-binding sites (112,122,275). E2 binds $ACCN_6GGT$ motifs as a dimer; the DNA-binding dimerization domain localizes to the carboxyl terminus of E2 (188).

The E2 proteins have been best studied in the BPV system, where three species have been identified (Fig. 9). The full-length protein (E2TA) can function as a transactivator or a repressor, depending on the location of the E2-binding sites within the enhancer or promoter region (Fig. 10). The two shorter forms of E2, called E2TR and E8/E2, have been described as repressors because they can inhibit the transactivation function of the full-length E2TA (161,162). The shorter E2 proteins contain the DNA-binding and dimerization domains of the C-terminus but lack the transactivation domain. E2TR and E8/E2 can inhibit the transcriptional transactivating function of the full-length polypeptide by competing for its cognate DNA-binding sites and by forming inactive heterodimers with the full-length transactivator protein. The crystal structure of the dimeric DNA-binding domain of BPV-1 E2 revealed a previously unobserved structure for a DNA-binding protein, which is a dimeric antiparallel b-barrel (116). The crystal structure of the N-terminal transactivation domain has also been resolved for HPV-16 and HPV-18 (5,110). The structural studies of the E2 N-terminal domain indicated that it could form a dimer both in the crystal and in solution. Because amino acids that are necessary for transactivation are located at the dimer interface, the dimer structure may be important in the interactions of E2 with viral and cellular transcription factors. The dimer formation may contribute to the stabilization of DNA loops, which may serve to relocate distal DNA-binding transcription factors to the site of human papillomavirus transcription initiation (5).

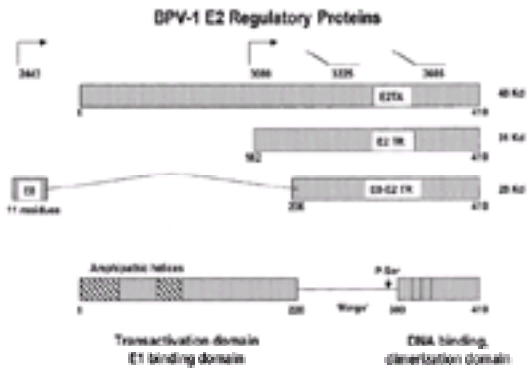

FIG. 9. Structure of the BPV-1 *E2* gene products. The structures of the three known proteins encoded by the BPV-1 *E2* open reading frame are indicated. The 48-kd full-length E2 transactivator can be expressed from an unspliced message from P_{2443} or from a spliced messenger RNA (mRNA) from upstream promoters by using a splice acceptor at nucleotide 2558. The 31-kd and 28-kd forms of the repressor are expressed from P_{3080} and as an E8:E2 fusion by a spliced mRNA as shown, respectively. The transactivation domain consists of a region of about 200 amino acids at the N-terminal region of the full-length E2 protein that is relatively well conserved among papillomaviruses. This region, which is acidic and is predicted to contain amphipathic helices, is only present in the full-length form of E2. The N-terminus of E2 contains the site for binding E1. The 110 C-terminal amino acids are also conserved and make up the DNA-binding and dimerization domain. (Modified from ref. 188, with permission.)

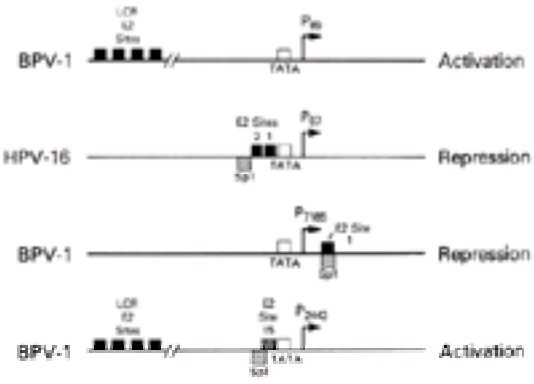

FIG. 10. Papillomavirus E2 transcriptional regulation. Transcriptional activation or repression by E2 depends on the position and proximity of the E2-binding sites in the promoter with respect to the promoter. In this figure, only the E2-binding sites in close proximity to the promoters are indicated. Several E2-binding sites in the BPV-1 long control region (*LCR*) are positioned several hundred base pairs upstream of P_{89}, which is activated by E2 (111,276). The HPV-16 P_{97} promoter (and the analogous P_{105} and P_{97} promoters in HPV-18 and HPV-31, respectively), which directs the synthesis of the E6 and E7 viral oncoproteins, is repressed by E2 through occupancy of E2-binding sites, which overlap an SP1 site and are in close proximity to the TATA box (22,298). It is thought that through displacement of SP1 from the promoter and interference with the formation of the transcription preinitiation complex, E2 may repress transcription. In a similar manner, E2 may repress the BPV-1 P_{7185} promoter by interfering with SP1 binding to a site downstream of the promoter (280,312). The P_{2443} promoter has a low-affinity E2-binding site overlapping an SP1 site, but this does not appear to play an important role in its regulation. The promoter is activated by E2-binding sites located 2.5 kb upstream in the LCR (120,277). (From ref. 188, with permission.)

Mutations in the BPV-1 *E2* ORF have pleiotropic effects on the virus, disrupting transformation, replication, and transcriptional regulation functions. Studies have shown that expression of the early region viral genes is under the control of the viral *E2* gene product through E2-responsive elements located within the viral LCR. The BPV-1 genome contains 17 E2-binding sites (ATTN$_6$GGT), of which 12 are located in the LCR (174). Pairs of the E2-binding sites are sufficient to function as an E2-dependent enhancer (2,113,275). The major E2-dependent enhancer in the LCR, E2RE1, contains four high-affinity E2-binding sites (276) and is located upstream of the P_{89} promoter complex. In addition to activating the P_{89} promoter, E2 can also activate each of the early region promoters (P_{890}, P_{2443}, and P_{3080}) through the E2-dependent enhancer elements in the LCR. Despite this dependence on a common E2-responsive element in the LCR, the various promoters have different sensitivities to the E2 transactivator (293). These differences are most likely due to specific promoter elements in the vicinities of the individual promoters. For instance, there is an SP1 site upstream of the P_{2443} promoter that is necessary for both its basal and E2-transactivated expression (277).

E2 transcriptional regulation has also been well studied for the genital tract–associated HPVs. The binding of E2 to its cognate sites within the LCR of the HPV genomes results in the modulation of viral promoter activity. The *E6* and *E7* transforming genes of HPV-16 and HPV-18 are transcribed from the major early promoter (P_{97} and P_{105}, respectively) contained within the LCR of their respective genomes (272,300). Analyses of promoter activity in human epithelial cells have shown that the P_{97} promoter of HPV-16 and the P_{105} promoter of HPV-18 possess a basal activity that can be repressed by full-length *E2* gene products (22,241,298,300). There are four E2-binding sites within the LCRs of the HPV-16 and HPV-18 genomes. Two E2-binding sites are located immediately adjacent to the TATA box of the P_{97} and P_{105} promoters of HPV-16 and HPV-18, respectively. The basal activity is dependent on the keratinocyte-dependent enhancer contained within the LCR, and E2 repression occurs through binding to the ACCN$_6$GGT sites in close proximity to the TATA box of the early promoter, most probably by interfering with the assembly of the preinitiation transcription complex (22,55,241,291,300). In the context of the full genome, the modulation of HPV gene expression by *E2* is even

more pronounced. In human keratinocyte immortalization assays dependent on the expression of the *E6* and *E7* genes, an intact *E2* gene can decrease the efficiency of HPV-16 immortalization (240). E2 can also suppress the growth of HPV-positive cervical cancer cell lines through transcriptional repression of the viral *E6* and *E7* genes (76,89,136,208,300). These results are consistent with the model that at certain concentrations, E2 can repress the viral P97 promoter through binding to the E2 DNA-binding sites in the proximity of the promoter. In contrast to the repression mediated by E2 on the expression of the high-risk HPVs, in BPV-1, the full-length E2TA stimulates the expression of a number of viral genes, including *E2* itself and *E5* (120,229). This finding has raised the question of whether the transcriptional activation function of E2 is essential for the high-risk HPVs. Indeed, it was recently shown that an HPV-31 genome that carried a mutant *E2* gene, which was defective for transactivation but competent for DNA replication, could still be established as a stable episome and could induce differentiation-dependent late functions (288). Thus, the specific role of E2 as a transcriptional regulator may vary among different papillomavirus types.

E2 is a multifunctional protein. Its functions as a transcriptional activator and repressor are likely mediated by interactions with specific cellular factors, some of which have now been identified (Table 1). In addition to its role as a transcriptional regulator, E2 has critical roles in viral DNA replication and in plasmid maintenance. E2TA, together with the viral E1 protein, is essential for viral DNA replication (41,62,309). E2 may serve as an auxiliary protein in viral DNA replication. This aspect has been best studied in the BPV system, in which E2 was first shown to complex with E1 and to strengthen the affinity of E1 for binding to the origin of DNA replication (195,309). Long-term maintenance of plasmids containing a papillomavirus origin of DNA replication, however, also requires a minichromosome maintenance element, a cis element consisting of multiple E2-binding sites (226). The role of E2TA in plasmid maintenance appears to be due to its role in linking the viral plasmids to the cellular mitotic chromosomes, thereby ensuring that the viral genomes are enclosed within the nuclear envelope for when it reforms during telophase (16,170,271).

TABLE 1. *Cellular targets and functions of the papillomavirus E2 oncoproteins*

Late Gene Expression

The viral late functions, such as vegetative viral DNA synthesis, capsid protein synthesis, and virion assembly, occur exclusively in differentiated keratinocytes. Transcriptional regulation of the late genes has been most extensively studied for BPV-1, HPV-11, HPV-16, and HPV-31. For each of these viruses, there is a specific promoter, which becomes active only in terminally differentiated keratinocytes. For BPV-1, the late RNAs are transcribed from a wart-specific or late promoter (P_L) at nucleotide 7250 that is located in the 5' end of the LCR (9) (see Fig. 7). Both the *L1* and *L2* genes are expressed from mRNAs transcribed from P_L (14). In addition to the L1 and L2 mRNA species, this promoter also gives rise to other viral mRNAs that are specific for terminally differentiated cells. For instance, one abundant mRNA from P_L gives rise to the message that appears to encode the E4 protein (9), an abundant cytoplasmic protein found predominantly in the differentiated keratinocytes of the wart (73). Thus, although E4 is located in the early region of the viral genomes (see Fig. 3 and Fig. 4), it is a late protein by virtue of the promoter from which it is expressed. Interestingly, the late promoters for the human papillomaviruses that have been analyzed do not map to the LCR. Instead, a differentiation-specific promoter has been identified within the E7 coding region of the HPV-31 genome that gives rise to mRNA species whose 5' ends map to nucleotide 742 (134) (see Fig. 8). The late promoter in HPV-11 also maps to the E7-coding region (46).

Polyadenylation of the BPV-1 L1- and L2-specific mRNAs occurs 3' to the *L1* ORF at nucleotide 7175, a site not used in transformed cells and therefore considered the late poly(A) site (A_L) (9) (see Fig. 7). In the HPVs that have been analyzed, polyadenylation occurs in a similar region of the genome, 3' to the *L1* ORF (see Fig. 8).

Papillomavirus *L1* and *L2* gene expression is also regulated at a posttranscriptional level. There are cis-acting elements that have been described for BPV-1, HPV-16, and HPV-1, which serve important roles in regulating late gene expression for these viruses at a posttranscriptional level. In the 3'-untranslated regions (3'-UTRs) of the late RNAs of each of these viruses, there are negative regulatory elements that can inhibit the generation of stable late mRNAs. In the BPV-1 late 3'-UTR, there is an unused 5' splice element that binds the U1 small nuclear ribonuclear protein and inhibits late polyadenylation, thereby favoring use of the early polyadenylation site (93,94). A negative regulatory element in the HPV-16 3'-UTR contains multiple 5' splice-like sequences, as well as an inhibitory GU-rich region that reduces mRNA stability, that bind to (65,147,154) three different cellular factors (the U2 auxiliary splicing factor 65-kd subunit, the cleavage stimulation factor 64-kd subunit, and the Elav-like HuR protein) (154). In HPV-1, an AU-rich inhibitory region has been identified in the 3' UTR that also binds the Elav-like HuR protein (273). The model emerges that these, and perhaps additional cellular factors, are responsible for the nuclear retention or cytoplasmic instability of the nuclear retention element (NRE)–containing late transcripts. Keratinocyte differentiation would then lead to changes in these cell-encoded factors, thus relieving the inhibition of late mRNA processing.

E4 Proteins

The *E4* ORF of the papillomaviruses is located in the early region (see Fig. 3, Fig. 7, and Fig. 8), yet it is expressed as a late gene with a role in productive infection. It overlaps the *E2* ORF in a different reading frame and therefore encodes a protein with an entirely different amino acid sequence. In general, the *E4* gene is not highly conserved among the papillomaviruses. Transcripts that could encode E4 proteins have been described both for BPV-1 and the HPVs (see Fig. 7 and Fig. 8). A viral transcript formed by splicing a few codons from the beginning of E1 to E4 appears to be the major RNA in HPV-induced lesions for the viruses that have been studied. In papillomas, the E4 proteins are expressed primarily in the differentiating layers of the epithelium, and the E4 proteins are expressed in cells in which vegetative viral DNA replication is ongoing (75). The expression of E4 is not coincident with the expression of the capsid proteins (75), and E4 expression precedes the expression of L1 (56). Although the E4 proteins are expressed at high levels in infected tissues, their precise role in the viral life cycle is unclear. E4 proteins are not found in the virion particles. Mutational analysis of the *E4* gene in BPV-1 showed that E4 was not essential for viral transformation or viral DNA replication (119,204).

In cultured epithelial cells, the E4 proteins are associated with the keratin cytoskeleton (74,236,239). The HPV-16 E4 protein has been shown to induce the collapse of the cytokeratin network (74,236), suggesting that it may function to aid the virus in its egress from the cell. A dramatic collapse of the keratin intermediate filaments has not, however, been observed with cells expressing HPV-1 E4, raising some question as to the generality of this effect (236,239). The available data are compatible with the possibility that E4 may contribute to vegetative DNA replication or to altering the cellular environment in a manner that may favor virus synthesis or perhaps virus release.

Virus Assembly and Release

Little is known about the papillomavirus assembly or release. Virus particles are observed in the granular layer of the epithelium and not at lower levels. The virus is not believed to be cytolytic, and the release of the virion particles does not occur before the cornified layers of a keratinized epithelium (see Fig. 4 and Fig. 5).

VIRAL DNA REPLICATION

The papillomaviruses have three modes of viral DNA replication. The first occurs during the initial infection of a basal keratinocyte by the virus, when there is an amplification of the viral genome to about 50 to 100 copies. Little is known of this process. The next phase is one of genome maintenance, which occurs in dividing basal cells of the lower portion of the epidermis as well as in the dermal fibroblasts in fibropapillomas such as those induced by BPV-1. In these cells, the viral DNA is maintained as a stable multicopy plasmid. The viral genomes replicate an average of once per cell cycle during S phase in synchrony with the host cell chromosome (98) and may be faithfully partitioned to the daughter cells. This type of DNA replication ensures a persistent and latent infection in the stem cells of the epidermis. The third type of DNA replication is vegetative DNA replication, which occurs in the more differentiated epithelial cells of the papilloma. In these cells, which no longer undergo cellular DNA synthesis, one observes a burst of viral DNA synthesis, generating the genomes to be packaged into progeny virions.

Plasmid Maintenance

Plasmid maintenance has been examined in greatest detail in BPV-1 transformed mouse cells, in which the viral genome exists as a stable multicopy plasmid (163). This system has provided a model for studying nonvegetative viral DNA replication, and it has been assumed that viral DNA replication in these mouse cells may be analogous to the stable plasmid replication seen in the dermal fibroblasts of a fibropapilloma and in the basal keratinocytes of a papillomavirus–associated lesion. During the maintenance phase, the viral genome copy number remains relatively constant for many cell generations.

Origin of DNA Replication

The origin of BPV-1 DNA replication was initially localized to the LCR by electron microscopic analysis of replicative intermediates isolated from BPV-1 transformed rodent cells harboring extrachromosomal viral DNA (317). Papillomavirus DNA replication requires the origin of DNA replication in cis and the viral E1 and E2 proteins in trans. *In vivo,* the minimal origin of replication (nucleotides 7911 to 7927) contains an A+T-rich region (ATR), the E1-binding site that includes a region of dyad symmetry (DSR), and an E2-binding site (310) (Fig. 11). The origins of DNA replication have been mapped for a number of the HPVs and contain similar ATR and DSR domains adjacent to E2-binding sites (41,62). Furthermore, in transient replication assays, the viral E1 and E2 proteins can function in trans on replication origins from heterologous papillomavirus genomes (41). Origin-dependent DNA replication of BPV-1 can be achieved *in vitro* with cell extracts containing high levels of E1 alone in the absence of E2 (267,328).

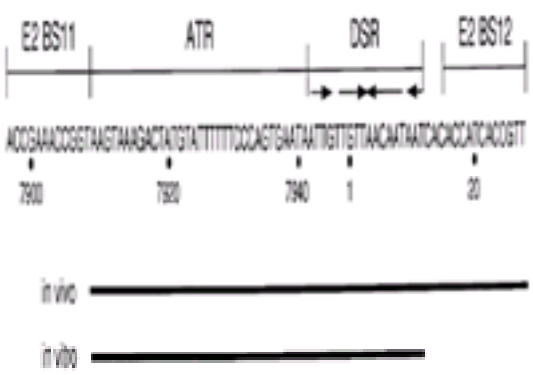

FIG. 11. The BPV-1 origin of DNA replication. The minimal origin for *in vivo* DNA replication (nucleotides 7911 to 7927) requires the A+T-rich region (ATR), the dyad symmetry repeats (DSR), and a binding site for the E2 protein. For *in vitro* DNA replication, there is a requirement only for the ATR and DSR.

E1 Protein

Genetic studies have revealed that stable BPV-1 plasmid replication requires the expression of the viral *E1* and *E2* genes. Initial studies of mutated BPV-1 genomes implicated both E1 and E2 as essential for stable viral DNA replication (70,230) and for transient viral DNA replication (309). However, E1 is the only viral factor that is directly involved in plasmid replication; E2 has auxiliary roles in DNA replication and in plasmid maintenance as discussed below. The *E1* ORF is the largest ORF in the papillomavirus genome and is relatively well conserved among all of the papillomaviruses (Fig. 12). The E1 proteins share structural similarities with portions of the SV40 large tumor antigen (TAg), which is an essential replication protein of that virus. The similarity includes regions of TAg with ATPase, helicase, and nucleotide-binding activities (49,267). The BPV-1 E1 protein is a 68-kd nuclear phosphoprotein that binds specifically to the origin of replication (304,310,324). By itself, E1 binds the origin with weak affinity. However, the binding of E1 to the origin is stabilized through its interaction with E2 and the binding of E2 to its cognate sites adjacent to the origin (195,310).

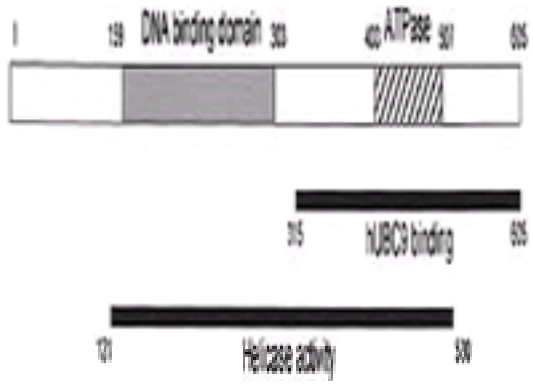

FIG. 12. Schematic representation of the BPV-1 E1 replication protein. The DNA-binding domain of E1 has been mapped to amino acid residues 159 to 303 for BPV-1. The crystal structure of the DNA-binding domain of BPV-1 E1 has recently been determined and shown to resemble (despite an amino acid sequence identity of only 6%) the DNA-binding domain of SV40 tumor antigen (84). The E2-binding domain maps to the C-terminal 266 amino acids.

The papillomavirus E1 protein has DNA-dependent ATPase and DNA helicase activities (28,267,329). E1 is required for both the initiation and elongation of viral DNA synthesis (175). In addition to its interaction with E2, E1 has been shown to bind a number of cellular proteins. E1 interacts with the p180 subunit of the cellular DNA polymerase a-primase and presumably thereby recruits the cellular DNA replication initiation machinery to the viral replication origin (26,215). Several additional host cellular proteins have been found to bind E1, including histone H1 (292), SW1/SNF5 (165), cyclin E/Cdk2 (58,181), Hsp40/Hsp70 (176), and Ubc9 (231,332). Although the physiologic significance of some of these interactions remains to be determined, several appear to be quite interesting. In particular, the efficient cell cycle–regulated replication of papillomavirus genomes is dependent on the association of E1 with the S-phase–specific cyclin E–Cdk2 complex (58). In addition, the interaction of E1 with Ubc9 is required for efficient origin-dependent replication (332). E1 is SUMO-1 modified by Ubc-9, and this modification is required for the intranuclear accumulation of E1 (232).

In addition to the 68-kd protein encoded by the entire gene, the 5' end of BPV-1 E1 encodes a protein with an apparent molecular weight of 23,000 (303). Although the protein has been detected by BPV-1 transformed cells, no function has yet been ascribed to this N-terminal E1 protein (129).

Role of the E2 Proteins

As noted previously, papillomavirus DNA replication also requires the viral E2 protein (309,328). A requirement for E2 in origin-dependent DNA replication has been shown for the HPVs as well as BPV-1 in transient assays. Although not essential for origin-dependent DNA replication *in vitro,* E2 greatly stimulates the ability of E1 to initiate DNA replication (328). E2 interacts with E1 (24,179,195) and greatly enhances the ability of E1 to bind the replication origin (195,264,268). E2 can relieve nucleosome-mediated repression of papillomavirus DNA replication *in vitro* (172). E2 may also stimulate viral DNA replication by recruiting host replication factors to the origin. One of these host factors is RPA (replication protein A), which is a single-stranded DNA-binding protein that can bind to acidic transactivation domains such as the one found in E2 (173). The E1:E2 complex is a precursor to a larger multimeric E1 complex, which after the removal of E2 can distort the replication origin and ultimately unwind the DNA (180) (Fig. 13). E2 serves as an auxiliary factor that fosters the assembly of the preinitiation complex at the origin, but E2 itself plays no intrinsic role in viral DNA replication. A hexameric form of E1 protein is associated with the ATPase and DNA helicase activities intrinsic to its initiator function in DNA replication (88,265).

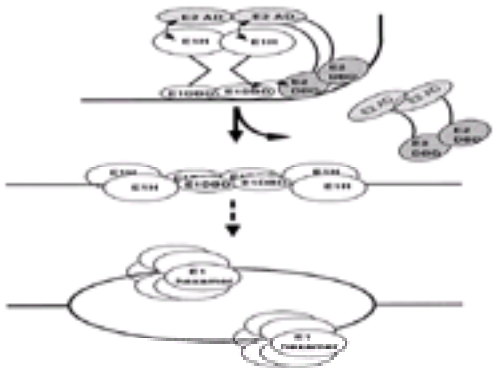

FIG. 13. Proposed pathway for the assembly of an initiation-competent complex at the BPV origin of DNA replication. The E1 initiator binds cooperatively with E2 to the ori, forming a specific E1 $_2$E2$_2$–DNA complex. As a consequence of the interaction between the E1 and E2 DNA-binding domains (*DBDs*), a sharp bend is induced in the ori DNA. The bend promotes the interaction between the E1 helicase domain (*E1H*) and the E2 transactivation domain (*E2AD*). The resulting highly sequence-specific complex serves to recognize the ori. In a reaction requiring ATP hydrolysis, E2 is displaced, and additional E1 molecules are added to the complex, resulting in the formation of a complex in which four molecules of E1 are bound to the ori. This complex can distort the DNA duplex and give rise to partially single-stranded regions. Subsequently, additional molecules are added. In a final step, E1 is assembled onto the exposed single strands, forming a hexameric ringlike structure that constitutes the replicative helicase. (Modified from ref. 84, with permission.)

E2 also has a role in genome maintenance. Plasmids containing the minimal origin of DNA replication are capable of transient replication in cells expressing E1 and E2. With time, however, the plasmids are lost. Long-term, stable plasmid maintenance requires a cis minichromosome maintenance element, which consists of multiple E2-binding sites (226). This, together with the observation that E2TA and the viral genomes are associated with the mitotic chromosomes (137,170,271), suggests that viral E2 protein–mediated attachment of the viral genomes to the host cell chromatin could provide a mechanism for the coupling of viral genome multiplication and partitioning to the host cell cycle during viral latent infection. This association would ensure the localization of the viral genomes within the nuclear envelope when it is reformed during telophase.

Model for Plasmid Replication

In the initial intracellular stages of a papillomavirus infection, the viral genome may undergo amplification for a short period of time. There is then a transition to a maintenance stage in which the plasmids replicate an average of once per cell cycle, in a manner analogous to chromosomal DNA replication. It was initially thought that stable plasmid DNA replication might involve the “marking” of the daughter viral genomes so that they did not return to the replicating pool until the next cell cycle, and that each viral plasmid molecule replicated only once per cell cycle. However, the evidence currently favors an alternative model, in which the plasmid replication is not restricted to once per cell cycle but occurs an average of once per cell cycle and does not rely on plasmid marking (98,202). However, precise mechanisms involved in regulating plasmid maintenance, as well as vegetative DNA replication, have not yet been elucidated.

Vegetative Viral DNA Replication

Vegetative replication of papillomavirus DNA is necessary to generate the genomes to be packaged in virions, a process that normally occurs only in the terminally differentiated epithelial cells of a papilloma. The mechanisms regulating the switch from plasmid maintenance to vegetative viral DNA replication are not known. The switch may involve the presence or absence of controlling cellular factors in differentiating keratinocytes. In addition or alternatively, the relative levels of viral factors such as E1 or E2 (or their modification) may change in terminally differentiating keratinocytes. A high level of BPV-1 DNA amplification occurs in transformed cells after growth arrest, in a process in which both E1 and E2 have been implicated (34,35). There have been few studies that have examined the mode of vegetative viral DNA replication in differentiated cells. One might anticipate that, as with the polyomaviruses, vegetative DNA replication occurs bi-directionally through theta structure intermediates, as it does in the maintenance replication phase. One intriguing study, however, suggests that there may be a switch from a bi-directional mode of replication to what could be a rolling circle mode (87). Additional studies on the mechanism of vegetative replication would appear to be warranted.

VIRAL TRANSFORMATION

BPV-1 Transformation

Certain papillomaviruses are capable of inducing cellular transformation in tissue culture. The most completely studied of the transforming papillomaviruses as been BPV-1. Morphologic transformation in tissue culture was first described for BPV in the early 1960s (23,25,302). In the late 1970s, a focus assay was developed using established cell lines to study BPV-1 transformation (79). In general, investigators have relied on mouse C127 cells and NIH-3T3 cells for these transformation studies, although a variety of other rodent cells, including hamster and rat cells, are susceptible to BPV-1–mediated transformation. Transformation of mouse C127 cells by BPV-1 causes alterations in morphology, loss of contact inhibition, anchorage independence, and tumorigenicity in nude mice (79).

One interesting characteristic of BPV-1 transformed rodent cells is that the viral DNA is maintained as a stable multicopy plasmid (163). Integration of the viral genome is not required for either the initiation or maintenance of the transformed state. However, transformation is dependent on the continued expression of viral DNA, as evidenced by the loss of the transformed phenotype in mouse cells which have been “cured” of the viral DNA by treatment with interferon (308). The extrachromosomal state of the viral genome, however, is not a prerequisite for this transformation because replication

defective viruses are capable of transforming cells (250). In cells in which the extrachromosomal DNA is maintained, it is likely that a high gene dosage resulting from the viral plasmid replication is necessary for efficient transformation by the wild-type genome. Cells harboring BPV-1 mutants, which maintain a low copy number of extrachromosomal DNA, do not have a transformed phenotype (21).

The initial studies with cloned BPV-1 DNA indicated that the entire viral genome was not required for transformation of rodent cells (177). A specific 69% subgenomic fragment was sufficient for inducing cellular transformation; hybrid plasmids containing this 69% fragment could be maintained as stable plasmids within transformed cells. Genetic studies have mapped the BPV-1 transforming genes to the *E5, E6,* and *E7* ORFs, as discussed later. The initial studies establishing that the BPV-1 genome could be maintained as a stable plasmid in rodent cells led to the development of BPV-1–based plasmid vectors for mammalian cells (71,248,249).

BPV-1 has three independent transforming proteins, encoded by the *E6* (258,331), *E7,* and *E5* ORFs (104,259,330). Each of these genes is contained within the 69% transforming fragment, and each is expressed in transformed cells. The *E5* gene is the major transforming gene of BPV-1 in transformed cells. This gene is highly conserved among the group of papillomaviruses that induce fibropapillomas in their natural host and have the capacity to induce fibroblastic tumors in hamsters. The *E5* gene is believed to be responsible for the proliferation of dermal fibroblasts in fibropapillomas.

In addition to the *E5, E6,* and *E7* genes that are directly involved in BPV-1 transformation, the early region also encodes genes that are indirectly involved in transformation. The products of the *E1* and *E2* ORFs that are involved in the transcriptional regulation and replication of the virus regulate the expression of the transforming genes. Initial studies with BPV-1 E2 mutants suggested they were defective for transformation (68,104,230). This defect, however, is not due to the loss of a direct transforming activity of E2 but rather occurs because E2 is necessary for sufficient expression of the E5 viral oncoprotein. Mutations in the *E1* ORF may result in a higher transforming activity as a result of an increase in the transcriptional activity of the mutant viral genome (160,257). BPV-1 E1 can repress the E2 transactivated expression of the virus (246).

BPV-1 E5 Oncoprotein

The BPV-1 *E5* ORF encodes a 44–amino acid protein (262) and is sufficient for the transformation of certain established rodent cells in culture (66,104,230,259). The amino acid sequence of E5 and its predicted structure are shown in Figure 14. Structurally, E5 is composed of two protein domains: a very hydrophobic segment at its amino terminus, which is responsible for localization of E5 in membrane fractions (262), and a carboxyl-terminal hydrophilic domain. The E5 protein is associated with intracellular membranes and is thought to be an integral membrane protein (31). In transformed cells, the E5 protein exists largely as a homodimer and is localized primarily in the Golgi apparatus and in the endoplasmic reticulum (32,33). E5 is not secreted, and the hydrophilic C-terminus extends into the lumen of the Golgi (32). The E5 protein contains two cysteine residues involved in dimer formation that are required for transformation (31,124).

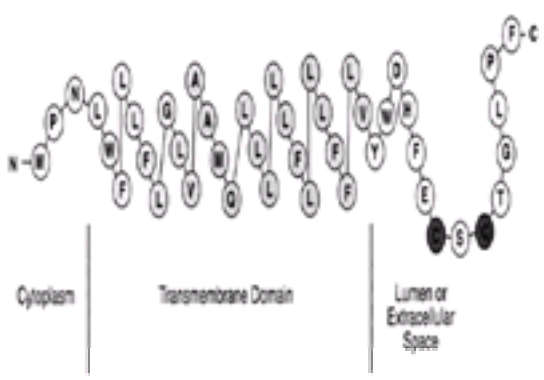

FIG. 14. Amino acid sequence and predicted secondary structure of the BPV-1 E5 oncoprotein. The 27 hydrophobic amino acids composing the first two thirds of the 44–amino acid protein (*shaded lightly*) are predicted to be in a-helical conformation. The 14 carboxyl-terminal residues are predicted to be in a nonhelical configuration. The cysteine residues, which are highly conserved among the E5 proteins of the transforming ungulate papillomaviruses, are *shaded darkly.* These cysteines mediate dimer formation (31,124).

The E5 protein does not possess intrinsic enzymatic activity and functions by altering the activity of cellular membrane proteins involved in proliferation. The first direct evidence that BPV-1 E5 can affect the activity and metabolism of growth factor receptors came from experiments that showed that E5 can cooperate with exogenously introduced epidermal growth factor (EGF) receptor or colony-stimulating factor 1 receptor in the transformation of NIH-3T3 cells (183). Subsequently, it was established that the primary endogenous target for the BPV-1 E5 protein in fibroblasts is the b-receptor for the platelet-derived growth factor (PDGF) (220). There is an increase in the level of tyrosine phosphorylation of the endogenous PDGF receptor in the E5-transformed rodent cells and bovine fibroblasts (218,220), and a prominent form of the tyrosine phosphorylated PDGF receptor in the transformed cells is an intracellular, membrane-associated, premature form of the receptor. Similarly, gene transfer experiments in heterologous cell types demonstrate that BPV-1 E5 transformation can be mediated by the PDGF b-receptor but not by a variety of other growth factor receptors (102,206). E5 activates the receptor and transforms cells in a ligand-independent manner (218,219). The mechanism of E5 activation of the PDGF b-receptor involves complex formation with the receptor, thereby inducing receptor dimerization, trans-phosphorylation of tyrosine residues in the cytoplasmic domain of the receptor, and recruitment of cellular SH2 domain–containing proteins into a signal transduction complex (67). This is depicted in Figure 15, which shows a model suggesting that the individual subunits of the E5 dimer each bind to two different molecules of

the PDGF b-receptor, resulting in receptor dimerization and activation (69). This model is supported by mutational analyses of the E5 protein–PDGF b-receptor interaction, which have identified in E5 the cysteines 37 and 39, glutamine 17, and aspartic acid 33 as essential for receptor binding (124,190,207). Similarly, mutations in the PDGF b-receptor at the transmembrane threonine 513 and juxtamembrane lysine 499 prevent complex formation and transformation (221).

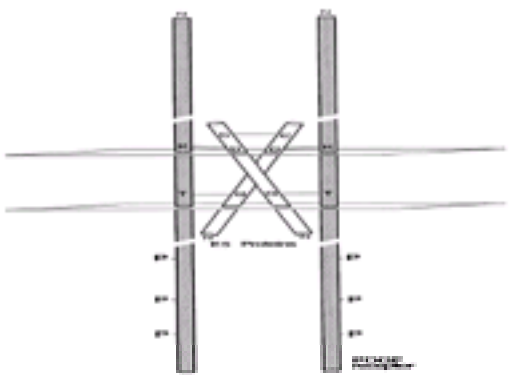

FIG. 15. Schematic model of the E5 protein–platelet-derived growth factor (PDGF) b-receptor complex. The *open rods* represent the E5 dimer, and the *shaded rods* represent two molecules of the PDGF b-receptor. The amino termini of the proteins are designated *N.* The *planes* represent the two faces of the cell membrane. The figure also shows the postulated glutamine-threonine (*Q-T*) hydrogen bond and aspartic acid–lysine (*D-K*) salt bridge linking these two proteins as well as the disulfide bond between the cysteine residues that stabilize the E5 dimer. *P* represents the phosphotyrosines in the cytoplasmic domain of the activated PDGF b-receptor. Not depicted in this figure is the 16-kd transmembrane channel-forming subunit of the vacuolar H^+-ATPase, which also binds E5 (101). (Modified from ref. 67, with permission.)

BPV-1 E5 has also been shown to form a complex with the 16-kd transmembrane channel–forming subunit of the vacuolar H^+-ATPase (101,103), an abundant cellular protein located in the membranes of intracytoplasmic membranes and plasma membranes. Golgi acidification has been found to be impaired in cells transformed by the BPV-1 E5 protein, owing to the inhibition of the vacuolar H^+-ATPase (252). It has not yet been shown directly that Golgi alkalinization plays a role in cellular transformation, but there is a good genetic correlation between the ability of specific E5 mutants to transform cells and Golgi alkalization (252). Because many important growth regulatory proteins, including the PDGF b-receptor, transit through the Golgi apparatus, it is possible that the ability of E5 to perturb the pH of intracellular organelles might affect the activity of some of these proteins and, in so doing, contribute to the transformed phenotype. It is additionally possible that the BPV-1–mediated Golgi alkalinization may affect cellular functions unrelated to transformation that are important in the life cycle of the virus.

BPV-1 E6 and E7 Oncoproteins

The BPV-1 *E6* and *E7* genes also encode proteins with transforming activities. In mouse cells, the full transformed phenotype requires the expression of the *E6* and *E7* genes as well as *E5* (203,250). Furthermore, BPV-1 E6 expressed from a strong heterologous promoter is sufficient for transformation of C127 cells (258). The E6 and E7 proteins are themselves structurally related and are conserved, at least in part, among all of the papillomaviruses. In BPV-1 transformed cells, cyclic DNA (cDNA) has been isolated and characterized, which could encode the full-length E6 protein, the full-length E7 protein, as well as the E6 fusion protein in which the amino-terminal half of E6 could be fused to portions of downstream genes (331) (see Fig. 7). To date, no studies have been done on these potential BPV-1 *E6* spliced genes. The *E6* and *E7* genes of all the papillomaviruses encode proteins with conserved structural motifs. They contain domains of almost identically spaced CYS-X-X-CYS motifs (four in *E6* and two in the carboxyl-terminal portion of *E7*). It has been postulated that the *E6* and *E7* genes may have arisen from duplication events involving a 39-codon core sequence containing one of these motifs (52). The CYS-X-X-CYS motifs found in a number of nucleic acid–binding proteins are characteristic of zinc-binding proteins. The papillomavirus E6 and E7 proteins bind zinc through these cysteine residues (13,105).

The E6 protein of BPV-1 is present at low levels in stably transformed cells. Cell fractionation experiments have localized the BPV-1 E6 protein to the nucleus and to nonnuclear membranes of transformed cells (3). No intrinsic enzymatic activities have been identified for BPV-1 E6, and like the oncogenic HPV E6 proteins, it is believed to function through binding cellular targets. Four different cellular proteins have been found to interact with BPV-1 E6: the ubiquitin protein ligase E6AP (see later), E6BP (also known as ERC55), the g subunit of the AP1 clatherin adaptor complex, and the focal adhesion protein paxillin (38,305,306,311). Unlike the oncogenic HPV E6 proteins (see later), the BPV-1 E6 interaction with E6AP does not result in the binding and degradation of p53. It is not yet known whether the interaction of BPV-1 E6 with E6AP has physiologic consequences for the cell. Similarly, no *in vivo* consequences of the interaction of BPV-1 E6 with either ERC55 or the g subunit of the AP1 on the cell have yet been determined. Analysis of a series of BPV-1 E6 mutants has shown a good correlation between the binding to paxillin and cellular transformation (59,306,311). This binding has also been shown to correlate with the disruption of the cellular actin cytoskeleton, a characteristic of transformed cells (306). E6 binds to charged leucine motifs in paxillin known as LD motifs and, in doing so, competes with the ability of paxillin to bind to vinculin and the focal adhesion kinase (307,311). Nonetheless, a detailed understanding of the mechanisms by which BPV-1 E6 transforms cells remains to be determined.

The product of the *E7* ORF has been detected in BPV-1 transformed cells (138). Although the *E7* gene by itself is not able to induce foci in transformation assays, its integrity is necessary for the fully transformed phenotype as assayed by anchorage independence and by tumorigenicity (203). BPV-1 E6 and E7 are under the negative regulatory control of the viral *E1* and *E2* genes, and in the absence of these gene products, *E6* and *E7* together are potent oncogenes that are

sufficient for the full transformation of C127 cells (314). To date, there have been no functional studies of the BPV-1 E7 protein. Unlike the HPV E7 proteins, BPV-1 E7 does not contain an LXCXE motif for binding the retinoblastoma tumor suppressor gene product (pRB), suggesting that it does not share the property of pRB binding and inactivation with the HPV E7 proteins (see later).

HPV Transformation and Immortalization

Transformation studies with the papillomaviruses have not been limited to BPV-1. Assays have also been developed for the transformation and immortalization functions encoded by those HPVs associated with anogenital cancers in humans. The HPV-16 and HPV-18 genomes are not as efficient as BPV-1 at inducing transformation of established rodent cells; however, alternative assays have been developed. DNA cotransfection with a second dominant selective marker, such as the neomycin resistance gene, and biochemical selection for the transfected cells permit HPV-16 and HPV-18 to transform established rodent cells (333). Assays employing primary rodent cells and primary human fibroblast and keratinocyte cultures have proved even more informative (78,143,185,224,228,261,318). In these assays, the high-risk HPVs, such as HPV-16 and HPV-18, are transformation positive, whereas the low-risk viruses, such as HPV-6 and HPV-11, are not (261,285). These assays have permitted the mapping of the viral genes directly involved in cellular transformation to the *E6* and *E7* ORFs of the high-risk HPV types, which are discussed in detail later.

In established rodent cells, such as the NIH-3T3 cells, the *E7* ORF scores as the major HPV transforming gene (224,296,316,319,334). HPV-16 and HPV-18 by themselves are not able to transform primary rat fibroblasts or baby rat kidney cells (159,224). However, the *E7* gene can cooperate with an activated *ras* oncogene to transform primary rat cells completely (18,174,209,224,285).

The DNA of the high-risk HPVs can also be distinguished from the DNA of the low-risk HPVs by the ability of the high-risk types to immortalize primary cultures of human fibroblasts, human foreskin keratinocytes, and human cervical epithelial cells (78,228,261,318,325). The resulting cell lines are neither anchorage dependent nor tumorigenic in nude mice, but they do display altered growth properties and are resistant in the response to signals for terminal differentiation (78,146,228,261). All of the genital tract HPV types (i.e., HPV-6, HPV-11, HPV-16, and HPV-18) are capable of transiently inducing cellular proliferation. Only the high-risk HPVs, however, are able to extend the life span and give rise to immortalized cell lines that are refractory to differentiation signals (261).

HPV E5 Oncoprotein

As noted previously, the *E5* ORF is highly conserved among those papillomaviruses that induce fibropapillomas and that readily transform rodent fibroblasts in tissue culture, including BPV-1, the deer papillomavirus (DPV), and the European elk papillomavirus (EEPV) (156), suggesting that E5 may play an important role in the tropism for fibroblasts observed *in vivo* for these viruses. Many of the other papillomaviruses that induce purely epithelial papillomas (such as CRPV and the HPVs) also contain *E5* genes with the potential to encode short hydrophobic peptides. The structural similarity of these peptides to the BPV-1 E5 protein has prompted studies of the potential transforming activities of these putative genes. Studies have shown that the HPV-6 *E5* gene can induce some transformation-associated changes of NIH-3T3 cells (39). However, the precise role of HPV-6 E5 in this process is unclear because the HPV-6 DNA is often not retained in transformed mouse cells (196). Transforming activity has also been demonstrated for the HPV-16 *E5* gene. HPV-16 E5 can induce some transformed alterations in mouse fibroblast lines or mouse epidermal keratinocytes (169,171,287), increase the proliferative capacity of human keratinocytes (284), and stimulate cellular DNA synthesis in human keratinocytes in a manner that is potentiated by EGF (287). The biochemical mechanisms by which the *E5* genes of the epitheliotropic papillomaviruses exert their growth stimulatory effects have not yet been fully elaborated. HPV-16 E5 has been localized mainly to the Golgi apparatus, to endosomes, and to some extent to cell membranes (53). HPV-16 E5 has also been associated with the activation of the EGF receptor and with MAP kinase activation (57,287). As with the BPV-1 E5 protein, HPV-16 E5 can bind the 16-kd subunit of the vacuolar ATPase and can inhibit the acidification of endosomes (53,238,286). It should be noted, however, that the *E5* gene is not expressed in most HPV-positive cancers, suggesting that if the *E5* gene does stimulate cell proliferation *in vivo,* it presumably functions in benign papillomas and not in the cancers. It might also participate in the initiation of the carcinogenic process or in some other aspects of the viral–host cell interaction relevant to the pathogenesis of the HPV infection.

HPV E6 Oncoprotein

Although HPV-16 E7 is sufficient for the transformation of established rodent cells such as NIH-3T3 cells and for cooperation with *ras* in the transformation of baby rat kidney cells, the combination of E6 and E7 is required for the efficient immortalization of primary human fibroblasts or keratinocytes (114,198,318). E6 and E7 together can extend the life span of human keratinocytes and lead to the outgrowth of immortalized clones that are resistant to terminal differentiation. This property is dependent on the full-length *E6* gene; mutational analysis has shown that the putative HPV-16 *E6** gene, encoding a truncated form of E6, cannot provide this function (198). Indeed, it appears that the *E6**, if it is actually made *in vivo,* might function in a dominant negative manner to inhibit some of the activities of the full-length E6 oncoprotein of the cancer associated HPV types (227).

The HPV E6 proteins are about 150 amino acids in size and contain four Cys-X-X-Cys motifs, which are believed to be involved in binding zinc (13,105,106). The E6 proteins from the low-risk and high-risk HPVs appear to have similar transcriptional activation properties, as has been shown using “minimal” promoters containing a TATA box element only (266). Because the E6 proteins of the low-risk HPVs have little or no transformation activity in any of the assays tested, this transactivation property of the E6 proteins may not be linked mechanistically to the transforming functions of the E6 proteins of the high-risk HPVs.

The small DNA tumor viruses have evolved mechanisms to complex and functionally inactivate the tumor suppressor gene product p53 (see Chapter 10). Like the SV40 TAg and the Ad5 E1B 55K proteins, the E6 proteins encoded by the high-risk HPVs can complex with p53; however, a functional *in vivo* interaction between the low-risk HPV E6 proteins and

p53 has not been detected (320). Although p53 is not required for normal cellular proliferation, it plays a fundamental role in directing the cellular response to genotoxic and cytotoxic stresses that threaten genomic stability. The function of p53 as a sequence-specific transcriptional activator (92,148) is necessary for its activity in regulating cell growth and in tumor growth suppression. The first downstream target of p53 to be identified was the p21 cyclin-dependent kinase inhibitor, encoded by the *WAF1* or *CIP1* gene (83,109,327). Thus, the p53-mediated suppression of cell growth is due in part to the transcriptional activation of p21 leading to the inhibition of the cyclin-dependent kinases critical for G_1 progression and cell growth. The p53 protein directly regulates the transcription of additional genes involved in the cellular response to genotoxic and cytotoxic stress, apoptosis and cell cycle control, including *Bax, GADD45, IGF-BP3, cyclin G,* and *14-3-3*g (315). The viral oncoproteins SV40 TAg, AdE1B 55K, and the high-risk E6 proteins can each efficiently abrogate the transcriptional transactivation activity of p53 (193,335). Thus, as with SV40 TAg and Ad E1B, HPV E6 has anti-apoptotic activities and can interfere with the negative cell cycle regulatory functions of p53.

Although SV40 TAg, the Ad5 E1B 55-kd protein, and the high-risk HPV E6 proteins can all complex p53, the consequence of these interactions are different with respect to the stability of the p53 protein. In SV40 and adenovirus-transformed cells, levels of p53 are usually quite high, and the half-life of p53 is increased (212,234). In contrast, the levels of p53 in HPV-infected cells are low compared with uninfected primary host cells (128,254). Unlike TAg and the E1B 55-kd protein, which inactivate p53 in part by sequestering it into stable inactive complexes, the E6 proteins of the high-risk HPVs counter p53 by inducing its proteolysis. This was first demonstrated by *in vitro* studies that showed that the high-risk HPV E6 proteins facilitate the rapid degradation of p53 through ubiquitin-dependent proteolysis (256). Under the same conditions, the low-risk HPV E6 proteins, which do not bind detectable amounts of p53, have no detectable effect on p53 stability *in vitro* (256). HPV-16 E6 induces p53 degradation by forming a complex with the cellular ubiquitin–protein ligase E6AP (131,132), which is then able to bind and ubiquitinate p53 (253). E6AP is a component of the ubiquitin-proteasome pathway, which targets proteins for degradation by covalently linking them to multimeric chains of the 76–amino acid protein ubiquitin. In this pathway (shown in Fig. 16), ubiquitin is first activated in an ATP-dependent reaction and then passed from the ubiquitin-activating enzyme (E1) to a ubiquitin-conjugating enzyme (E2). Ubiquitin is then transferred to lysine residues of the target protein with the aid of a ubiquitin–protein ligase (E3). Multi-ubiquitinated proteins are subsequently recognized and degraded by the 26S proteasome (121). Although some classes of E3 proteins, such as the SCF complexes, function as adapters that bring E2 enzymes into complex with their substrates, E6AP belongs to a class of ubiquitin–protein ligases called HECT E3 proteins, which directly transfer ubiquitin to their substrates (255). The catalytic domain of HECT proteins is a conserved 350–amino acid region defined by its *h*omology to the *E*6AP *c*arboxyl *t*erminus (i.e., HECT) (130). The HECT domain binds to specific E2 enzymes (157) and contains an active-site cysteine residue that forms a thiolester bond with ubiquitin (130,255). X-ray crystallography studies have determined that the HECT domain is a bilobed structure, with a larger N-terminal lobe that interacts with the ubiquitin-conjugating enzyme, and a smaller C-terminal lobe containing the catalytic cysteine residue (126). Both E6 and E6-AP are necessary to detect complex formation with p53, and it has not yet been determined whether E6, E6-AP, or both actually contact p53.

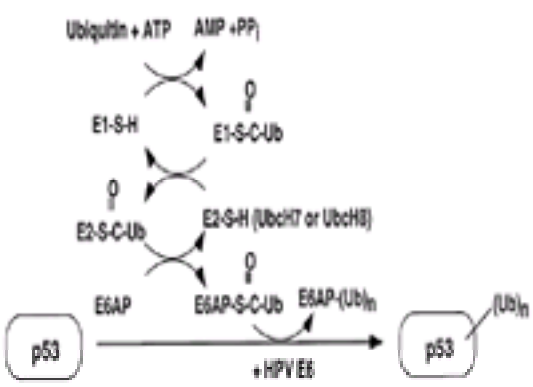

FIG. 16. A ubiquitin thiolester cascade model for the HPV E6–dependent ubiquitination of p53. The E6 protein binds to the cellular protein E6-AP, and the complex together functions as an E3 (ubiquitin protein ligase) in facilitating the ubiquitination of p53 (253). The ubiquitination of a protein involves three cellular activities: E1 (ubiquitin-activating enzyme), E2 (ubiquitin-conjugating enzyme), and E3 (ubiquitin protein ligase). Ubiquitin is activated in an ATP-dependent manner and forms a high-energy thiolester with E1, which can then be transferred to E2 through a thiolester linkage. Ubiquitin can then be transferred to a cysteine within the Hect domain of E6AP, again as a thiolester linkage (255), through the direct binding of E6AP with UbcH7 or UbcH8 (157). In conjunction with HPV-16 E6, E6AP then recognizes p53 and catalyses the formation of an isopeptide bond between the carboxyl-terminal glycine of ubiquitin and a lysine side chain of p53. In catalyzing the ubiquitination of p53, HPV-16 E6 also induces the self-ubiquitination and proteolysis of E6AP (144).

In addition to the *in vitro* evidence that the high-risk HPV E6 proteins accelerate the degradation of p53, E6 also affects the stability of intracellular p53 *in vivo* (11,128,164,254). Levels of p53 in E6 immortalized cells or in HPV-positive cervical carcinoma cells are, on average, twofold to threefold lower compared with primary cells (254). The half-life of p53 is reduced from several hours to 20 minutes in human keratinocytes expressing E6 (128). In uninfected cells, intracellular p53 levels increase significantly in response to DNA damage or genotoxic agents (145). The higher levels of p53 result in either a G_1 growth arrest or apoptosis as part of a cell defense mechanism that allows for either the DNA damage to be repaired before the initiation of a new round of DNA replication or removal of the cell. E6-expressing cells, however, do not manifest a p53-mediated cellular response to DNA damage (149), indicating the ability of E6 to promote the degradation of p53 and prevent the steady level of p53 to rise above a certain threshold level (Fig. 17). Under DNA-damaging conditions, the E6-stimulated degradation of p53 abrogates the negative growth regulatory effect of p53 and as such contributes to genomic instability (321). *In vivo* studies have confirmed the role of E6AP in mediating the E6-dependent ubiquitination of p53 and have established that E6AP in the absence of E6AP is not involved in the

regulation of p53 stability (19,294). Instead, mdm2 functions as the ubiquitin protein ligase for p53 in normal cells (315).

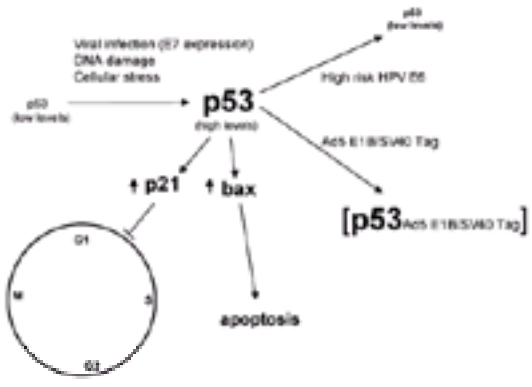

FIG. 17. The level of p53 in primary cells is generally low. DNA damaging agents, viral infection, and expression of E7 increase the level of p53. Elevated levels of p53 can lead to either apoptosis or a cell cycle checkpoint arrest in G_1 phase through the transcriptional activation of *bax* or $p21^{cip1}$. Viral oncoproteins may interfere with this negative growth-regulatory function of p53, either by sequestering p53 into a stable but nonfunctional complex (such as with SV40 TAg or the Ad5 55-kd E1B protein) or by ubiquitination and enhanced proteolysis, as observed with the high-risk HPV E6 proteins.

The HPV-16 E6 protein binds to E6AP within the N-terminal substrate recognition domain, directing E6AP to ubiquitinate p53 (133). Several potential E6-independent substrates of E6AP have now been identified, including the human homolog of the yeast RAD23 protein involved in nucleotide excision repair (HHR23A), the src-family kinase Blk, and the MCM7 subunit of replication licensing factor (155,158,211). In addition, E6 induces self-ubiquitination of E6AP (144). It is conceivable that the redirection of E6AP activity toward p53 by E6 might affect (either enhance or inhibit) the targeting of the normal substrates of E6AP and that such an alteration of E6AP activity could account for some of the transforming activity of E6. Indeed, recent studies suggest that E6 has p53-independent transformation activities. For example, transgenic mice expressing E6 from the epithelial-specific K14 promoter developed epidermal hyperplasia even in a p53-null background (274). Other experiments have shown that an E6 mutant that is unable to bind or degrade p53 can still promote colony formation and growth on soft agar as well as induce cell cycle reentry in cells even when p53 transactivation activity is inhibited (279). Another p53-independent activity of HPV-16 E6 is its ability to activate telomerase, a characteristic of many different types of cancer (152).

A number of additional cellular targets have now been identified for the high-risk E6 proteins in an attempt to define additional p53-independent cellular targets (Table 2). As discussed previously, paxillin, which appears to be a relevant target for the BPV-1 E6 transformation function, can also bind HPV-16 E6, at least *in vitro* (306,311). Interestingly, the high-risk E6 oncoproteins contain a X-(S/T)-X-(V/I/L)-COOH motif at the extreme C-terminus that can mediate the binding of cellular PDZ domain–containing proteins. This motif is unique to high-risk HPV E6 proteins and is not present in the E6 proteins of the low-risk HPV types. The high-risk HPV E6 proteins have been shown to bind a number of cellular PDZ domain–containing proteins, including hDlg (the human homolog of the *Drosophila melanogaster* tumor suppressor disk's large protein), MUPP1 (the multi-PDZ domain protein) and hScrib (the human homolog of *Drosophila scribble*) (151,167,168,201). E6 binding to these PDZ-containing proteins results in their E6AP-mediated ubiquitination and proteolysis (97,201). These PDZ-containing proteins have been shown to be involved in negatively regulating cellular proliferation. At least some of the p53-independent transforming activities of the high-risk E6 oncoproteins may be linked to their ability to bind and degrade some of these PDZ motif–containing proteins. E6 has also been reported to bind the transcriptional coactivator p300/CBP, a target also of adenovirus (Ad) E1A and SV40 large TAg (216,340). The physiologic relevance to the transformation functions of the other E6 cellular targets listed in Table 2 have not yet been elucidated. It is possible that the binding of E6 to some of these targets could contribute to the viral pathogenic functions unrelated to cellular transformation.

TABLE 2. *Cellular targets of the papillomavirus E6 oncoproteins*

HPV E7 Oncoprotein

The E7 protein encoded by the high-risk HPVs is a small nuclear protein of about 100 amino acids, has been shown to bind zinc, and is phosphorylated by casein kinase II (CK II) (199). Insight into its mechanism of action came initially from

the recognition that E7 has functional similarities with the Ad 12S E1A product (224). Like Ad E1A, E7 can transactivate the Ad E2 promoter (224), induce DNA synthesis in quiescent cells (251), and cooperate with an activated *ras* oncogene to transform primary rodent cells (185,224).

In addition to these functional similarities, the HPV-16 E7 shares important amino acid sequence similarity with portions of the Ad E1A proteins and the SV40 large TAg (Fig. 18). These conserved regions are critical for the transforming activities in all three viral oncoproteins and have been shown to participate in the binding of a number of important cellular regulatory proteins, including the product of the retinoblastoma tumor suppressor gene *pRB,* and the related pocket proteins, p107 and p130 (61,81,322). Complex formation with pRB involves conserved region 2 of the Ad E1A protein and the corresponding region in the E7 protein and in SV40 large TAg (61,323).

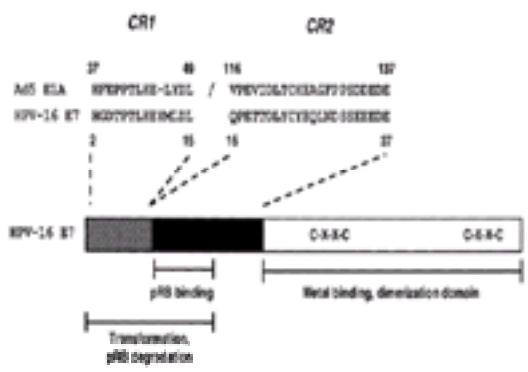

FIG. 18. Amino acid sequence similarity between portions of conserved regions 1 and 2 (*CR1, CR2*) of the Ad5 E1A proteins and the amino-terminal 38 amino acids of HPV-16 E7. CR2 contains the pRB binding site and the casein kinase II (*CKII*) phosphorylation site of HPV-16 E7.

The retinoblastoma protein is a member of a family of cellular proteins that also includes p107 and p130, which are homologous in their binding “pockets” for E7, Ad E1A, and SV40 TAg. The retinoblastoma protein is the most extensively studied member of this family of proteins. Its phosphorylation state is regulated through the cell cycle, being hypophosphorylated in G_0 and G_1 phase and phosphorylated during S, G_2, and M phase. The pRB protein becomes phosphorylated at multiple serine residues by cyclin-dependent kinases at the G_1-to-S phase boundary and remains phosphorylated until late M phase, when it becomes hypophosphorylated again through the action of a specific phosphatase (Fig. 19). The hypophosphorylated form represents the active form with respect to its ability to inhibit cell cycle progression. HPV-16 E7, like SV40 TAg, binds preferentially to the hypophosphorylated form of pRB, consistent with the model that this interaction results in the functional inactivation of pRB and permits progression of the cell into S phase of the cell cycle (50). This property of the viral oncoproteins to complex pRB would appear to account, at least in part, for their ability to induce DNA synthesis and cellular proliferation.

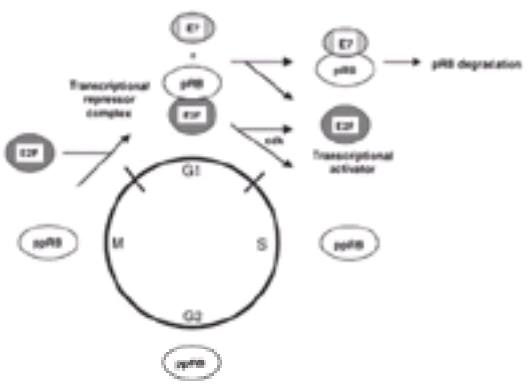

FIG. 19. E7 abrogates the cell cycle regulation mediated by pRB (as well as the related proteins p107 and p130) by complex formation. During the cell cycle, pRB is differentially phosphorylated, and the underphosphorylated form is detected only in the G_0/G_1 phase. This underphosphorylated form is the active form of pRB, acting as a negative regulator of the cell cycle. During the transition to S phase, pRB is phosphorylated by cyclin-dependent kinases (*cdk*), resulting in the inactivation of its cell cycle regulatory functions. Members of the E2F family of cellular transcription factors are preferentially bound to the underphosphorylated form of pRB, and in complex with pRB, they cannot activate transcription. Phosphorylation of pRB or complex formation with E7 results in the release of the E2F factors, allowing them to function as transcriptional activators of cellular genes involved in cellular DNA synthesis and progression into S phase of the cell cycle.

Members of the E2F family of transcription factors are involved in mediating the functions of the pocket proteins (see Chapter 10). The transcriptional activity of E2F is modulated by pRB; when bound to the G_0- and G_1-specific hypophosphorylated form of pRB, E2F functions as a transcriptional repressor. When pRB is phosphorylated by cyclin-dependent kinase complexes near the G_1-to-S phase boundary, the pRB–E2F complex dissociates, and E2F can act as a transcriptional activator (see Fig. 19). The regulated conversion of the transcriptional activity of E2F between repressor and activator contributes to the regulation of G_1-to-S phase progression. The high-risk HPV E7 proteins, like Ad E1A and SV40 TAg, contribute to carcinogenic progression, therefore, at least in part, by disrupting this regulatory

network (205). In the case of the E7–pRB interaction, E7 destabilizes pRB, promoting its proteolysis (27).

The E7 proteins of the HPV high-risk and low-risk types differ in a number of biochemical and biologic properties. The E7 proteins from the low-risk HPV types 6 and 11 bind pRB with about a 10-fold lower efficiency than the E7 proteins of HPV types 16 and 18 (95,200). Furthermore, the E7 proteins of the low-risk HPVs function inefficiently in cellular transformation assays with an activated *ras* oncogene and are phosphorylated by CK II at a lower rate (12). Studies with chimeric E7 proteins containing domains of high-risk and low-risk HPV E7 proteins showed that the difference in transformation efficiency in rodent cells was due to the pRB-binding site (115). Sequence comparison of the pRB-binding sites revealed a single consistent amino acid sequence difference between the high-risk and the low-risk E7 proteins: an aspartic acid residue (Asp 21 in HPV-16 E7) corresponding to a glycine residue in the low-risk E7 sequence (Gly 22 in HPV-6 E7). Substitution of this residue in the respective *E7* genes revealed that this single amino acid residue was the principal determinant responsible for the difference in pRB-binding affinity and in the transforming capacity of the low-risk and the high-risk E7 proteins (115,247).

Mutations in the carboxyl-terminal half of E7 that interfere with E7 function have also generally affected the intracellular stability of the protein (82,223). Nevertheless, several studies have suggested some specific contributions of the carboxyl terminus to E7 functions. E7 can exist as a dimer, and the C-terminal half is important in mediating dimerization (159). The ability of E7 to disrupt the complex between the cellular transcription factor E2F and pRB also involves sequences in the carboxyl terminus of E7, in addition to the pRB-binding site (127,326). Although the ability of E7 to transform rodent cells requires an intact pRB-binding domain, a mutant of HPV-16 E7 that is defective for pRB binding was reported to be competent to cooperate with E6 for the immortalization of primary human genital keratinocytes, indicating that other properties of E7 may also be involved in this function.

Genetic studies indicate that complex formation between E7 and the pocket proteins, including pRB, is not sufficient to account for its immortalization and transforming functions, suggesting that there are likely to be additional cellular targets of E7 that are relevant to cellular transformation (140). Table 3 provides a list of various cellular targets with which E7 has been shown to bind. The physiologic relevance of many of these interactions is unclear. It is possible that some of the interactions may reflect artifacts of the biochemical or yeast two-hybrid approaches used in their identification. It is also possible that some of the interactions may be of physiologic importance to functions of the E7 protein that are not involved in cellular transformation.

TABLE 3. *Cellular targets of the human papillomavirus E7*

Of particular interest are the reports that E7 can interact with cyclin-dependent kinase inhibitors. As with E1A, HPV-16 E7 interacts with and abrogates the inhibitory activity of $p27^{kip1}$ (336). Because $p27^{kip1}$ is involved in mediating the cellular growth inhibition by transforming growth factor-b (TGF-b) in keratinocytes, this activity may contribute to the ability of E7 to override TGF-b–associated growth arrest (225). HPV-16 E7 can also associate with $p21^{cip1}$ and abrogate its inhibition of cyclin dependent kinases as well as its inhibition of PCNA-dependent DNA replication (91,141). The $p21^{cip1}$ is normally induced during keratinocyte differentiation (194), and presumably its inhibition by E7 may be critical to allowing the replication of papillomavirus DNA in differentiated squamous epithelial cells (40).

HPV-16 E7 has also recently been shown to induce abnormal centrosome duplication (77). Although E6 can potentiate this effect, E7 plays a major role in inducing these centrosome-related mitotic disturbances. The mechanism by which E7 affects these centrosome abnormalities are not yet known. Abnormal centrosome duplication rapidly results in genomic instability and aneuploidy, one of the hallmarks of a cancer cell. This activity is therefore likely to be functionally relevant to the contribution of high-risk HPV to malignant progression.

What are the roles of the E6 and E7 oncoproteins in the normal life cycle of an HPV infection? It is likely that they contribute critical functions by providing a cellular environment that fosters the replication of the viral DNA. The viral E1 and E2 proteins are necessary for the initiation of viral DNA replication, but the virus is otherwise totally dependent on host cell factors, including DNA polymerase a, thymidine kinase, PCNA, and so forth, for the replication of its DNA. These are proteins that are normally only expressed in S phase during cellular DNA replication in cycling cells. Vegetative DNA replication for the papillomaviruses, however, occurs only in the more differentiated cells of the epithelium that are no longer cycling (see Fig. 4 and Fig. 5). Thus, the papillomaviruses have evolved a mechanism similar to that of the polyomaviruses and the adenoviruses, to activate the cellular genes necessary for the replication of their own DNA in otherwise quiescent cells. These viruses may do so through the E7 proteins and their ability to release the E2F transcription factors by binding the pocket proteins, including pRB (see Fig. 19). In addition, E7 binds and inhibits the cdk inhibitor $p21^{cip1}$ that is normally induced during keratinocyte differentiation, again presumably for the purpose of permitting viral DNA replication in a differentiated cell. Why, then, does E6 target p53 for proteolysis? The high-risk HPV E7 proteins, when expressed in the absence of E6, result in increased levels of p53, resulting in either a G_1-mediated cell

cycle arrest or apoptosis, depending on the cell type (125,214). The mechanistic link between the pRB and p53 pathways is discussed in Chapter 10. The proposed model, for which there is some evidence, involves the deregulation of pRB by E7, resulting in the induction of E2F-1, which in turn activates p19 ^{arf}, which interferes with the ability of mdm2 to regulate p53 stability. Thus, E7 creates a signal that increases p53 levels. E6, by promoting the degradation of p53, resulting in a lower steady-state level in the cell, counters this activity of E7 and permits the E7-dependent activation of the cellular DNA replication genes required for viral DNA replication.

CHAPTER 66 Papillomaviruses

Douglas R. Lowy and Peter M. Howley

The papillomaviruses (PVs) comprise a group of nonenveloped epitheliotropic DNA viruses that induce benign lesions of the skin (warts) and mucous membranes (condylomas). Some PVs have also been implicated in the development of epithelial malignancies, especially cancer of the uterine cervix and other tumors of the urogenital tract. The recognition that PVs are an important cause of human cancer has heightened their medical importance and stimulated efforts to develop vaccines against these viruses.

HISTORY

Warts were known to the ancient Greeks and Romans. Their infectious nature was recognized, but until the 19th century, genital warts were usually considered to be a form of syphilis or gonorrhea. The viral nature of human warts was demonstrated in the early 1900s when cell-free filtrates from lesions were shown to transmit the disease (50). Although PVs have been identified in a variety of vertebrate species in addition to humans, most PVs are species specific in their host range (reviewed in 161 and 304).

The first animal PV was identified in the 1930s by Richard Shope, who identified and characterized the transmissible nature of papillomas arising in cottontail rabbits (282). The Shope PV, now designated the cottontail rabbit papillomavirus (CRPV), was the first DNA tumor virus identified. Some warts induced by CRPV were shown to undergo malignant progression (256), and for the next two decades, CRPV in the rabbit was an important model for the fundamental study of viral tumorigenesis (157,309). However, the continuing inability to culture CRPV led to its use as a model tumor virus being largely supplanted by the discovery in the late 1950s of the polyomaviruses, which could replicate in cultured cells, could induce morphologic transformation *in vitro,* and were tumorigenic for experimental animals (4) (see Chapter 10).

The advent of molecular cloning in the 1970s initiated an ongoing renaissance in the study of PVs. This technical advance enabled investigators to circumvent partially the inability to culture PVs because the cloning of PV genomes greatly enhanced the ability to study their biologic and biochemical properties. It permitted researchers to determine the function of viral genes, including the multiple PV oncogenes, which fostered a much wider interest in PV research. The bovine papillomavirus type 1 (BPV-1) represented the standard PV for initiating these studies because the virus induced readily identifiable focal transformation of certain established rodent cell lines (21,73). This property meant the genetics of transformation could be studied as well as the biochemical functions of the encoded viral proteins (182). Molecular cloning of PV genomes also led to the recognition that there may be multiple PV genotypes that infect a particular species and that a subset of human papillomaviruses (HPV) was closely associated with human cancers, including cervical cancer (24,62,72,223). The appreciation of their medical importance, combined with improved tools for analyzing PVs, further enhanced the utility of PVs as a model of viral tumorigenesis. Although the study of animal PVs continues to bring new information to the field, the medical importance of human viruses has shifted the emphasis toward the analysis of HPV, especially when it was established that the biochemical properties of some nonstructural viral proteins differed from those of their BPV counterparts (74,263).

INFECTIOUS AGENT

As discussed in detail in the previous chapter, PVs are nonenveloped viruses whose 8-kb closed circular double-stranded DNA genome is surrounded by a 55-nm icosahedral capsid (reviewed in 81 and 301). Most PVs are

classified according to their species of origin and the homology of the viral genomes. There are more than 100 HPV genotypes (types) (62). PVs have been divided into five clades or supergroups, designated A to E (41) (Fig. 1). Animal PVs are found in each of the five supergroups, whereas HPVs are found in three of them. It seems likely that humans were infected more than once with primordial prototypic HPVs because HPVs in the different supergroups are more closely related to animal PVs in the supergroup than to HPVs in the other supergroups. HPVs have infected humans for millennia: at least some genotypes appear to have coevolved with human ethnic groups (123,219). Complete sequence data on many PVs are available (215). Most PV genotypes appear to have arisen through a series of small mutations scattered throughout the genome, rather than by recombination between genomes, because the relative homology between various PVs is often similar regardless of the region of the genome that is compared (41,259).

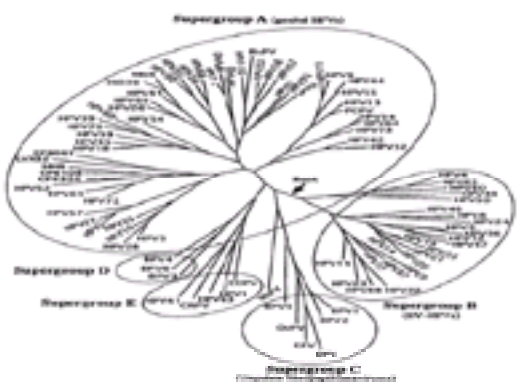

FIG. 1. Phylogenetic tree of human and animal papillomaviruses. The classification is based on the nucleotide sequence comparison of a 291-bp segment of L1. (From ref. 41, with permission.)

Propagation and Assay in Cell Culture

PVs have a similar genetic organization, with all open reading frames (ORFs) present on one strand (Fig. 2). The PV genome contains a main regulatory region, designated the *long control region* (LCR), and coding regions for the nonstructural and structural viral proteins, as described in detail in the previous chapter and reviewed elsewhere (301). Most PVs have six well-described nonstructural viral genes: *E1, E2, E4, E5, E6,* and *E7,* and two ORFs, *E3* and *E8,* whose function is unknown (Table 1). Most viral genes are multifunctional. *E1* has a DNA replicase activity that is required for viral DNA replication. The E2 proteins encode trans-activating and trans-repressor transcription functions and also participate in viral DNA replication. These activities are mediated by E2 binding to specific motifs in the viral genome, particularly in the LCR. *E4* encodes a cytoplasmic phosphoprotein whose biologic function has not been elucidated. PVs have three oncogenes: *E5, E6,* and *E7* (342). The E5 proteins interact with and activate growth factor receptors (192,299). The E5 oncoprotein of BPV-1 preferentially activates the platelet-derived growth factor (PDGF) receptor (68). This property may account for the ability of BPV-1 to induce focal transformation of cultured fibroblasts and contribute to the ability of BPV-1, and related PVs, to induce fibropapillomas, instead of only papillomas. Some E6 proteins induce ubiquitin-dependent degradation of the p53 tumor suppressor protein (261), and many E7 proteins bind and inactivate the underphosphorylated forms of the pRb retinoblastoma suppressor protein (74,113,267). PVs encode two structural viral proteins: L1 and L2. The L1 protein gives rise to the capsid, which is composed of 72 L1 pentamers (12). The immunodominant neutralization epitopes are located on L1. The L2 protein, which is less abundant than L1, interacts with a subset of L1 pentamers (313). It is required for encapsidation of the viral genome (249,339) and also contains neutralization epitopes (38,251).

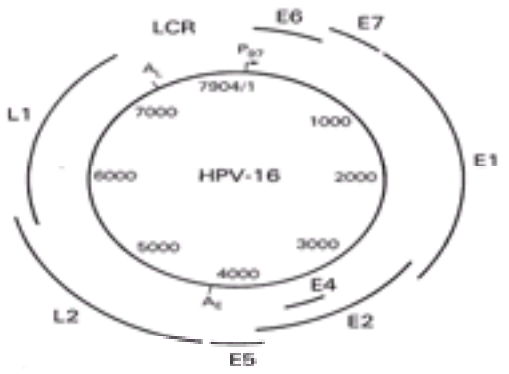

FIG. 2. Genomic map of HPV-16. The genome is a double-stranded circular DNA molecule of 7904 base pairs. Transcription occurs in a clockwise manner; the only transcriptional promoter presently mapped for HPV-16 is designated P_{97}. The open reading frames deduced from the DNA sequence are designed E1 to E7, L1, and L2 and are indicated outside of the circular genome. A_E and A_L represent the early and late polyadenylation sites. The viral long control region (LCR) contains transcriptional and replication regulatory elements.(From ref. 276, with permission.)

ORF	Function
L1	L1 protein, major capsid protein
L2	L2 protein, minor capsid protein
E1	Initiation of viral DNA replication
E2	Transcriptional regulatory protein with an auxillary role in viral DNA replication
E3	No known function
E4	Late protein; disrupts cytokeratins
E5	Membrane-transforming protein; interacts with growth factor receptors
E6	Transforming protein of HPVs; targets degradation of p53
E7	Transforming protein of HPVs; binds to the retinoblastoma protein
E8	No known function

ORF, open reading frame; HPV, human papillomavirus.

TABLE 1. *Functions assigned to the papillomavirus open reading frames*

PVs have proved difficult to propagate *in vitro* because these viruses replicate in stratified squamous epithelium, which is not mimicked in monolayer cultures. Therefore, most clinical identifications of PV infection rely on a technique that identifies the viral DNA, such as polymerase chain reaction (PCR) or a molecular hybridization technique, rather than on virus isolation.

Although the species specificity of PVs has also limited the utility of animals for the study of HPVs, one approach for PV propagation has been to expose initially the primary cultured epithelial cells to virus and then to place the cells under the renal capsule of nude mice (124). This immunologically protected site can support the growth of heterologous cells and foster formation of a multilayer epithelium that resembles a stratified squamous epithelium. The xenograft approach has led to the successful propagation of several HPVs, although it is not suited to routine virus isolation. The technique is difficult to use for large-scale virus production or for the molecular or biochemical analysis of virus replication.

It has been shown that the complete virus life cycle can be recapitulated in cultured cells by using a “raft” culture system composed of stratified squamous epithelial cells placed at an air–water interface (205). This technique is more complex than growing cells in monolayers, and complete replication occurs in a small minority of the cells. However, it can be used to analyze aspects of PV biology, genetics, and biochemistry (195) (Fig. 3). Late gene expression can also be studied by suspending HPV containing epithelial cells in semisolid medium (257).

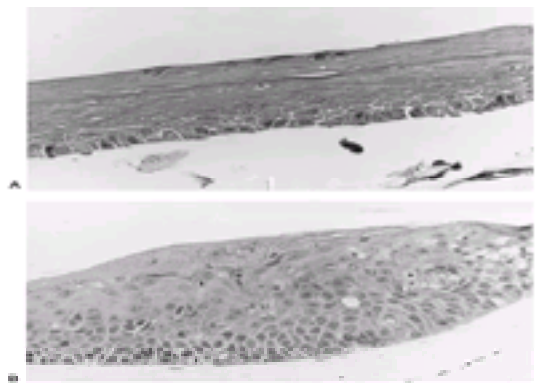

FIG. 3. Raft cultures showing normal keratinocytes (**A**) and keratinotcytes transfected with the full-length HPV-16 genome (**B**). The normal keratinocytes stratify and differentiate with an increase in the cytoplasm-to-nucleas ratio in cells of the upper half of the epithelium and a prominent granular layer. In keratinocytes transfected with HPV-16, while stratification takes place, differentiation is abnormal. There is hyperplasia of cells in the parabasal layer, and mitotic figures are observed in the upper half of the epithelium. No granular layer is seen, and the cytoplasm-nucleas ratio does not change throughout the stratified epthelium. This morphology is similar to that of cervical intraepithelial neoplasia (CIN). (Courtesy of D. McCance, University of Rochester. From ref. 276, with permission.).

Many aspects of PV replication can be studied with monolayer cultures. The most frequently used source of infectious virus is BPV-1 obtained from cattle carrying experimentally produced lesions, which have a high density of infectious virions. The availability of cloned plasmid DNAs for many PVs, including HPVs, makes it possible to use transfection, or infection with heterologous viral vectors, as another approach to study aspects of viral replication.

PV infection of monolayer cultures, whether epithelial cells or fibroblasts, leads to expression of the nonstructural proteins, except for E4, and to episomal viral DNA replication (116). It is therefore possible to use monolayers to analyze these nonstructural viral genes and viral DNA replication (reviewed in 47,235, and 301). The principal restriction to virus replication in cell monolayers is the lack of expression of the structural viral proteins. Infectious virus can be generated in monolayers if the genes encoding the two structural viral proteins are provided to PV-infected monolayer cells through other vectors, such as defective Semliki Forest virus (SFV) vectors (249). This type of system permits dissection, in monolayers, of the requirements for the production of infectious virus.

Biologic Characteristics

Important parameters of PVs include their species specificity, their epitheliotropism, their ability to stimulate abnormal cell growth and establish chronic infection, and the capacity of particular types to infect preferentially particular regions of the

body. The molecular basis for many of these fundamental properties is incompletely understood.

The receptor for PVs has not been clearly identified. Biochemical evidence that the receptor might be a $_6$,b$_4$ integrin (199), although plausible, has not been supported by genetic studies (283). Biochemical and genetic analyses suggest that all PVs may use the same receptor, that the receptor is evolutionarily conserved, and that it is expressed on many cells in addition to epithelial cells (210,250). Indeed, mouse fibroblasts can be readily infected with BPV-1 or with a BPV-1 genome pseudotyped by the HPV-16 structural proteins, and virus-like particles composed of HPV-16 L1 can interfere with BPV-1 infectivity (249).

These results imply that the species specificity of PVs probably lies in their responding to yet to be determined species-specific host regulatory proteins rather than to a restriction at the level of virus adsorption and penetration. Conversely, the epitheliotropism of PVs is likely to result from intracellular restrictions in nonepithelial cells. Consistent with this hypothesis, the LCRs of epitheliotropic PVs bind epithelial-specific factors that regulate viral gene expression (258).

The animal PVs that cause fibropapillomas, such as BPV-1, represent an exception to the strict epithelial tropism of most PVs (161). The viral genomes from this class of PV nonproductively transform the dermal fibroblasts underlying the papillomatous portion of the lesion, in addition to inducing papillomatous changes analogous to those that occur with other PVs. The efficient transformation of the fibroblasts by these PVs probably occurs because their genomes are adapted to be regulated appropriately by factors present in fibroblasts (258) and because their oncogenes are also adapted to transform fibroblasts (68). As noted earlier, such adaptation appears to have occurred with the BPV-1 *E5* oncogene, which in cultured fibroblasts accounts for most of the transforming activity of the BPV-1 genome. BPV-1 *E5* induces a potent activation of PDGF receptors, which are found on fibroblasts but not on epithelial cells, whereas HPV E5 oncoproteins appear to transform cells through a partial activation of epidermal growth factor (EGF) receptors (299) and have weak activity in fibroblasts.

The correlations that have been made between the various HPV types and their clinical manifestations have disclosed preferential sites of infection for many types. Most HPVs can be broadly classified into one of three groups: cutaneous types, EV types, and genital-mucosal types. The cutaneous types cause nongenital skin warts in otherwise normal individuals. The EV types of HPV cause nongenital skin lesions primarily in individuals with epidermodysplasia verruciformis (i.e., EV), a rare condition characterized by a susceptibility to widespread chronic infection by this class of HPVs, or in immunosuppressed individuals. However, inapparent infection with EV HPVs is quite common (25). The genital-mucosal types may infect the genital skin, genital mucosa, or nongenital mucosa. The genital-mucosal types are often further subdivided into high-risk and low-risk types, depending on whether or not they are found regularly in cervical cancer.

Despite evidence that the cutaneous types and the genital-mucosal types tend to infect nonoverlapping areas of the body, there is no molecular insight into what accounts for these distinct profiles of infectious sites. Because, as noted previously, the initial steps in PV infection appear to be through conserved mechanisms that are neither region specific nor species specific, it seems likely that putative intracellular regional-specific regulatory factors would account for the regional restriction of the HPV types.

The ability to induce papillomas, which is the hallmark of PVs, derives from their capacity to alter the normal growth characteristics of the infected epithelium. As described in detail in the previous chapter, *in vitro* studies have examined the biologic and biochemical characteristics of the viral oncogenes and their encoded protein products in considerable detail. These studies imply that three oncoproteins, E5, E6, and E7, perturb cell growth by nonoverlapping, but cooperative, mechanisms. The papillomas themselves appear to arise by means of increased cell proliferation combined with a prolonged retention of the superficial epithelial layers (296).

Papillomavirus Infection of Experimental Animals

The species-specific nature of PVs has thus far prevented adaptation of HPV infection to experimental animals. Despite these limitations, several useful animal models have been described. Animal PVs are found in a variety of mammals and in birds (161,217,304), and transgenic rodent models that use HPV genes have also been developed.

Wild cottontail rabbits (*Sylvilagus floridanus*) represent a natural host for CRPV (33,157,282). Experimental studies of CRPV can be carried out in the natural host, but difficulties in maintaining cottontail rabbits under typical cage conditions have led to most CRPV studies being carried out with domestic rabbits (*Oryctolagus cuniculus*). Cottontail and domestic rabbits represent closely related species, which probably accounts for the ability of CRPV to infect domestic rabbits. CRPV infection of cottontail rabbits induces papillomas, which can progress to cutaneous squamous cell carcinomas, although most lesions remain benign papillomas that will eventually regress. CRPV can also readily induce papillomas in domestic rabbits, and progression to cutaneous cancers occurs more frequently. Another difference is that although papillomas in cottontails usually contain large amounts of infectious CRPV, the lesions in domestic rabbits contain little or no infectious virus.

The canine oral papillomavirus (COPV) causes oral mucosal lesions (217). The papillomas it induces usually regress 1 to 2 months after infection, which makes this model well suited to studying aspects of host defense mechanisms against PV infection.

BPV-1 is the prototype of a group of animal PVs, found in ungulates, that cause fibropapillomas (161). The ability of these PVs to induce nonproductive transformation of dermal fibroblasts leads to their having a wider host range than other PVs, although the increased host range is limited to fibroblasts. Benign dermal tumors, known as *equine sarcoid tumors,* appear to arise after accidental dermal infection of horses with BPV-1. An experimental counterpart is the ability to induce nonneuronal tumors in hamsters inoculated intracerebrally with BPV-1.

BPV-4 can induce oral mucosal lesions, as well as esophageal papillomas, in cattle (37). When cattle are fed bracken fern that contains chemical carcinogens, it can lead to esophageal cancers. One interesting feature of these cancers is that although the BPV-4 infection plays a role in their induction, the tumors themselves do not contain detectable BPV-4 DNA. This represents a rare instance of virally induced tumors that arise by means of a “hit-and-run” mechanism.

A rhesus papillomavirus (RhPV) has been described that appears to be sexually transmitted between monkeys and to be associated with the development of cervical cancer (224). RhPV and HPV-16 are highly homologous, which suggests this animal model might have many similarities to human cervical infection with HPV. However, infectious RhPV has not yet been isolated or propagated, severely limiting experimental analysis of this potentially useful model.

Although no PV has been identified that is infectious for laboratory mice or rats, several useful transgenic mouse models that express a subset of viral genes have been developed. In one model, mice transgenic for BPV-1 develop dermal fibromas, which can progress to fibrosarcomas (286). In another system, when the early region of HPV-16 was placed under control of the keratin 14 (K14) promoter and female mice were treated with estrogen, cervical and vaginal tumors developed in a high proportion of the animals (8). A fivefold lower dose of estrogen resulted in tumors that were localized to the transformation zone of the cervix (77). Neither dose of estrogen was associated with a change in viral gene expression, suggesting that estrogen was stimulating tumor formation, in cooperation with the HPV genes, by altering the expression of one or more cellular genes.

Other mouse transgenic systems have examined the activities of high-risk *E6* and *E7* genes because these are the two viral genes that are preferentially retained and expressed in cervical cancer (270). In one, the expression of *E6* and *E7* from high-risk HPV-16 was directed to the eye by placing each gene under control of the lens crystalline promoter (229). The E7 transgenic mice displayed increased cell proliferation and increased apoptosis, and the E7 activities depended on the Rb-binding site in E7. The E6 mice had impaired lens fiber denucleation and a decrease in the apoptotic-like DNA degradation normally seen in the developing lens. Cooperation between E6 and E7 was seen, in that tumors developed in the lens of E6 × E7 double-transgenic mice but did not develop in E6- or E7-only mice. When the transgenic mice were placed on a p53 null background, it was determined that the E7-dependent apoptosis and the E6 inhibition of apoptosis were each mediated by processes that were partially p53 dependent and partially p53 independent (230).

The *E6* and *E7* genes from high-risk HPV-16, or HPV-18, when placed under control of the K14 promoter, lead to the development of benign or malignant cutaneous tumors (102, 160). Transgenic mice that express HPV-16 E6 or E7 alone, under control of the K14 promoter, were constructed, and cooperation between E6 and E7 was demonstrated for tumor formation, in that E6 × E7 double-transgenic mice developed benign and malignant cutaneous tumors much faster than lesions developed in E6- or E7-only mice (292). The role of E6 and E7 in the tumorigenic process has also been analyzed by testing the ability of the mice expressing only E6 or E7 to function in a standard cutaneous carcinogenesis protocol, which consists of initiation, promotion, and progression. In the K14 transgenic model, E7 functioned primarily as a promoter, leading to the formation of benign papillomas in skin that had been initiated with a chemical carcinogen. By contrast, E6 was found to foster progression from benign papillomas to malignant tumors. These distinct roles of E6 and E7 in tumorigenesis provide at least a partial explanation for the cooperation noted previously in the E6 × E7 double-transgenic mice.

PATHOGENESIS AND PATHOLOGY

Papillomas

Papillomas are benign epithelial lesions that arise following a variable latency period of weeks to months. The papillomas may develop on virtually any stratified squamous epithelium and may therefore involve the skin or mucous membranes. They are usually called *warts* when they are found on the skin and *condylomas* on the genitalia. Lesions may remain for months to years and then regress spontaneously. To establish this chronic infection, it is believed that the virus must infect those epithelial cells that possess long-term proliferative capacity. Minor trauma to the upper layers of the epithelium is probably required at the time of inoculation because the proliferative cells are located in the basal cell layer of the epithelium. Such trauma occurs frequently during intercourse, which may account for the high rate of genital HPV transmission following sexual exposure. Based on X-chromosome–linked marker studies, nongenital skin warts have been reported to be clonal in origin (213), but it remains unclear whether genital warts are similar in this regard (36).

The lower layers of the epidermis harbor low numbers of viral DNA genomes and transcribe low levels of viral RNA (81, 298). Vegetative viral DNA replication, high-level expression of the viral proteins, and virus assembly all occur in the upper epidermal layers, which are undergoing terminal differentiation. Virus assembly occurs in the nucleus, where virions often remain until after the cells are desquamated into the environment.

Papillomas are characterized by a thickened epidermis (acanthosis) with elongated rete pegs (papillomatosis), often with hyperkeratosis and parakeratosis. Cells in the upper layers of the epidermis may have abnormal nuclei (koilocytosis), which are eccentric, pyknotic, and surrounded with a halo. The increase in basal cell mitoses is usually slight, and the basement membrane is intact. The dermal capillary vessels may be prominent and thrombosed.

Although these lesions arise as a direct result of viral infection, the mechanisms by which the virus induces these pathologic changes are poorly understood. Koilocytic atypia was described first in cervical dysplasia and is diagnostic of PV infection (154, 200). However, most of the abnormal nuclei are not associated with viral particles or viral protein, and the mechanisms underlying these cytopathic changes are unknown. As noted earlier, the E5, E6, and E7 proteins of PVs can directly stimulate abnormal cell growth. However, with the possible exception of E5 (35, 194), these genes are expressed at very low levels in infected basal cells (298). It seems possible that viral gene expression in suprabasal cells may stimulate the release of cytokines that in turn stimulate growth of the basal cells. Part of the increased epithelial thickening arises secondary to abnormal retention of cells in the upper epidermis (296). The mechanisms that underlie

this process are not known.

PVs are resistant to desiccation (247). They can remain infectious in the environment for extended periods, and transmission through fomites may occur relatively commonly for nongenital warts (95). However, genital warts, because of their location, are generally transmitted by person-to-person contact. Because of the apparent need for PVs to infect basal cells at the time of inoculation, maceration of the skin may predispose to cutaneous infection. An individual's own PV can represent potentially important sources of infectious virus for transmission to uninfected areas. Lesions involving apposing areas of skin or mucous membrane, as occurs frequently, probably develop by auto-inoculation.

Dysplasias and Carcinomas

A subset of PVs is clearly implicated in the development of malignancy in humans and animals (33,37,342) (Table 2). In humans, these HPVs include those found in cervical cancer and anal cancer (especially HPV-16, HPV-18, HPV-31, and HPV-45) as well as those found in cutaneous squamous cell cancers associated with EV (especially HPV-5 and HPV-8). HPVs are also present in some cases of vulval and vaginal cancer, penile cancer, and oral cancer, especially tonsillar cancer. There is some evidence associating HPV infection with some esophageal cancers, and sensitive HPV DNA detection techniques have identified a variety of HPV types in nonmelanoma skin cancers (NMSCs; basal cell and squamous cell tumors) arising in long-term renal transplant recipients as well as in nonimmunosuppressed individuals. In animals, CRPV and BPV-4 have been shown most clearly to have oncogenic potential.

Species	Cancer	Predominant viral type	Cofactors
Humans	Skin carcinomas in EV patients	HPV-5, -8	Sunlight, genetic defect
	Lower genital tract cancers	HPV-16, -18, -45, -31	Not known
	Malignant progression of respiratory papillomas	HPV-6, -11	X-irradiation
Cattle	Alimentary tract carcinoma	BPV-4	Bracken fern
	Eye and skin carcinoma	Not characterized	Sunlight
Sheep	Skin carcinoma	Not characterized	Sunlight
Cottontail rabbit	Skin carcinoma	Cottontail rabbit papillomavirus (CRPV)	Methylcholanthrene and coal tar (experimentally)

EV, epidermodysplasia verruciformis.

TABLE 2. *Naturally occurring cancers associated with papillomaviruses*

The cancers attributable to PV infection do not occur until many years after the initial infection, which typically induces either benign papillomas or mild dysplasia. Persistent infection with high-risk types, especially with high viral loads, places women at considerable risk for progression to high-grade dysplasia and more severe pathologies, with continuing infection appearing to be necessary for the development of malignancy (119,122,174,325,333). Most infections, even with oncogenic HPV types, have a benign outcome. Lesions that progress to invasive cancer may begin as papillomas or as lesions with low-grade dysplasia and then become more dysplastic over time. However, malignant progression is not an inevitable outcome. Lesions at any stage before the development of invasive cancer may fail to progress or may regress, although the likelihood of regression is inversely related to the degree of dysplasia.

The long interval between the initial infection and the development of cancer implies that other factors in addition to HPV infection play crucial roles in malignant progression. Immune status represents one important host parameter, with impaired cellular immune function being associated with a greater risk for persistent infection and progression to high grades of dysplasia (266). Women who are long-term renal transplant allograft recipients are at increased risk for HPV and for progression to cervical cancer (6,9,284). Women who are infected with human immunodeficiency virus (HIV) are also at increased risk for these outcomes, as discussed in greater detail in the section on HIV and HPV infection (228,315).

Exogenous exposure of PV-induced lesions to co-carcinogens represents another mechanism that can contribute to malignant progression. This phenomenon probably operates in the malignant tumors that arise in EV. Most of the cutaneous cancers in EV occur on sun-exposed skin, which implies that ultraviolet light is serving as a co-carcinogen (187,222). In rabbits with CRPV-induced lesions, malignant tumors develop more frequently, and with a shorter latency period, if the lesions are exposed to dimethylbenzanthracene, methylcholanthrene, or tar (252). In the BPV-4 model of esophageal cancer, the presence of carcinogens in the bracken fern that the cattle eat contributes to the malignant progression (37). Some epidemiologic studies of cervical HPV infection suggest that smoking may be a risk factor for malignant progression, which raises the possibility that chemicals in cigarette smoke could be functioning as co-carcinogens, promoters, or immunosuppressants (58,92,149,240).

As suggested previously, viral genotype also plays an important role in progression. This aspect is clearly seen in EV and cervical cancers. In EV, many different HPV types may cause chronic benign papillomas, but about 90% of the malignant tumors arise in lesions that contain HPV-5 or HPV-8 (187,222). The critical molecular differences that account for their greater oncogenicity has not been determined. In cervical infection, a variety of HPV types can infect the cervix, but only some of these types are consistently associated with cervical cancer (23,181). Based on the differences in the frequency with which these types are found in cancer, compared with their distribution in nonprogressed lesions, the HPV types found regularly in cervical cancers may be designated as high risk or intermediate risk; low risk applies to those HPVs that infect the cervix but do not appear to be associated with malignant potential in the cervix. Important molecular differences have been identified between high-risk or intermediate-risk and low-risk types. These include the much greater efficiency with which high-risk HPVs inactivate the tumor suppressor proteins p53 and pRB as well as other cellular proteins that may negatively regulate cell growth, in contrast to the low-risk HPVs (74,263). There are also

probably quantitative differences in oncogenic potential between high-risk and intermediate-risk types (181) and even within a single high-risk type (40,180,331,332,335), but the molecular basis for these differences has not been clearly delineated.

Although viral DNA remains exclusively episomal in benign papillomas, integration of a partially deleted viral genome is present in most cervical cancers (270). Integration occurs most often in conjunction with the development of high-grade dysplasia, which is also associated with an increase in viral gene expression in basal cells (298). The E6 and E7 viral oncogenes are preferentially retained and expressed in severe dysplasias as well as in frankly malignant lesions. The viral DNA integration occurs in transcribed areas of the host DNA, is often associated with increased expression of E6 and E7, and results in selective growth advantage (129,130). *In vitro* studies of cervical cancer cell lines make it likely that the E6 and E7 oncoproteins contribute directly to the abnormal growth characteristics of dysplasias and carcinomas. The consistent loss of expression of viral genes other than E6 and E7 implies that the process of progression has selected against them. Expression of these other genes may be less compatible with E6 and E7 activities in lower levels of the epidermis and may render the cells more susceptible to immune recognition.

In contrast to the continued expression of E6 and E7 in cervical cancer, viral gene expression may not be obligatory for all cancers that are associated with HPV. In at least some human tumors that contain HPV DNA, viral gene expression appears to have been selectively suppressed (99). As noted earlier, the development of esophageal cancer in cattle by BPV-4 and bracken fern is associated with complete loss of the viral genome in the malignant tumor (37). This hit-and-run phenomenon suggests that the virus is required for tumor induction but that its continued presence is selected against in progressed lesions. The evidence for the involvement of HPV in human esophageal cancers is somewhat controversial (289,305). However, the failure of some investigators to find viral DNA in these cancers could represent a phenomenon analogous to the situation in cattle.

Immunity

The virus life cycle, which occurs in maturing keratinocytes and results in the release of virions through desquamating cells, appears to have evolved to minimize the exposure of the immune system to viral antigens. However, many aspects of papillomavirus biology point to the importance of the immune response in determining the course of infection (32,87,188,297,311). T-cell immune responses appear to be most important after the host has been infected, whereas humoral immunity may help prevent the spread of infection to new sites within the host and reduce the likelihood of reinfection. Protection appears to be largely type specific (310), which may provide at least a partial explanation for the large number of HPV types. However, the apparent antigenic stability within a given HPV type may suggest that each type is currently subjected to relatively little pressure for immune selection.

When multiple warts are present, it is not uncommon for removal of one wart to be followed by the regression of others, suggesting an immunologic response triggered by release of antigen from the treated wart. The spontaneous regression of flat cutaneous warts, in which many lesions may regress simultaneously, or of condylomas or cervical dysplasia, is associated with a mononuclear cell infiltrate consistent with a cellular immune response (52,127). Cutaneous warts occur more frequently in patients with tumors associated with depressed T-cell function, such as leukemias and lymphomas, whereas their frequency is not increased in patients with tumors associated with impaired humoral immunity, such as multiple myeloma (207). Patients with other conditions that affect T-cell immunity, such as pregnancy, immunosuppressive chemotherapy, or HIV infection, are at increased risk for HPV infection that persists as well as for cervical cancer (6,9,84,90,228,315). Even benign HPV infections in immunosuppressed patients are notoriously difficult to treat, and reduction of the immunosuppression may be associated with the spontaneous improvement of the HPV-induced lesions.

While these observations indicate that the immune system, especially T cells, can influence the outcome of HPV infection, protective immunity is incompletely understood, and the viral determinants that induce the immune responses responsible for regression remain uncertain. It seems likely that several viral antigens may possess this capacity, given the genetic heterogeneity of human immune responses and the fact that HPV infection is self-limited in most immunocompetent individuals. Animal papillomavirus models support this possibility, with experimental evidence that cellular immune responses to E1, E2, E6, E7, and L2 may each contribute to the regression of lesions (38,163,178,271). Indeed, experimental CRPV infection of outbred rabbits appears to be prevented in a higher proportion of rabbits when they are immunized with a “cocktail” consisting of genes encoding several nonstructural viral proteins rather than with only one of the viral genes (110). In women, T-cell responses to HPV-16 E6 and E7 occur more frequently in patients with a history of regressed lesions than in those with persistent lesions (133,216,314). However, it is difficult to know whether these particular antigenic responses helped to mediate the regression or are simply markers for regression.

Regression of infection and resistance to reinfection appear to be type-specific phenomena. For example, infection with more than two HPV types occurs relatively frequently, and in these situations, the duration of infection by one type does not appear to be influenced by the duration of infection by the other HPV type (310). Conversely, resistance to reinfection by one HPV type does not appear to confer resistance to reinfection by other types. These results are consistent with the finding that most T-cell and B-cell epitopes in HPV proteins are type specific.

Prevention against reinfection probably depends on both B-cell and T-cell immunity. The ability of T-cell responses to various viral proteins to protect against experimental infection in animal models was noted previously. In addition, L1 induces the immunodominant neutralizing antibodies, which are conformationally dependent and type specific (87). As discussed in greater detail in the section on prevention, neutralizing antibodies are able to protect against experimental challenge with the homologous virus in animal PV models, although the antibodies do not induce regression of established infection (31,145,306). Most women infected with HPV-16 develop low titers of type-specific serum and vaginal antibodies directed against conformational L1 epitopes, as measured in HPV-16 enzyme-linked immunosorbent assays (ELISAs) that use virus-like particles (VLPs) with L1 as the target antigen (39,65). Similar results have been found for VLP-based ELISAs for other HPV types.

There is evidence that certain HLA polymorphisms may predispose individuals toward or against the development of cervical dysplasia and cervical cancer, some with type specificity, presumably because they influence the likelihood of persistent infection (reviewed in 32 and 297). The issue is complicated because various studies have implicated different haplotypes, perhaps because of confounding ethnic factors or choice of control group. The most consistent associations have involved class II alleles, particularly DQ3 and DQB1*03, and two DR-DQ haplotypes, which have been reported to be associated with an increased risk in different populations. A negative association with DRB1*13 has also been reported in some populations. In addition, a naturally occurring HPV-16 E6 variant that affects a putative HLA-B7–restricted cytotoxic T-lymphocyte epitope has been found in the cancers of HLA-B7–positive women, raising the possibility that this mutation might render the virus less immunogenic for these women (76). The plausibility of class II alleles serving an important role in the immune response to HPV infection is strengthened by data obtained with CRPV infection of rabbits. In this animal PV system, both susceptibility and resistance to persistent infection and progression to carcinoma have been linked to class II alleles (32). In addition, infection with two closely related CRPV strains, which differ primarily in their E6 and E7 amino acids, has identified some class II alleles associated with regression against one strain and persistence in the other (259). These observations support the notion that an allele-specific restriction in the binding and presentation of CRPV antigens plays a critical role in determining the outcome of infection.

Patients who develop one HPV-associated tumor are at increased risk for a second HPV-associated tumor (89,92,242,302). In renal transplant recipients, this association is almost certain to depend on their immunosuppression. By extension, it is possible that nonimmunosuppressed individuals who develop additional HPV-associated tumors may have an impaired immune response to the HPV infection. Although a genetic component is plausible, cigarette smoking, which may be carcinogenic or immunosuppressive, has been found to be an associated risk factor.

Asymptomatic Infection and Latency

PVs have the ability to establish clinical latency, although it remains unclear to what degree these situations represent true latency versus persistence in association with very low levels of virus replication. The presence of viral DNA has been documented in the larynx during disease-free periods in patients with laryngeal papillomas (191,295). In genital lesions, the presence of viral DNA in clinically normal tissue surrounding lesions may be associated with a greater likelihood for recurrence (26,83). In the cervix, infection is more readily detectable in pregnant women or in women who have been on long-term immunosuppressive therapy (6,9,84). It is likely that many of these infections represent reactivation of latent disease rather than being secondary to new exogenous exposure. Scarification of domestic rabbits with CRPV DNA represents an experimental model of latent papillomavirus infection (338).

The advent of highly sensitive techniques, such as nested PCR, has also shown that HPV infection can be completely inapparent (10,27). EV-specific types have been isolated regularly from plucked eyebrows of normal individuals. Similar techniques have also identified the DNA of various HPV types in clinically normal skin and mucosa. Their presence in normal tissue means that when sensitive techniques are used to find HPV DNA in a lesion, additional evidence should be sought to determine whether the virus has contributed to the development of the lesion. EV-specific types, or antibody responses to them, have also been found in patients with psoriasis and other conditions associated with rapid epidermal cell growth (79,80,319). The relationship of HPV infection to these disease processes is unclear.

There is also evidence for asymptomatic perinatal HPV transmission, although its relative frequency and potential biologic significance remain conjectural. Pregnancy is associated with a high proportion of cervical samples being HPV positive, which places infants at risk for exposure to genital HPV types during the perinatal period (84). Epidemiologic data support the conclusion that most childhood cases of recurrent respiratory papillomatosis (RRP) arise after intrapartum transmission of HPV from mother to child, as discussed in greater detail in the section on RRP (137). Many cases of childhood RRP occur in children older than 1 year of age, which implies that there has been a period of latent HPV infection at least in these cases. Such data, and the occasional identification of HPV DNA by Southern blotting in neonatal foreskins (253), indicate that perinatal HPV transmission occurs. However, discrepant results have been reported regarding the frequency of such transmission (66,151,241,244,318). Some groups reported that when sensitive nested PCR techniques were employed, up to half of children younger than 11 years of age harbored asymptomatic HPV-16 DNA in their buccal mucosa; other groups found that samples from children, taken from buccal mucosa or the anal region, yielded positive results in fewer than 5% of samples. The reported differences in frequency do not appear to result only from differences in sensitivity of sampling techniques. The presumed high carrier rate of HPV-16 has suggested the possibility to some investigators that genital HPV infection may frequently arise by auto-infection or that many HPV-16 carriers would be immunologically tolerant to this infection. These scenarios appear unlikely to be a common occurrence, in view of the overwhelming epidemiologic evidence that most genital HPV infections in adults are transmitted sexually and the recent evidence, discussed in more detail in the section on prevention, that an HPV-16 L1 virus-like particle vaccine has thus far been found to be immunogenic in all subjects who have received the vaccine (111).

CLINICAL FEATURES AND EPIDEMIOLOGY

Nongenital Skin Warts

These benign papillomas occur most commonly on the hands and feet, although they can arise in almost any location (34,127,128). They occur frequently in older children and young adults, with some surveys of schoolchildren indicating a prevalence of about 10% (164). Most lesions are present for several months and regress spontaneously within 2 years (204), although some may persist indefinitely.

Multiple lesions are most common, and they may be distributed symmetrically or be unilateral. Common warts are scaly, rough, spiny papules or nodules. They often occur as single or grouped papules on the hands and fingers. Flat warts are slightly elevated flat-topped papules that have minimal scale and are found most frequently on the face, arms, or lower extremities. Filiform warts occur most frequently on the face or neck. Plantar warts (on the plantar surface of the foot) and

palmar warts (on the palms) may be thick, endophytic, and hyperkeratotic lesions. Mosaic warts result from the coalescence of plantar or palmar warts into large plaques.

Although not absolute, there is a reasonably good correlation between the clinical lesion and the HPV type (Table 3). HPV-1, HPV-2, and HPV-4 are usually associated with common warts and plantar warts, including mosaic warts, whereas HPV-3, HPV-10, HPV-28, and HPV-41 are found in flat warts. Butchers and meat handlers may have an unusually high prevalence of hand warts. There is no evidence that these warts are caused by animal PVs. Instead, HPV-7 is found in most lesions. It is believed that the combination of maceration and trauma predispose these workers to the development of clinical lesions when they are exposed to this HPV type.

Clinical type	Location and characteristics	Associated HPV (s)[a]
Deep plantar wart	Bottom surface of feet; generally single	HPV-1
Common wart	Mostly on hands; generally multiple	HPV-2, -4
Mosaic wart (superficial spreading wart)	Feet and hands; resistant to treatment	HPV-2
Flat wart	Arms, face, around knees; multiple	HPV-3, -10, -28, -41
Reddish-brown (macular) plaques of EV	Potential for malignancy in light-exposed areas	HPV-5, -8, -9, -12, -14, -15, -17, -19, -20, -21, -22, -23, -24, -25, -36, -37, -38, -47, -49
Butcher's warts	Common warts on hands of butchers and meat handlers	HPV-7

[a] HPV-27, -29, -37, -38, -46, -48, -49, and -49 are also recovered from skin warts.
EV, epidermodysplasia verruciformis.

TABLE 3. *Association of HPV types to morphology and location of skin warts*

Regression of lesions is believed to be mediated immunologically. When most lesions regress spontaneously, there may be a mild mononuclear cell infiltrate, although regression of flat warts may be associated with an erythematous reaction around the lesions in association with an intense inflammatory infiltrate. The low incidence of warts in older people may imply that immune mechanisms have rendered them resistant to infection.

Epidermodysplasia Verruciformis

EV is a rare disorder in which affected individuals have a unique susceptibility to cutaneous HPV infection (187,222). The warts usually develop in childhood, become widespread, do not tend to regress, and in some instances may progress to squamous cell cancers.

There are two predominant types of lesions. Some have the appearance of flat warts, whereas others are flat, scaly, red-brown macules that resemble lesions of pityriasis rosea or tinea versicolor. Both types often occur in the same patient. The flat warts are caused by the same HPV types that induce flat warts in the general population, usually HPV-3 or HPV-10. The pityriasis-like lesions are associated with EV-specific HPV types, most frequently HPV-5 and HPV-8. EV patients are frequently infected with several HPV types.

In about half of affected patients, EV occurs as an inherited disorder, and many EV families have a history of parental consanguinity. Inheritance appears to have an autosomal recessive pattern in most affected families, although one family with apparent X-linked recessive inheritance has been reported (7). Cases with autosomal recessive inheritance are genetically heterogeneous because the condition in different families has been mapped to two distinct chromosomal loci (243). EV patients do not ordinarily display an increased susceptibility to clinical infection with other microbial agents, including the mucosal HPV types or those HPV types associated with common warts. Because many normal individuals have been found to harbor EV-specific HPV types in normal skin, EV patients are unusual in that these HPV types produce clinically apparent lesions. The lesions in EV patients are resistant to usual treatment modalities. These features make it likely that EV patients suffer from an inadequate immune response to infection by the subset of HPV types to which they are susceptible. Consistent with this possibility, global defects in cellular immune function, such as inability to be sensitized to dinitrochlorobenzene (DNCB) and impaired mitogenic responses of cultured lymphocytes to phytohemagglutinin, can be demonstrated in most, but not all, patients with EV. In addition, acquired EV has been described in association with HIV infection (17), and clinical lesions associated with EV-specific HPV types have been described in other immunosuppressed individuals (172).

About one third of EV patients develop skin cancers in association with their lesions. Most of the malignant tumors remain local, but regional and distant metastases may occur. The risk for malignant progression is limited to the pityriasis-like lesions, which are the lesions that contain the EV types. HPV-5 and HPV-8 appear to be the most oncogenic because about 90% of the skin cancers contain one of these two types. Another important feature of the skin cancers is that they usually develop on sun-exposed areas. It therefore appears that carcinoma develops in EV by a combination of infection by an oncogenic EV HPV type plus the co-carcinogenic effects of ultraviolet light. Some EV patients may develop more than one skin cancer. However, cancer progression is a relatively rare event for EV lesions because even in these individuals, most lesions remain benign. Because the tumors do not undergo normal differentiation, the tumors do not contain detectable virions. However, multiple copies of viral DNA are found in primary tumors and in their metastases.

Nonmelanoma Skin Cancer

NMSCs, which are extremely common, are generally subdivided into basal cell carcinomas and squamous cell carcinomas (239). They generally arise on exposed areas of skin; exposure to sunlight is a predominant risk factor; and tumors associated with sun exposure are usually locally invasive but only rarely metastasize. The skin of

immunosuppressed individuals is at high risk for warts as well as premalignant lesions and NMSC, especially squamous cell, in exposed areas (reviewed in 146).

The known oncogenic potential of at least some HPVs and the consistent finding of certain HPV types in squamous cell carcinoma associated with EV make HPV infection an attractive etiologic agent for at least some NMSCs in individuals who do not have EV. Consistent with this possibility, sensitive detection techniques, such as nested PCR, have led to HPV DNA being identified in a substantial proportion of NMSCs in immunocompetent and immunosuppressed patients (60,63,278). When these sensitive techniques are used, about 30% to 40% of NMSCs from immunocompetent patients may be HPV positive, with the rate being about twice as high in tumors from immunosuppressed patients. However, the fraction of these tumors that should be attributed to HPV remains unclear.

The current evidence favoring a pathogenetic role for HPV is stronger in immunosuppressed individuals than in immunocompetent individuals (61,146,233). Several factors contribute to the uncertainty. Predominant HPV types have not been as clearly identified in NMSC in these populations, in contrast to squamous cell carcinoma in EV or to cervical cancer. One heterogeneous range of HPV types appears to be associated with NMSC in immunocompetent patients, and another in immunosuppressed patients. This observation differs from what is seen in cervical cancer, in which the HPV types detected appear to be relatively independent of the immune status of the patient. The NMSCs that arise in immunosuppressed patients are preferentially associated with EV-specific types, but precisely which ones has not reached consensus. In immunocompetent patients, less sensitive detection techniques, such as Southern blotting or type-specific PCR, have identified HPV DNA in only a small minority of NMSCs, although these techniques are adequate to detect HPV DNA in most cases of squamous cell carcinoma in EV or in cervical cancer. One large study that employed these less sensitive techniques identified HPV DNA in less than 3% of the tumors from immunocompetent patients (141). However, these techniques have identified HPV DNA in 30% to 45% of NMSCs in immunosuppressed patients (reviewed in 233). The positive HPV results that require the use of extremely sensitive detection techniques imply that these tumors contain low levels of HPV DNA, probably much fewer than one copy per cell. These positive results also need to be compared with those obtained when noninvolved skin is examined. Using highly sensitive techniques, one study reported HPV DNA in 90% of NMSC lesions from immunosuppressed patients, compared with 35% positive in samples from nonlesional skin (61,63). A recent report of basal cell carcinoma in immunocompetent patients examined paired samples and found that tumor tissue was not more likely to be HPV DNA positive than was normal uninvolved skin (320).

Infection of the Genital Tract

HPV infection of the anogenital tract represents the most important medical burden from infection with this group of agents (Table 4). Infection affects the genital skin and mucosa, including the vaginal tract, cervix, and anal canal. Most of these infections are sexually transmitted, which means that their prevalence is usually correlated with measures of sexual promiscuity, such as number of lifetime sexual partners, recent change in sexual partners, and a history of other sexually transmitted infections.

Clinical association	Viral type(s)
Genital tract	
Subclinical infection	All genital HPVs
Exophytic condyloma (any site)	HPV-6, -11
Flat condyloma (especially cervix)	HPV-6, -11, -16, -18, -31, others
Bowenoid papulosis	HPV-16
Giant condyloma (Buschke-Lowenstein tumor)	HPV-6, -11
Cervical cancer	
Strong association	HPV-16, -18, -31, -45
Moderate association	HPV-33, -35, -39, -51, -52, -56, -58, -59, -68
Weak or no association	HPV-6, -11, -26, -42, -43, -44, -53, -54, -55, -62, -66
Vulvar cancer	HPV-16
Penile cancer	HPV-16
Respiratory papillomas	HPV-6, -11
Conjunctival papillomas	HPV-6, -11
Oral cavity	
Focal epithelial hyperplasia	HPV-13, -32
Infection with genital tract HPVs	HPV-6, -11, -16
Lesions on lip	HPV-2

TABLE 4. *Major clinical association of genital tract and other mucosal HPVs*

Infection of the anogenital tract with HPV is extremely common and has a wide range of clinical manifestations and outcomes, varying from asymptomatic and self-limited to persistent and associated with malignant progression. Viral factors and host factors each contribute to determining the outcome.

Anogenital Warts

In contrast to nongenital warts, these lesions are most prevalent among young sexually active adults, and their frequency usually parallels that of other sexually transmitted conditions. One study reported that condylomas developed in about two thirds of the sexual partners of individuals with condylomas (221). The mean incubation period was 2.8 months, with a range of 3 weeks to 8 months. It is possible that viral transmission might have been delayed in some cases with longer incubation periods. Penile lesions occur commonly in sexual contacts of women with cervical intraepithelial neoplasia (14).

The increase in sexual promiscuity that began in the mid-1960s was associated with a substantial increase in the incidence of condylomas. Between 1966 and 1981, the number of visits to private physicians increased sixfold, from about 170,000 to almost 1 million (1). The number of office visits in 1981 for condylomas was about three times higher than that for genital herpes. Similar findings were made in a population-based study in Minnesota, where the incidence of condylomas between the early 1950s and the mid-1970s increased from 13 per 100,000 to 106 per 100,000 population (49).

Condylomas are usually exophytic lesions that are frequently multiple (220). They may arise anywhere on the external genitalia and may be found simultaneously in multiple sites. In males, they occur most commonly on the penis and anus, and in females on the perineum and anus. The anus may develop multiple lesions that coalesce to surround the anal canal. Most condylomas are usually self-limited, regressing spontaneously or after local treatment, but some lesions may persist for years. As with other HPV infections, genital warts when they arise in patients with impaired cellular immunity may be extremely refractory to treatment. They may also increase in size and number during pregnancy and regress after delivery. This sequence of events may also be a reflection of the immunosuppression associated with pregnancy.

Most genital warts are caused by HPV-6 or HPV-11, which are closely related to each other, with HPV-6 being responsible for most of them (104). Other HPV types, including HPV-16, may also be found in these lesions. Bowenoid papulosis is a related entity (105). The lesions usually consist of multiple small papules, which histologically resemble Bowen's disease or squamous cell carcinoma *in situ.* Most of these lesions contain HPV-16, but the rate of transition to frank malignancy appears to be much lower for the external genitalia than for the cervix. Genital warts in children may be sexually transmitted, secondary to sexual abuse (51,218). However, the genital lesions in children may commonly result from virus inoculation at birth or from incidental spread from cutaneous warts. In contrast to anogenital lesions in adults, a significant proportion of genital warts in children contain HPV types that are usually isolated from nongenital warts, perhaps because, compared with adults, the genital skin in children is more susceptible to infection with these “nongenital” HPV types.

Cervical Cancer

Cervical cancer is the third most common cancer among women worldwide, with about 400,000 newly diagnosed cases each year (231,237). Despite its worldwide distribution, the frequency of cervical cancer varies considerably, being about 10 times more common in some countries than in others (2,126,266). Cervical cancer is the most common cancer of women in most developing countries, where it may account for as many as one fourth of female cancers. It occurs less frequently in developed countries. In the United States, there are about 15,000 newly diagnosed cases annually, and about one third of these women die from malignant disease. The incidence of cervical cancer in the United States varies considerably between ethnic groups, with the rate among black women being about twice that of white women.

Most cancers occur in the transformation zone of the cervix, where the columnar cells of the endocervix form a junction with the stratified squamous epithelium of the exocervix (156,327). About 85% of cervical cancers are squamous cell cancers. Most of the other cases are adenocarcinomas, with a small number being small cell neuroendocrine tumors.

Lesions that are destined to become malignant squamous cell carcinomas typically undergo a series of dysplastic changes over a time span of many years (156,245,327). The severity of the lesion is determined by the degree to which the squamous epithelium is replaced by basaloid cells, with the entire thickness being replaced in the most severe dysplasias. In the traditional classification of cervical intraepithelial dysplasia (CIN), grades I,II , and III correspond, respectively, to mild dysplasia, moderate dysplasia, and severe dysplasia or carcinoma *in situ* (Fig. 4). In the more recently described Bethesda system (158), these abnormalities have been classified as low-grade and high-grade squamous intraepithelial lesions (SIL), with low grade corresponding to mild dysplasia and high grade encompassing the more advanced lesions (Fig. 5). There is also a designation ASCUS (for *a*typical *s*quamous *c*ytology of *u*ndetermined *s*ignificance) for equivocal lesions.

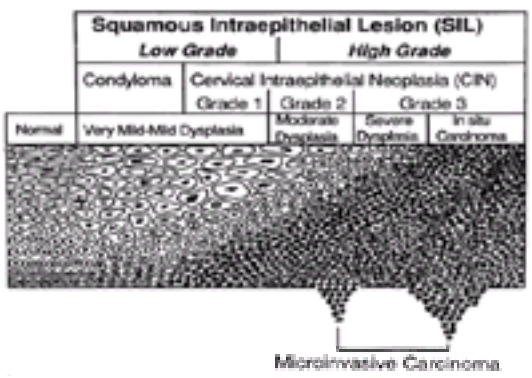

FIG. 4. Cervical squamous carcinoma precursors. Schematic representation of cervical cancer precursors and the different terminologies that have been used to refer to them. The risk for microinvasion from different states of squamous intraepithelial lesions (cervical intraepithelial neoplasia) is arbitrarily represented and is not necessarily proportional to that illustrated in this scheme. (From ref. 327, with permission.)

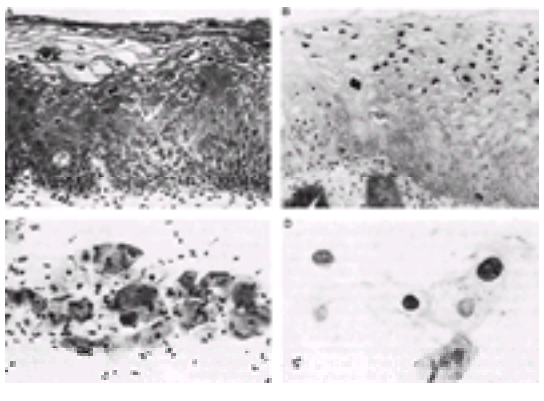

FIG. 5. Low-grade squamous intraepithelial lesions of the cervix. **A:** Histologic section showing koilocytes with vacuolated cytoplasm and parakeratosis (H&E, ×234). **B:** The darkly stained nuclei contain papillomavirus capsid antigen. [Immunoperoxidase stained with genus-specific antiserum (H&E, ×234)]. **C:** Cervical smear. The squamous epithelial cells are rounded. They occur in clumps and display koilocytic changes (Papanicolaou stain; H&E ×375). **D:** Cervical smear. The darkly stained nuclei contain papilloamavirus capsid antigen. (Immunoperoxidase staind with genus-specific antiserum; H&E, ×750). (Courtesy of P. Gupta, University of Pennsylvania. From ref. 276, with permission.)

Most dysplasias do not progress and, in fact, resolve spontaneously, with the likelihood of resolution decreasing with the severity of the dysplasia (Fig. 6). However, the more severe dysplasias generally arise from less dysplastic lesions after several years (132,174), although some high-grade dysplasia may develop rapidly without passing through a low-grade stage (155). The cervical dysplasias have their counterpart in the exfoliated cells present in the Papanicolaou (Pap)smear, by the presence of basaloid cells and koilocytosis. Because of the long interval between the development of cervical dysplasia and the development of invasive cancer, Pap smear screening programs can identify most premalignant lesions. Appropriate follow-up of women with these abnormalities, together with appropriate treatment, can thereby prevent the development of most cases of cervical cancer.

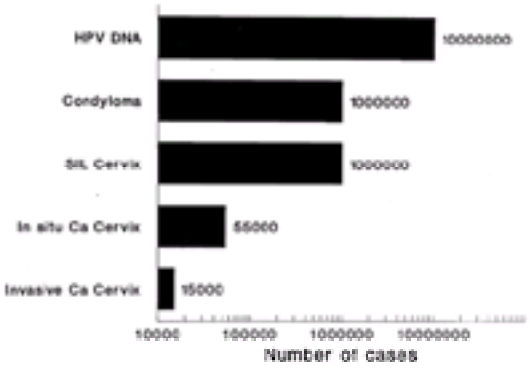

FIG. 6. Estimates of prevalence of genital tract HPV infections and of HPV-associated diseases, in U.S. women. Estimates of number of invasive and *in situ* carcinoma cases are from the American Cancer Society. Other estimates are crude and derived from many sources. (From ref. 276, with permission).

Cervical cancer has been recognized for decades to behave as a sexually transmitted disease, long before sexually transmitted HPV infection was implicated in its pathogenesis. Many studies have concluded that this cancer does not occur in virgins, is most common among prostitutes, and is correlated with number of lifetime sexual partners. Indeed, most of the wide differences in the incidence of cervical cancer in different populations can be accounted for by the sexual practices of the men and women in these populations and by the availability of effective Pap smear screening programs (Table 5).

Number of lifetime sexual partners				
Females	Males	Health care	Cervical cancer incidence	Example
0	–	Variable	0	Nuns, virgins
Few	Few	Variable	Very low	Religious groups, e.g., Amish, Mormons
Few	Many	Poor	Very high	Latin America
Many	Many	Poor	Very high	Some countries in Africa
Many	Many	Good	Low	U.S., Europe

TABLE 5. *Relationship of risk factors to cervical cancer incidence*

Human Papillomavirus and Cervical Cancer

In the mid-1970s, Meisels and his colleagues recognized, on morphologic grounds, that papillomavirus infection of the cervix occurred frequently, often with the histologic characteristics of mild CIN (200). These observations coincided with the proposal by zur Hausen that HPV infection might be the putative sexually transmitted agent responsible for cervical cancer (341). The CRPV system had provided experimental evidence that animal PVs could induce malignant tumors, whereas the development of skin cancer in EV patients had demonstrated that some HPVs might have malignant potential. As noted earlier, another known feature of EV was that only a subset of the HPVs isolated from EV patients were found in the skin cancers, implying that HPV types might vary in their oncogenicity. The identification in the early 1980s of HPV-16 and HPV-18 by zur Hausen and his colleagues (24,72) provided the field with HPV types that could be shown to be present in most cervical cancers and could, by lower stringency hybridization techniques, identify HPV DNA

in an even greater proportion of these tumors. Subsequent studies, carried out by many investigators, have sought to understand the natural history of HPV infection of the genital tract, determine the biologic properties of different HPV types, elucidate the role of the virus in the pathogenesis of cervical disease, and identify nonviral factors that may influence the outcome of HPV infection.

More than 25 HPV types can infect the genital tract and be associated with cervical dysplasia in some infected women, with no single HPV type accounting for most infections. However, only a subset of the genital-mucosal HPV types are found regularly in cervical cancers. Furthermore, the likelihood of finding certain genital types in more severe dysplasias and in the cancers can be shown to increase rapidly with some types, to remain approximately unchanged with other types, and to decrease with others (Fig. 7). These differences, in association with progression to cervical cancer, have led some types to be designated as high risk (such HPV-16, HPV-18, and HPV-45), intermediate-risk (such as HPV-31, HPV-33, HPV-35, HPV-51, and HPV-52), and low-risk (such as HPV-6, HPV-11, HPV-42, HPV-43, and HPV-44) (23,126,181). This classification has considerable utility but must not be overinterpreted. The classification for a particular HPV type is based on the assumption that the relative frequency of exposure and infection has remained constant over many years, which may not be warranted in some instances. Another issue is that even low-risk HPV types may occasionally be associated with cervical cancer (100). HPV-6 and HPV-11 isolated from cervical cancers may have alterations in their genome that could have increased their oncogenic potential, or an HPV type might be more oncogenic in an immunocompromised host. It should also be recognized that this classification may not apply to HPV infection in all sites. For example, the Buschke-Lowenstein tumor, which is a low-grade squamous cell carcinoma of the external genitalia, is usually associated with the low-risk HPV-6 or HPV-11 (106,193). Laryngeal cancer complicating recurrent respiratory papillomatosis also involves these low-risk types (136).

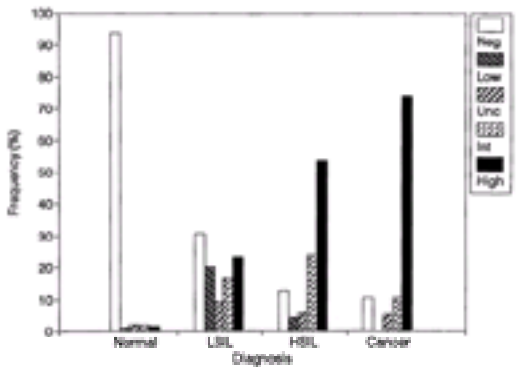

FIG. 7. Patterns of HPV type distribution within four diagnostic categories: Neg, negative; Low, low-risk HPVs (HPV-6, HPV-11, HPV-42, HPV-43, HPV-44); Unc, unclassified HPVs; Int, intermediate-risk HPVs (HPV-31, HPV-33, HPV-35, HPV-51, HPV-52); High, high-risk HPVs (HPV-16, HPV-18, HPV-45, HPV-56); LSIL, low-grade squamous intraepithelial lesion; HSIL, high-grade squamous intraepithelial lesion. (From ref. 181, with permission.

Nonmalignant and Premalignant Cervical Infection

Cervical HPV infection is extremely common among young sexually active women (2,126,266). The estimated prevalence of infection varies with the age of the population and depends on the sensitivity of the assay used to detect HPV DNA in clinical isolates. The peak prevalence is seen in women 15 to 25 years of age, which may be 25% to 40%, and then declines with increasing age (Fig. 8). The decreased rate of HPV infection with age probably results from the self-limited nature of most infections, decreased HPV exposure, and resistance to reinfection. An increase in HPV DNA positivity in women older than 60 years of age has been identified in some populations (119). It is not clear whether to attribute this phenomenon to a cohort effect, a decrease in immune surveillance, or some other explanation.

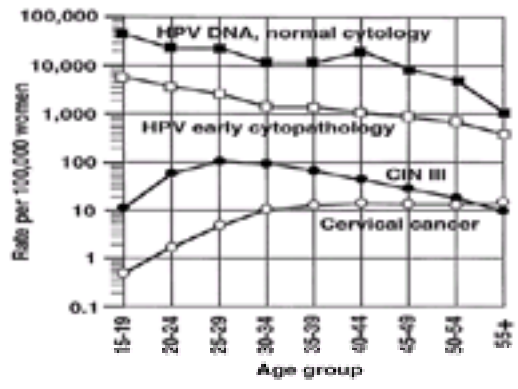

FIG. 8. Age-specific rates of cervical HPV infection and associated abnormalities. HPV infection with normal cytology is much more common than HPV infection associated with abnormal cervical cytology. The prevalence of HPV infection decreases with age. Peak incidence of cervical intraepithelial neoplasia type III (CIN III) develops in women who are older than those with the highest rates of HPV infection. Peak incidence of cervical cancer develops in women who are older than those with the highest rates of CIN III. HPV DNA with normal cytology and early cytopathology are point-prevalence data, whereas the CIN III and cervical cancer data are incidence rates. The data are from several sources in the United States. (Adapted from ref. 266, with permission.)

Although most women with HPV infection of the genital tract do not have any detectable cytologic abnormalities, the epidemiology of genital HPV infection appears to account for the epidemiology of cervical neoplasia, including the dysplasias that precede cervical carcinoma. Some analyses published in the 1980s failed to show a strong association between HPV infection and cervical neoplasia. These conclusions were the consequence of false-negative and false-positive HPV DNA results obtained with incompletely validated assays. More recent analyses, based on validated assays, have consistently shown that HPV infection represents a major risk factor for cervical neoplasia (2,126,266).

In multivariate analyses, HPV infection accounts for at least 80% to 90% of the attributable risk for the development of cervical dysplasia. In one cross-sectional study, HPV prevalence in patients with SIL was 81%, compared with 18% in cytologically normal specimens (264). When five cytologists examined the same set of “atypical” Pap smears, the HPV DNA prevalence was 100% for those specimens classified by all of them as abnormal, compared with 21% for those smears that they all classified as normal (280). A key epidemiologic question is whether HPV infection precedes the development of cytologic abnormalities. In this context, cohort studies of cytologically normal women have shown that HPV infection frequently precedes the development of cytologic abnormalities and that women infected with HPV-16 or HPV-18 are at highest risk for dysplastic changes. In a cohort of women with negative cytology at recruitment, the cumulative incidence of SIL at 2 years was 28% in the HPV-positive women, compared with 3% in the HPV-negative women (155). In another study, cytologically normal women who were HPV DNA positive at recruitment were 3.8 and 12.7 times more likely to develop low-grade and high-grade SIL, respectively, compared with HPV DNA–negative controls (174).

Human Papillomavirus in Invasive Cervical Cancer

A worldwide study of almost 1,000 cervical cancers, from paraffin-embedded sections, indicated that more than 90% contain HPV DNA (23). The results confirmed and extended observations made in more restricted studies of cervical cancer (2,126). Although more than 20 HPV types were found in the tumors, four types (HPV-16, HPV-18, HPV-31, and HPV-45) accounted for close to 80% of the HPV-positive cancers. Conversely, low-risk HPVs were found in only two of these cancers. In almost all areas of the world, HPV-16 appears to be the most common type found in the cancers. However, there does appear to be some regional variation in the specific proportion of HPV types. A follow-up evaluation of the cancers in the international study that were initially thought to be HPV-negative indicated either that they were false-negative results or that the DNA in the specimens was too degraded for the negative results to be deemed reliable (317). The conclusion from this study was that at least 99.9% of cervical cancers contain HPV DNA.

Most studies have focused on the more common squamous cell cancers. However, most adenocarcinomas, adenosquamous carcinomas, and carcinomas with neuroendocrine differentiation also contain HPV DNA. One apparent difference is that most studies have found HPV-18 to be the predominant type in adenocarcinomas and neuroendocrine carcinomas, in contrast to HPV-16 being most common in the squamous cell cancers. Some evidence has suggested that HPV-18 infection may progress more rapidly and carry a poorer prognosis than HPV-16.

A Mechanistic Role for HPV in Cervical Neoplasia

Epidemiologic data have clearly established that cervical HPV infection precedes the development of cytologic abnormalities, that strong previous risk factors associated with cervical dysplasia and cervical cancer tend to be eliminated when controlled for the presence of HPV, that HPV infection can account for most cervical dysplasias, and that HPV DNA is found in virtually all cases of cervical cancer. Odds ratios of 10 to more than 200 have been found for HPV infection as a risk factor for these clinical abnormalities, with the highest odds ratios seen for infection with HPV-16 and HPV-18. These odds ratios are the highest for a human carcinogen. In addition, results of a validated serologic assay that can identify currently and previously infected individuals also implicate HPV-16–related viruses in the development of cervical cancer (171).

Laboratory-based studies of HPVs also strongly support the inference that HPVs are etiologically involved in cervical cancer. The viral DNA is present in all cells of the primary tumors, as well as in metastases, and is transcriptionally active. In mildly dysplastic lesions, each of the viral ORFs appears to be expressed, mainly in the upper levels of the epithelium (298). In high-grade dysplasias, by contrast, a more restricted number of ORFs are expressed, primarily *E6* and *E7,* and their expression is now found in the basal, proliferating layer of the epithelium. More progressed lesions are associated with a higher expression of these genes. High-grade dysplasia and progression to carcinoma is associated with integration of the viral genome, with deletion of large segments of the viral genome and with transcription of sequences downstream from the integrated LCR (11,270) (Fig. 9). In this integrated form, the *E6* and *E7* ORFs remain intact in the integrated viral DNA, from which they can be transcribed. Disruption of the viral *E1* and *E2* genes as well as of downstream viral sequences may permit higher levels of *E6* and *E7* transcription (64,130,254), whose RNA is stabilized following fusion to downstream cellular sequences. Viral DNA integration occurs in almost all tumors and tumor-derived cell lines that harbor HPV-18, and in most with HPV-16, although the DNA remains episomal in some HPV-16 tumors and cell lines (57). Most cell lines derived from cervical cancer contain HPV DNA, either HPV-16 or HPV-18 (270). They continue to express E6 and E7, which appear to be necessary for their continued viability and their ability to proliferate (64,316). However, some tumor-derived cell lines are negative for HPV DNA (262,324), raising the possibility that some primary cervical cancers may be HPV DNA-negative.

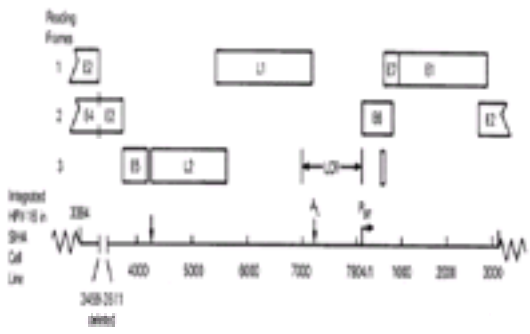

FIG. 9. Structure of the single copy of HPV-16 DNA integrated into the SiHa cell line derived from a cervical carcinoma. The *jagged line* represents human chromosomal sequences; the nucleotide numbers pertain to the integrated HPV-16 genome. The *open boxes* indicate the early and late open reading frames (ORFs). Integration has occurred in the *E2* ORF, and a portion of the *E2* ORF has been deleted. (From ref. 11, with permission.)

Experimental studies with HPV genomes and individual viral genes emphasize the greater biologic activities of the high-risk HPVs compared with the low-risk types, especially the critical role of E6 and E7. In organotypic raft cultures, high-risk HPV can induce changes that resemble dysplastic lesions (195). Furthermore, the high-risk HPV genomes, such as HPV-16 and HPV-18, are capable of immortalizing human keratinocytes, in contrast to the low-risk HPV genomes, although cooperating cellular changes are probably also necessary (342). In experimental results that parallel the observations in the cervical cancers and cell lines derived from them, efficient immortalization requires cooperation between high-risk E6 and high-risk E7 (114,211). Substitution of either low-risk E6 or low-risk E7 severely reduces the efficiency of immortalization.

Thus, the *E6* and *E7* genes from high-risk HPVs collaborate to interfere with normal growth and cell cycle checkpoint controls, and with the regulation of chromosomal stability (94). Mutational and biochemical analyses of the proteins encoded by *E6* and *E7* have provided insight into some of the complex mechanisms by which these multifunctional genes act. As noted previously, the high-risk E6 proteins inactivate p53, whereas the high-risk E7 proteins bind and inactivate pRb. HPV-16 and HPV-18 positive cell lines derived from cervical and anal cancers harbor wild-type versions of pRb and p53, whereas HPV-negative tumor-derived cell lines have mutant Rb and p53 (55,56,262,324). These results imply that E6 and E7 generally induce substantial functional inactivation of p53 and pRb *in vivo* and support the conclusion that inactivation of pRb and p53 make an important contribution to the biologic activities of these proteins. In at least some instances, however, there may be some residual p53 activity, as evidenced by HPV-positive tumors with mutant p53 in metastases (54). The p53 protein is a transcription factor that, by means of its ability to regulate a series of target genes, orchestrates a pleiotropic cellular response to various genotoxic and cytotoxic stresses, to preserve genomic integrity and normal cell growth (173). Abrogation of p53 activity by E6 therefore disrupts a critical inhibitor of genomic instability and of abnormal cell growth (190). E6 interferes with p53 function primarily by inducing the ubiquitin-dependent degradation of p53, a function that is mediated by the ubiquitin ligase E6-AP (261,263). However, E6 can also interfere more directly with p53 activity by other mechanisms. These include the ability of E6 to inhibit the interaction of p53 with its cognate DNA-binding sites in transcriptional targets and the ability of E6 to bind to p300/CPB, which is a coactivator of p53 (168,340). One important biochemical consequence of the interaction between E7 and pRb is the release of the transcription factor E2F1, which, in the absence of E7, is bound to the underphosphorylated pRb that inhibits growth (43,225). The release of E2F1 leads to its activation, which probably makes an important contribution to the pRb-dependent biologic activity of E7 (202,208).

At least some effects of E6 and E7 are p53 independent and pRb independent, respectively (190,343). Mutants with impaired biologic activity *in vitro* have been described for E6 proteins that still induce degradation of p53 and for E7 that still bind pRb (13,85,179). Several cellular proteins in addition to p53 and pRb have been reported to interact with E6 or E7, as described in the previous chapter, although their precise role in tumorigenesis is still unclear. For example, E6 can interact with and inhibit the protein encoded by the discs large gene (DLG), and with interferon regulatory factor 3, resulting in the inhibition of its transcriptional activity (148,169,255). In addition to its interaction with Rb, E7 has been reported to bind and interfere with at least two additional cell cycle inhibitors, p21CIP1 and p27KIP1, and to activate cyclins A and E (93,131,198,336,343).

One important HPV-dependent effect relevant to cancer is the activation of telomerase (147,150). In human keratinocytes, this activity is induced primarily by E6, by a mechanism that is largely independent of p53. Efficient immortalization of keratinocytes by E6 and E7 probably depends on the ability of E6 to inactivate p53 and to activate telomerase, although keratinocyte immortalization can be induced by E7 plus either a mutant p53 or the catalytic component of telomerase. In cervical lesions, telomerase activation is associated with progression to severe dysplasia and cervical cancer, and cell lines derived from cervical cancers are uniformly positive for telomerase (139,214,291).

There is also evidence that high-risk HPV can induce abnormal centrosome duplication, which can result in genomic instability and aneuploidy (69). The deregulation of this mitotic event appears to depend on E6 and E7, with the latter protein being most responsible for the effect.

It has also been found that the oncogenic potential of some intratypic variants may be greater than that of others (40,180,331,332,335). This phenomenon has been best documented for HPV-16, but it also appears to apply to HPV-18 and perhaps to other HPV types. Although HPV types have a worldwide distribution, certain variants are more frequently identified in certain regions. By this criterion, HPV-16 can be divided between those that are considered to be European variants (also referred to as *prototype-like* because a European variant was the first HPV-16 identified) and those that are more distantly related (designated *non–prototype-like*). Several studies have now found that non–prototype-like variants

are associated with a greater likelihood of persistent infection and with high-grade cervical dysplasia and cervical cancer as well as with anal carcinoma *in situ.* It should be recognized, however, that prototype-like HPV-16 variants still account for most cases of severe dysplasias and cancer associated with HPV-16. It is unclear whether the differences in oncogenic potential are attributable primarily to variation in the LCR (134), in the biologic activity of one or more viral proteins, or in the immune response they induce (334).

In summary, the evidence linking HPVs to cervical cancer meets all the criteria for an etiologic relationship. The association of HPVs with cervical cancer is very strong, consistent, and specific; it holds for cervical cancers throughout the world; cohort studies show that HPV infection precedes dysplasias and malignancy; and important aspects of the disease can be reproduced in experimental models. Thus, the evidence for biologic plausibility is as strong as for any human carcinogen.

Cellular Events in Cervical Cancer

Although infection with high-risk HPV may be necessary for the development of cervical cancer, or other cancers attributable to HPV infection, it is clearly not sufficient. Cancer must arise only after other factors have collaborated with the infection. Some changes may be virus specific, as discussed previously. For example, viral integration into the host DNA leads to decreased expression of some viral genes, increased expression of E6 and E7, selective growth advantage, and progression to high-grade dysplasia and cancer (57,129,130,270).

Other changes associated with progression include genetic alteration of cellular genes. Cervical cancers are aneuploid, and as discussed previously, the *E6* gene probably plays an important role in fostering genomic instability, although *E7* may also contribute to this abnormality. Tumors typically have several cytogenetic alterations, which implies loss or gain of function of several cellular genes. In most instances, the specific gene that has been affected by a given cytogenetic alteration has not been identified. Although most of these cytogenetic changes are probably not a direct consequence of viral DNA integration, cellular genes can be directly affected by the viral integration. For example, viral DNA integration near *Myc* and *JunB* has been associated with increased expression of these protooncogenes (46,71).

Consistent with the multistep nature of tumorigenesis, cervical cancers may show additional cytogenetic alterations when compared with adjacent dysplastic lesions (143). Certain cytogenetic changes have been found in a relatively high proportion of tumors (reviewed in 166). Those found in one fourth to one half of tumors include loss of heterozygosity in chromosome regions 3p14, 4p16, 4q21 to 4q35, 6p21 to 6p22, 11p15, 11q23, 17p13.3, and 18q12 to 18q22. Loss of heterozygosity in 3p has been identified in cervical dysplasias adjacent to cancers that also have this alteration (108). This observation implies that inactivation of a putative tumor suppressor gene in this region may occur as an early event that could predispose to further progression. The *FHIT* (fragile histidine triad) gene, which is a putative tumor suppressor gene, is a candidate for the 3p locus. It is located at 3p14.2, and its expression is inversely correlated with the severity of dysplasia or cancer (20). However, reintroduction of the *FHIT* gene into tumor cell lines did not alter their biologic properties (329). In contrast to the multiple loci with loss of heterozygosity, a gain of chromosome 3q24 to 3q28 has been reported to be present in almost all cervical cancers but to be absent from most cases of severe dysplasia (120). PIK3CA, which is located in 3q26.3 and is involved in the PI3 kinase–AKT signaling pathway, has been proposed as a candidate oncogene for this amplified locus (184). Amplification or overexpression of other oncogenes may occur, including *c-Myc, EGFR,* and *Her-2/Neu,* and may be associated with a poorer prognosis (142,206,236,246). A possible difference in risk for cervical cancer was recently proposed for individuals whose p53 contains Arg or Pro at residue 72, which are common allelic variants of p53 (reviewed in 190). This proposal was based on the experimental finding that the Pro-72 allele was more resistant to E6-dependent degradation than the Arg-72 allele, raising the possibility that individuals with the Arg-72 might be at increased risk for cervical cancer. However, an initial report that suggested such an increase in patients with cervical cancer has not been confirmed in several subsequent studies.

Insights into the collaboration between viral oncogenes and cellular genes in tumorigenic progression have also been obtained with cervical cancer–derived cell lines, by inducing their reversion and retransformation. Studies by Stanbridge indicated that the tumorigenic phenotype was recessive by showing that it could be suppressed by fusion of HeLa cells, a cervical adenocarcinoma–derived cell line that contain HPV-18, with normal human fibroblasts or keratinocytes (294). Reversion could be reproduced by microcell transfer of only chromosome 11 into the HeLa line or the SeHa line, which are HPV-16 positive (152). Conversely, loss of the short arm of chromosome 11 in fibroblasts was associated with their being more efficiently transformed by HPV-16 than wild-type fibroblasts (287). Taken together, the results are consistent with the existence of a tumor suppressor gene on the short arm of chromosome 11. It is unknown whether this gene and the 11p15 locus identified as a frequent site for loss of heterozygosity in cervical cancers are the same or distinct. Regardless, suppression of HeLa cell tumorigenicity in nude mice is associated with a decrease in the level of E6 and E7 expression *in vivo* (although not *in vitro*), in which tumor necrosis factor-a (TNF-a) probably plays an important role. Suppression can be abrogated by ectopic expression of the *c-fos* oncogene, which increases AP-1 transcription activity and renders the cells resistant to the inhibitory effects of TNF-a (293).

There is also evidence that cervical cancers may have undergone changes that help them to evade the immune system (reviewed in 32,87,188,297, and 311). The most frequent changes involve the down-regulation of HLA class I alleles, which are normally expressed on keratinocytes, in contrast to class II (53,297). Consistent with a role in progression, down-regulation of one or more class I alleles occurs in most tumors, is reported to be greater in metastases compared with the primary tumor, HLA-B7 positive patients whose tumors down-regulate this allele have a poorer prognosis, and selective loss of HLA-B7/40 allelic products is associated with lymph node metastases. Several mechanisms may account for the down-regulation of class I expression (28,53,153). Some affect class I alleles directly by mutation or deletion, whereas others affect the class I processing system, primarily by down-regulation of the TapI transporter, which is required for class I processing. The HLA region is located on the short arm of chromosome 6, at 6p21.3, which is within the 6p21 to 6p22 region that, as noted previously, has been reported to be a frequent site of cytogenetic abnormalities in cervical cancer. It is therefore likely that many of the cytogenetic rearrangements in this region reflect alterations in class I alleles. In addition to these class I changes, most primary tumors aberrantly express HLA class II molecules, perhaps in response to inflammatory cytokines produced by infiltrating lymphocytes (32,53,297). Class II expression is not a feature

of metastatic lesions.

Human Immunodeficiency Virus

The immunosuppression resulting from HIV infection is associated with an increased susceptibility to infection by many other microbial agents. The risk for genital HPV infection may be particularly high for HIV-infected individuals because infection by both viruses is often through sexual transmission, and it is well known that exposure to one sexually transmitted agent places an individual at higher risk for exposure to other sexually transmitted agents. Thus, individuals at high risk for sexual exposure to HIV would also tend to be at high risk for exposure to genital HPV infection. On the other hand, the lesions of uncomplicated cases of genital HPV infection are not usually associated with erosion or ulceration and thus would not be expected to provide an efficient portal of entry for HIV, in contrast to the predisposition to the acquisition of HIV infection associated with genital ulceration.

It has been well documented that cervical HPV infection is detected more frequently in HIV-positive women than in those who are HIV negative, the infection is even more likely to persist, it is more likely to result in cytologic abnormalities, and there is much greater risk for high-grade dysplasia (228,303,328). In a prospective study of women in New York at high risk of HPV infection, cervical swabs taken at the initial examination detected HPV DNA about twice as frequently in HIV-positive women compared with HIV-negative women (56% versus 31%), and persistent infection was six times as frequent in the HIV-positive women (24% versus 4%) (303). Low-grade dysplasia (CIN I) was about three times as frequent in HIV-positive women (13% versus 4%), whereas high-grade was seven times more frequent (7% versus 1%) (328). Low CD4 counts in HIV-positive women represent an independent risk factor.

These features of HPV biology in HIV-positive women make it likely that HIV-positive women would suffer from a high rate of cervical cancer. Indeed, retrospective studies from New York reported that an unexpectedly high proportion of cervical cancers diagnosed in women under 50 were HIV-positive (186), leading the CDC in 1993 to designate cervical cancer as an AIDS case-defining illness. Analysis of large cohorts has documented that HIV infection places women at increased risk of developing cervical cancer (90,272). In a report from the AIDS-Cancer Match Registry Study in the United States, HIV infection was associated with a relative risk of about 5 for women of any age (90).

HIV infection appears to represent a risk factor for other malignancies associated with HPV infection, including cancers of the vulva, penis, and anus (90). The relative risk for developing these cancers was higher for individuals who were under 30 years of age than for older individuals. As discussed below, the relative risk for anal cancer is especially high for HIV infected male homosexuals.

Other Cofactors for Cervical Cancer

Many additional factors have been examined for their possible influence on the incidence of cervical cancer and its precursor lesions. When controlled for the presence of HPV infection, the factors of smoking, oral contraceptives, pregnancy, parity, nutrition, micronutrients, and sexually transmitted diseases have been found in some studies to be associated with increased risk (15,58,97,149,212,266). In most instances, it is not clear how the cofactor may contribute to dysplasia and carcinogenesis. Possibilities include increasing the risk for establishing nfection, decreasing local or systemic immunity, stimulating the growth of HPV-infected tissue, and inducing mutations in infected tissue. It may be relevant that higher levels of a tobacco-specific carcinogen have been identified in the cervical mucus of cigarette smokers (240). The possible relationship between cervical cancer and certain HLA class II alleles was also noted previously (32,297). It is not surprising, therefore, that some evidence exists for an hereditary contribution to the risk for cervical cancer (117).

Although those factors may make some contribution to the development of cervical cancer, they are unlikely to explain the wide variation in cervical cancer incidence in different populations throughout the world. In this context, the incidence of cervical cancer in an area depends primarily on the relative endemnicity of HPV infection and the effectiveness of cervical cancer screening programs (126).

Anal Cancer

Anal cancer appears to share important similarities with cervical cancer, as well as some differences. The disease is somewhat more frequent in women than in men, with about 1,900 female cases and 1,400 male cases per year in the United States (162). Anal HPV infection appears to be sexually transmitted in most instances, and a history of receptive anal intercourse in women and of homosexual activity in men is associated with an increased risk for this cancer (91). However, such a history is often lacking, which makes it likely that some anal infections have spread from other genital areas. Consistent with this interpretation, simultaneous cervical and anal infection, often with the same HPV type, may be relatively common. The rate of anal infection by HPV appears to be similar to that of cervical infection, although anal HPV infection has been studied less systematically than cervical infection (323). As with cervical cancer, high-risk HPVs have been found in most anal cancers, with an even greater preponderance of HPV-16 than in cervical cancer, and most anal cancers arise in the transition zone between columnar and squamous epithelium. In one large study from Scandinavia, 83% of HPV-positive tumors contained HPV-16; 93% of tumors from women were HPV positive, whereas 69% of the male tumors were HPV positive (91). It would therefore appear that most of these cancers in the women were attributable to HPV infection, whereas some proportion of the anal cancers in men might not be associated with HPV infection.

One important difference from cervical cancer is that the risk for anal cancer in the general population appears to be much lower than for cervical cancer, although it is not known what may account for these differences in rates of progression. In countries with effective cervical cancer screening programs, comparisons between the incidence of cervical cancer and anal cancer underestimate the difference in risk for progression because these programs prevent many potential cases of cervical cancer. However, in developing countries where there is almost no impact of Pap smear screening on the incidence of cervical cancer, the incidence of anal cancer in women is less than one tenth that of

cervical cancer (231).

The risk for anal cancer among HIV-positive individuals is much greater than in the general population, with especially high rates for HIV-positive male homosexuals. According to the AIDS–Cancer Match Registry Study in the United States, HIV infection was associated with a relative risk, for invasive cancer, of 6.8 for women and 37.9 for men (90). The difference in risk between women and men was attributable to the group of HIV-positive homosexual men, whose relative risk was 59.5, compared with a relative risk of 5.9 for HIV-positive male intravenous drug users. A very high proportion of men and women with HIV infection also have anal HPV infection. Studies from San Francisco report anal HPV infection in 93% of HIV-positive male homosexuals (versus 61% of HIV-negative homosexual males) (226), compared with 76% of HIV-positive women (227). It is therefore unlikely that the increased risk in male homosexuals for anal cancer results primarily from a higher incidence of anal HPV infection. Instead, it appears reasonable to postulate that an additional feature specific to receptive anal intercourse, such as trauma, may collaborate with HIV and HPV infection (90). Consistent with this interpretation, at least some of the increased risk in male homosexuals for anal cancer appears to have predated the HIV era (201). The high risk for anal cancer among homosexual and bisexual men who are HIV positive has led some authors to advise routine screening of this population for anal squamous epithelial lesions (98).

Human Papillomavirus in Other Genital Sites

Genital HPV may also routinely infect other genital areas that contain stratified squamous epithelium. The risks associated with HPV infection at these sites appears to be similar to those of cervical infection (126). The penises of male partners of women with cervical dysplasia are frequently infected with HPV, often with the same HPV type as their partner (14,322). HPV DNA, usually HPV-16, is found in a subset of cancers of the vulva, vagina, and penis. Giant condyloma acuminata, also called the *Buschke-Lowenstein tumor,* is a low-grade locally invasive squamous cell carcinoma that involves the external genitalia, most frequently the penis. It is associated with low-grade HPV types, such as 6 and 11 (106,193). HPV may also be present in a high proportion of urethral tumors (321).

In squamous cell carcinoma of the vulva, most of those invasive tumors designated morphologically as being warty or basaloid arise in younger women and contain HPV DNA, especially HPV-16 (126). Smoking and infection with herpes simplex virus type 2 have been identified as possible cofactors for vulval cancer. In contrast to basaloid vulval cancers, HPV DNA is found in only a minority of keratinizing squamous cell carcinomas of the vulva, which is associated with older women and with mutation of p53 (170).

Human Papillomavirus in the Aerodigestive Tract

RRP (laryngeal papillomas), which is caused primarily by HPV-6 and HPV-11, is the best characterized HPV-associated disease in the aerodigestive tract (5,137,209). The oral cavity may be infected with any of the genital-mucosal types (238,308). Infection by HPV-13 and HPV-32, which are responsible for focal epithelial hyperplasia, may be limited primarily to the oral cavity. HPV infection has also been implicated in cancer of the oral pharynx (96,203,269,289) and may also play a role in some cases of esophageal cancer (305).

Recurrent Respiratory Papillomatosis

RRP is a rare condition whose papillomas may severely compromise the airway, particularly in young children (5,137,209). Most lesions are caused by low-risk genital HPV types, especially types 6 and 11. Lesions frequently recur after surgical treatment.

Hoarseness or change of voice is the usual presenting symptom in RRP. The vocal cords of the larynx is the site most commonly affected, but papillomas may arise at other sites, such as the trachea, lungs, nose, and oral cavity, even without laryngeal involvement. Lesions may be single or multiple. Papillomas may be life-threatening if their bulk severely restricts the passage of air to or from the lungs. This complication may arise more frequently in infants because of the small size of their airway. Symptomatic papillomas are generally treated surgically. The treated lesions frequently recur, and surgery may lead to an increase in the number of lesions. The recurrent nature of the disease means that periodic surgical treatment may be required. Although most patients do not need to be treated more than once a year, some papillomas grow very rapidly, requiring surgical intervention as frequently as every 2 weeks. It is important to avoid the necessity of performing a tracheostomy in patients with RRP because papillomas often grow along the tissues involved in the tracheostomy, resulting in severe morbidity.

Epidemiologic studies suggest there may be at least two modes by which RRP develops (138,277). One primarily affects young children and the other is first diagnosed in older individuals. There is a steep rate of rise in the incidence of RRP during the first 5 years of life, with about half of cases developing in children by the time they are 5 years old (Fig. 10). RRP may occur at any age, but the risk for developing it decreases after the age of 5 years. In younger children, a history of genital warts in the mother is a risk factor for RRP. Depending on the study, 30% to 60% of mothers whose children develop juvenile RRP have a history of genital warts, compared with less than 5% of mothers of unaffected children. Children born by cesarean section are at much lower risk for RRP, and HPV transmission, than those born by vaginal delivery (277). Taken together, these observations suggest that most cases of RRP that arise in early childhood are attributable to intrapartum transmission of HPV from the mother to the child. *In utero* transmission probably also occurs, as suggested by occasional cases of neonatal RRP, but this mode of transmission appears to be rare. In addition to a history of genital warts and vaginal delivery, other risk factors in the mother associated with juvenile onset of RRP include young age of pregnancy and first pregnancy. It appears reasonable to speculate that these risk factors may represent markers for the likelihood of high levels of HPV being present in the genital tract at the time of delivery. A history of oral-genital sex may be a risk factor in adult RRP.

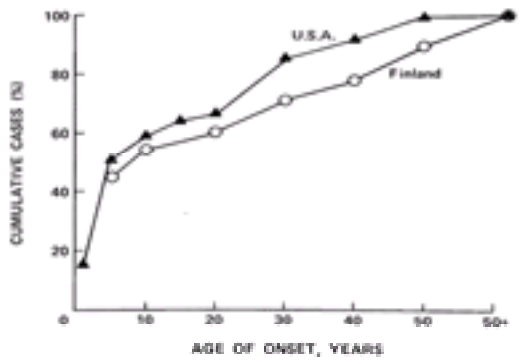

FIG. 10. Cumulative percentage of cases of respiratory papillomatosis in the United States and Finland, by age of onset. (From ref. 209, with permission.)

Infection with HPV-6 and HPV-11 accounts for most cases of RRP. Although the relationship between childhood RRP and genital HPV infection in the mother is well established, the incidence of RRP is much lower than that of adult genital infection with HPV-6 and HPV-11, which suggests that other factors also contribute to determining whether an exposed neonate will develop symptomatic RRP. One possible factor might be the HPV type to which the infant is exposed because HPV-6 accounts for most cases of genital condylomas, whereas HPV-11 is found in most cases of RRP (137,209). Given the presumed single exposure to HPV during vaginal delivery, the long and variable latent period of up to 5 years for childhood RRP remains to be explained. One possible explanation could be that viral latency is established in a proportion of exposed neonates before they develop symptomatic infection. If that were the case, activation of the latent HPV after a variable interval might account for the first clinical episode developing almost any time during childhood. The plausibility for this scenario is supported by two observations. First, it is known that the larynxes of patients with RRP who are in remission can harbor latent HPV DNA, which can subsequently be reactivated (5,295). Second, persistent asymptomatic carriage of HPV DNA in the oral cavity may occur in some children, although, as discussed previously in the section on latency, its frequency and significance remain controversial.

RRP is associated with a low risk for progression to severe dysplasia and even more rarely to cancer. The risk for such progression is increased if the papillomas have been subjected to x-irradiation, which was a common treatment of RRP in the 1940s. In one report, the average time interval between papilloma onset and diagnosis of cancer was 10 years in the irradiated cases, compared with 30 years in the nonirradiated cases (136). In contrast to cervical cancer, HPV-6 and HPV-11 in RRP are clearly associated with severe dysplasia and cancer, although high-risk types, such as HPV-16, may sometimes be found in laryngeal cancer.

Nasal Papillomas

Nasal papillomas are uncommon and may be present by themselves or with papillomas elsewhere in the respiratory tract. They are classified as *squamous* or *fungiform papillomas* (which closely resemble laryngeal papillomas clinically and histologically), *inverted papillomas* (in which the mucosa extends inward into the underlying stroma), and *cylindrical cell papillomas.* Most lesions are associated with HPV-6, HPV-11, and HPV-57, although some have been found to harbor HPV-16 (274,330). Carcinomas develop rarely and may be associated with HPV, including type 57.

Human Papillomavirus in the Oral Cavity

HPV infections of the oral cavity occur commonly (reviewed in 238 and 308). They may be asymptomatic or associated with single or multiple lesions in any part of the oral cavity. Genital-mucosal HPV types, especially HPV-6, HPV-11, and HPV-16, have frequently recovered from oral tissue. HPV is usually identified in at least half of papillomatous lesions in the oral cavity lesions, but some lesions appear to be HPV negative. Papillary lesions are traditionally classified as follows: (a) oral squamous cell papilloma, which are mostly solitary tumors and are the most frequent benign epithelial tumors of the oral cavity: (b) oral condyloma acuminatum, which are often multiple and present a cauliflower-like appearance: and (c) oral verruca vulgaris, which show marked keratinization. The designations *condyloma acuminatum* and *verruca vulgaris* implied that the infections were derived, respectively, from genital and common warts. Indeed, when verruca vulgaris involves the vermilion border of the lip, HPV-2, which is a nongenital cutaneous type that is a frequent cause of skin warts, has usually been found. However, when the lesion is present in the oral mucosa, HPV-6, HPV-11, and HPV-57 have been the most prevalent types. HPV-6 and HPV-11 appear to be responsible for most oral condylomas. Results in oral squamous cell papillomas have been less consistent, with HPV-6, HPV-11, and HPV-16 reported to be present in a variable proportion of the lesions. The association of HPV with malignant tumors of this region is discussed in the next section.

Focal epithelial hyperplasia (FEH) is a well-defined clinical entity that occurs only in the oral mucosa (238,308). Its distribution is worldwide, but it is most prevalent in the indigenous populations of Central and South America and of Alaska and Greenland. In Greenland Eskimos, the prevalence in different localities varied between 7% and 36%. In contrast, the prevalence among white residents in the same localities was less than 1 in 300. Cases of FEH in whites have been reported from many European countries (323). Clinically, FEH is characterized by discrete, multiple, elevated nodules on the oral mucosa. The disease may affect children or adults and in areas of high prevalence my affect several members within a single family. The lesions may be self-limited or persist for years without dissemination. They do not ordinarily undergo malignant transformation. Most are attributed to HPV-13 or HPV-32, two types that appear predominantly to infect the oral cavity (118).

Conjunctival Papilloma

Conjunctival papillomas are rare and occur at any age. HPV-6 and HPV-11 are associated with nearly all childhood conjunctival papillomas and with a proportion of the adult tumors (197).

Cancers of the Aerodigestive Tract and Other Regions

A consistent association of HPVs with the rare cancers that arise in respiratory papillomas, discussed previously, and in oropharyngeal and tonsillar carcinomas has been established (96,203,269,289). Cigarette smoking and alcohol consumption are two well-known risk factors for oral cancer. Although HPV does not appear to play a role in most cancers in this region, a subset of these cancers do appear to be attributable to HPV infection. Most of these HPV-associated cancers are located in the oral pharynx, which includes the tonsils, tonsillar fossa, base of the tongue, and soft palette. HPV-positive tumors have a characteristic basaloid morphology and are less likely to harbor mutations of p53 or pRb. They may also have improved disease-specific survival. Genital-oral sex may be a risk factor for these tumors, and the risk of HPV infection and cigarette smoking may be more than additive. HPV-16 is by far the most frequent HPV type isolated, accounting for 90% of the HPV-positive tumors in one study.

The evidence for the role of HPVs in respiratory cancers unassociated with RRP has been inconsistent (289). HPVs have been recovered from a small proportion of squamous carcinomas of the larynx (29). However, a firm association between specific HPV types and a specific respiratory cancer has not been established.

The role of HPV in esophageal cancer is uncertain (42,165,305). HPVs have been identified in a variable proportion of these cancers, ranging from 0% to 70%. HPV may be detected in esophageal tumors more frequently in regions with a high incidence of this cancer, such as China and South Africa. HPV-16, as well as other types, have been detected. Results from serologic studies, using antibodies to HPV-16 capsid antigen, have also given conflicting results, with some suggesting a strong association and others not (65,67,159). Because BPV-4–induced esophageal cancers of cattle may be negative for viral DNA (37), a hit-and-run phenomenon for HPV might be given some consideration in this tumor.

HPVs have been recovered from a minority of conjunctival and lacrimal sac carcinomas (185,196,312). These tumors are more frequent in HIV-infected individuals. HPV may also be found in a small proportion of bladder cancers (285). The suggestion that HPV might be implicated in cancers of the ovary, endometrium, colon, and prostate has not been confirmed (18,167,275,300).

DIAGNOSIS AND TREATMENT

Human Papillomavirus Diagnosis

Diagnosis of an HPV type in a tissue requires nucleic acid hybridization studies. Election microscopic examination for viral particles and immunologic detection of viral capsid antigens (with a broadly cross-reactive, genus-specific antiserum) are of limited value because viral particles and capsid antigens are not uniformly present, even in histologically diagnosed warts, and are seldom found in high-grade intraepithelial neoplasias and invasive cancers. Antisera are generally not available for identification of individual HPV types in clinical samples.

Hybridization Assays

A variety of hybridization assays have been employed for detection of HPVs (62,101,107,273). Nick-translated or random-primed DNA probes and *in vitro*-transcribed RNA probes are prepared from reference DNA clones. The probes can be labeled with radioactive or nonradioactive compounds. Southern hybridization of DNAs extracted from fresh or fresh-frozen tissues has served until recently as the gold standard for HPV detection because the sizes of the hybridizing bands provide an internal positive control for the specificity of the annealing reaction. In addition, the information allows identification of HPV subtypes and can provide evidence suggestive of integration, which occurs in many HPV-associated cancers. Also, Southern hybridization under low-stringency conditions allows identification of related viral types. However, the technique is labor intensive, and it may result in interlaboratory discrepancies when used as the only criterion for the presence of HPV DNA. Dot-blot and slot-blot hybridization techniques avoid the gel electrophoresis and transfer steps of Southern hybridization. These tests are suitable for large-scale studies, but faint true-positive signals are difficult to distinguish from the background because the size of the hybridizing fragment is not known. The Southern and dot-blot hybridizations can detect 10^5 to 10^6 copies of the HPV genome. In reverse-blot hybridization, cellular DNA is labeled and is used as a probe to hybridize at a high effective temperature with a panel of reference HPV DNAs that have been electrophoresed, denatured, and transferred onto a membrane. The test is somewhat less sensitive than PCR but allows screening of an HPV in a tissue against a large number of known HPVs in a single test.

In tissue *in situ* hybridization tests, cells or tissue sections on slides are hybridized using radioactive or nonradioactive probes (109,298). This is the only test in which the signal is seen in topographic relation to the pathologic lesion. The demonstration that the viral genome is in the affected cells can be an important step in investigating the role of HPVs in the etiology of cancers. By using exon-specific probes, it is possible to correlate the pathology of a lesion with the expression of specific viral genes.

HPV diagnosis based on amplification of segments of the viral genome by PCR combines sensitivity and specificity, when properly performed. Emerging data implicating viral load as an important correlate of risk for progression imply that quantitative or less sensitive assays might have utility in some clinical settings (132,333). The reverse hybridization procedure is very specific, can be used as a semiquantitative assay, and appears to detect most clinically relevant infections (265). Several different strategies for PCR amplifications for detection of genital-mucosal HPVs have been reported (100a,101,288,290). In a PCR method that has been widely used in the United States, consensus, degenerate primers targeted to amplify a segment of the L1 region of HPVs and capable of amplifying a large number of HPV types are employed; the PCR products are identified by type-specific oligonucleotide probes of several HPV types (264). The method is highly sensitive and highly specific, requires a small amount of the specimen, and is capable of amplifying a

large number of HPV types in a single amplification reaction. A wide range of nongenital cutaneous or EV-associated HPVs can be detected by a nested PCR approach (25,60,63,112). PCR-based methods can detect 10 to 100 copies of the viral genome, as compared with the conventional methods, which can detect 10^5 to 10^6 copies of the viral genome.

Utility of Diagnosis

The recognition that HPVs are etiologically associated with cervical cancer raises the possibility that HPV diagnosis might be useful, as an adjunct to Pap smear or even as a replacement for it, in screening for cervical cancer and in the clinical management of women who have abnormal cervical cytology. A significant proportion of women with invasive cancer give a history of negative Pap smears before onset of disease (59). It has been suggested that the presence of HPV DNA in the cervix would help identify the 20% to 30% of women with cervical disease who have false-negative results of Pap smear screening. These considerations need to be addressed in the context of the resources available to the population being evaluated, to evolving technology of Pap smear screening (119,125,279), and to the apparent utility of self-collection of cervical samples (100a, 325,326). Because the major goal of such testing is to prevent cervical cancer, it is possible that tests for nonviral molecular abnormalities might eventually have utility (177,260).

There may be specific settings in which the inclusion HPV determination may aid in the management of patients, but it does not appear at this time that an HPV diagnosis would be a useful adjunct to the general screening of a population that also undergoes high-quality Pap smear screening. However, the high rate of cervical HPV infection, especially in younger women, means that the routine use of HPV diagnosis would reveal, in the United States, millions of young women who have HPV DNA in the genital tract, normal cervical cytology, and little risk for cervical cancer. In the absence of an antiviral agent that is effective against HPV, there is little that can be done to eliminate these infections, and the perception of a woman that she is infected with a “cancer virus” could create needless anxiety and subject her to unnecessary treatment. On the other hand, it may possibly be useful to include HPV diagnosis with Pap smears in older women because HPV DNA prevalence is low and cervical cytology less reliable in this group (175). In older women, the presence of HPV DNA has a higher predictive value for cervical disease than in younger women. HPV diagnosis may also help clarify the interpretation of equivocal cytology and help with its management (189,219a). However, in younger women with low-grade cervical SIL in high-resource settings, HPV diagnosis does not appear to enhance clinical management (3). On the other hand, HPV diagnosis may be more useful in settings that lack high-quality Pap smear screening (265,326). It is also possible that tests that determine HPV type and measure viral load might have improved clinical utility (132,333).

Clinical Diagnosis and Treatment

Clinically, the diagnosis of a viral wart is usually made by the clinical appearance but can also be suggested by histologic examination. At times, other dermatologic conditions may be confused with warts (34). Depending on the location of the lesions, these conditions may include molluscum contagiosum (caused by a poxvirus), plantar corns, skin tags on the neck and in the axillae, keratoses, lichen planus, condylomata lata (secondary syphilis), and other diverse conditions. Virologic diagnosis was described previously.

Most warts regress spontaneously, although some may persist indefinitely. Depending on the location and extent of the infection, patients may seek treatment for cosmetic reasons, pain, discomfort, disability, hoarseness of voice, and so forth. The response of nongenital warts to treatment may be better in children and is also better for single warts and for warts of short duration. Pregnant women, children with recurrent laryngeal papilloma, immunodeficient patients, and patients with EV pose difficult problems for therapy.

There is no specific antiviral therapy for HPV lesions (234). Most treatments are aimed at destroying the lesional tissue while causing little long-term damage to the surrounding normal tissue. There is no treatment that will cure all warts, which has led to the wide range of therapies. Effectiveness of therapy is difficult to assess because of spontaneous regression on the one hand and recurrence on the other. At least partial regression can be obtained with many therapies, but even complete clearance that is then followed by recurrence is usually of limited clinical value. Traditional therapies include topical application of caustic agents (e.g., salicylic acid, podophyllin), cryotherapy, inhibitors of DNA synthesis (5-fluorouracil), and surgical therapy or laser treatment. Immunotherapy with autogenous vaccines, as well as sensitization to DNCB followed by application of DNCB to lesions, has been tried, with limited success.

In genital warts, topical application of imiquimod, which is an immunomodulating agent that can induce interferon and other cytokines, is more effective than placebo (19,75,307). Complete clearance of lesions in 50% to 70% of patients has been reported, compared with placebo group clearance of 3% to 11%. Lesions recurred in 3% to 19% of patients with complete clearance.

Intralesional and parenteral interferon therapy has been shown to be more successful than placebo for refractory genital warts (78,88,268). In two trials, repeated intralesional administration of interferon-a resulted in cure rates of 62% and 36%, as compared with cure rates of 21% and 17%, respectively, in the placebo recipients. Interferons have antiviral, antiproliferative, and immunomodulating effects. Parenteral administration was associated with even better responses.
