FIG. 12. Measles incidence in Iceland, 1900 to 1940. (Data from ref. 79, with permission.)

By contrast, outbreaks of arbovirus disease are unrelated to the proportion of susceptibles because infection is infrequent and a high proportion of the population is always susceptible. (Areas with hyperendemic yellow fever or dengue may represent a rare exception.) Epidemics are a reflection of the proportion of susceptibles infected; because humans are deadend hosts who do not act as links in the infection chain, the key determinants are ecologic factors, which result in a high concentration of vectors and a high infection rate in the vector population. Epidemics are most commonly preceded by those climatic conditions (rainfall, temperature, and the like) that maximize the vector population.

In some cases, an outbreak is clearly associated with an increase in the ratio of cases to infections, often associated with a virus strain of high virulence. Such occurrences are probably frequent but are rarely well documented. One well-studied example is the pandemic of avian influenza that overwhelmed the poultry industry of Pennsylvania in 1983. In this instance, there was a sudden increase in the virulence of an influenza virus, which was already enzootic in the poultry population, resulting in a pandemic that led to major commercial losses and that was controlled only by a widespread slaughter program. Unusually, isolates of the virus from before and after the epidemic were available for analysis, and a classic series of studies (82) showed that a point mutation in the viral hemagglutinin enhanced the replication ability and virulence of the virus.

Molecular Epidemiology

Expanding knowledge of basic virology has begun to provide molecular insights into the determinants of viral epidemics. In certain instances, it is possible to identify some of the molecular determinants of each of the three parameters (proportion immune, proportion infected, and case/infection ratio) that are responsible for propagated epidemics.

The proportion of the population immune is a relatively inflexible parameter for most viruses; however, influenza is a special instance. This virus is transmitted so effectively that it exhausts the supply of susceptible hosts. The major antigenic protein of influenza virus is the viral hemagglutinin, which is the viral attachment protein and the target for neutralizing antibodies. Influenza virus has a genome composed of eight segments, and these segments may reassort when two type A influenza viruses co-infect the same cells, with the creation of viruses containing a mixture of segments from the two parents. It has been proposed that, on rare occasions, a human strain of virus reassorts with an animal strain and acquires the hemagglutinin of the animal virus (42). This leads to major shifts in the antigenicity of the virus, such as occurred in 1957 with the appearance of the Asian strain, which had an H2 hemagglutinin, whereas previous influenza viruses had an H1 hemagglutinin. Such a radical shift in antigenicity provides the newly created virus with a global population that is relatively susceptible; as a result, a worldwide influenza pandemic may occur.

The proportion of susceptibles infected during a set time period will be determined by two characteristics of a given virus, namely, the generation time and the transmissibility. A virus with a relatively short generation time and high transmissibility, such as influenza will spread much more rapidly than a virus such as poliovirus. Generation time and transmissibility reflect the kinetics of the infection and the titers of virus excreted, and these parameters may be influenced by specific viral genes. Analysis of the genetic determinants of reovirus transmission have demonstrated that the l2 spike protein encoded by the L2 gene segment is a major determinant of transmissibility (41). Likewise, the transmission of California serogroup bunyaviruses, by their mosquito vector, *Aedes triseriatus,* is determined by the middle RNA segment that encodes the viral glycoproteins (31,36).

A major determinant of the case/infection ratio is viral virulence. Most viruses exhibit great natural variation in virulence. One classic example is variola virus (26), which caused virulent forms of smallpox (variola major) in India and Africa and much milder disease (alastrim or variola minor) in South America (Table 13). It has been known for many years that natural isolates of poliovirus varied greatly in their neurovirulence. Attenuated isolates were the starting point for the development of avirulent vaccine strains. Recent molecular analysis has begun to delineate the genomic determinants of virulence, which are located both in the structural genes and in the noncoding 5' region of the genome (1). This natural variation might have been a factor in the severity of poliomyelitis epidemics of the past. Another example is the 1983 pandemic of avian influenza cited previously (82), which was traced to a point mutation that increased the cleavability of the HA molecule, thereby enhancing viral maturation and infectiousness, with dramatic epidemiologic consequences.

Disease	Place and years	Cases	Deaths	Case fatality ratio (per 100)
Variola major	Minneapolis, 1924–1925	1,410	355	25.5
Variola minor	London, 1928–1934	13,395	34	0.2

PERPETUATION AND ERADICATION OF VIRUSES

Persistence of a virus in a population is a distinct phenomenon compared with persistence in a cell culture or individual host, and the term *perpetuation* may be used to emphasize that distinction. All viruses, whether they cause short-duration acute or long-term persistent infections, are capable of perpetuating in populations because perpetuation is a requirement for survival. Eradication is the converse of perpetuation and represents the ultimate method for control of an infectious disease. To determine the potential for eradication, it is necessary first to understand the requirements for perpetuation.

The principal ecologic patterns of viruses in host populations were discussed previously (Table 3 and Table 4), with emphasis on human viruses. In most cases, a virus is perpetuated in a single species, and discussion is limited to this dominant ecologic pattern.

Parameters that determine perpetuation include population variables (2,52) and viral variables. The following are population determinants: (a) the size of the population; (b) the turnover rate (rate at which susceptibles are introduced); (c) the density of the population; and (d) the proportion of the population susceptible. Viral determinants include the following: (a) transmissibility; (b) generation time; and (c) duration of infectiousness (acute or persistent). These three viral variables determine the rate of spread of a virus through a population (for a given set of population parameters). Paradoxically, an agent that spreads rapidly may exhaust susceptibles and disappear more rapidly from a small population than a virus that moves indolently through the same population. Perpetuation is discussed separately for large and small populations because population size is such an important determinant.

Small Populations

For small populations, a crude prediction of perpetuation may be made by determining the number of susceptibles entering the population per generation period. If this number is less than one, persistence will almost certainly not occur (87).

Isolated Human Populations

Small primitive human populations that have minimal contact with the outside world are occasionally available for serologic study. These populations provide a unique opportunity to determine the ability of viruses to perpetuate in their natural hosts. There are two principal patterns (10). Viruses that cause acute short-term infections produce abrupt outbreaks after introduction into human populations and then die out until reintroduced. Viruses that are capable of persisting in individual hosts are able to perpetuate in small, isolated groups.

Figure 13 presents the age distribution of antibodies to poliovirus types 1, 2, and 3 in an isolated Eskimo village. The profiles show that type 1 virus had infected essentially the entire population 25 years before the study, type 2 virus had

caused a similar wave of infections 15 years before the study, and type 3 virus had been present shortly before the collection of sera. Also, it is clear that after its intrusion, each virus had disappeared from the population, because there were few people younger than 25 years of age with type 1 antibody (the few individuals probably represent cross-reacting antibody after type 2 infection) and few younger than 15 years of age with type 2 antibody.

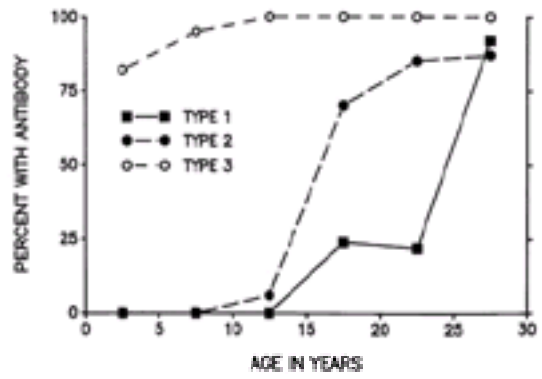

FIG. 13. Age-specific prevalence of antibodies to poliovirus types 1, 2, and 3 in an isolated Eskimo village in Greenland. (Data from ref. 62, with permission.)

In contrast, hepatitis B produces a considerable proportion of persistent infections, particularly in primitive populations, where infection occurs early in life. Figure 14, from another study of Eskimos, shows that infections occurred at all ages, with a gradual rise in cumulative incidence to 60% by 60 years of age; there was no evidence of disappearance of virus from the population or of exhaustion of susceptibles. The curve for hepatitis B surface antigen indicates that there were many persistently infected carriers in the population accounting for perpetuation in this small community.

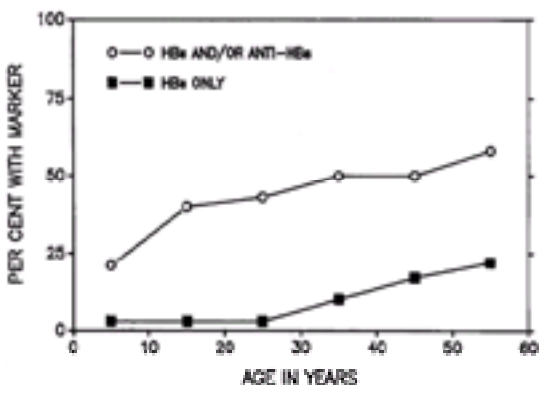

FIG. 14. Age-specific prevalence of hepatitis B antibodies (anti-HBs) and antigen (HBs) in Eskimos in southwest Greenland. (Data from ref. 76, with permission.)

Small Animal Populations

Animal populations differ radically from human populations in their relatively rapid rate of turnover, and this is a critical variable in virus perpetuation. Mean life expectancy in many animal populations ranges from 6 to 12 months, in contrast to a range of 30 to 70 years for humans. However, the kinetics of infection are similar in an individual human or animal host. For instance, the median incubation period (to rash) is about 14 days in smallpox and 10 days in mousepox. The consequence is that perpetuation may occur in animal populations (with rapid turnover) that are much smaller than the minimal human population required to sustain a virus that causes acute infections.

Laboratory animal colonies have provided an opportunity to document the quantitative impact of population turnover. Perpetuation in such colonies is of more than academic interest because enzootic infections present an important practical problem that frequently confounds biomedical research. One documented example is ectromelia (mousepox), which closely resembles variola in humans (25). Infection is initiated either by entry through the skin or by inhalation, and there is a generalized poxlike rash of the skin from which aerosolized virus is transmitted. As in smallpox, infections can be fatal, but recovered mice are solidly immune. Ectromelia is a relatively infectious agent and a notorious cause of acute and devastating epizootic results. When a few infected mice are placed in a larger group of susceptible animals, the virus spreads rapidly, all mice are infected within two incubation periods, and many mice die.

In these circumstances, ectromelia would not be expected to perpetuate in a small mouse population. A series of classic studies (33), however, demonstrated that this virus was readily perpetuated in a population of 100 to 200 animals. In one representative experiment, a mouse colony was established with 25 normal and 20 infected mice, and 3 uninfected mice were added daily; animals were removed only if dead. During a 30-month observation period, the total colony size gradually rose to a constant level of about 230 animals. The infection was maintained throughout the observation period; at equilibrium, about one fifth of the mice were uninfected, one fifth were actively infected (mortality rate, 50% to 60%), and three fifths were recovered immune subjects. It was possible to maintain this acute highly lethal virus over long periods of time in mouse populations with as few as 70 animals, demonstrating that high turnover markedly reduces the population size required for perpetuation.

Large Populations

To follow the pattern of virus infection in large populations, it is necessary to rely on reportable diseases that can be identified from clinical observations alone and that exhibit relatively high case/infection ratios. Measles is one of the few virus diseases that meets these criteria; however, even measles has its limitations because only a fraction (usually, 10% to 50%) of cases are reported. Although measles is a ubiquitous and highly infectious virus, its ability to perpetuate in human populations is surprisingly fragile (9). Table 14 shows that in cities of 200,000 to 300,000, measles faded out for at least 1 month in 56 of the 100 years recorded. Because a population of 300,000 might be expected to experience about 5,000 cases of measles in an average year, it is initially surprising that this would be insufficient to maintain the infection. The explanation becomes more apparent when the seasonal cycle of measles is examined (46,86,87). Data for the city of Baltimore (population 900,000) for 32 years of observation showed that annual reports averaged about 5,000 cases representing about 35% of cases; incidence rates ranged more than 100-fold from the peak in March to the seasonal low in August, when about 10 cases were reported. Because there were about three generation periods per month, this represents no more than 3 cases per generation period, barely sufficient to perpetuate the virus. A similar city of 300,000 would experience only 1 case per generation period; in such an instance, it is plausible that periodic fadeouts would occur.

Size of city (millions)	Number of cities	Average annual measles reports (thousands)	Years of study	Years with fadeout
1.0–7.5	6	3.5–91	120	0
0.5–0.9	9	2.9–4.0	180	1
0.2–0.3	5	0.9–2.1	100	56

[a]Estimate of reporting ranged from 14%–85% of measles incidence. Cities were as follows: large—New York, Chicago, Philadelphia, Detroit, Los Angeles, Montreal; medium—Cleveland, Baltimore, Boston, Toronto, Washington, Pittsburgh, Milwaukee, Buffalo, Minneapolis; small—Vancouver, Rochester, Dallas, Akron, Winnipeg.

Source: Data from refs. 9 and 86, with permission.

TABLE 14. *Fade-outs of measles in North American cities, 1921–1940*[a]

This analysis suggests that persistence of a short-cycle infection in a large population is dependent on the relationship between incidence during the seasonal trough and the generation time. Influenza, with a generation time of 1 to 3 days, has difficulty persisting in human populations through the seasonal trough. It probably circumvents the problem by shuttling between northern and southern hemispheres each year.

Requirements for Eradication

The recent history of smallpox (26) has demonstrated that eradication is an attainable objective for selected human viral infections. The salient epidemiologic features that made smallpox eradication possible were its relatively long incubation period (about 14 days) and low infectiousness; its marked seasonality; a case/infection ratio approaching 1; and the lack of an extrahuman reservoir. These features made it possible to abandon mass vaccination in favor of a search-and-containment strategy in which local outbreaks were identified and aborted by intensive immunization around each focus. The small number of local outbreaks during the seasonal trough was essential to the success of this strategy.

Several other human viral infections are now candidates for eradication, particularly poliomyelitis and measles (58). There are copious data available from the United States that provide an instructive comparison of these two viruses. Poliomyelitis in the United States exhibited marked seasonality, as shown in Figure 7. This means that it required a considerable population to maintain the virus through the seasonal trough. Computation suggests that in the northern United States, such as New England, before the introduction of vaccine, a population of 100,000 was just sufficient to perpetuate poliovirus. At the seasonal trough, it is estimated that there were about two infections per generation. In the United States in the prevaccine era, the poliovirus-susceptible pool was slightly more than 20% of the population. After the regular use of oral poliovirus vaccine, the susceptible pool of children was markedly reduced, perhaps to one fourth of its previous level (about 5% of the population). In the hypothetical city of 100,000 population, there would have been less than one infection per generation period at the seasonal trough, below the level required for perpetuation (58). In the United States, the stepwise drop in natural poliomyelitis was well documented (Fig. 15) and indicated that disease due to wild poliovirus totally disappeared after the summer of 1972 and has not reappeared since, with the exception of a localized introduction in 1979. During the period of fadeout, 1967 to 1972, poliomyelitis maintained its seasonality; furthermore, there was an annual stepwise reduction in the number of states reporting any natural poliomyelitis (58). These observations suggest that each year, after the seasonal disappearance of infection, fewer and fewer areas experienced reintroduction of virus during the summer upswing.

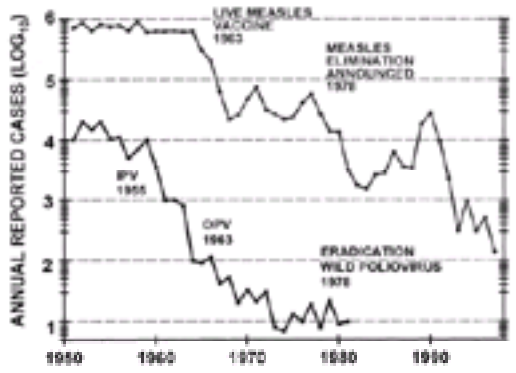

FIG. 15. Comparison of the decline in poliomyelitis and in measles in response to immunization programs, United States, 1951 to 1986. **Lower panel:** annual reported cases of paralytic poliomyelitis in the United States, 1951 to 1981. For the years 1973 to 1982, residual cases are either vaccine associated or imported, with the exception of an outbreak in 1979 in the unvaccinated Amish population. (Data from refs. 14 and 58, with permission.) **Upper panel:** reported cases of measles in the United States, 1960 to 1993. (Data from refs. 14,15,17,18 and 19, and 58, with permission.)

Measles has also been the target of elimination efforts in the United States, but with less success than for poliomyelitis, as shown in Figure 15. Surveillance data indicate that mass immunization has gradually reduced the number of states with endemic measles. Nevertheless, measles has stubbornly resisted eradication. Although measles fadeouts have periodically occurred in almost all states, during the period 1972 to 1987, no more than half (26 of 52), the states were measles free in any 1 year (58). This suggests that a critical epidemiologic difference between measles and poliomyelitis is the frequency of reintroduction of virus after a fadeout. In turn, this may be due to the greater transmissibility of measles, which is reflected in the fact that the mean age of infection with measles was 5 years of age, whereas that for poliomyelitis was 11 years of age, before the introduction of vaccines.

Eradication will continue to be a major public health goal in the future. Experience with smallpox, poliomyelitis, and measles indicates that a thorough understanding of the dynamics of perpetuation is essential to selecting virus diseases that are realistic targets for eradication.

APPLICATIONS OF EPIDEMIOLOGY

Identification of Etiologic Agents

Acute infections, which are readily transmitted and cause intense outbreaks, are often first identified as distinct clinical entities during epidemiologic studies. Furthermore, their epidemiologic behavior offers strong circumstantial evidence that they are caused by transmission of an infectious agent. Recent examples include rotavirus disease, fifth disease, AIDS, and hantavirus pulmonary syndrome. Epidemiologically, it is usually impossible to infer whether the cause is a virus or other infectious agent. Epidemiologic observations, however, may suggest the portal of virus shedding and the period of infectiousness, which is important for the collection of specimens for isolation.

Epidemiologic observations may also contribute insights into more obscure persistent infections associated with atypical chronic diseases. The spongiform encephalopathies or prion diseases are an example. This group of agents includes the causes of scrapie of sheep, kuru and Creutzfeldt-Jakob disease of humans, and BSE. The initial definitive evidence that scrapie, a chronic degenerative neurologic disease, could be transmitted as an infectious agent, occurred as an unwanted complication of the use of louping ill vaccine in Scotland in 1935 (32,34). Table 15 shows that three lots of vaccine against louping ill, a flavivirus, were injected into sheep in Scotland; unexpectedly, there was a very high incidence of scrapie in recipients of one of the three lots. Subsequent epidemiologic investigation showed that louping ill vaccine was prepared by formalin treatment of virus grown in sheep brain and that several of the sheep used were probably incubating scrapie because their parents subsequently came down with the disease. Because the scrapie agent is extremely resistant to inactivation by formalin, contamination of the vaccine was readily explained. Before this episode, it was not generally accepted that scrapie was due to a transmissible agent with an incubation period of several years.

Vaccine batch	Number of sheep vaccinated	Percentage with scrapie
1	>22,000	<0.1
2	18,000	5
3	>4,000	<0.1

[a]Batch 2 was prepared from 122 sheep infected with louping ill; of these 8 were offspring of scrapie-affected ewes. Interval between subcutaneous injection of vaccine and onset was 20 months or longer.

Source: Data from ref. 34, with permission.

TABLE 15. *Occurrence of scrapie in sheep immunized with louping ill vaccine, Scotland, 1935*[a]

A more recent episode in the United States has documented the potential transmissibility from human to human of the agent that causes Creutzfeldt-Jakob disease. Between 1964 and 1985, about 7,000 pituitary dwarfs were treated with

injections of growth hormone prepared from autopsy-collected human pituitary glands. From 1970 to 2000, more than 30 cases of Creutzfeldt-Jakob disease have occurred in these growth hormone recipients, and epidemiologic investigation (11,12) has provided strong evidence of the association with pituitary injections based on the fact that this disease has been virtually unknown in young adults and that the cases were associated with a few lots of hormone.

Evaluation of Vaccines

The ultimate test of viral vaccines is their efficacy and safety in humans. Epidemiology provides well-established methods for the design and analysis of prospective studies of vaccine efficacy (61). These are illustrated by the 1954 field trial of poliomyelitis vaccine (28). In this trial, a large number of children in the first three grades of elementary school were enrolled. As shown in Table 2, the trial comprised two different study designs: placebo and observed. In the placebo design, children fell into three categories: vaccinated, placebo inoculated, and nonvolunteers (uninoculated). In the observed design, the groups were vaccinated second graders, nonvolunteer second graders (uninoculated), and controls (all children in the first and third grades). The most valid comparison was vaccinated and placebo inoculated children in the placebo areas; this group yielded an estimated efficacy of 72% for paralytic poliomyelitis, whereas the observed control area yielded an efficacy of 63%. The discrepancy was explained by the fact that the nonvolunteer children in both areas experienced an attack rate that was considerably lower than that of the placebo controls or the observed controls. Apparently, volunteer children were at higher risk (presumably because of a higher percentage of susceptibles) than were nonvolunteer children. Thus, the strict placebo control was the best comparison group. When the placebo study was further refined by limiting analysis to laboratory-confirmed cases, efficacy was estimated even higher (85%), underlining the importance of etiology-proven cases in vaccine evaluation. Curiously, the 1954 field trial was the only properly designed large-scale trial of any viral vaccine now in regular use in the United States.

Epidemiology has also played a vital role in documenting vaccine complications. The occurrence of Guillain-Barré syndrome associated with the use of swine influenza virus vaccine in the fall of 1976 provides a good illustration (73). About 40 million people received influenza vaccine in a mass campaign. Cases of a relatively rare neurologic disease, Guillain-Barré syndrome, were reported in vaccinees at a frequency considered excessive, and the vaccine was withdrawn. When vaccine-associated cases were compiled by interval after immunization (Fig. 16), they exhibited a log-normal distribution typical of many incubation periods. This pathognomonic epidemiologic feature, along with the excessive rates seen during the early weeks after immunization, provided strong evidence of an association and justified termination of the vaccine program. Epidemiologic evidence was the key in this episode because the association (less than 1 case per 100,000 vaccinees) was only detectable in a massive field study. Because Guillain-Barré syndrome occurs at a baseline rate in the population and because those cases associated with the vaccine were not clinically distinguishable from the baseline cases, this episode presented a special epidemiologic challenge. The occurrence of Guillain-Barré syndrome was not predictable by any small-scale human trial or laboratory test, and the biologic explanation is still unclear. In fact, epidemiologic studies conducted with influenza vaccines used after 1976 have demonstrated that these vaccines (produced from nonswine strains of virus) apparently carry no risk of Guillain-Barré syndrome (74).

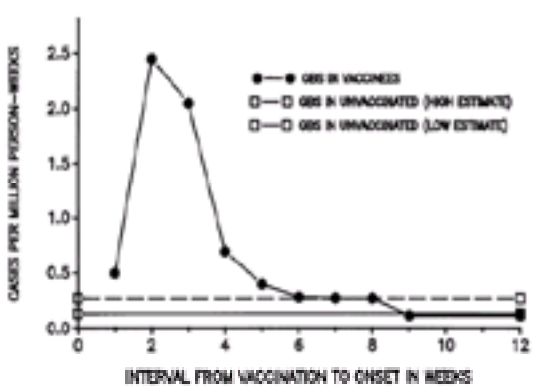

FIG. 16. Guillain Barré syndrome (limited to cases with extensive involvement) associated with swine influenza vaccine, according to interval between immunization and onset, United States, 1976. Two baseline rates are shown (upper and lower limits of *hatched area*) to define the expected rate of spontaneous Guillain Barré syndrome. The period of the epidemic is readily defined (1 to 6 weeks after immunization) and the intervals during this period of excess incidence form a classic log-normal curve. (Data from ref. 43, with permission.)

Development and Assessment of Control Measures

In addition to vaccines, other control measures are sometimes useful against virus infections. Such approaches seek to reduce the risk for exposure and are usually suggested by epidemiologic studies of transmission mechanisms. Examples include reduction of risk associated with blood or blood products for viruses such as hepatitis B and hepatitis C viruses, HIV, and human T-cell leukemia viruses types I and II. Another classic example is the control of urban yellow fever and dengue through reduction of *Aedes aegypti* mosquitoes. The use of epidemiologic control of virus infection is illustrated by a study of Bolivian hemorrhagic fever (40), an arenavirus that was endemic in certain rural villages. Ecologic studies suggested that this virus was enzootic in one species of peridomestic house-dwelling mouse, *Callomys callosus,* and was transmitted by aerosolized fomites. Table 16 shows a study in which rodent control was initiated in one half of a village and then extended to the other half. The dramatic effect of rodenticides confirmed the hypothesis of the virus reservoir and its transmission mechanism and provided a practical approach to control of a serious viral infection. A similar approach is being applied to the recently discovered pulmonary syndrome hantavirus (39,60).

CHAPTER 15 Antiviral Therapy

Clyde Crumpacker

One of the remarkable scientific achievements of the past quarter century has been the growth of the infant science of antiviral therapy. There has been a steady stream of effective drugs being developed against an increasing number of viral pathogens. As recently as 1975, it appeared that antiviral therapy would not be possible because animal viruses were such complete obligate intracellular pathogens that inhibition of viral functions would necessarily mean cell death as well. The breakthrough occurred because of the identification of virally encoded enzymes that are essential for virus replication and that differ enough from cellular enzymes to permit selective chemical interactions to occur with viral enzymes but not cellular enzymes. The structural differences between viral and cellular enzymes that have similar functions have permitted chemicals to target viral enzymes and to spare cellular processes. The success of this approach is indeed a surprise. Resistance to antiviral therapy has been a most powerful tool for understanding the mechanism of drug action and the reasons for clinical treatment failure.

In this chapter, the virus groups in which antiviral therapy has succeeded will be described, and the mechanisms of drug action will be outlined. Progress in new antiviral therapies is developing rapidly, and there will be new drugs to inhibit new classes of viruses; these will undoubtedly be developed using principles described here.

HERPESVIRUSES

Historical Background

The first demonstration that antiviral therapy would be successful for treating herpesvirus infections was the use of 5'-iodo-2'-deoxyuridine (IDU) to treat herpetic keratitis. Iododeoxyuridine has significant toxicity in systemic use but was a real advance in the treatment of keratitis caused by herpes simplex virus (HSV), a significant cause of blindness (203). The successful use of IDU proved that herpes infections could respond to antiviral therapy. However, IDU was not a successful therapy in the treatment of HSV encephalitis (122), and its systemic use was associated with significant toxicity. Trifluorothymidine (TFT) is a nucleoside analog that is converted by cellular enzymes to the triphosphate, which inhibits herpes DNA polymerase. It is also used as a topical treatment for herpes keratitis and corneal ulcers (67) and for acyclovir-resistant mucocutaneous human immunodeficiency virus (HIV) lesions (284).

The first antiviral therapy that improved survival in a life-threatening viral disease was adenine arabinoside (Ara-A, or vidarabine), a nucleoside analog of adenine activated by cellular enzymes to form the triphosphate, which is the active inhibitor of the HSV DNA polymerase. Ara-A was administered intravenously to treat patients with biopsy-proven HSV encephalitis in 1977 (383). Because many other neurologic diseases might present with symptoms similar to those of herpes encephalitis, it was important to use a rigorous diagnostic test to establish a diagnosis. (The ability to culture HSV from temporal lobe brain biopsy tissue was required for enrollment in this study.)

Ara-A also provided effective therapy for other HSV infections, such as neonatal herpes and varicella zoster virus (VZV) infection in the immunocompromised host (380,382). An ointment containing a related compound, Ara-A monophosphate (Ara-Amp), was the first topical ointment to demonstrate an antiviral effect against recurrent herpes simplex labialis (cold sores) (338).

Another nucleoside analog, which possesses strong *in vitro* activity, is bromovinyl deoxyuridine (BVDU), which requires activation by the viral thymidine kinase (TK) to inhibit viral DNA polymerase (84). BVDU is metabolized in humans to bromovinyluridine (BVU), which possesses significant hepatic toxicity, but this drug was never approved for human use. A close relative, bromovinyluridine arabinoside (BVaraU; sorivudine), is much safer for humans; *in vitro* results showed that this nucleoside analog was the most effective inhibitor of the nucleoside analogs tested against human VZV (243). A multicenter clinical trial comparing sorivudine with acyclovir in patients with HIV and herpes zoster showed that the

former was more effective for cessation of new vesicle formation and total lesion crusting (147). It was not approved for use in the United States, however, because it enhances the severe toxicity of 5-fluorouracil (5-FU), and the U.S. Food and Drug Administration (FDA) was concerned that the drug would be used in patients receiving 5-FU for cancer treatment.

Acyclovir

Acyclovir [9-(2-hydroxyethoxymethyl)guanine; Zovirax] is a guanosine analog with an acyclic side chain at the nine position and a broken sugar ring. The chemical structure of acyclovir and related drugs for herpesviruses are shown in Figure 1. The structure of deoxyguanosine is included for comparison, to show the position of the broken sugar ring in drugs such as acyclovir, ganciclovir, and penciclovir. Acyclovir is the first truly specific antiviral drug, as it requires activation by a viral enzyme (TK) and has remarkably little toxicity for uninfected cells. Acyclovir is a specific inhibitor of HSV-1, HSV-2, and VZV replication (20,76,109). It is transported into cells either by passive diffusion or by a nucleoside transporter, which also transports guanine in erythrocytes (244). When in the cell, it is readily phosphorylated by the viral TK (see Fig. 1). The viral-encoded TK enzymes of HSV-1, HSV-2, VZV, and Epstein-Barr virus (EBV) catalyze the formation of acyclovir monophosphate (ACVMT), whereas acyclovir is a poor substrate for cellular TK enzymes (114,141,271,272). This accounts for the remarkable selectivity of acyclovir and the lack of toxicity in uninfected cells (35,271).

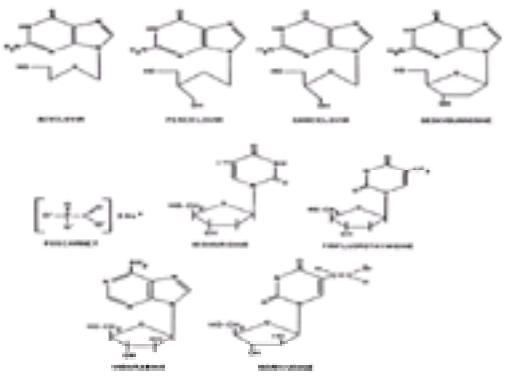

FIG. 1. Chemical structure of antiherpes, antiviral agents, acyclovir (*ACV*), penciclovir (*PCV*), ganciclovir (*GCV*), foscarnet (*PFA*), iodoxuridine (*IDU*), trifluorothymidine (*TFT*), vidarabine (*Ara-A*), and sorivudine (*SVD*). (Reprinted from ref. 172, with permission.)

In uninfected cells, the cytoplasmic 5' nucleotidase catalyzes the formation of very low levels of ACVMP (207), but in HSV-infected cells, the level of acyclovir triphosphate (ACVTP) may be 100-fold higher than in uninfected cells, because acyclovir is a much better substrate for the HSV-specific TK and thymidylate synthetase phosphorylating activities (113,138,141,206). A third important area of specificity derives from the fact that acyclovir triphosphate is a highly polar compound that does not easily pass through biologic membranes to exit cells, whereas acyclovir easily enters infected cells and is trapped there in high concentrations. Following its initial phosphorylation, ACVMP is converted by cellular kinases to the acyclovir di- and triphosphates. ACVTP actively inhibits HSV DNA polymerase (139,271,272) and may bind to it 30 times more effectively than to cellular alpha polymerase (97,143). ACVTP competes effectively with deoxyguanosine triphosphate (dGTP) for the viral DNA polymerase and is preferentially incorporated into elongating DNA chains as ACVMP (114,139). The 3'-terminal ACVMP results in chain termination because ACVMP lacks a 3' hydroxyl group on the 2' deoxyribose sugar, which is required for a 3'-to-5' reaction with the next incoming nucleoside triphosphate. A DNA chain that has been terminated with ACVMP is not a substrate for the 3', 5' exonuclease activity of the herpesvirus DNA polymerase and thus ACVMP is not excised (92). ACVTP has been described as an *obligate* chain terminator because viral DNA elongation stops completely when ACVMP is incorporated into the elongating viral DNA chain (305). In addition to inhibiting viral chain elongation, ACVTP has also been called a suicide inhibitor, because it is an example of an induced substrate inhibitor forming an inactive “dead-end” complex involving viral polymerase, ACVMP-terminated primer template, and the next specific deoxynucleoside triphosphate (dNTP) encoded by the template (305). Cellular DNA polymerases have poor affinity for ACVTP, and very little ACVMP is incorporated into the host cell DNA.

All this accounts for the very low genetic toxicity for host cells associated with acyclovir use (113). The role of ACVMP in chain termination of elongating viral DNA is illustrated in Figure 2. The binding of the next dNTP, which is incorporated immediately following ACVMP, prevents the viral polymerase from disassociating and moving to an alternative extendible primer template. This results in a time-dependent inactivation of HSV-1 DNA polymerase activity (305,306). This mechanism may be selective for the HSV-1 polymerase, as ACTVP does not inhibit the HeLa cell a polymerase (139,304,305). The HSV-1 polymerase is a single polypeptide of 1,235 amino acids. It has been expressed *in vitro*, in yeast, and in insect cells (101,159,249). The cloned protein possesses polymerase activity and can be inhibited by ACVTP in a manner very similar to purified HSV-1 polymerase (101). The functional enzyme consists of a heterodimer involving the HSV-1 DNA polymerase peptide and a smaller polymerase accessory viral protein designated UL42, which enhances polymerase activity and increases processivity of the HSV-1 polymerase (142,152). All herpesviruses probably utilize a similar mechanism—a functionally active polymerase peptide that exhibits greatly enhanced DNA polymerase activity in the presence of a virally encoded polymerase accessory protein. The inhibition of HSV-1 DNA polymerase activity by ACVTP occurs in the absence of the UL42 protein, indicating that ACVTP is able to bind to the polymerase peptide by itself (101).

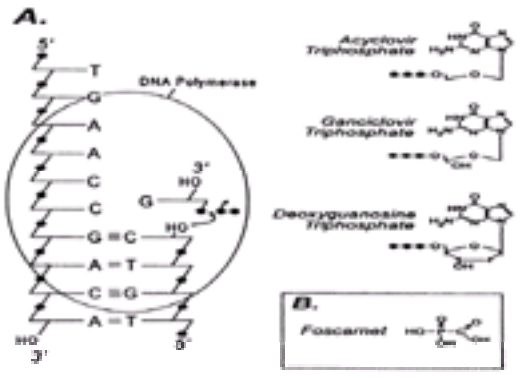

FIG. 2. Inhibitors of the polymerization reaction of herpesvirus DNA polymerase. (Reprinted from Fields BN, Knipe DM, Howley PM, et al., eds. *Fields Virology*, 3rd ed. Philadelphia: Lippincott-Raven, 1996, with permission.)

In summary, the selective action of acyclovir against HSV-1, HSV-2, and VZV is the result of several virus-specific factors: (a) specific phosphorylation by a virus-encoded TK enzyme; (b) specific inhibition of viral DNA polymerase polypeptide by ACVTP acting as a competitive inhibitor with the natural substrate dGTP; (c) chain termination of viral DNA by incorporation of ACVMP, and inactivation of viral DNA polymerase after the incorporation of ACVMP in the presence of dNTPS; and (d) failure of ACVMP and ACVTP to be exported out of cells, with build-up of high levels of intracellular ACVTP. In isolates of HSV-1, HSV-2, VZV, and cytomegalovirus (CMV) from human infections, the relative potencies of inhibition of virus replication in tissue culture are HSV-1 > HSV-2 > VZV, and there is a relative lack of inhibition of CMV replication (Fig. 3) (76). The reason that acyclovir is less active than HSV against VZV is probably related to the short half-life (t½) of ACVTP in VZV-infected cells, and to VZV's slower replication cycle. The slow replication cycle of VZV would require that a high level of ACVTP be present for a prolonged period, and this is not achieved with the short half-life (2.5 hours) of ACVTP in VZV-infected cell cultures. For comparison, penciclovir triphosphate has a half-life in VZV-infected cells of close to 12 hours. The main reason acyclovir is relatively inactive against CMV is that, because CMV does not possess a virus-encoded TK enzyme analogous to that of HSV, the intracellular concentration of ACVTP achieved in CMV-infected cells is very low. In contrast, ganciclovir triphosphate is specifically phosphorylated through the action of the viral phosphokinase UL97 gene product, and its levels have a prolonged half-life of 16.5 hours in CMV-infected cells (29).

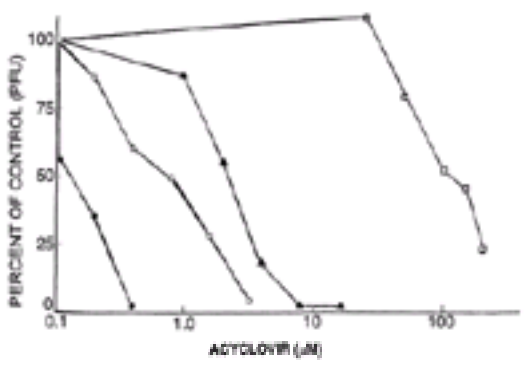

FIG. 3. Plaque reduction assay of herpesvirus clinical isolates from patients by acyclovir (acycloguanosine in Vero cells). HSV-1 (·); HSV-2 (○); VZV (▲); CMV (□). (Reprinted from ref. 76, with permission.)

Resistance

Resistance of HSV to acyclovir develops rapidly *in vitro* when HSV is grown in the presence of the drug, and this occurs also in animals and patients receiving acyclovir (75,128,329). The detection of drug-resistance mutations in a specific viral gene has been important to understanding the functions of these genes. Resistance to acyclovir is conferred by mutations in two viral genes, the viral TK and the DNA polymerase genes (55,129,329). The viral TK gene is important for HSV replication in resting or neuronal cells, and TK-deficient mutants of HSV reactivate inefficiently from latency (128,355,356). In many tissues, however, cellular TK enzymes appear to be able to substitute for the viral TK and to support replication of HSV TK mutants.

The most common form of acyclovir-resistant HSV isolate is the TK mutant (35). This may be the result of a single point mutation or a deletion mutant (35,72,212). It has been estimated that about 50% of mutations associated with acyclovir resistance in clinical isolates occur by deletion or addition of bases in strings of guanosine residues (G-strings) or cords of cytosine residues (C-cords) within the TK gene (144,324). These mutations usually result in stop codons producing premature shortening or truncation of the viral TK protein (34). The selection of mutant viruses with truncated TK enzymes also occurs in patients treated with acyclovir (34). The other 50% of point mutations can occur anywhere in the TK gene (144). A loss of almost all TK activity has also been associated with a single point mutation, producing an alanine-to-proline change in a region of the TK protein forming an alpha helix and still forming a full-length peptide (34). A single nucleotide deletion in a region with no G-string or C-cord residues, resulting in a truncated TK peptide, has also been associated with acyclovir resistance in a newborn infant (291). The three discrete classes of TK mutations that confer the acyclovir-resistant phenotype are as follows:

1. TK-negative mutants: The enzyme activity has been abolished, usually by truncation of the peptide and

phosphorylation of acyclovir does not occur.
2. TK-low producers: Partial TK activity is present but TK is not abolished. These are still able to produce disease in animals and reactivate from latency (80,121,354,355).
3. TK altered mutants: These can still phosphorylate thymidine, but they fail to phosphorylate acyclovir (80).

An early report that a TK virus could cause latency but not reactivate from ganglia referred to only a single mutant of HSV and should not be generalized to many TK-deficient viruses (54). Furthermore, in a neuronal culture with an HSV TK-negative mutant, the replication, latent infection, and successful reactivation of this mutant has been described (384). A study of 13 clinical acyclovir-resistant HSV-2 isolates from patients with acquired immunodeficiency syndrome (AIDS) revealed that the majority of these isolates establish ganglionic infection and reactivate in tissue culture, even though most of the strains contained truncated TK proteins (34,121). Another study showed that the human TK can effectively substitute for the viral TK, allowing the reactivation of a TK-mutant HSV-1 from murine ganglion (38). The HSV TK-low-producer and TK-negative mutants still retain an ability to reactivate, and they possess pathogenic potential in patients, particularly those who are immunocompromised (121,291).

Resistance to acyclovir is also mediated by mutations in the viral DNA polymerase gene (55,329). The acyclovir-resistant mutations result in an altered viral DNA polymerase, which functions in the synthesis of viral DNA in the presence of a high concentration of ACVTP (214). These mutations may also confer cross-resistance to other drugs that act directly on the viral DNA polymerases, such as phosphonoacetic acid (33,55,72). The herpesvirus DNA polymerases all contain regions of highly conserved amino acid sequences, which have strong homology to each other and to the human alpha polymerase (146,213,392). These form the family of alpha DNA polymerases. All the acyclovir-resistant mutations are found in conserved regions of the enzymes, designated I, II, III, V, VII, and A (230,392).

Drug-resistant polymerase mutations that are found to lie outside these regions may represent natural polymorphisms in the DNA polymerase and not actual resistant mutations (44,50). The conserved regions are probably involved in important enzymatic functions such as dNTP substrate recognition and binding, and pyrophosphate binding (145,146,214,230). In the absence of a crystal structure for the alpha DNA polymerase, the exact relationship among the most highly conserved regions of the herpesvirus polymerases is not clear. The HSV polymerase contains a consensus sequence, YMDTDS, which is remarkably similar to the sequence YMDD found in the active center of HIV reverse transcriptase (RT), hepatitis B virus polymerase, and many RNA polymerases (1). Site-specific mutagenesis of this highly conserved region of HSV-1 DNA polymerase revealed that a single amino acid change from serine (S) to alanzine (A) results in a highly acyclovir-resistant DNA polymerase that still maintains active catalytic functions (102,103). The acyclovir-resistant mutants in the DNA polymerase are relatively infrequent and have been identified only in immunocompromised patients (59,319).

Patterns of cross-resistance to other antiviral drugs occur with both TK mutants and DNA polymerase mutants. Acyclovir-resistant mutants caused by TK deficiency usually exhibit cross-resistance to all drugs that require the viral TK for activation, such as ganciclovir and penciclovir, which are phosphorylated by the viral TK (131,363). TK mutants retain susceptibility to drugs that do not require phosphorylation and that act directly on the viral DNA polymerase, such as phosphonoacetic acid or phosphonoformic acid (foscarnet, or PFA) (33,55,70).

Acyclovir resistance in humans was first documented in 1982 in a child with a severe combined immunodeficiency syndrome (75); in 1991, it was shown to be clinically significant in a study of patients who had TK-deficient mutants of HSV, all of whom responded to foscarnet therapy (320). The polymerase mutants selected with acyclovir therapy may also cause cross-resistance to other drugs that act on viral DNA polymerase, such as ganciclovir, vidarabine (52,53,59,73,74,319), and foscarnet. Double mutants in both the TK and polymerase genes exhibit a broad degree of cross-resistance to most antiviral nucleoside drugs with activity for HSV. The replication of both wild-type and acyclovir-resistant viruses can be inhibited in cells co-infected with a mixture of TK-deficient and wild-type HSV, because the wild-type TK is able to produce sufficient ACVTP to inhibit both viruses, but polymerase mutants are not inhibited in cells co-infected with wild-type and pol mutant HSV (55).

Clinical Trials

The clinical usefulness of therapy for HSV infection was established through a series of randomized placebo-controlled trials, which are models for clinical investigation. As mentioned, the first successful antiviral therapy to improve survival in a life-threatening viral infection was intravenous Ara-A (vidarabine) in biopsy-proven herpes simplex encephalitis (383). In a controlled trial, acyclovir was found superior to vidarabine for improving survival and reducing morbidity in herpes encephalitis (378).

The efficacy and safety of acyclovir for the prevention and treatment of infection with HSV-1, HSV-2, and VZV has been established through numerous multicenter, placebo-controlled, randomized clinical trials. An important result of these studies is that acyclovir is more effective in preventing infection when used early in the disease than when used for fully established viral disease, a finding also demonstrated with other antiviral drugs. Once a viral disease has become clinically evident, the effectiveness of acyclovir is less pronounced. Also, acyclovir is most beneficial when used to treat infections in the immunocompromised patient. This is because the replication of viruses is greater in immunocompromised patients, and the infections are more severe and cover a larger surface area, providing a greater opportunity to observe the effectiveness of the treatment.

The first study documenting the efficacy of acyclovir in prophylaxis involved patients receiving bone marrow transplantation (323). Bone marrow transplantation is frequently followed by reactivation of HSV. This infection may disseminate, producing systemic disease and compromising the regeneration of the marrow graft. In a study of 10 patients in the acyclovir treatment group and 10 patients in the placebo group, intravenous acyclovir was shown to prevent 90% of mucocutaneous herpes simplex (323). This result was highly statistically significant and established the usefulness of acyclovir therapy after transplantation to prevent herpes simplex recurrences. Other studies involving larger number of immunocompromised transplant recipients, patients receiving cancer chemotherapy, or patients with

HIV infection have confirmed and extended the usefulness of acyclovir as a safe and effective treatment and prophylaxis (105,321,322,368,379,382).

In the immunocompromised patients with large areas of mucocutaneous HSV infection, intravenous acyclovir markedly accelerates healing (75,100,379). Intravenous acyclovir is the drug of choice for treating serious infections of HSV or VZV (10,75,368).

Intravenous and oral acyclovir are effective for treating primary genital HSV infection, shortening the disease by about 50% (273,284). However, oral acyclovir has minimal clinical effect on recurrent disease (311). Oral acyclovir is primarily used for chronic suppression, to decrease the frequency of symptomatic recurrences, and to decrease asymptomatic shedding of HSV (104,274,343,370,371). Patients with frequent episodes of recurrent genital herpes infections (more than 12 episodes per year) will show a marked decline to less than one episode per year receiving while receiving oral acyclovir at a dose of 400 mg twice daily (343). Oral acyclovir is also effective for chicken pox in children (110) and herpes zoster (191).

The benefits persist even when patients take oral acyclovir for many years. Yet suppressive acyclovir is not a cure. When oral acyclovir that had produced prolonged suppression of genital herpes for 6 years was discontinued, infection recurred in 1 to 3 months. Acyclovir must be taken daily to prevent recurrence of genital herpes. When breakthrough episodes occur on chronic suppressive therapy, the episodes are usually not correlated with the emergence of acyclovir-resistant virus. Recurrences caused by resistant virus in a normal host have been reported but are rare (217,351). Acyclovir-resistant HSV has been reported in 0.1% of cultures from normal adults attending a sexually transmitted disease (STD) clinic in Northwest England, and in 5.9% of cultures from HIV-infected patients taking acyclovir (47). In the United States, a study by the Herpes-Resistance Task Force and the Centers for Disease Control has shown a similar prevalence, and resistance has been associated with the use of topical acyclovir ointment. This study enrolled a large number of normal patients attending STD clinics in many cities and over 1,000 patients who were infected with HIV.

In serious and life-threatening HSV infections, acyclovir has been successful in adults and newborn infants (100,379). Ara-A (vidarabine) has also been successful in the treatment of neonatal HSV infection (382). When acyclovir and Ara-A were compared directly in a randomized controlled clinical trial of patients with biopsy-confirmed herpes simplex encephalitis, acyclovir therapy was superior to Ara-A for improving survival and morbidity. After 6 months of treatment with acyclovir, 67% of survivors were back at work or school (378). Acyclovir is the therapy of choice in this infection. A controlled trial of vidarabine versus acyclovir in neonatal HSV infection showed that the two drugs were similar but acyclovir was easier to administer, had fewer undesirable side effects, and was the treatment of choice (377).

Valaciclovir is a valine ester of acyclovir. The valine group is cleaved by esterase enzymes in the intestinal mucosa and then free acyclovir is found in the portal vein (302). The presence of the valine group greatly enhances the bioavailability of valaciclovir and 68% of the drug is absorbed. This results in plasma levels of acyclovir that are 8 to 10 times higher than the level obtained by oral absorption of acyclovir, which is only 12%. This high degree of bioavailability makes it an attractive therapy for several herpesvirus infections. Valaciclovir may be taken at one 500-mg pill per day to provide effective suppression of genital herpes (312). It also provides effective therapy for herpes zoster infections in the immunologically normal host (19).

The use of valaciclovir to treat infections in the immunocompromised patient has been controversial because of an unexpected mortality and vasculitis with features of hemolytic uremic renal syndrome observed in patients infected with HIV who received 8 gm of valaciclovir per day to suppress cytomegalovirus retinitis. The direct association between this syndrome and high-dose valaciclovir remains unclear. When compared with acyclovir in the treatment of herpes zoster in immunocompetent adults, oral valciclovir at 1 gm, three times daily for 7 days, speeds resolution of pain and decreases the frequency of persistent pain (19).

Penciclovir is similar to acyclovir, with two CH_2OH groups instead of one (see Fig. 1). Following intravenous dosage, penciclovir is taken up by HSV-infected cells. It is then phosphorylated by the viral TK and by cellular enzymes to form the active inhibitor, penciclovir triphosphate, which has a longer intracellular half-life than ACVTP, persisting in cells for 12 hours (363).

A double-valine ester of penciclovir (famciclovir) has been developed. Following oral administration of famciclovir, of which approximately 68% is absorbed, one valine ester is removed by esterase enzymes in the gastrointestinal tract, and the second valine ester is cleaved by an enzyme in the liver. The plasma then contains high concentrations of penciclovir (363). Penciclovir is converted to the triphosphate and is effective in treating and preventing HSV and VZV infection (318,361). When HSV becomes resistant to acyclovir due to a mutation in the viral TK gene, the mutant virus is also resistant to penciclovir or famciclovir because viral TK is required to phosphorylate penciclovir to the monophosphate.

Penciclovir ointment (Denavir) shortens the duration of labial herpes (cold sores) caused by HSV-1 (339). With daily use, famciclovir has also been effective in preventing episodes of recurrent genital herpes (318). If begun within 24 hours of the onset of rash, oral famciclovir will decrease the severity of chicken pox in children (300) and is also effective to treat localized, ophthalmic, or disseminated herpes zoster infection (300,361).

Intravenous acyclovir is most effective in preventing visceral complications of varicella zoster in immunocompromised patients with disseminated cutaneous zoster. Acyclovir prevents the development of encephalitis, pneumonia, and hepatitis due to VZV dissemination (380). It is likely that penciclovir will also be found to be effective at preventing visceral complications, but this is has not been extensively studied. Acyclovir and the related compounds valcyclovir, penciclovir, and famciclovir inhibit viral DNA polymerase as the final antiviral target. Only acyclovir and the prodrug valcyclovir are clearly chain terminators for viral DNA elongation. Penciclovir greatly slows growth of replicating viral DNA by incorporation into the elongating viral DNA strand, but chain termination does not strictly occur. These drugs are the main therapies employed to treat infections with HSV and VZV (19,191,300,361,380).

CYTOMEGALOVIRUS

The b herpesvirus, CMV is the largest virus known to cause infection in humans. It produces acute illness with a mononucleosis syndrome in young adults, severe congenital infection in newborn infants, and primary infection or reactivation producing retinitis, gastrointestinal disease, or pneumonia in patients with AIDS or following organ transplantation (71). The first-line therapy for many CMV infections is ganciclovir (71,252), an analog of guanosine, containing an acyclic sugar ring and two CH_2OH groups at positions 3 and 5. The addition of the single CH_2OH group makes ganciclovir about 100 times more active at inhibiting CMV replication *in vitro* than acyclovir, another guanosine analog (71).

The three drugs approved for use against CMV are ganciclovir, foscarnet, and cidofovir (71). The structures of these drugs and others for herpesvirus infections are shown in Figure 1.

Ganciclovir

Mechanisms of Action

Like acyclovir, ganciclovir must be phosphorylated by a viral enzyme and cellular enzymes to form ganciclovir triphosphate, an active inhibitor of CMV DNA polymerase. CMV, however, does not possess a TK homolog. The CMV enzyme that phosphorylates ganciclovir is putatively a protein kinase, the product of the UL97 gene of CMV (27,36,238,348).

The best evidence that UL97 alone is necessary for phosphorylation of ganciclovir was obtained by insertion of the gene for CMV UL97 into a ganciclovir-insensitive vaccinia virus, which renders the recombinant virus fully susceptible to ganciclovir (266). The exposure of CMV-infected MRC-5 cells to the same concentrations of ganciclovir and acyclovir results in relatively large amounts of ganciclovir triphosphate being formed, but the formation of ACVTP is minimal because acyclovir is a poor substrate for UL97 enzyme (22). In CMV replication, the role of UL97 is still being defined, but the protein is able to phosphorylate serine residues (182). Its main function may be to phosphorylate CMV proteins, which are important in genome-packaging steps late in infection. After UL97 converts ganciclovir to ganciclovir monophosphate, cellular enzymes convert this to ganciclovir triphosphate, which is a potent inhibitor of CMV DNA polymerase and competitively inhibits the incorporation of dGTP into elongating viral DNA. On a molar basis, ganciclovir triphosphate is not as effective an inhibitor of CMV DNA polymerase as ACVTP, but the concentration of ganciclovir triphosphate in CMV infected cells is 10 times that of ACVTP (22,40,127). The very high and persistent levels of ganciclovir triphosphate within the infected cell effectively inhibits CMV DNA replication.

The half-life of ganciclovir triphosphate in CMV infected cells is 16.5 hours, compared to 2.5 hours for ACVTP; the prolonged intracellular half-life makes ganciclovir far superior to acyclovir for inhibiting CMV replication (22). Unlike ACVTP, ganciclovir triphosphate is not an absolute chain terminator. Ganciclovir monophosphate is incorporated into elongating viral DNA, but short subgenomic-length fragments of CMV DNA continue to be synthesized, especially in the region of the origin of CMV replication (166,165). Ganciclovir was employed in a series of creative experiments to map the origin of CMV DNA replication in CMV (166).

Ganciclovir monophosphate greatly slows the rate of CMV DNA elongation, and all of the drug's antiviral effects result from inhibition of CMV DNA elongation (40,71). In the presence of ganciclovir, CMV immediate-early and early proteins continue to be made, as these are produced before CMV DNA replication begins in infected cells. If one were to measure production of these CMV early gene products in the presence of ganciclovir, it might be mistakenly concluded that ganciclovir is not an effective antiviral drug for CMV (336).

Ganciclovir is also an effective antiviral drug for HSV because the HSV TK effectively phosphorylates ganciclovir to its monophosphate (71). Cellular enzymes in HSV-infected cells convert this to ganciclovir triphosphate, which is an effective inhibitor of HSV DNA polymerase (40,41,127). Some mutations within HSV DNA polymerase that confer resistance to ganciclovir do not confer cross-resistance to acyclovir (73). TK-deficient mutants of HSV, which are resistant to acyclovir, are also cross-resistant to ganciclovir (71,121).

Cytotoxicity

Uninfected mammalian cells do not phosphorylate ganciclovir and it has little toxicity for these cells. If murine cells are transfected with the gene for HSV TK, the transformed cells that express the viral TK are easily killed by ganciclovir (288). This fact has been exploited in gene therapy. When genetically altered cells are given to patients to correct genetic defects or treat diseases such as cancer, the inclusion of the HSV TK gene in these cells can serve as a safety feature or “suicide gene” to allow ganciclovir to kill the altered cells in case they proliferate too aggressively or otherwise harm the patient.

Ganciclovir also prevents proliferation of murine melanoma cells transfected with the HSV TK gene after they are inoculated into syngeneic mice (364). There is thus a potential utility for ganciclovir as an antitumor drug if tumor cells can be effectively transformed with a herpes simplex gene so that they are able to phosphorylate ganciclovir. Furthermore, when ganciclovir is used to treat tumors, not only are the cells that contain the HSV TK gene killed but surrounding tumor cells are also killed. This “bystander effect” may be the result of the diffusion of ganciclovir triphosphate into surrounding tumor tissue.

In addition to direct cell-killing effects, ganciclovir has significant mutagenic, carcinogenic, and teratogenic properties. In dogs receiving anciclovir, interference with spermatogenesis has been observed (71).

Mechanisms of Resistance

Ganciclovir-resistant mutants of CMV contain mutations in the UL97 gene, in the CMV DNA polymerase (UL54) gene, or in both (9,21,42,43,71,241,242,347). The selection of viral mutants that are unable to phosphorylate ganciclovir is the main mechanism of resistance (21,341). Most mutations that confer resistance to ganciclovir are located in two main regions of the UL97 gene (9,241). The position at codon 460 is important for ATP binding (241); the other region, located from codons 590 to 596 (9), is important for nucleoside binding. For efficient phosphorylation to occur, the phosphate group on ATP needs to be transferred to ganciclovir. It is reasonable then that mutations in both regions affecting this process would confer resistance to ganciclovir. A third mutation in the UL97 gene at codon 520 has also been found to confer resistance to ganciclovir in clinical isolates of CMV (118).

The initial ganciclovir-resistant mutant of CMV was selected in the laboratory by passage of the AD 169 strain of CMV in the presence of increasing concentrations of ganciclovir (21). A mutant was selected that was unable to phosphorylate ganciclovir, and it exhibited a decreased sensitivity to ganciclovir (21). This mutant virus contained a deletion in the UL97 gene from codons 590 to 593 (348). On further analysis, it also contained a mutation in the viral DNA polymerase gene (347). This mutant remained sensitive to inhibition by phosphonoacetic acid (PAA) and phosphonoformic acid (PFA), two pyrophosphate analogs, which act directly on the CMV DNA polymerase (21). Since the majority of clinical isolates that exhibit resistance to ganciclovir have mutations or deletions in a few discrete regions of the UL97 gene, it has been possible to develop a rapid diagnostic test for resistance based on restriction enzyme analysis of the UL97 gene (42). This assay detects about 80% of ganciclovir-resistant clinical isolates (42,43).

The CMV DNA polymerase gene is the other site for mutations that confer resistance to ganciclovir, as well as to foscarnet and cidofovir (50). Mutations that confer resistance to ganciclovir in the CMV DNA polymerase are found almost exclusively in the highly conserved regions of the enzyme (50). There is some natural polymorphism in the DNA polymerase gene of CMV clinical isolates, but a nucleotide sequence analysis of 40 clinical isolates revealed that with one exception all the variability in the ganciclovir- and foscarnet-sensitive CMV isolates occurred in regions other than the highly conserved regions of the DNA polymerase (Fig. 4) (44). A marker transfer experiment analyzed drug-resistance mutations within the CMV DNA polymerase of recombinant viruses. These viruses were created in a Cos cell line containing DNA fragments of a CMV genome into which the DNA polymerase from drug-resistant mutants had been inserted. The results showed that only mutations in the highly conserved regions of DNA polymerase would successfully transfer the resistant phenotype to the recombinant virus (50). Some ganciclovir-resistant mutants that exhibit a high level of antiviral resistance also exhibit cross-resistance to cidofovir, a nucleotide analog of cytosine that has been approved for treatment of CMV retinitis. The specific point mutations in the CMV DNA polymerase gene that produce resistance to ganciclovir were first identified in 1992 (242). Some of these mutations, such as those in region IV (N408D, F412V, F412C, D413E), in d region-C (L501F, L501I, K513N), and in region V (G987A), have been reported to produce cross-resistance between ganciclovir and cidofovir (HPMPC) (50). The L802M mutation has been reported to produce cross-resistance between ganciclovir and foscarnet without changing the sensitivity to cidofovir (45).

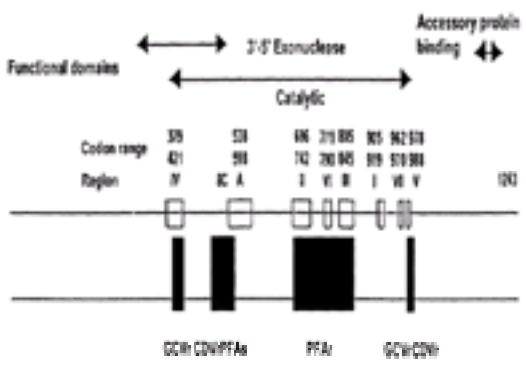

FIG. 4. Map of the cytomegalovirus (CMV) DNA polymerase. The CMV DNA polymerase showing functional domains and highly conserved regions of DNA nucleotide sequences (I–VII). *Shaded areas* are regions associated with drug resistance phenotypes. Codons, mapped to drug resistance in clinical isolates, are shown as *bars.* CDV, cidofovir; GCV, gancyclovir; PFA, foscarnet. (Reprinted from ref. 44, with permission.)

The V781I mutation in CMV polymerase region VI has been shown to induce resistance to PFA when the mutation was transferred to the Towne strain by cosmid recombination (9). A fivefold change in the susceptibility to PFA was noted, and the recombinant remained sensitive to ganciclovir. The same technique of cosmid recombination revealed that the L802M mutation conferred resistance to foscarnet, and the recombinant remained sensitive to ganciclovir (50). The difference between this report (50) and the one described in the preceding paragraph (45) may be due to different techniques, as the generation of recombinants in the Towne virus uses cosmids with many CMV DNA fragments, which may result in incorrect recombinations between some of the DNA fragments (45,50,70). Mutations at codons 700 and 715 have been reported to produce resistance to foscarnet and a slow-growth phenotype when these mutations were transferred to strain AD 169 (9A). A point mutation at K513N selected *in vitro* by cidofovir also has been reported to cause a slow-replication phenotype (50).

These two examples provide biologic support that drug-resistant mutations may also confer a loss of replication fitness because of mutations in the CMV DNA polymerase gene. In one case, a clinical isolate of CMV has been shown to be cross-resistant to ganciclovir, cidofovir, and foscarnet, and to possess a single nucleotide deletion in the DNA polymerase gene (46). To be sure that drug-resistant mutations in the CMV DNA polymerase really confer a

drug-resistant phenotype, marker transfer experiments through the generation of recombinant viruses are essential.

Clinical Trials

Multiple placebo-controlled trials have documented the efficacy of ganciclovir, foscarnet, and cidofovir for the treatment of selected CMV diseases in immunocompromised patients, mainly HIV-infected patients and transplant recipients (71). The most common CMV infection in HIV-infected patients is CMV retinitis. Before effective antiretroviral therapy was developed, 40% of all HIV-infected patients manifested CMV retinitis at some point during the course of the disease (193). This usually developed in patients with CD4 T-cell counts of less than 100 cells/mm ^{3}, and if untreated it progressed to blindness. Intravenous ganciclovir was shown to stabilize the retinitis in 2 weeks in over 91% of cases, whereas 61% had complete healing with intravenous ganciclovir therapy at 5 mg/kg twice daily (193). Another study in 108 patients treated with a similar regimen resulted in healing in 85% (30). Ganciclovir treatment of CMV retinitis was associated with clearing of viremia in 7 to 8 days (30) and clearing of CMV DNA from the plasma of infected blood in 8 days (69).

Foscarnet is also effective at treating CMV retinitis, and a direct comparison of foscarnet and ganciclovir in a multicenter randomized open-label trial in AIDS patients revealed no difference in the rate of progression of retinitis (286). The mortality rate, however, was higher in patients treated with ganciclovir, with a median survival of 8.5 months compared with 12.6 months in the foscarnet group (286). This important difference in survival was not fully explained, but it might result from the antiretroviral activity of foscarnet. A follow-up study showed no difference in survival between the two treatment groups, and a combination of foscarnet and ganciclovir was superior to either drug alone for treatment of retinitis (285). The conclusion of both studies was that ganciclovir and foscarnet were equally efficacious for CMV retinitis treatment, and that the combination of both drugs was superior, but that neither drug provided an advantage over the other for survival (71,285).

It was noted that essentially all patients had a relapse of retinitis after 20 to 30 days (median time) after the initial intravenous ganciclovir or foscarnet treatment was terminated. Maintenance therapy with daily intravenous ganciclovir at a dose of 6 mg/kg per day may delay time to relapse up to 72 to 75 days. Maintenance regimens of daily drugs are important to prevent relapse (30,106,285).

Oral ganciclovir was found to be almost as effective as intravenous ganciclovir as a maintenance treatment in patients treated initially with ganciclovir intravenously for 3 weeks (106). When progression of CMV retinitis was assessed by retinal photographs, the mean time to progression was 62 days for patients receiving intravenous maintenance therapy, and 57 days for those receiving oral maintenance. The oral ganciclovir group had fewer serious side effects, such as neutropenia and sepsis, related to the intravenous therapy (106,290). The study also showed that there was a marked decrease in the number of patients with positive urine cultures for CMV, indicating that both preparations decreased the replication of CMV in patients (106). For patients with sight-threatening retinitis, maintenance treatment with intravenous ganciclovir would still be preferred to preserve vision.

For the treatment of the gastrointestinal manifestations of CMV in patients with AIDS (e.g., esophagitis, cholecystitis, and colitis), ganciclovir has been the main therapy (57,97). Successful treatment of CMV colitis was first reported in 1986 (57), and a follow-up study of intravenous ganciclovir at a dose of 5 mg/kg given twice daily or placebo given for 14 days showed a greater reduction in the frequency of CMV infected colonic and urinary cultures in the ganciclovir group (97). Colonoscopy scores improved in patients who completed 14 days of ganciclovir therapy, but the frequency of diarrhea did not differ in the two groups (97). New, extracolonic CMV disease developed in 23% of patients in the placebo group, but in only 9% of patients in the ganciclovir group (p = .03). These results may indicate that treatment for 14 days is not adequate for the colon to heal and diarrhea to resolve. In bone marrow transplant recipients who had fecal CMV cultures on a regular basis, the cultures became negative in patients given ganciclovir, but gastrointestinal symptoms improved in both the ganciclovir and placebo groups, so there was no apparent clinical benefit of ganciclovir therapy (308). There is no evidence that maintenance therapy is useful in preventing a relapse of CMV colitis.

Treatment of primary CMV pneumonia with ganciclovir has been most successful in renal transplant recipients (184). In recipients of bone marrow transplants, however, attempts to treat CMV pneumonia with ganciclovir, acyclovir, vidaradine, human leukocyte interferon, or interferon plus acyclovir have been unsuccessful or of only limited success (71,334). For example, of the first seven patients treated with ganciclovir, four died of respiratory failure before completing a 14-day course of therapy (57). The three patients who survived for at least 14 days to complete therapy, died of pneumonia within 7 weeks. None of the other drugs that are active against CMV (foscarnet and cidofovir) have been successful at treating CMV pneumonia. In a group of 10 bone marrow transplant patients treated with ganciclovir for CMV pneumonia, only one patient survived, even though CMV was promptly cleared from pulmonary secretions (334).

Three uncontrolled studies showed that patients with CMV pneumonia who were treated with a combination of ganciclovir and high-dose intravenous CMV immune globulin had an improved survival of between 52% and 69%. As a result, this is the treatment of choice for CMV pneumonia (115,307,328).

Oral ganciclovir at a dose of 3 gm per day prevents CMV disease in patients with AIDS and fewer than 100 CD4 cells per cubic millimeter (337). A study in 725 patients comparing oral ganciclovir at 100 mg every 8 hours with placebo showed that 26% of patients in the placebo group acquired CMV disease, compared with only 14% of the ganciclovir recipients (337). In another study, in which retinal examinations were not routinely performed, however, and endpoints of disease progression may have been missed, oral ganciclovir could not prevent progression (28). Oral ganciclovir has proven to be effective in preventing CMV disease in recipients of kidney and liver transplants as well (26,129,143). Because it is the only oral agent for CMV, ganciclovir has been the only drug used to prevent disease. Prevention of pneumonia or other CMV disease with ganciclovir in recipients of bone marrow, heart, and liver transplants was clearly proven in several independent studies and was a major accomplishment (149,265,327,386). Intravenous ganciclovir was initially employed in prevention, but oral ganciclovir is also proving successful (26,143,185,335).

In some of these studies, a preemptive strategy was employed. It used measurement of CMV antigen in blood to determine when to start treatment with ganciclovir in renal transplant patients (185) and liver transplant patients (335). The presence of CMV antigen in bronchiolar lavage samples was used to deterine when to initiate ganciclovir treatment in bone marrow transplant patients (149). Preemptive strategies are effective and may avoid the expense of providing prophylaxis for all patients including those who are not at high risk of CMV disease.

Infection of the Nervous System

Progressive polyradiculopathy in patients with AIDS was the first peripheral nerve syndrome associated with CMV to be documented (112). This syndrome usually begins as low back pain with radicular or perianal radiation, followed in 1 to 6 weeks by progressive flaccid paraparesis.

Marked pathologic changes are found in the cauda equina and lumbosacral roots, with mononuclear-cell infiltrates, the destruction of axons, and CMV inclusions in Schwann cells and epithelial cells (112). This polyradiculopathy improved in a few patients who were treated early in the disease with ganciclovir alone or with ganciclovir and foscarnet, but treatment is more usually disappointing (117,136,153,196,269). Prospective clinical trials are needed to assess the possible benefits of combined ganciclovir and foscarnet therapy for this condition. Mononeuritis multiplex and painful peripheral neuropathy have also been described in patients with AIDS and have been attributed to CMV (135). Some of these patients were given ganciclovir with uncertain benefit. Anecdotal evidence suggests that CMV meningoencephalitis may respond to ganciclovir and foscarnet (117).

RETROVIRUSES

The human retroviruses associated with significant diseases are HIV-1 and HIV-2, the cause of AIDS (345), and human lymphotropic virus 1 (HTLV-1), the cause of T-cell leukemia and tropical spastic paralysis (393). Because AIDS is a devastating worldwide epidemic, it has been the subject of intense investigation, and a great deal is known regarding its molecular biology and the key events in HIV-1 replication.

Three classes of drugs are useful in treatment of serious HIV-1 infection in humans: nucleoside RT inhibitors, nonnucleoside RT inhibitors, and protease inhibitors. A massive program involving cooperation between the U.S. government, the pharmaceutical industry, and academic medical centers resulted in the development of over 15 antiviral agents that have been approved for therapy and prevention of HIV-1 disease. These drugs prolong life, decrease overall mortality, and prevent opportunistic infections, the hallmark of immune system decline caused by HIV-1 (293). One of the most remarkable consequences of effective antiviral therapy for HIV-1 is the resultant considerable immune reconstitution (4).

Successful antiviral therapy for HIV-1 to date has been directed at two viral enzymes that are essential for virus replication and maturation. These include the viral RT and the viral protease enzymes. Entry of HIV into cells involves the interaction of the envelope protein gp120 and the membrane-spanning protein gp41 with the cellular viral receptor CD4 and the chemokine receptors CCCR5 or CXCR4. This process of viral entry is itself a potential target for experimental therapies. Drugs that prevent viral entry by binding to the viral envelope gp120 protein (such as a bis-azo compound, FP21399) have been described (403). A potent peptide inhibitor of the conformational change in gp41 needed for fusion to occur between the viral envelope and the cell membranes has also been developed. This 36-amino-acid peptide (known as T-20) corresponds to amino acids 638 to 673 of the HIV-1 transmembrane protein gp41. When administered intravenously for 14 days to 16 HIV-infected adults, T-20 exhibited a dose-response effect; a dose of 100 mg twice daily was associated with a median decline in plasma viral RNA of 1.96 $\log_{10}$ (210). Another viral enzyme, viral integrase, is also a potential target of HIV replication inhibition. Compounds that inhibit integrase have been identified but not yet developed into proven drugs (181). Following receptor binding, the virion of HIV is internalized and uncoated, and reverse transcription takes place early in the cytoplasm. Components of RT are packaged and ready to function at once. There is evidence to indicate that reverse transcription begins within the virion (402). In the cytoplasm, in a preintegration complex of viral and probably cellular proteins, the conversion of single-stranded genomic RNA to a double-stranded DNA occurs. The HIV-1 RT catalyzes DNA synthesis and polymerization and also possesses RNase H activity to cleave the single-stranded RNA following initial single-strand DNA formation. The HIV RT, however, lacks an editing function, and errors that arise in the formation of double-stranded DNA are the source of the extensive genetic heterogeneity of HIV.

It is estimated that the mutation rate of this process is 10^{-4}, so an average of one nucleotide base error occurs for every round of reverse transcription (246). The viral preintegration complex is then transported into the nucleus, and the HIV-1 transcribed from proviral DNA is formed after the process of HIV integration. Replication of HIV can proceed following integration into the cellular chromosomal DNA of nondividing terminally differentiated monocyte macrophages and of CD4 T lymphocytes, which are arrested in stages G_2 and S (234,375).

Reverse Transcriptase Inhibitors

The first clinically useful drugs developed for HIV-1 were the nucleoside RT inhibitors (39,139). These drugs first require phosphorylation for the triphosphate to inhibit the HIV-1 RT in a manner analogous to that of most antiherpes drugs.

Phosphorylation is accomplished completely through cellular enzymes, as HIV does not encode any enzyme with similarities to the TK of the HSV. The mechanisms of action have strong similarities to acyclovir, in that the triphosphate is the active inhibitor of HIV-1 RT. Zidovudine (also known as azidothymidine, Retrovir, 3-azido-3-deoxythymidine, or AZT) is a synthetic pyrimidine analog that differs from thymidine in having an azido group at the 3' position of its deoxyribose ring instead of a hydroxyl group (188) (Fig. 5B). AZT was initially developed as an anticancer drug and was then found to inhibit RT of Friend leukemia virus in 1974 (188,292). In 1985, AZT was also shown to inhibit the RT of

HIV-1 *in vitro* (275). The active inhibitor is AZT triphosphate, which is a competitive inhibitor of RT. AZT-TP binds to the HIV-1 RT better than to the natural substrate deoxythymidine triphosphate (dTTP), and it functions as an alternative substrate for the enzyme (137,139,340). AZT-TP possesses a 100-fold greater affinity for the HIV-1 RT than for cellular DNA polymerases alpha or beta (137,139).

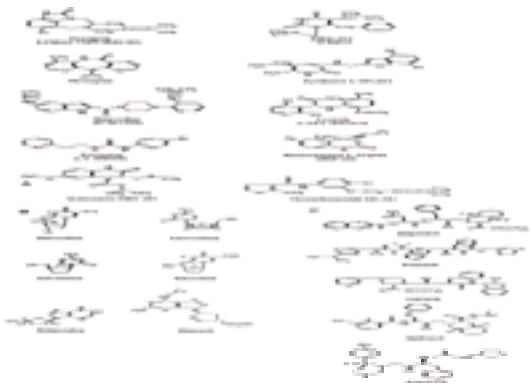

FIG. 5. A: Structures of nonnucleotide reverse transcriptase inhibitors. (Reprinted from ref. 86, with permission.) **B:** Nucleotide reverse transcriptase inhibitors. **C:** HIV-1 protease inhibitors. (Reprinted from ref. 167, with permission.)

This high affinity for HIV-1 RT makes the intracellular concentration of AZT-TP greater than the K_i value for HIV-1 RT but less than the K_i value for cellular DNA polymerase alpha and beta (139). The claim has also been made that AZT-MP is incorporated into growing DNA, and that this leads to premature chain termination (139). HIV-1 RT lacks an exonuclease, so the incorporated nucleoside analog cannot be excised and an incorporated AZT-MP does not posses a 3'-hydroxyl group to form a phosphodiester bond with an incoming nucleotide, so chain elongation is prevented and termination occurs at thymidine residues. The interaction of AZT-TP with the RT produces the selectivity of AZT for inhibiting HIV-1 replication (139,340). The phosphorylation is accomplished by cellular enzymes, and zidovudine is an efficient substrate for cellular TK. Cells exposed to AZT, whether infected or uninfected, accumulate high concentrations of AZT-MP because formation of AZT-DP (the rate-limiting step in the formation of AZT-TP) by host-cell thymidylate kinase is slow. AZT-MP is actually a competitive inhibitor of thymidylate kinase and reduces formation of the natural substrate dTTP. The high intracellular levels of AZT-MP may also impair the RNase H activity of HIV-1 RT (352). The formation of AZT-TP from AZT-DP is catalyzed by the cellular nucleoside diphosphate kinase (139).

As indicated, the phosphorylation of AZT is more efficient in rapidly replicating CD4+ T lymphocytes than in resting monocyte/macrophages. Other drugs may inhibit the phosphorylation of AZT. Ribavirin, a nucleoside analog, is also actively phosphorylated by cellular enzymes. In HIV-infected cells exposed to both zidovudine and ribavirin, the concentration of AZT-TP is diminished and the anti-HIV-1 activity of AZT is reduced (365). Ribavirin, however, increases the antiviral activity of purine analogs such as dideoxyinosine (ddI) by increasing the intracellular concentration of the inhibitor dideoxyadenosine triphosphate (ddATP) and decreasing the intracellular concentration of the natural substrate dATP. These effects of ribavirin are achieved by its inhibition of cellular inosine monophosphate dehydrogenase, which provides a competitive advantage for incorporation to ddATP over the natural substrate dATP (5).

Other nucleoside analogs, including didanosine (2',3'-dideoxyinosine, ddI), zalcitabine (2',3'-dideoxycytidine, ddC), lamivudine (3'-thiacytidine, 3TC), stavudine (didehydrodeoxy thymidine, d4T), and abacavir, also have activity against HIV-1 and have been approved for clinical use (167) (Fig. 5B). Didanosine is a prodrug of dideoxyadenosine (ddA) and avoids the reproductive toxicity of orally administered ddA. In the cell, ddI is converted to ddA and the active inhibitor of HIV-1 RT is, in fact, ddA-TP. The mechanism of action for all these nucleoside analogs is similar to that of AZT. Each triphosphate drug functions as a competitive inhibitor of the natural nucleoside triphosphate, and chain termination occurs following incorporation. The ddA, ddC, d4T, and 3TC are phosphorylated by cellular enzymes to the triphosphate and compete with dATP, deoxycytidine triphosphate (dCTP), dTTP, and dCTP (again), respectively, for binding to HIV RT. Abacavir is a guanosine analog and competes with dGTP for incorporation (167).

Resistance

Our knowledge regarding mechanisms of resistance of HIV-1 to RT inhibitors was greatly enhanced by solving the high-resolution crystal structure of this enzyme. The HIV RT is a heterodimer consisting of p51 and p66 subunits. The crystal structure has been determined at a resolution of 3.5 Å. The initial crystal structure was determined on HIV-1 RT complexed to the nonnucleoside RT inhibitor nevirapine, which enabled the enzyme to be stabilized in a conformation that would permit a structure to be determined (216). This was quickly followed by the determination of the HIV-1 RT crystal structure in a complex with a Fab antibody fragment (194). This same research team also determined the crystal structure of many mutant RT molecules. The structure of the HIV-1 RT at 3.2 Å in a complex with the double-stranded DNA template primer and a dNTP has also been described (190).

All of the RT crystal structures show a great deal of agreement, but there are also some contrasts. The structure of the covalently trapped catalytic complex of HIV-1 RT obtained at 3.2 Å, which shows the structure of HIV-1 RT complexed with the DNA template-primer and dNTP, provides a great deal of information regarding mechanisms of resistance and the key role of resistance mutations in RT function (190). The structure of RT containing the Try181Cys mutation and bound to the nonnucleoside RT inhibitor tetrahydrobenzodiazepine (TIBO) has also provided direct evidence of drug binding to an altered RT (82). The p66 subunit of RT contains the active center for dNTP binding, composed of a 183-tyrosine-methionine-aspartate-aspartate (183Y-M-D-D186) region that is absolutely conserved among all RT enzymes in retroviruses and hepatitis B virus (1). It is also conserved in the RNA-dependent RNA polymerase of poliovirus. The p66 subunit has been described as resembling the right hand, whose fingers interact with the position of

the template primer, with a palm region and a highly flexible thumb (216). The binding site for the nononucleoside RT inhibitor nevirapine in the first crystal structure of HIV-1 RT was found in the palm region (216). One of the surprises about the p51 subunit is that although it has the same amino acid sequences as the p66 subunit, its three-dimensional structure is completely different. The p51 subunit appears to function as a scaffold to hold the p66 subunit in place. The catalytic domains of RT are only within the p66 subunit (190,194,216).

The first report of HIV-1 clinical isolates exhibiting resistance to AZT involved patients who had received treatment for at least 6 months. Although the clinical significance of resistance could not be assessed initially (228), HIV-1 also develops resistance to AZT *in vitro* after serial passage of the virus in the presence of the drug (227). The mutations in the HIV-1 RT that confer resistance to AZT were initially reported at codons 67, 70, 215, and 219 (229), and later, mutations at codons 41 and 210 were added (187,205). Mutations at codons 215 and 41 are associated with a high level of phenotypic resistance to AZT and clinical progression of disease (79,200). The AZT-resistance mutations at codons 67 and 70 are associated with an RT enzyme that possesses increased processivity, whereas the mutations at codons 215 and 219 are associated with mutant enzymes possessing increased rates of pyrophosphorolysis, a reaction that is the reverse of nucleotide incorporation (2). This suggests that chain termination with the incorporated AZT-MP is reversible, and that the AZT-MP can be removed and viral DNA synthesis can be rescued. This appears to be a mechanism for AZT resistance.

Numerous studies to find altered binding of AZT-TP to the mutant enzymes have not conclusively shown it to occur. The rescue of chain-terminated DNA synthesis mediated by ATP or pyrophosphate (PPi) is considered to be an important mechanism that would explain HIV resistance to AZT (2,267). The finger region of the HIV-1 RT is flexible and able to position the incoming RNA template, and many drug-resistant mutations occur as point mutations affecting this domain of the HIV-1 RT. These include the change at K70R and D67N for AZT resistance, the change at K74V for ddI resistance, the change at codon 69 effecting ddC resistance, and the suggestion *in vitro* of codon 75 for d4T resistance (220,253).

Using wild-type RT, the sensitivity to dideoxynucleotides (25) was shown to depend on template length. When the template extension was more than three nucleotides, the wild-type RT began to incorporate dideoxynucleotides. If the RT contained the K74V mutation associated with ddI, then RT did not incorporate dideoxynucleotides, even with a long template extension (25). This clearly suggests a mechanism of resistance involving an altered response to the RNA template. In addition, a series of insertion substitutions, such as a run of serine-serine-serine at codon 69, has been associated with high-level AZT resistance and confers resistance to almost all of the nucleoside analogs (226,387).

An antiviral susceptibility assay that could measure phenotypic resistance to AZT in all the clinical viruses that grow in peripheral blood mononuclear cells was needed to assess the significance of AZT resistance in patients enrolled in clinical trials (199). Using such an assay, a high level of resistance [i.e., a 50% inhibiting concentration (IC_{50}) > 1.0 μM] was established in 1995, clearly showing that AZT resistance was strongly correlated with enhanced disease progression and death in patients with advanced HIV disease, even when other factors such as CD4 cell counts were controlled for (79). The association of clinical progression with AZT-resistance mutations was observed both in patients with extensive AZT treatment (66) and in those with little or no prior treatment (376). In the case of AZT, resistance and high levels of HIV RNA both strongly correlate with clinical disease progression (66,200,376). The presence of two AZT mutations at codons 41 and 215 in patients who were heavily pretreated with AZT is associated with high HIV RNA levels and enhanced clinical progression (200). Treatment of patients with another nucleoside chain-terminating compound, 3TC, is also associated with rapid selection of a single mutation in the active center of HIV-1 RT, known as the M184V mutation (24,303). The M184V mutation in RT confers high-level resistance to 3TC; it is caused by a change in the residue located in the YMDD motif that contributes to a portion of the polymerase active site of RT and other polymerases (303). The mutant RT containing the M184V mutation can discriminate between 3TC triphosphate (3TC-TP) and dCTP, resulting in an incorporation of 20 to 100 times less 3TC monophosphate (3TC-MP), than the wild-type enzyme (151,282,303). The mechanism of AZT resistance is quite different from 3TC resistance, as RT enzymes containing a combination of mutations conferring AZT resistance (M41L, D67N, K70R, T215Y, and K219Q) incorporate AZT-MP at rates that are almost equal to that of the wild-type enzyme. It has been shown that these AZT resistant enzymes have an increased rate of pyrophosphorolysis, a reaction that is the reverse of nucleotide incorporation (2). Thus, chain termination may be reversible and DNA synthesis can be rescued through removal of the incorporated AZT-MP. Unblocking of chain-terminated primers can also occur with nucleoside triphosphates in the case of AZT-MP (267,268).

The term *processivity* is defined as the property of an enzyme that determines the length of time that the viral RT remains in contact with the RNA template, permitting generation of long nucleotide polymers. The term *fitness* is defined as the capacity of the virus for efficient replication capacity. In comparison with wild-type RT, the HIV-1 RT M184V enzyme possessed diminished processivity (8,333), an increased fidelity (369), and diminished nucleotide misincorporation in the RNA-dependent and DNA-dependent DNA polymerase steps of reverse transcription as well as a diminished incorporation of 3TC-MP (313,369). However, a decreased pyrophosphorolytic cleavage and virtual inability to remove 3'-terminated 3TC-MP may be the strongest effect of the M184V mutation on RT function (151). The decreased pyrophosphorolysis may be an important factor, as it contributes to the reduced replication fitness of M184V-containing variants of HIV-1. The diminished rate of 3TC-MP incorporation by RT-M184V ensures that a low level of viral replication can continue in the presence of the drug. The RT enzymes associated with resistance to AZT possess properties that are opposite to those of the RT associated with 3TC resistance. AZT resistance is associated with increased pyrophosphorolysis in the presence of pyrophosphate (PPi) or ATP, and increased rates of rescue of DNA synthesis (2,267,268). AZT resistance and 3TC resistance appear to occur by opposite mechanisms, providing an explanation for data from clinical trials that shows that AZT-resistant viruses are not cross-resistant to 3TC (231). The fact that AZT and 3TC combination therapy is effective may be due to the diminished rescue capacity for AZT-terminated DNA synthesis in the presence of the RT M184V mutant virus (151,231) and the maintenance of AZT-sensitive virus. It has been claimed that several amino acid changes in addition to M184V (283) or polymorphisms at codon 333 (208) can facilitate coresistance to 3TC and AZT.

Resistance to other nucleoside analogs such as ddI and the active intracellular metabolite ddA is mediated by a mutation in the finger domain of the RT, specifically a mutation at L74V, and to a lesser extent at RT M184V (155,253). The L74V mutation confers only two- to fourfold resistance to ddI (332,385). This is very different from the 100- to 1000-fold

resistance to 3TC associated with the M184V mutation. The didanosine resistance mutation results in a decrease in inhibition of RT enzymatic activity by ddATP (332), which is very different from the case of AZT-associated mutations and AZT-TP. The AZT-associated mutation at K70A does result in a decrease in inhibition by ddATP (332), suggesting a possible mechanism for cross-resistance between AZT and ddI. The RT L74V mutation associated with ddI resistance results in a mutant virus with decreased fitness and diminished replication capacity (333). The decrease in fitness is associated with a diminished processivity of the RT L74V enzyme, which is similar to a decrease in processivity associated with the RT M184V enzyme (333). In a study comparing development of resistance in 34 paired isolates obtained at baseline and at follow-up of 6 to 12 months from patients treated with didanosine (ddI) and stavudine (d4T), only a 1.6-fold increase in resistance was observed to ddI and a 1.9-fold resistance to d4T (51). This study also showed that the combination of d4T and ddI apparently allows the selection of AZT-associated mutations, an observation also reported by others (89,388).

The thymidine analog d4T is also an effective inhibitor of HIV RT and is associated with much less anemia and neutropenia in patients than AZT. There are reports that resistance to d4T in tissue culture is associated with the RT V75T mutation (220). In clinical studies, the use of d4T has rarely been associated with the selection of V75T mutants, and the role of this mutation in virologic failure of d4T therapy is controversial, as isolates containing V75T remain susceptible to d4T (237). Resistance to almost all nucleoside agents for HIV has been associated with two distinct mutational patterns in the viral RT. The multinucleoside resistance complex has been characterized as a combination of A62V, V75I, F77L, F116Y, and Q151M mutations in the RT (192). A series of serine insertions at codon 69 has also been associated with multinucleoside resistance (230,387).

The mechanism of multidrug resistance associated with these mutations has not been characterized. The negative impact associated with AZT-resistance mutations on subsequent treatment with RT inhibitors has been frequently noted (258), and these mutations may make the virus less susceptible to other antiviral drugs.

Nonnucleoside RT Inhibitors

The p66 subunit of the HIV-1 RT has a hydrophobic pocket that is a binding site for drugs belonging to a family of compounds called nonnucleoside RT inhibitors (NNRTIs) (Fig. 5). These drugs do not need to be metabolized intracellularly to exert antiviral activity. They do not compete with a natural substrate for binding to HIV-1 RT but are able to directly inactivate the enzyme. They do not present the risks of toxic side effects due to interference with nucleotide metabolism and nucleic acid biosynthesis that are associated with nucleoside RT inhibitors. They may act very early in viral replication and may inactivate RT within the virion itself (402).

The NNRTIs were historically important in enabling the crystal structure of the HIV-1 RT to be determined (216). More than 25 different subclasses of NNRTIs have been described, and they show a great variety of chemical structures. Tivirapine is the candidate drug derived from the TIBO class of compounds, the first HIV-1-specific inhibitors targeted to the nonnucleoside binding site of HIV-1 RT (296,297). Hydroxyethoxymethyl phenothiothymine (HEPT) was the first NNRTI compound to be identified as a specific HIV-1 inhibitor (7), and MKC-442 is its clinically active derivative (6).

Nevirapine was the first NNRTI to be approved for clinical use after multicenter clinical trials demonstrated the benefit of adding it to regimens with AZT and ddI (78,278). Addition of nevirapine further improved virologic and immunologic parameters of HIV disease. In antiretroviral naive patients, this combination has been dramatically effective (278). Two other NNRTIs have also been approved for clinical use, delavirdine and efavirenz (DMP-266). Efavirenz is currently the most potent NNRTI (395). The IC_{50} to inhibit viral replication in tissue culture is 0.001µM, and the dose required to achieve a 50% reduction in the viability of noninfected cells (CC_{50}) is 80µM. This provides a selectivity index, the ratio of CC_{50} to IC_{50}, of 80,000 (395). Another NNRTI, pyridinone C-697,661, was shown to be markedly effective as monotherapy in reducing the HIV-1 viral RNA level in plasma, but this was a temporary effect because there was a rapid emergence of resistance to the drug (317). The rapid emergence of resistance has strongly limited the use of NNRTIs as monotherapy: Each must be used in conjunction with another antiretroviral drug to have substantial benefit.

Delavirdine is a highly active bisheteroarylpiperazine (BHAP) NNRTI that decreases viral load and increases CD4+ T-lymphocyte counts when used in combination with other antiretroviral drugs (90). Delavirdine selectively inhibits HIV-1, but it has no activity against HIV-2 or other retroviruses. It is synergistic with each of the five approved RT inhibitors: AZT, ddI, ddC, d4T, and 3TC (see Fig. 5). It binds to a hydrophobic pocket in the p66 subunit of HIV-RT near the catalytic site of the enzyme (86). Residues important for NNRTI binding include those at codons 181, 188, and 103 (108). Binding of all of the NNRTIs is thought to induce a conformational change in the RT that inhibits polymerization (353).

The NNRTIs share several features: They are active against HIV-1 but not against HIV-2 or other retroviruses. They inhibit HIV-1 replication at very low concentrations, a factor of 10^5 below the cytotoxicity threshold. They specifically bind to an allosteric nonsubstrate binding site of the HIV-1 RT. The mutations conferring resistance to these drugs are found surrounding this binding pocket (353). Dr. Edward Arnold and colleagues at Rutgers University employed x-ray crystallography to determine the structure of the first NNRTI, TIBO bound to the wild-type enzyme and to the mutant RT containing a Tyr181Cys substitution (Fig. 6). The amino acids whose mutations confer resistance to NNRTIs are Glu-138, Leu-100, Lys-101, Lys-103, Pro-236, Tyr-181, Tyr-188, Val-106, Val-108, and Val-179; the relatively conserved amino acids in the binding pocket are Leu-234, Phe-227, Pro-95, Tyr-229, and Tyr-318 (82).

FIG. 6. Computer graphics representation of the structure of HIV-1 reverse transcriptase (RT) showing the pocket region where nonnucleoside RT inhibitors (NNRTIs) bind. Shown is the inhibitor 8-C1 TIBO (tetrahydrobenzodiazepine). Edward Arnold and colleagues have used x-ray crystallography to determine structures of TIBO bound to both wild-type and Tyr181Cys HIV RT. Amino acids whose mutations confer resistance to NNRTIs are Glu-138, Leu-100, Lys-101, Lys-103, Pro-236, Tyr-181, Tyr-188, Val-106, Val-108, and Val-179; relatively conserved amino acids in the binding pocket are Leu-234, Phe-227, Pro-95, Trp-229, and Tyr-318. HIV-1 RT secondary structural elements (b6, b9, b10, b12, b13, and b14) are represented by ribbons. (Courtesy of Kaylan Das and Edward Arnold, Center for Advanced Biotechnology and Medicine, Piscataway, NJ, and Rutgers University, NJ.)

In contrast to the resistance mutations arising from *in vitro* cultures with the other NNRTIs such as nevirapine and efavirenz (Y181C or K103N), delavirdine induces a proline-to-leucine change at codon 236 of the HIV-RT (108). This p236 mutation is in the “roof” of the nonnucleoside binding pocket and confers a higher level of resistance to delavirdine than does K103N or Y181C (123). Delavirdine maintains some activity against the Y181C or K103N mutants *in vitro*, which is different from nevirapine or the pyridinones (108,124). The P236L mutant exhibits a hypersensitivity to other NNRTIs *in vitro* (123).

In patients receiving delavirdine as monotherapy, the most common mutations observed are at codons Y181C and K103N, even though P236L is the most common resistance mutation associated with delavirdine drug exposure *in vitro* (Fig. 7). In a trial of delavirdine as monotherapy, resistance to delavirdine developed within 8 weeks of therapy, but only 10% of resistance isolates had the P236L mutation. The majority of patients had isolates with the Y181C and the K103N mutations, even though these double mutants were considered to be unlikely (90). In patients taking AZT and delavirdine, the Y181C mutation was not detected, but when patients received delavirdine monotherapy, 50% of the isolates had the Y181C mutation (88,90). This is similar to what has been observed with nevirapine and AZT (89,315).

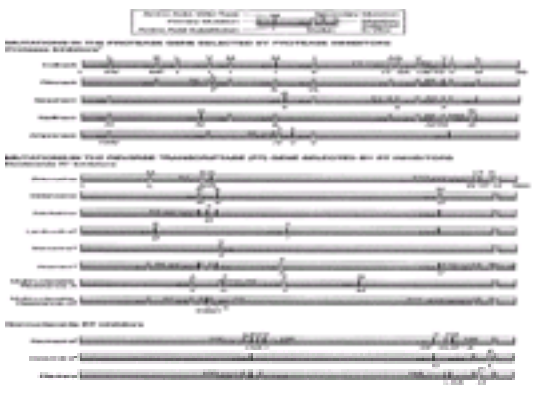

FIG. 7. Shown are the most common mutations in HIV-1 genes that confer drug resistance. For each residue, the *letter above* indicates the amino acid associated with the wild-type virus. The *italicized letters below* are substitutions that confer viral resistance. *Black bars* are primary mutations and cause decreased inhibitor binding. *White bars* contribute to drug resistance and may have less direct effect on inhibitor binding *in vitro*. *Black and white bars* are mutations selected *in vitro* and rarely seen in patients with treatment failure. (Reprinted from Hirsch MS, Brun-Vezinet F, D'Aquila RT, et al. Antiretroviral drug resistance testing in adult HIV-1 infection: recommendations of an International AIDS Society-USA Panel. *JAMA* 2000;283:2417–2426, with permission.)

NNRTIs inhibit RT noncompetitively with respect to its normal substrates (dATP, dGTP, dCTP, dTTP), commonly referred to as the deoxynucleoside triphosphates (dNTPs). The specific site (the pocket) of the HIV-1 RT where NNRTIs interact is functionally related to the substrate (dNTP) binding site. This pocket is located 10 Å from the substrate-binding polymerase (pol) active site within the palm domain of the p66 subunit of HIV RT. The binding of the NNRTIs to this site might indirectly affect the conformation of aspartate residues (Asp-185, Asp-186, and Asp-110) in the nearby pol active site (219). The binding of NNRTI to this pocket may lead to a repositioning of these aspartate residues; thus, the NNRTI may inhibit HIV-1 RT by locking the pol active site in an inactive conformation, reminiscent of the conformation of the p51 subunit of HIV RT (86,353).

Most of the NNRTIs assume a butterfly-like structure, with two hydrophobic wings connected by a polar central body consisting of urea (e.g., MKC-442), thiourea (e.g., tivirapine and trovirdine), carboxamide (e.g., loviride), or thiocarboxamide (e.g., thiocarboxanilide UC-781) (86). The NNRTIs appear to function as p-electron donors to aromatic side chain residues surrounding the NNRTI binding pocket. The side chain residues adapt to each bound NNRTI in a

highly specific manner, closing around the surface of the drug to make tight van der Waals contacts (219).

The contact points between the NNRTI butterfly and its surroundings in the HIV-RT pocket represent hot spots, where the HIV-1 RT preferentially undergoes mutations conferring resistance to the NNRTIs (i.e., L110I, K101E/I/Q, K103N/Q/R/T, V106A/I, E138K, V179D/E, Y181C/I, Y188C/L/H, G190A/E/Q/T, and P236) (86) (Table 1, and see Fig. 7). Amino acid substitutions at these sites give rise to resistance to the individual compound to which the HIV-1 RT has been exposed, often leading to cross-resistance to other NNRTIs.

Drug class	Mutations
Nucleoside reverse transcriptase inhibitor	Reverse transcriptase gene
Zidovudine (AZT)	41,67,70,210,215,219
Didanosine (ddI)	65,74,184
Zalcitabine (ddC)	65,69,74 184
Lamivudine (3TC)	44 118 184
Stavudine (d4T)	75
Abacavir (ABC)	41,65,67,70,74,115,184,210,215
Multinucleoside resistance A	62,77,116,151
Multinucleoside resistance B	41,67,69 (insert), 70,210,215,219
Nonnucleoside RT inhibitor	Reverse transcriptase gene
Nevirapine	100,103,190,108 181,188,190
Delavirdine	103 181,236
Efavirenz	100,103,190 [illegible] 188,190,225
Protease inhibitor	Protease gene
Indinavir (IDV)	10,20,24,32,36,46,54,71,77,82,84,90
Ritonavir	20,32,33,36,46,54,71,77,82,84,90
Saquinavir	10,48,54,71,73,77,82,84,90
Nelfinavir	10,30,36,46,71,77,82,84,88,90
Amprenavir	10,32,46,47,50,54,84

TABLE 1. *Mutations associated with resistance of HIV-1 to antiretroviral drugs*

Exposure to an NNRTI does not necessarily lead to cross-resistance to other NNRTIs, and switching compounds or combining drugs that have different resistance patterns is possible. To prevent the emergence of HIV-1 resistance to NNRTIs, the compounds should be administered in adequate doses. Several NNRTIs (e.g., tivirapine, MKC-442, nevirapine, pyridinone, delavirdine, quinoxalines, and thiocarboxanilides), when added to cells *in vitro* at high concentrations, can completely suppress viral replication so that repeated passage of the virus-infected cells in the presence of the compounds clears (“cures”) the cells of the virus (86). Failure to detect the presence of proviral DNA in the cells by using the polymerase chain reaction (PCR) was reported. The concentration at which viral clearance is achieved varies from one compound to another; the most potent compounds among the NNRTIs (i.e., HBY097 and thiocarboxanilide UC-781) achieve viral clearance at concentrations as low as 0.1 µg/mL, a concentration that is readily attainable *in vivo* through systemic (oral) administration of the compounds. This apparent “knock out” of virus *in vitro* can be achieved at lower drug concentrations when drugs are used in combination (12). Combinations of 3TC and any of the NNRTIs (e.g., MKC-442 and delaviradine) completely suppress viral replication under conditions and at concentrations where the individual compounds, when used as single-agent therapy, fail to do so (11). To achieve a synergistic effect on viral replication, compounds must be administered together, not sequentially. Only when 3TC is added to cells concomitantly with another NNRTI did the compounds act synergistically in preventing virus breakthrough (11).

Protease Inhibitors

The HIV-1 protease enzyme is a homodimer of two identical subunits composed of 99 amino acids. It is a member of the aspartate protease family, because the active center of the enzyme consists of two aspartate molecules. Other members of the family include cathepsin D, and angiotensin-converting enzyme. The HIV-1 protease was the first viral enzyme for which a crystal structure was determined, and atomic details are well understood (299,389). The homodimer has all the enzymatic activity and the monomer is enzymatically inactive (299).

Solution of the three-dimensional crystal structure of the protease enzyme allowed design of antiviral drugs and an understanding of HIV protease resistance and cross-resistance (Fig. 8) All of the HIV-1 protease-inhibiting drugs fit into an active center pocket that is large enough to accommodate seven amino acids. This binding pocket consists of several smaller subpockets designated S_1, S_2, and S_3. Each protease inhibitor binds preferentially to one or more of these subpockets. The seven amino acids define the recognition sequence required for HIV-1 protease to carry out cleavage in the viral replication cycle. The HIV-1 protease cleaves itself from the gag-pol precursor peptide. The protease acts at 11 distinct cleavage sites on the HIV-1 polyprotein precursor. All of the sites are located in the *gag* and *pol* genes except for one cleavage site within the nef protein (133). It is not clear how a single viral enzyme is able to effectively recognize and cleave at 11 distinct regions of amino acid sequence, but three of the HIV cleavage sites involve phenylalanine-proline or tyrosine-proline bonds, which are unusual sites of attack for mammalian proteases (119). This activity, however, is essential for HIV replication and maturation (133,215).

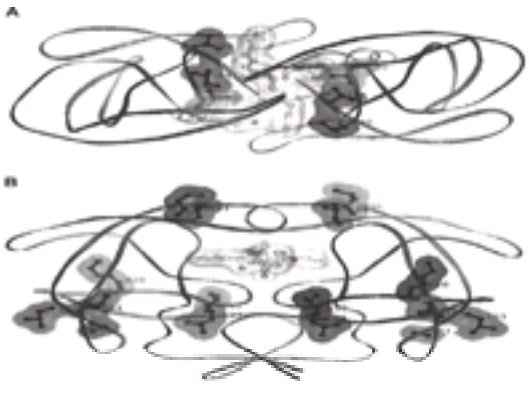

FIG. 8. Crystal structure of the HIV-1 protease showing locations of amino acid residues that induce drug resistance to indinavir. **A:** Top-down view showing residues known to affect inhibitor binding (V82, I84, L90). **B:** End-on view showing

eight residues away from the drug binding site. The structure of indinavir is shown; the catalytic D25 residue is on the loop below the drug. (Data courtesy of J. H. Condra et al. Structure by Z. Chen et al. Graphics by M. K. Holloway of Merck Research Laboratories.)

The work that established that HIV-1 protease is essential for viral replication was published as a landmark article by Dr. Irwin Siegel and his colleagues at Merck Research Laboratories (215). They described molecular approaches to construct viruses containing mutations within the HIV-1 protease gene. A single mutation involving the aspartate in the active center of the protease enzyme was shown to result in an inactive protein and the absence of viral infectivity. When viruses containing the mutant protease gene are transfected into cells, the gag p55 precursor polyprotein can be detected in cells, and RT precursors are still present. The RT, however, is not processed to its p66 and p51 functional subunits. Virion particles are produced by these cells but the virions are not infectious and do not contain mature core proteins or the processed RT components p66 and p51 (215).

The assay employed to measure processing of precursor proteins was effectively used to screen for potent antiviral compounds, which could inhibit the HIV-1 protease function, leading to the discovery of the protease inhibitor indinavir (133). The first protease inhibitor approved for human use was saquinavir in 1995. In 1996, ritonavir and indinavir were approved. There are now six licensed HIV-1 protease inhibitors in use, including nelfinavir, amprenavir, and ABT378 $_{R}$ (Kaletra, Lopinavir/Retonavir). All of these protease inhibitors fit in the active center. The protease inhibitors bind in this region and interact with several amino acids of this binding pocket depending on the size of the protease inhibitor molecule. Indinavir is the largest protease inhibitor and interacts with the largest number of amino acids in the protease dimer. The most frequent mutations associated with indinavir resistance occur at codons 48, 82, and 84 (63) (see Fig. 7 and Table 1).

Other protease inhibitors that, like ritonavir and saquinavir, are also large give almost complete cross-resistance profiles with indinavir (65). With saquinavir use, the first mutations selected are located at codons 48 and 90 (195). With prolonged use, many more mutations throughout the entire protease gene are selected. Retonavir selects for a broad cross-resistance among all the protease inhibitors (276). The initial mutation conferring resistance to retonavir is usually a change at codon 82, but with prolonged use, multiple mutations occur, producing high-level cross-resistance to all of the protease inhibitors (276).

The protease inhibitor with the smallest known molecular structure is amprenavir (133). The most common mutation selected by amprenavir occurs at codon 50, and it confers resistance in approximately half of the cases (294). The other half of the resistance cases to amprenavir are conferred by multiple mutations other than at codon 50. In addition to mutations occurring at codons for amino acids that directly touch the protease inhibitor, other amino acids associated with resistance are present in positions distant from the binding site of the drug to the protease enzyme (63,70). These altered amino acids are primarily considered compensatory mutations that increase the biologic activity of the drug-resistant enzyme (63). Some of the latter mutations, such as substitutions at L10, M46, and L63, were observed as initial events in the development of resistance to indinavir, leading to increased fitness of the viral protease. Specifically, studies of recombinant enzymes containing the M46I and L63P substitutions showed that the mutant proteins have improved catalytic efficacy (330).

Some mutations occur very commonly *in vitro* and were not expected to be associated with cross-resistance. For example, the drug nelfinavir, a very small molecule, touches the protease enzyme most closely at the position presented by codon 30. The D30N mutation predominates when resistance occurs *in vitro*. In clinical use of nelfinavir, however, other mutations are readily selected, particularly at position L90M. Virologic failure with nelfinavir is associated primarily with the mutation L90M (295). When HIV is grown in tissue culture, or the virus is isolated from patients receiving protease inhibitors, multiple amino acid mutations are observed in the protease enzyme and in the gag and gag-pol polyproteins that are the cleavage sites (404) for the protease. These mutations in the protease and in the gag-pol polyprotein cleavage sites result in processing defects and a loss of viral fitness (245,400). These less fit protease variants replicate more slowly in patients and are associated with a decrease in pathogenicity.

The inhibitors of the HIV-1 protease enzyme have had a greater impact on HIV disease than any other class of drug (186,293,374). For patients with a high level of HIV-1 RNA (100,000 copies of HIV-1 RNA per milliliter of plasma), protease inhibitors are dramatically effective at lowering viral load and improving patient outcome (157,164). It is not unusual for protease inhibitors alone to decrease the level of HIV RNA by a factor of three logs (133). A decrease of greater than two logs was essentially not seen with RT inhibitors. In some cases, the use of a protease inhibitor results in prolonged suppression of HIV replication (157,158). Thus, protease inhibitors are main components of antiretroviral combination therapies (137,157,164). This will be discussed later in the Clinical Trials section.

A major limitation of protease inhibitor effectiveness, however, is the high degree of protein binding by human sera that all of these drugs exhibit (277). Only the free drug penetrates cells and inhibits HIV. The most potent protease inhibitor, indinavir, is also the least protein bound. Penetration of indinavir into tissue compartments where viral replication is ongoing, such as the central nervous system, and into seminal fluid is higher than that of other protease inhibitors, and this may contribute to its considerable clinical effectiveness (133). An important observation for all of the protease inhibitors is that the presence of human serum attenuates the activity of the inhibitors, both for wild-type and utant HIV-1 strains (277). A careful study comparing the effect of human serum on the IC_{50} of retonavir, saquinavir, and nelfinavir when used against wild-type and protease mutant viruses found that their activities were markedly attenuated in the presence of human serum, whereas indinavir, amprenavir, and the compound ABT378 were only modestly affected (277). All of the HIV protease inhibitors also inhibit the cytochrome P450 enzymes, which metabolize these drugs, but ritonavir is the most potent inhibitor of these enzymes (91). When ritonavir is coadministered with other protease inhibitors, a powerful pharmacokinetic enhancement is observed, which greatly increases the plasma level of other protease inhibitors (209). This concept has been exploited to show that the phenotypic susceptibility of a clinical isolate (as an IC $_{95}$

corrected for human serum) could be greatly exceeded by a minimal concentration of drug (C_{min}) obtained when a protease inhibitor is coadministered with ritonavir. The ratio of C_{min}/IC_{95} (corrected) can give the value of the enhancement factor (called an inhibition quotient) that could be expected when small doses of ritonavir are used to increase the C_{min} of another protease inhibitor. This pharmacokinetic boost can be employed to achieve high plasma concentration and overcome virologic failure due to resistance to protease inhibitors. For example, a dose of indinavir at 800 mg and ritonavir at 200 mg given twice a day could achieve a C_{min}/IC_{95} ratio of 78.6-fold above the concentration achieved with indinavir alone (64). This provides a rationale for drug intensification with a twice-daily regimen of two protease inhibitors to overcome the virologic failure of a single protease inhibitor (64).

HIV-1 Drugs

Clinical Trials

Many randomized, controlled, double-blind clinical trials of antiretroviral therapies have examined the use of antiretroviral drugs in combination, as this is remarkably effective at decreasing viral replication and increasing the CD4 cell count in HIV-infected patients.

Assessment of the effectiveness of antiretroviral therapy has been closely linked to measurement of HIV-1 RNA levels in plasma (263). Plasma HIV-1 RNA, well established as an accurate measure of viral replication in patients (263), can be measured precisely by two commercially approved assays that show remarkably similar values when compared directly (66,376). One method employs RT-PCR to amplify the copies of RNA in plasma. The standard commercial assay has a limit of detection of 400 copies of HIV-1 RNA per milliliter of plasma and a dynamic range of up to 2 million copies per milliliter of plasma (66,376). An ultrasensitive PCR-based HIV-1 RNA assay detects HIV-1 RNA down to 50 copies per milliliter of plasma. Other experimental assays can detect as little as two to five copies of HIV-1 RNA per milliliter of plasma. Another method of detecting HIV-1 RNA is based on a signal amplification of RNA in plasma. This is called the branched DNA method for detection, and the latest version can detect 100 copies of HIV-1 RNA per milliliter of plasma (263). These two methods for detecting HIV-1 RNA in plasma and fluids in other body compartments are widely used to follow the response to antiviral therapy and to assess virologic failure.

The first effective antiviral drug for treating HIV disease was AZT, which was licensed in the United States in 1987 (132). In a study of 4 months' duration, AZT yielded an improvement in survival, and fewer opportunistic infections, which led to its approval by the FDA. In this study, however, the placebo recipients had an unusually high mortality, rarely seen in other trials. The short-term benefits of AZT were transient and not supported in longer-term studies (162). In a trial comparing two doses of AZT, the lower-dose regimen was found to be associated with improved clinical outcome, but patients receiving the lower dose also received more prophylaxis to prevent *Pneumocystis carinii* pneumonia (PCP), the main infection to which patients with HIV were subject. The favorable response of the lower-dose AZT treatment regimen was attributed to a decrease in the toxic side effects of AZT. This interpretation, however, is confounded, because more patients also received prophylactic treatment against opportunistic infections in the low-dose AZT arm (131). AZT does have significant side effects, including anemia, neutropenia, and lymphocyte toxicity (314). There were claims initially that disease markers such as the CD4 cell count could be improved in patients who were treated at an early stage of disease with AZT, and disease progression was decreased in patients treated for 1 year with AZT (366).

The Concorde Study, conducted by the British and the French, evaluated treatment early in disease with AZT for 3 years. It concluded that AZT provided no survival benefit even though CD4 cell counts were slightly improved after 1 year of treatment (61). In time, it became clear that treatment of HIV-1 disease with a single RT inhibitor produces little long-term benefit, and that resistance rapidly emerges. With AZT therapy alone, HIV RNA levels decreased transiently and then returned to baseline levels. One of the few exceptions to the limitations of monotherapy was with didanosine therapy. In the first study of the AIDS Clinical Trials Group (ACTG 175) to show an improvement in survival with the use of two RT inhibitors, ddI monotherapy performed as well as the use of two drugs in providing clinical benefits and improving mortality (163). Therapy with ddI provided a greater decrease of HIV RNA than did AZT monotherapy, but over the short duration of treatment, two nucleoside RT inhibitors had a more significant effect on lowering HIV RNA than did ddI alone. After 1 year of treatment, however, there was no statistical difference between therapy with ddI alone and therapy with a combination of two RT inhibitors (163,202). The first ACTG study to show a statistically significant decrease in viral RNA levels was ACTG 116/117, a study that enrolled patients heavily pretreated with AZT (66,201). This study showed that if patients switched to ddI there was a significant decrease in viral RNA levels compared to those who stayed on AZT alone (191). The drop in RNA was small, only about 0.5 log, and no survival benefit could be documented with ddI therapy (66,201).

The data from ACTG 116/117 also provided the first evidence to show that high-level resistance to AZT resulted in a more rapid progression of AIDS and an enhanced rate of death (79). This association of clinical failure with high-level AZT resistance is the best example of the clinical significance of resistance to any antiretroviral therapy. For other antiretroviral agents, virologic failure with an increasing HIV RNA level in plasma has been noted, but the clinical consequences have not rigorously been determined.

Although the ACTG 175 trial using two RT nucleoside inhibitors was the first study to clearly show a persistent survival benefit associated with treatment, it was not until a protease inhibitor was included in the treatment regimen for patients with advanced HIV disease that a dramatic improvement in survival was shown. In the ACTG 320 study, patients treated with indinavir, AZT, and 3TC had a 50% decrease in mortality at a mean follow-up of 36 weeks, and this was superior to results in patients treated with AZT and 3TC alone (164). The study was terminated early because of the statistically significant increase in survival benefit noted. There was a major drop in deaths caused by the major opportunistic infections of CMV, *Pneumocystis carinii*, and *Mycobacterium avian* complex in patients receiving triple therapy. This clinical improvement was associated with a greater drop in viral RNA level in those receiving triple therapy compared to two-nucleoside therapy (164). The Merck 035 study looked at the same regimen of indinavir, AZT, and 3TC; it showed that markers of HIV-1 RNA and CD4 cells improved in a group of heavily treated patients with HIV-1 infection (157). The Merck study showed that even in a group of patients in whom 81% had AZT drug-resistance mutations, after 2 years of

follow-up 84% of those still taking their medication had an HIV-1 RNA level below the limit of detection of 400 copies per milliliter of plasma (157). After 3 years of follow-up, 67% of these patients had an HIV-1 RNA level of less than 400 copies per milliliter of plasma (158). Although the number of patients who were still on this regimen was small, 21 of 31 (65%) had viral RNA levels of less than 50 copies per milliliter. There was a steady increase in CD4 cells in the patients in this study, with a mean increase of 230 cells noted after 3 years (158). It was shown in a study by Autran et al. that patients on highly active antiretroviral therapy (HAART) initially have an increase in CD4 memory T-cells in the peripheral blood, largely from mobilization from lymph nodes (4). With continued time on HAART, naive CD4 lymphocytes also contribute to the increase in CD4 cell numbers.

In addition to antiviral drug regimens containing protease inhibitors, regimens containing the potent NNRTIs efavirenz, AZT, and 3TC are also highly effective at suppressing HIV-1 replication for a prolonged period of time. In the 48-week Dupont 006 trial, the efavirenz, AZT, and 3TC combination was superior to indinavir, AZT, and 3TC in the number of patients who were suppressed below the limit of detection of 50 copies per milliliter of plasma (342). It is important to keep in mind that this was an open trial, where patients knew the regimens that they were receiving and the group taking indinavir, AZT, and 3TC needed to take a very high number of pills every day, and this was associated with a very high drop-out rate (342).

Long-term suppression of HIV-1 RNA levels has been most convincingly demonstrated for patients receiving the protease inhibitor indinavir and two nucleoside RT inhibitors, such as AZT and 3TC, or d4T and 3TC. It is clear that other regimens containing NNRTIs, such as efavirenz, AZT, and 3TC (Dupont 006 Study) (342), or nevirapine and d4T and ddI (INCAS Study) (278), can also suppress HIV-1 RNA for considerable periods. Whether the duration of suppression will be as long as that seen in patients on protease-inhibitor-containing regimens is the subject of ongoing clinical trials. Regimens containing three nucleoside RT inhibitors such as AZT, 3TC, and abacavir are also able to suppress HIV-RNA effectively, but the results of longer-term suppression studies are awaited. A clear finding emerging from all of these studies is that replication-competent HIV-1 remains in resting memory CD4 lymphocytes in spite of plasma suppression by highly active antiretroviral therapy (48,130,391). The amount of virus detected in plasma may be undetectable (less than 50 copies of HIV-1 RNA per milliliter of plasma), but replication-competent virus is still present in the patient.

HIV-1 is likely to accrue drug-resistant mutations as long as it is replicating. With prolonged time, increased replication is likely to result in virologic failure in spite of antiretroviral therapy. When viral rebound does occur, the virus is usually not resistant to all of the components of active antiretroviral treatment, but primarily to the RT inhibitors (93,168). Since the rebounding HIV remains sensitive to the protease inhibitors, there is hope that treatment strategies based on intensifying the protease part of the combination regimen will be successful at lowering viral RNA (64).

A major success of antiretroviral therapy has been achieved in the ability of Zidovudine to decrease the rate of transmission of HIV-1 from mother to infant by almost 70% (65A,337A). A double-blind, placebo-controlled trial enrolled HIV-1–infected women with more than 200 CD4 T-cells/mm^3, who were between 14 to 34 weeks of gestation, and most were Zidovudine-naïve. The mothers took Zidovudine at 100 mg orally 5 times per day through pregnancy and received intravenous Zidovudine by continuous infusion of 1 mg/kg/hour during labor until delivery. The newborn took Zidovudine at 2 mg/kg orally every 6 hours for the first 6 weeks of life. This regimen decreased perinatal transmission of HIV-1 from 22.6% to 7.6%. The benefits of Zidovudine could not be fully explained by reductions in maternal viral load (337A). Another regimen, studied in African women, of one capsule of nevirapine to a mother during labor and one pill of nevirapine to the newborn in the first 72 hours of life was successful in reducing transmission by 50%. The effects of combination antiretroviral therapy on decreasing perinatal transmission are still under study.

In many regimens that show the capacity to decrease HIV-1 RNA levels in plasma to very low levels, replication-competent virus remains. When antiretroviral therapy is stopped, viral rebound will occur quickly. The source of rebounding virus may not be predicted by virus present in latent reservoirs—it may emerge from unknown sources. The current goal of antiretroviral therapy is to find new therapies that act on other virologic targets, such as viral entry or the integration of viral provirus by integrase, to suppress viral replication for many years.

HEPATITIS B

The human hepatitis B (HBV) is a small DNA virus that is hepatotropic and infects only humans. Infected humans are the only known reservoir of the virus (250). Similar viruses are found in American woodchucks, ground squirrels in California, Peking ducks in China, and some other rodent hosts (250,256,350). The HBV genome, one of the smallest of all known or animal viruses, consists of a 3,200-base-pair, double-stranded, circular DNA molecule that contains a single-stranded region of different lengths of viral DNA molecules (189,225). The virion DNA molecules are packaged into virions before viral DNA replication is complete in the synthesis of the plus strand. Viral DNA replication by RT is a unique mechanism for a DNA virus, and it is shared by the hepadnaviruses and the cauliflower mosaic virus (357). The similarity in replication mechanisms and the nucleotide sequence homology between HBV, retroviruses, and cauliflower mosaic virus indicate a phylogenetic relationship between these virus families (270,357). When HBV infects cells, the relaxed circular virion DNA genome is converted to a closed circular DNA, which serves as a template for viral transcription. This is accomplished by the product of the polymerase gene (which makes up 75% of the viral genome), a 90-kd polypeptide that possesses RT DNA polymerase and ribonuclease H activities. The polymerase protein also serves as a primer for DNA minus-strand synthesis (23,349).

The long RNA transcript and the RT product of the *pol* gene are encapsidated in immature core particles, and viral DNA synthesis takes place by reverse transcription of this long transcript in the cytoplasm of infected cells (349). Unlike HIV, HBV does not possess an integrase enzyme. HBV DNA is found in infected liver as an episomal form involved in virus replication, and it is also integrated in cellular DNA. It is not known whether viral integration occurs in all or some virus-infected cells. Without an integrase for orderly integration of the viral genome, integrated viral DNA is found at many random cellular DNA sites. Moreover, integrated HBV sequences are not preserved and small deletions or rearrangements are present in all integrants (316). The process of integration has been called illegitimate recombination (316), because HBV integration interrupts the viral genome so that replication is not possible from integrated sequences

in naturally infected cells.

Because of the strong similarities between the HBV DNA polymerase and the HIV RT, drugs that inhibit HIV RT also inhibit HBV RT-like functions and HBV replication. Lamivudine (3TC) is an effective inhibitor of HBV replication *in vitro* and it proved to inhibit HBV effectively in humans as well (96,222) (Fig. 9). In a 1-year trial of 358 patients with chronic HBV hepatitis in China, 56% of patients taking 100 mg of 3TC daily improved histologically, and 72% had a sustained normalization of aminotransferase activity (222). Sero conversion to the presence of antibody to HBe antigen (HBeAG), indicating an improvement in the immune protection against severe hepatitis progression, occurred in 16% of patients after 1 year and increased to 27% after 2 years of treatment (154,222). For patients who undergo a liver transplant for HBV-induced cirrhosis and liver failure, 3TC at 100 mg daily for 90 weeks reduces the risk of HBV reinfection (154).

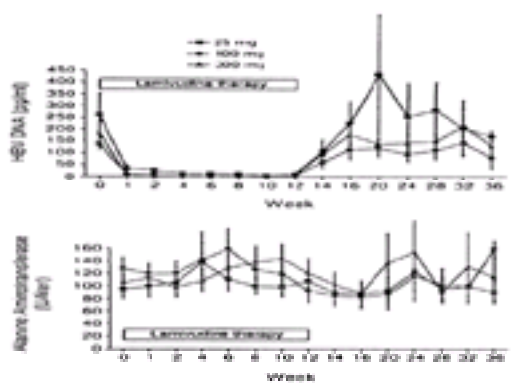

FIG. 9. Changes in mean (±SE) serum levels of HBV DNA (*upper panel*) and alanine aminotransferase (*lower panel*) in patients with chronic hepatitis B undergoing 12 weeks of therapy with 25, 100, or 300 mg of lamivudine per day. (Reprinted from ref. 96, with permission.)

The HBV RT pol enzyme contains the conserved YMDD motif, which is common to all of the avian and mammalian RT enzymes. When using 3TC for patients with chronic HBV infection, drug resistance can emerge (17). In a study of patients with chronic HBV infection and active hepatitis, 14% developed resistance after taking 3TC for 1 year and 38% developed resistance after 2 years (17). Although 3TC-resistant variants of HBV replicate less well *in vitro* (262), they have been associated with progressive liver disease in transplant recipients (17). Resistance is most commonly associated with an M552V change in the YMDD motif in the highly conserved catalytic center of the HBV RT where resistance to 3TC in the HIV RT occurs, the M184V change (17). For those HBV mutant viruses that possess the M552V mutation, a loss of fitness and a slower viral replication cycle have been reported (262). When an additional mutation at codon 526 of the polymerase occurs, replication fitness is restored to wild-type levels.

Another HIV RT inhibitor, adefovir, is also a potent inhibitor of HBV DNA replication. Adefovir is an experimental nucleotide analog that contains a phosphonate group; it is phosphorylated by cellular enzymes to adefovir triphosphate. Adefovir triphosphate is an active inhibitor of HBV DNA replication (Fig. 10) (87). HBV mutants that contain the M552V mutation and exhibit resistance to 3TC, retain susceptibility to adefovir (289). Thus, adefovir may provide an alternative treatment for those patients who have failed with lamivudine.

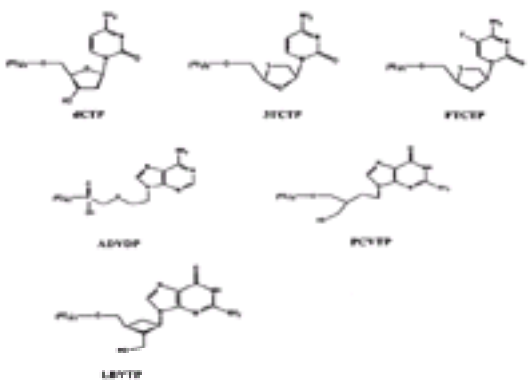

FIG. 10. Structure of the triphosphate of nucleosides and nucleotides that inhibit hepatitis B polymerase. dCTP, deoxycytosine triphosphate; 3TC-TP, lamivudine triphosphate; FTC-TP, emtricitabine triphosphate; ADV-TP, adefovir diphosphate; PCV-TP, penciclovir triphosphate; LBV-TP, lobucavir triphosphate. Molecular modeling and biochemical characterization reveal the mechanism of hepatitis B virus polymerase resistance to Lamivudine (3TC) and Emtrilitabine (FTC). *J Virol* 2001;75, with permission.)

Human a interferon or recombinant a interferon expressed from the human a interferon gene in *Escherichia coli* is a potent inhibitor of HBV replication and is useful as a treatment for chronic active hepatitis B infection. Until the development of 3TC, the use of human a interferon was the mainstay of treatment for chronic active hepatitis B infection in humans and provided one of the first examples of effective antiviral therapy for any disease. With interferon treatment, about 30% of patients exhibit a dramatic decrease in circulating HBV DNA, and improvement in liver function tests and histology on follow-up liver biopsies. In some patients, these favorable responses are maintained when treatment is discontinued. The difficulty is that the favorable outcome is observed in only a small percentage of patients, and the benefits of treatment are usually short-lived. The side effects of interferon therapy are frequently severe, with flu-like

illness characterized by fatigue, headache, muscle aches, chills, and fever being commonplace. Other problems such as neuropsychiatric problems and the need for continuous parenteral therapy make treatment difficult. These side effects limit the ability of patients to tolerate therapy for an extended duration (260,281).

Human a interferons are a group of potent glycoproteins that have many actions in addition to antiviral activity. One of the first demonstrations of antiviral efficacy of a interferon was in the treatment of chronic HBV infection (282). Of the three major classes of human interferon (interferon-a, interferon-b, and interferon-g), only interferon-a is approved for treating viral infection. The gene for human interferon-a, which can be expressed in a recombinant form in *E. coli* in a cost-effective manner, is produced by two companies for human use (Roche and Schering). These are designated interferon-a2a and interferon-a2b, respectively. Both of these recombinant interferons are approved for treatment of chronic HBV hepatitis (see Fig. 10).

Interferons do not act directly on the virus but induce cellular proteins to produce an antiviral state. These include proteins that inhibit the synthesis of RNA, enzymes that cleave viral and cellular DNA, and proteins that alter cell membranes so that release of replicated virions is blocked (204,282). The use of subcutaneous or intramuscular interferon-a2a (3 million units) three times per week for 6 months in chronic HBV hepatitis patients produced a normalization of abnormal alanine aminotransferase (ALT) levels in 40% of patients, and a virologic response of decreasing HBV DNA levels in 30%. Within 6 months of treatment, however, 50% of patients relapsed (204). In another study of interferon-a2b treatment of chronic hepatitis B, subcutaneous injections three times per week for 16 weeks resulted in clearance of hepatitis e antigens and HBV DNA in 50% of patients compared to 7% of control subjects (282). The normalization of liver function tests and a loss of hepatitis B surface antigens occurred in fewer patients. Although interferon-a and 3TC are effective in treating chronic HBV infection, there is no evidence that combining these agents results in a higher response rate.

HEPATITIS C

The hepatitis C virus (HCV) is a positive sense single-stranded RNA virus with a lipid envelope. The virus is classified as a genus of the *Flavivirus* family, which also contains the yellow fever virus (95,309). The viral particles are 50 to 75 mm in diameter. Two types of viral particles have been described, a low-density one with a specific gravity of 1.03 g/mL, which is most infectious, and a high-density particle (1.2 g/mL), which is less infectious (309). The HCV genome contains a little more than 9,000 nucleotides and consists of a single open reading frame with nontranslated regions at the 5' and 3' ends. The HCV genome (Fig. 11) encodes structural proteins that comprise the core and envelope proteins, as well as nonstructural proteins required for viral replication.

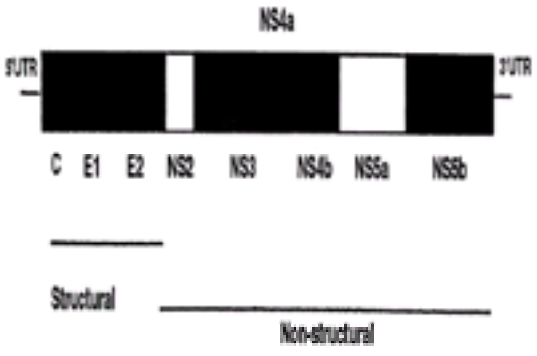

FIG. 11. Structure of HCV genome. C, core protein; E1 and E2, envelope proteins; NS2, cysteine protease; N3, serine protease, nucleotide triphosphatase, helicase; NS5A, putative interferon sensitivity–determining region; NS5B, RNA-dependent RNA polymerase. (Reprinted from ref. 100, with permission.)

In the middle of the viral genome, a single large HCV open reading frame encodes a large polyprotein that is processed into 10 polypeptides. The structural proteins consist of a capsid protein (C) and two envelope proteins, E1 and E2. The capsid protein binds to the 5' untranslated region of viral RNA and forms multimers, with several copies combining to form the capsid structure of the viral particle. The replication of HCV occurs mainly in the cytoplasm, but small forms of the capsid protein are transported to the nucleus. HCV core protein in the nucleus may interact with cell genes related to the cellular growth and contribute to HCV-mediated liver disease, such as hepatocellular carcinoma (95,309).

The HCV nonstructural proteins are designated NS2, NS3, NS4A, NS4B, NS5A, and NS5B. The NS2 protein is the cysteine protease, which is necessary to cleave NS2 and NS3 (239). The NS3 gene encodes three enzyme activities including serine protease, nucleotide triphosphatase, and helicase (211,239). The amino-terminal end of NS3 encodes the HCV serine protease, which is frequently found in a complex with NS4A and is necessary to cleave the polyprotein between NS8 and NS4A, and between NS4A and NS4B. The HCV protease is a serine protease, whereas the HIV-1 protease is an aspartate protease. The three-dimensional crystal structure of the HCV protease has been solved; it possesses a cleft in the active site where an inhibitor is likely to bind (239). Unfortunately, this cleft is very shallow, and it has proven very difficult to develop effective inhibitors to bind in this active site. The NSSA phosphoprotein is a replication component. The NS5B protein contains a GDD motif, which is characteristic of RNA-dependent RNA polymerases of other viruses such as influenza A; this enzyme may also prove an effective target for antiviral therapy (95,239).

Clinical Trials

The first active therapy for chronic hepatitis C infection was interferon-a. In studies of HCV treatment response to

interferon-a, treatment was defined as normalization of ALT levels and disappearance of HCV RNA from serum to levels below detection. A response was considered to be sustained if ALT levels remained normal and HCV RNA continued to be absent beyond 6 months after discontinuation of treatment. A nonresponder is a patient in whom HCV RNA never disappears from the serum. A patient who relapses is one in whom HCV RNA returns following an initial response.

Treatment with interferon-a at a dose of 3 million units subcutaneously three times a week for 6 months is effective in only a minority of patients. This regimen produced a biochemical response in 40% of patients (351), but it was usually short-lived, and only 15% to 20% of patients achieved a response that persisted for 6 months after treatment was completed. With a 6-month course of treatment, plasma HCV RNA levels fell to undetectable in 30% to 40% of patients. This was sustained in only 10% to 15% of patients at 1 year. By increasing the duration of therapy to 1 year, however, the sustained response rate could be increased to 20% to 25% (247). A meta-analysis of 20 randomized controlled clinical trials, which included only previously untreated patients who were randomized to at least 2 million units of interferon-a three times a week for 6 months, revealed an overall sustained response rate of only 14% (32). When the duration of therapy was extended for 12 to 24 months, a sustained response rate of 27% could be achieved ($p < .001$) (260). Thus, extended-duration interferon therapy is recommended as the standard treatment of chronic HCV in the United States (281). In those few patients who achieved a sustained response to interferon treatment, the long-term prognosis is very good. Most of them continued to have undetectable plasma HCV RNA levels and improving liver histology for the next 5 years (260).

Recently, it was shown that the covalent attachment of a 40-kd branched chain of polyethylene glycol (PEG) to interferon-a2a results in a compound (PEG-interferon-a2a) that has sustained absorption with a slower rate of clearance and a longer half-life than unmodified interferon-a2a. This form of PEG-interferon requires only a single dose of 180 mg subcutaneously once per week. In a study of 267 patients with chronic hepatitis, this favorable response at week 72 was more common in the PEG-interferon group (45%) than in the interferon group (25%) (401). The severity and frequency of adverse events were similar in the two groups and reflected the side effects typical of interferon-a. These findings were extended to a group of patients with chronic hepatitis C and cirrhosis, and again the main virologic end point was the proportion of patients with a sustained response of a hepatitis C RNA level of less than 100 copies per milliliter at week 72 (183). Those patients with cirrhosis or chronic hepatitis C received 180 mg of PEG-interferon subcutaneously once per week for 48 weeks, or 6 million units of interferon-a2a subcutaneously three times per week for 12 weeks, followed by 3 million units three times per week for 36 weeks. The PEG-interferon group was associated with a higher rate of virologic response, 69% compared to 28% at week 48, and 39% compared to 19% at week 72 (183).

The return to normal levels of serum ALT in patients with bridging fibrosis has been more difficult to achieve, but once-weekly administration of PEG-interferon-a2a was more efficacious in these patients than was a three-times-per-week regimen of unmodified interferon. The group of 271 patients with cirrhosis or bridging fibrosis received either 3 million units of interferon-a2a three times weekly (88 patients), 90 mg of PEG-interferon once weekly (91), or 180 mg of PEG-interferon (82) for 48 weeks, followed by an observation period of 24 weeks. HCV RNA was undetectable at week 72 in 8%, 15%, and 30% of patients treated with interferon, 90 mg of PEG-interferon, or 180 mg of PEG-interferon, respectively. Also at week 72, ALT had returned to normal in 15%, 20%, and 30%, respectively. There was also an improvement in liver biopsy histology in 184 patients with paired liver biopsies: 54% of patients receiving PEG-interferon showed improved liver histology by at least 2 points on a 22-point histology activity index. The histologic response correlated with a sustained virologic response at 72 weeks, as 80% of those receiving interferon-a2a had a histologic response, as did 100% of those receiving 90 mg of PEG-interferon-a2a and 88% of those receiving 180 mg PEG-interferon-a2a. HCV genotype influenced outcome: In patients with HCV genotype 1, the sustained virologic response was 2% for those receiving PEG-interferon (183). In patients with other than HCV 1 genotype, the sustained virologic response was 15% with interferon-a2a and 51% with 180 mg of PEG-interferon-a2a (183).

Interferon monotherapy, however, provides little hope of viral eradication in the majority of HCV-infected patients. The use of combination therapy for hepatitis C (as described for HIV-1) offers considerable promise. Ribavirin, a guanosine analog with an altered base, can be combined with interferon therapy to enhance biochemical and virologic benefit. Other combinations with interferon have been tried for HCV without benefit, including corticosteroids, nonsteroidal antiinflammatory drugs, quinoline antibiotics, amantadine, thymosin, granulocyte-macrophage colony-stimulating factor, and pentoxifylline (260).

Ribavirin monotherapy does not lower HCV RNA levels, but it yields improvements in liver histology and temporarily reduces levels of serum ALT in about 50% of patients with chronic hepatitis C infection (260). The effects of ribavirin on liver injury do not appear to be mediated by its antiviral properties (247). In fact, its mechanism of action against hepatitis C virus is not completely understood, but it inhibits replication of both RNA and DNA viruses, including several that are related to HCV. Ribavirin decreases mortality in patients infected with Lassa fever virus (259), and an aerosol formulation benefits infants with respiratory syncytial virus (RSV) pneumonia (161) (although it is no longer used to treat RSV routinely). Ribavirin inhibits inosine monophosphate dehydrogenase in Sindbis virus–infected cells, leading to a decrease in guanosine triphosphate concentrations, and it inhibits the RNA-dependent RNA polymerase of influenza A and influenza B viruses (120,344). Ribavirin also inhibits the 5' cap structure on vaccinia messenger RNA (155). Thus, ribavirin may have several antiviral mechanisms, and this may contribute to the lack of development of ribavirin-resistance mutants following passage in the presence of the drug (344). Ribavirin also has immunomodulatory actions, including macrophage inhibition, a decrease in CD4 cells in patients with AIDS, and alteration of the cytokine balance (223,310).

In three randomized trials, the combination of ribavirin plus interferon-a was compared to interferon monotherapy in treatment-naive patients. Each trial was small in sample size, but very consistent results were shown (37,223,310). In the largest of the three studies (100 patients), the sustained virologic response was 42% in the interferon–ribavirin combination group, compared to 20% in the interferon monotherapy group ($p = .03$). In a study of 40 patients treated for 48 weeks with interferon and ribavirin, a virologic response of 43% was observed, compared to 6% in those receiving interferon monotherapy. This response was maintained without additional therapy when observed at 96 weeks (223). In the third study of 30 patients, 43% of patients treated with the interferon–ribavirin combination had a sustained virologic

response, compared to 7% of the monotherapy patients (37).

These initial studies showed the promise of an interferon–ribavirin combination therapy regimen and led to a large multicenter trial in the United States. The aim of this trial was to compare safety and efficacy of interferon alone versus interferon plus ribavirin as initial treatment for chronic hepatitis C, and to determine the optimal duration of combination therapy (261). The study was carried out in 912 adult patients with chronic hepatitis C, elevated ALT values, detectable serum HCV RNA, and a liver biopsy showing changes of chronic hepatitis C infection within 12 months of study entry. Patients were randomized into four regimens: interferon plus placebo for 24 weeks (231 patients), interferon plus placebo for 48 weeks (225 patients), interferon plus ribavirin for 24 weeks (228 patients), and interferon plus ribavirin for 48 weeks (228 patients). Patients weighing less than 75 kg received ribavirin at 1,000 mg/day, and those weighing more than 75 kg received ribavirin at 1,200 mg/day (261). Interferon was given in the standard dose of 3 million units subcutaneously three times per week. The main endpoint of the study was a sustained virologic response, defined as the absence of serum HCV RNA at 24 weeks after treatment. Normalization of ALT levels and improvement in histology on liver biopsy were important secondary endpoints. Seventy percent of patients in the study were infected with HCV genotype 1.

The results showed that the sustained virologic response rate was higher in patients treated with interferon and ribavirin for 48 weeks (38%) or 24 weeks (31%) than in those receiving interferon-a alone for 48 weeks (13%) or 24 weeks (6%). The relapse after treatment was also less frequent in those receiving combination treatment, being 42% at 24 weeks and 28% at 48 weeks (260,261). Improvement was more common in both groups receiving interferon–ribavirin combination therapy than in the monotherapy group treated for 48 weeks ($p < .001$). Histologic improvement was the greatest in patients receiving combination therapy for 48 weeks. The biochemical responses, particularly reduction in ALT levels, were very similar to the virologic response rates. Histologic improvement was seen in all four treatment groups (260).

HCV genotype differences are of clinical importance, as they may reflect differences in response to therapy (83). In patients with genotype 1, sustained virologic response rates with combination therapy were fourfold higher than with interferon alone after 48 weeks of treatment (261). Moreover, the response in patients with genotype 1 treated with combination therapy for 48 weeks was significantly more gratifying than at 24 weeks ($p = .01$). The sustained virologic response rates for 24 and 48 weeks were similar for patients with genotype other than 1, indicating that 24 weeks of therapy may be adequate for such patients (261). The differences in responses among treatment-naive patients with genotypes 1 versus 2 or 3 is striking. In 70% of patients with genotype 2 or 3 they experienced a sustained virologic response to combination therapy with 24 weeks of treatment. In contrast, 12 months of combination therapy produced a sustained response in only 30% of patients infected with genotype 1 (260,261). Genotypic differences also have a significant effect on the response of relapsing patients to interferon-a2b and ribavirin: 75% of relapsing patients with genotype 2 or 3 achieve a sustained response, but only 30% of relapsing patients with genotype 1 achieve a response.

Like HIV-1, HCV isolates consist of groups of related genetic variants, which are designated quasi-species. These variants have only minor sequence differences, consisting of less than 5% of the viral genome (83). The response to therapy according to HCV genotype indicates that genotypic differences are clinically significant, but current evidence does not suggest that quasi-species are clinically important. Testing for quasi-species in an individual patient is not yet practical in clinical settings. In addition, since no specific therapies for genotype 1 exist and some patients with known genotype 1 do respond to therapy, genotyping is not recommended to predict eligibility for treatment. As shown previously, patients with genotypes other than HCV-1 respond better to PEG-interferon than do those with genotype 1. Studies of PEG-interferon and ribavirin combination are in progress.

A given inoculum of HCV may contain a large number of quasi-species, and not all quasi-species are infectious. The quasi-species possess a range of replicative efficiencies (83) and the diversity of quasi-species is related to the size of the original inoculum infecting that person (316). Some studies suggest that the greater diversity in HCV quasi-species correlates with more severe liver disease (298,358). The reasons for this observation have not been defined, but it has been suggested that the greater diversity results in an increased number of targets for cytotoxic T lymphocytes to attack the liver (358). Interferon therapy reduces the heterogeneity of quasi-species as viral replication decreases (358). Some quasi-species appear to be more responsive to interferon-a therapy than others, and after interferon therapy different quasi-species may become dominant. Resistance to interferon has not been clearly demonstrated and the change in quasi-species is usually interpreted as evidence that interferon therapy is effective (148,397). If patients have more than two major quasi-species, however, a response to interferon therapy may be poor (148). In the use of combination therapy to treat HCV infection, it is clear that the interferon part of the treatment is responsible for the antiviral effects, because ribavirin treatment alone has not been effective at decreasing HCV replication and decreasing plasma HCV RNA.

INFLUENZA A AND B

Influenza A and B viruses are members of the family *Orthomyxoviridae*, and they produce major worldwide epidemics. The influenza viruses contain single-stranded, negative-sense RNA genomes organized into eight individual segments (359). The RNA molecules are transcribed separately and are packaged into viral ribonucleoprotein particle (vRNPs) in association with a matrix protein (M1) and a nucleocapsid protein (NP). There is a nonglycosolated integral membrane (M2) protein that is expressed on the surface of infected cells and is present in limited amounts in virions (224,255,301). The transmembrane domain of the M2 protein is highly conserved for all human and avian strains of influenza A virus, and this protein functions as a channel for hydrogen ions (Fig. 12) (301). This channel allows hydrogen ions to flow from the endosome into the virion interior before fusion between the viral envelope and the endosome membrane can occur. A decreased pH within the virion may induce conformational changes in the nucleocapsid protein, allowing disruption of the vRNP-M1 complex and permitting transport of the vRNP into the nucleus during early infection (254,255). Influenza viruses also encode an RNA-dependent RNA polymerase, which is essential for viral RNA replication. This enzyme is another target for antiviral drugs.

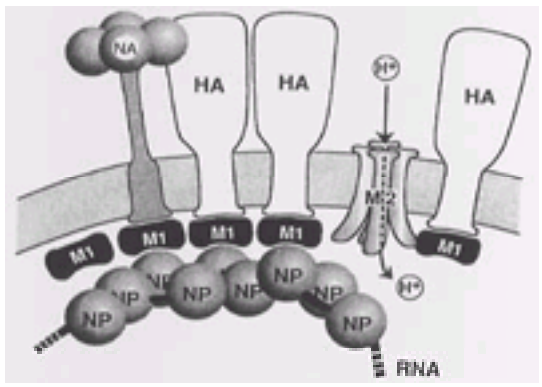

FIG. 12. Molecular interactions between structural components of influenza virus relevant to the mechanism of action of amantadine and rimantadine. (Reprinted from Fields BN, Knipe DM, Howley PM, et al., eds. *Fields Virology*, 3rd ed. Philadelphia: Lippincott-Raven, 1996:434, with permission.)

The influenza virus attaches by viral hemagglutinin (HA) to cells of the respiratory epithelium. Another viral surface protein, neuraminidase, cleaves terminal sialic acid residues and destroys receptors recognized by the HA (60). This action is essential for release of virus from infected cells, prevention of viral aggregation, and effective spread within the respiratory tract. Inhibition of the enzymatic function of the influenza neuraminidase by neuraminidase inhibitors has proven to provide a powerful approach to treatment of influenza and prevention of spread within families exposed to influenza (177,178,180,232).

Amantadine and Rimantadine

The first drug to be useful in preventing symptoms of influenza A infection was amantadine. It was joined later by a closely related drug that was better tolerated—rimantadine. Amantadine and rimantadine are symmetric tricyclic amines that specifically inhibit influenza A viruses at low concentration. By plaque reduction assay, the inhibitory concentrations of the drugs range from 0.1 to 0.4 μg/mL for many human influenza A viruses including H_1N_1, H_2N_2, and H_3N_2 subtypes (29,176). Both drugs work by similar mechanisms of action, but rimantadine is 4 to 10 times more active *in vitro* than amantadine (29). Both agents are active in prophylaxis and treatment of influenza A infection.

Amantadine and rimantadine exhibit two concentration-dependent mechanisms of action against influenza A viruses (171). The mechanism that appears to be primary and that occurs at a very low concentration is the inhibition of the ion channel formed by the influenza A matrix protein M2 (171,372). Inhibition of this ion channel involves inhibition of the M2-mediated reduction in pH, which is essential for viral uncoating and disassembly during the process of endocytosis (49). The other effect of amantadine occurs during the late steps of influenza replication, particularly for the H_7 subtype, in which assembly is mediated by a change in the pH of the trans-Golgi apparatus. This pH change induces an alteration in the HA during transport across the Golgi, which facilitates virion assembly (49,169,172). In the presence of amantadine, the intraluminal pH is decreased so that the HA undergoes a premature acid-induced conformational change, which decreases release of infectious viral particles (49). This has been shown especially for the fowl plague virus, a subtype of influenza A for which the M2 protein is known to regulate the pH of intracellular compartments and stabilize the HA into the native form that it assumes at neutral pH (287).

Resistance

The understanding of the mechanism of action of amantadine and rimantadine has been promoted by studies with amantadine-resistant influenza mutants. These have been selected both *in vitro* and *in vivo* and exhibit widespread cross-resistance to rimantadine (16,331). Resistance, as manifested by a 100-fold increase in the IC_{50}, is associated with single amino acid substitutions at critical points in the transmembrane region of the M2 protein (16,169).

Single nucleotide changes are observed at residues 26, 27, 30, 31, and 34, with mutations at codon 31 being the most common (16,169,331). The amino acid residues at these positions line the ion channel and thus may form the binding site for amantadine and rimantadine. The drugs appear to form “bird cage” structure that block the channel and prevent ion flow. Residues associated with drug-resistance residues prevent the drugs from binding in the channel. Usually, a single amino acid change is sufficient to cause resistance to amantadine, but mixed populations containing independent resistance mutations have been described (169,176,331). The same mutations in M2 that abolish drug susceptibility will abolish drug susceptibility to the early and late effects of amantadine. In avian strains of influenza A, the resistant viruses are virulent, genetically stable, and able to compete effectively with wild-type virus, and transmission of drug-resistant virus has been documented after therapy is stopped (13,179).

Amantadine- and rimantadine-resistant viruses emerge rapidly during virus passage *in vitro*, and in people within a few days of initiating therapy. Close to 30% of drug-treated children and adults shed resistant virus by day 5 of treatment (175,179). Immunocompetent persons shed resistant virus and still resolve their illness promptly, whereas immunocompromised patients can shed viruses for a prolonged period and remain ill (175,179). Transmission of resistant virus has occurred in household contacts of rimantadine-treated index cases and in nursing home residents who have received amantadine and rimantadine (175,257). These resistant variants can cause typical influenza illnesses. It is suggested that contact should be avoided between treated patients and susceptible high-risk individuals. For amantadine- and rimantadine-resistant viruses, ribavirin and the neuraminidase inhibitors zanamivir and oseltamivir are active *in vitro* and in patients.

Clinical Trials

The clinical usefulness of amantadine and rimantadine is limited primarily to prevention of influenza A virus infection (99,105). They are less useful in treatment of established influenza A infections (233,362). Amantadine and rimantadine are both used at a dose of 200 mg per day in adults, and they are between 70% and 90% protective against the development of clinical illness caused by strains of influenza A, including the worldwide pandemic strains (173). Prophylaxis has also been effective in preventing nosocomial influenza and in curtailing outbreaks in nursing homes (3), and protection against influenza A clinical illness adds to the protection afforded by influenza A subunit vaccine (236). Rimantadine at 5 mg/kg per day decreases the risk of influenza A in school-age children and possibly their household family contacts (68). Treating an index case before amantadine or rimantadine is given to other family members may select for resistant viruses, which spread to other members of the family and make their treatment ineffective. Therefore, all high-risk members of a family should probably receive treatment at the same time.

Amantadine and rimantadine are also effective for uncomplicated influenza A illnesses, especially if treatment is started early (18,170,362,396). It is uncertain whether treatment is effective at reducing complications in high-risk patients or whether it is useful in elderly patients with chronic pulmonary disease. In otherwise healthy individuals, when therapy is begun within 2 days of the onset of symptoms, a dose of 200 mg per day may reduce the duration of fever and systemic symptoms by 1 or 2 days. Some studies also report that duration of virus shedding is decreased by treatment, but this is not universally accepted. In elderly patients, therapeutic benefits were observed in treatment with rimantadine (18). In children with influenza A H_3N_2 subtype infection, rimantadine treatment reduced fever and virus titers during the first 2 days of treatment, but the rimantadine-treated patients were noted to have a longer total duration of virus shedding (160). In summary, the main use of rimantadine and amantadine has been in prophylaxis of influenza illness, and treatment benefits remain controversial.

Zanamivir and Oseltamivir

The viral neuraminidase enzyme is essential for pathogenicity of both influenza A and B virus. This enzyme cleaves the terminal sialic acid residues on cells, destroys the viral HA receptors, and permits the spread of virus in the respiratory tract. Zanamivir (4-guanidino-neu-5Ac2en, GG167) is a sialic acid analog that is a potent inhibitor of the influenza A and B virus neuraminidases (367). Zanamivir must be administered intravenously or by aerosol spray. A transition-state analog of sialic acid cleavage (GS 4071) was identified with antiviral potency and activity similar to that of zanamivir (232,264). Oseltamivir (GS 4104) is an orally bioavailable prodrug of this analog (264). Both zanamivir and oseltamivir are competitive, reversible inhibitors of the influenza viral neuraminidases and inhibit these enzymes at very low concentrations (232,394). The main differences between these drugs is that zanamivir is administered as an aerosol spray to upper airways, whereas oseltamivir is administered orally. Both drugs are nontoxic for cells and inhibit the neuraminidase from mammalian sources or other pathogens at million-fold higher concentration. The drugs inhibit the purified influenza neuraminidase at concentrations from 0.6 to 8μM, whereas a broader range of concentrations, from 0.002μM to 10μM, is required to inhibit influenza A and B replication in cell culture (394).

The active site of the influenza neuraminidase is designed to bind sialic acid, which is cleaved by the enzyme. Sialic acid, through its glycerol and carboxylate groups, binds to amino acids in the active site. Zanamivir replaces the hydroxyl group of sialic acid with a larger, positively charged guanidine, which forms strong attachments to two negatively charged amino acids in the cleft of the active site. Oseltamivir also binds to a hydrophobic pocket in the active site (Fig. 13). Because zanamivir and oseltamivir bind to different regions of the active site of neuraminidase, the active site that decreases binding to zanamivir may still be inhibited by oseltamivir (156,232). For example, the mutant Glu119Gly, with decreased binding of zanamivir, is still inhibited by oseltamivir (156,246). A mutation in part of a catalytic triad of neuraminidase at Arg292Lys may exhibit decreased inhibition by both drugs, so some mutations do confer cross-resistance (156). These altered neuraminidase enzymes may have reduced activity or stability and result in a less fit virus (156,246). Influenza viruses with these altered enzymes manifest decreased infectivity in animals (156,246).

Clinical Trials

The use of zanamivir and oseltamivir for prevention of influenza A has proven highly effective. Zanamivir prevents experimentally induced influenza in humans when virus is administered intranasally, and against naturally occurring influenza when given by inhalation once daily (279). Inhaled zanamivir provided a 67% rate of protection against

influenza-associated illness and 32% protection against infection during a 4-week trial of prophylaxis in young adults (279). Oral oseltamivir also proved effective in preventing naturally occurring influenza in a large study of 1,559 healthy nonimmunized adults who received oseltamivir at 75 mg, either once or twice daily for 6 weeks during a peak period of influenza activity (174). In the patients assigned to once or twice daily oseltamivir, the risk of developing influenza was 1.2% or 1.3%, compared to 4.8% in subjects assigned to placebo (p = .001). Thus, the protective efficacy of oseltamivir was 74%. For culture-proven influenza, the average protective effect of oseltamivir in preventing influenza efficacy was 87%. Moreover, oseltamivir led to a 50% decrease in the proportion of subjects with symptomatic or asymptomatic laboratory-confirmed influenza (174).

Inhaled zanamivir was also studied for the prevention of influenza A in families where amantadine and rimantadine have been ineffective because of transmission of drug-resistant variants. A double-blind placebo-controlled trial of inhaled zanamivir for the treatment of the index case and prevention of influenza in families showed a 79% reduction in the proportion of families with at least one affected contact (177). Zanamivir protected against influenza A and influenza B. Among the laboratory-confirmed and treated influenza cases, the median duration of symptoms was 2.5 days shorter in the zanamivir group than in the placebo group. The study concluded that prophylactic treatment of family members with once-daily inhaled zanamivir was well tolerated and prevented the development of influenza when combined with treatment of index cases. The emergence of resistant influenza variants was not detected (177).

The neuraminidase inhibitors zanamivir and oseltamivir are effective in treating influenza and offer the possibility of treating severe disease. In a study of oseltamivir in treating acute influenza, the clinical benefits of treatment were statistically significant in both young and middle-aged adults (360). Oseltamivir was well tolerated, but in this one study 12% of subjects taking it daily experienced nausea compared to 7.1% in the placebo group (360). Oseltamivir was most effective if used within 2 days of symptoms. In the treatment, 95% of patients were infected with influenza A, 3% with influenza B, and 2% were indeterminate, and all benefited from treatment (360). In a random controlled trial of experimental human influenza, oseltamivir treatment improved the symptom score, reducing days of fever and malaise and decreasing viral shedding (180). Inhaled zanamivir treatment has also shown efficacy in studies involving adults, adolescents, and children 5 years of age or older (178). Zanamivir has been effective at treating influenza in the elderly. The main side effect of inhaled zanamivir has been bronchospasm in elderly patients.

To prevent influenza in families, treatment of index cases with inhaled zanamivir shortens the median duration of symptoms by 2.5 days (178,359). Zanamivir does not impair the humoral immune response to inactivated influenza vaccine (177), and it is likely that zanamivir and oseltamivir can be used in conjunction with vaccination. Further studies need to be carried out in immunocompromised patients to determine that these drugs can act synergistically with vaccination against influenza. These two neuraminidase inhibitors provide treatment possibilities against influenza disease and may provide protection against the influenza pandemic strains.

FUTURE DIRECTIONS

The future of antiviral therapy will consist of a series of step-by-step advances against each viral pathogen, beginning with drug design, and followed by knowledge of mechanisms, resistance, and pharmacokinetics of each drug. The great successes so far have focused on drugs that inhibit viral enzymes, and this is likely to continue as the crystal structures of the herpesvirus protease enzymes have been determined, indicating that effective drugs may soon follow. The future may also show progress in preventing viral protein–protein interactions, such as blocking the herpes polymerase enzyme from binding to its accessory protein, or preventing the conformational change in the gp41 of HIV-1 needed for viral entry. Small molecules that mimic the three-dimensional structure of viral peptides will also show progress. The use of antisense oligonucleotides is just at the beginning and will continue to be an active area of investigation and promise. A newly developed antisense phosphorothiolate oligonucleotide (fomivirsen), which is complimentary to RNA of the human CMV major immediate-early gene, has been approved for topical treatment of CMV retinitis. This represents the first antisense molecule with antiviral activity approved for clinical use, and others may soon follow.

Several important human viral pathogens will continue to provide active areas for development of antiviral therapy. The human papillomas virus, which causes cervical cancer, may respond to antiviral therapy if targets can be identified. The human rhinoviruses, which cause the common cold, require the action of a viral protease for maturation to an infectious virion, and the viral protease has long been a target for development of effective therapy.

Effective protease inhibitors for rhinoviruses and enteroviruses appear close to receiving approval for human use. Although the protease for hepatitis C virus has not been shown to be an effective target for antiretroviral therapy, the RNA-dependent polymerase of hepatitis C may lead to effective antiviral therapy against this virus. The ability to develop new forms of antiviral agents such as Kaletra, valganciclovir, and PEG-interferon, which possess enhanced pharmacokinetic plasma levels, establishes the role of medicinal chemists in providing new antiviral agents. The continued collaboration between chemists, structural biologists, virologists, and experts in clinical trials will open new paths in the development of antiviral therapies.

CHAPTER 16 Immunization Against Viral Diseases

Brian R. Murphy and Robert M. Chanock

VIRAL ANTIGENS RECOGNIZED BY THE IMMUNE SYSTEM

Resistance to virus infection depends on the development of an immune response to antigens present on the surface of virions or virus-infected cells. Immunologic responses to viral glycoproteins or protein antigens displayed on the surface of virions or virus-infected cells are needed to effectively eliminate those viruses or cells. Responses to the nonsurface viral antigens are thought to play only a minor role in resistance to infection. Important historical evidence supporting these conclusions was acquired in studies of the 1957 Asian influenza pandemic and the 1977 Russian influenza epidemic. The 1957 Asian influenza A (H2N2) virus contained surface glycoproteins (the hemagglutinin and the neuraminidase) that were novel—that is, the human population had not been exposed to strains containing these or related surface antigens. In contrast, the major nonsurface proteins of the new virus, the nucleoprotein and the matrix protein, were closely related to corresponding antigens of previous strains of subtype H1N1, to which most individuals had been exposed. Despite this prior and (in many instances) recent experience with related nonsurface antigens, the Asian influenza A virus spread rapidly without apparent immunologically mediated restriction and caused a major pandemic (207). In contrast to this experience, observations following the reemergence of the H1N1 virus in 1977 indicated that homotypic humoral immunity provided a high level of resistance that lasted over 20 years.

Additional evidence for the importance of the surface glycoproteins of influenza A virus in immunity is provided by passive and active immunization studies in mice. Monoclonal antibodies directed against the hemagglutinin (HA) or the neuraminidase (NA) protected mice against challenge with virulent wild-type virus, whereas monoclonal antibodies specific for the internal nucleoprotein or matrix protein did not alter the course of disease (207). Analysis of a set of recombinant vaccinia viruses, each expressing one of the 10 known viral gene products of the influenza A virus, showed that only recombinants expressing the HA or the NA glycoprotein induced resistance to virus challenge (81). These and other observations with paramyxoviruses (291) indicate that a successful strategy of immunoprophylaxis against many virus infections requires the generation of an immune response to the surface antigens displayed on virions and on virus-infected cells. To facilitate discussion of these important proteins or glycoproteins, we will refer to them as *protective* antigens. Identification of protective antigens in the manner just described represents an important first step in the development of effective viral vaccines, whether nonliving or live.

The surface glycoproteins of enveloped viruses and the capsid proteins of nonenveloped viruses are generally the major protective antigens, and their important role in resistance has been confirmed using monoclonal antibodies directed against these antigens. The following generalizations can be made about the nature of protective antigens and about the antibody response to them. First, and most important, antibodies predominantly recognize conformational epitopes on protective antigens. Such conformational epitopes are very difficult to mimic with peptides or other forms of an immunogen in which the protective antigenic sites are denatured. Thus, an immunogen that assumes the structure of the

native protein induces antibodies that best recognize the conformational epitopes and that mediate immunity most effectively.

Second, antibodies recognize many antigenic sites on viral proteins. Within each antigenic site, there are multiple epitopes. For example, the parainfluenza virus attachment glycoprotein (HN) has at least six antigenic sites, three of which are recognized by neutralizing antibodies (51). After infection, not all individuals develop antibodies to each antigenic site of the infecting virus (50). After one or more reinfections, the antibody response broadens to recognize most of the antigenic sites. These findings provide a partial explanation for the failure of immunization to induce complete immunity in certain circumstances, and they also provide a rationale for recommending reimmunization to achieve optimal protection.

Third, immunoglobulin (Ig) molecules generally do not have direct access to most of the functional sites on viral protective antigens, such as (a) the receptor-binding site; (b) sites with enzymatic activity; and (c) fusion domains, which are mostly buried within the protein structure of the protective antigen. As a consequence, these sites remain relatively inaccessible to the antiviral activities of antibodies. Therefore, antibodies usually exert their antiviral activities by mechanisms other than direct inactivation of functional sites on the protective antigens. Instead, antibodies most often act directly or indirectly to impede attachment of virus to the cell or to prevent uncoating of virus that has attached to or entered the cell. In addition to viral structural proteins, protective immune responses can be directed at nonstructural proteins displayed on the surface of infected cells such as the NS1 protein of dengue virus or the T antigen of simian virus 40 (SV40).

IMMUNE ECHANISMS THAT ELIMINATE VIRUS OR VIRUS-INFECTED CELLS

Immune mechanisms have evolved to protect the host against a diverse assortment of viral pathogens. The major purpose of the immune response is to inactivate free virus and to eliminate infected cells that have the potential to release infectious virus. It is important to emphasize at this juncture that the various cellular and humoral antiviral immune mechanisms function together to eliminate virus after its first encounter with the host, as well as to protect the host against reinfection (11,69,180,207). Thus, there is considerable redundancy inherent in immunity to viruses. For example, both CD8+ T cells and antibody plus complement can lyse virus-infected cells. Another well-studied example of this redundancy involves CD4+ and CD8+ T cells, which can separately effect clearance of virus, as shown in studies of influenza A virus in mice. Animals lacking CD8+ T cells readily clear influenza virus from the lungs, indicating that CD4+ T cells and antibody are sufficient for viral clearance (158,265). The therapeutic efficacy of antibodies acting in the absence of other immune functions has also been demonstrated in experimental influenza A virus infection of mice. Antibodies to the influenza A virus surface HA cleared virus from the lungs of persistently infected several combined immunodeficient (SCID) mice (265). CD4+ T cell–deficient animals also readily clear influenza virus from the lungs by a CD8+ T cell–dependent mechanism (158). The popular concept that CD8+ T cells are solely responsible for viral clearance has been replaced with the knowledge that CD4+ T cells (plus the antibodies secreted by B cells for which they provide help) and CD8+ T cells can mediate viral clearance separately and that the relative importance of these two arms of the immune response varies in the resolution of particular viral infections. Even in the case of lymphocytic choriomeningitis virus (LCMV), the prototype arenavirus that has long been considered the paradigm for CD8+ T cell–mediated resistance, antibodies and CD4+ T cells each make a significant contribution to the resolution of primary viral infection, and antibodies play a major role in resistance to reinfection (11). Although it is clear that CD4+ and CD8+ T cells do play an important role in the resolution of viral infections, the major mediator of resistance to reinfection is antibody.

Cellular Immunity to Viruses

Major histocompatibility complex (MHC) class I–restricted CD8+ cytotoxic T lymphocytes (CTLs) and MHC class II–restricted CD4+ helper T cells (T_H cells) each function independently as antigen-specific antiviral effector cells.

CTLs

Cytotoxic T lymphocytes are the major T-cell effectors of antiviral activity. The CTL receptor recognizes a short peptide derived from an endogenously produced viral protein in the context of the MHC class I b2-microglobulin heterodimer expressed on the surface of an infected cell. Because the MHC class I restriction elements are present in a relatively high concentration on almost all cells except neurons, CTLs can exert their antiviral effects against most infected cells. In most instances, antigen presentation by the MHC class I b2-microglobulin heterodimer is restricted to viral peptides that are produced and processed during infection. Hence, the function of CTLs is not to prevent infection (87) but to eliminate cells already infected or, alternatively, to inhibit virus replication by the elaboration of antiviral cytokines (91,197,306). The net effect of CTL activity is to prevent further spread of virus and to terminate infection in cells that are already infected. The importance of CTLs in recovery from viral infection is indicated by the diverse strategies that viruses use to escape from CTL immunity (279). While CTL antiviral activity is generally associated with the clearance of virus and the reduction of virus-associated pathology, disease enhancement can be observed under experimental conditions in which CTLs have been passively transferred to viral antigen–bearing recipients (37,78,192).

The time course of CTL activation during viral infection in the lungs is consistent with its important role in clearance of primary virus infection. Primary (also called direct) CTL cytotoxic activity of pulmonary lymphocytes peaks early (day 7) during acute virus infection, such as that produced by influenza A virus or respiratory syncytial virus (RSV), and it declines to barely detectable levels by day 12 (6). Thus, restriction of virus replication mediated by CTLs is active early during the acute stage of virus infection, but this activity can wane rapidly (53). Residual memory CTLs were not able to accelerate the clearance of RSV after viral challenge on day 45 (149). These and other (87,284) observations suggest that the CTL component of the immune response is active primarily during the early phase of infection from the time just before the peak titer of virus is reached to the time virus-infected cells are cleared, and later these cells persist in an inactive (or memory) state that does not provide a high level of resistance to reinfection (87). For viruses that replicate rapidly in the host, such as the influenza viruses and paramyxoviruses, the proliferation of memory CTLs does not appear

to occur with sufficient rapidity to alter the peak titer of virus attained in the target organ (87). Because disease usually develops by the time the peak titer of virus is attained, it is not surprising that immunization with antigens that predominantly induce CTL activity without an accompanying stimulation of neutralizing antibodies is less effective in restricting virus replication and preventing illness than immunization that induces a sustained neutralizing antibody response (77,103).

Because of the important role of CTLs in clearance of established viral infections, the incorporation of CTL epitopes into viral vaccines has been considered a requirement. The following characteristics of the CTL response *in vivo* decrease the attractiveness of including CTL epitopes as the sole or main protective component of a viral vaccine. First, the ability of a CTL epitope to induce an immune response is MHC dependent. Because human MHC restriction elements are highly polymorphic, many protective CTL epitopes would have to be incorporated into a single vaccine to protect a large proportion of the population. Second, the duration of immunity mediated by CTLs following primary infection can be very short (10,87). However, some resistance to virus replication following reinfection can be mediated by CTLs (90,106), indicating that this arm of the immune response can restrict replication of virus during reinfection, but the level of restriction is generally weak. Third, there appears to be a limited number of protective CTL epitopes in most viruses (81,149,150). Thus, the number of protective CTL epitopes per MHC haplotype is small for many viruses. Fourth, viruses can escape from protective CTL responses by mutations within the CTL epitopes (190,232). Because of this, vaccinees whose resistance was induced by immunization with only one protective CTL epitope would be fully susceptible to infection with a CTL epitope escape mutant. Fifth, the protective effect of a CTL response can differ dramatically among CTL epitopes, some of which induce strong protection against disease, whereas others are only weakly protective (115). Thus, only those CTL epitopes capable of inducing a strong protective immune response could serve as suitable immunogens for inclusion in vaccines. Sixth, CTLs themselves can cause disease by an immunopathologic reaction in the target organs in which virus is replicating, indicating that a fine balance exists between protective efficacy and disease-enhancing capacity (37,78,192). Seventh, the induction of CTL responses using minimal peptide epitopes is problematic because peptides do not induce CTL responses efficiently. Finally, CTLs represent a second line of defense against infection because CTLs are effective only against infected cells, whereas antibodies can neutralize the infectivity of the virus and decrease the number of cells initially infected (87).

For these reasons, it is unlikely that CTL epitopes by themselves will replace native capsid proteins or surface glycoproteins in the formulation of viral vaccines. However, their inclusion in vaccines is expected to be beneficial. The induction of a CTL memory response by immunization might be helpful against viruses that replicate relatively slowly in their host or that cause persistent infection. In such situations, memory CTLs could be activated and amplified to an antiviral state and participate in the control of infection. It should be noted that live virus vaccines induce both antibodies and CTLs efficiently, whereas peptide, inactivated, or subunit virus vaccines as currently formulated are poor immunogens with respect to induction of CTLs.

T_H Cells

Helper T cells provide help to B cells, thereby augmenting the antibody response. However, T_H cells can also provide direct antiviral activity *in vivo* (117,170,194,305). The contribution to immunity made by the direct antiviral activity of T_H cells appears to be less than that of CTLs. This is consistent with the more limited distribution of the restricting element of T_H cells, namely the MHC class II, a,b heterodimer, which is present predominantly on lymphocytes and antigen-presenting cells such as macrophages and dendritic cells. In addition to having antiviral activity, T_H cells also can mediate immunopathology (5,179,297).

The T_H cell response to certain internal viral proteins may play a cooperative role in the development of effective resistance by augmenting the antibody response to a major protective antigen (258). For example, immunization with the membrane (M) protein of influenza A virus can prime for a subsequent augmented antibody response to the HA glycoprotein on virus particles (258). In this manner, the entire T_H cell repertoire developed against the viral surface and nonsurface proteins can be called into play to amplify a B cell response to a protective antigen. Because T_H cell epitopes are far more numerous on viral proteins than CTL epitopes (150), the repertoire of T_H cells capable of augmenting the antibody response is indeed large. A viral antigen can induce a protective immune response mediated by T_H cells in the absence of B cells or CTLs (170), indicating that this arm of the immune response can make an independent contribution to resistance against both acute and chronic viral infections (117). For these reasons, it may be necessary to include virus structural protein antigens capable of inducing T_H cell responses in live and nonliving virus vaccines to achieve maximal immunogenicity.

Humoral Immunity to Viruses

Antibodies have the major responsibility for rendering free virus noninfectious, and the principal manner in which this is achieved is by neutralization of infectivity. The lifelong immunity mediated by antibodies stems from plasma cells, whose considerable longevity contrasts with that of the short-lived, activated CTL response (272). Passive transfer of antibodies can also exert antiviral activity against cells that contain viral glycoproteins inserted into the outer cell membrane. Specific human antibodies have been shown to prevent disease caused by a wide variety of viruses belonging to diverse RNA or DNA virus families (41). Antibodies acting alone, even at low concentrations, are effective at preventing or modifying human disease caused by hepatitis A virus (HAV), hepatitis B virus (HBV), measles virus, poliovirus, and varicella zoster virus (VZV). When given at birth, human IgG was shown to be effective in preventing chronic HBV infection in high-risk infants whose mothers were chronically infected with HBV and who had HBV e antigen as well as HBV surface antigen (HBsAg) in their blood (15). The results of these studies in humans implied that vaccines that induced such antibodies should protect against disease. Subsequent field trials of immunogenic HAV, HBV, poliovirus, measles, and VZV vaccines validated this view. Passive antibodies were shown to protect against mucosal viral infections, such as those caused by RSV (109), but higher quantities of passive antibodies are needed to restrict virus replication on mucosal surfaces than at systemic sites.

Mechanisms by Which Antibodies Decrease Viral Infectivity In Vitro

Antibodies can decrease the infectivity of a virus by several distinct mechanisms. First, antibodies directed against a surface antigen can aggregate the virus particles, thereby causing a decrease in the virus titer and an accelerated clearance of virus from the bloodstream (127). Second, antibodies acting alone or in the presence of complement can irreversibly alter the structural integrity of the virus and render it noninfectious (65,317). Third, the major mechanism by which antibodies inactivate free virus is by neutralization in which the virus is rendered noninfectious, although its structural integrity remains largely intact. Neutralization of infectivity is achieved either by inhibiting attachment of the virus to its cell receptor (214) or, more commonly, by preventing release of the nucleocapsid from virus bound to the receptor on the cell surface or from virus present in an endocytic vacuole (68). Antibodies can act synergistically to achieve these goals (97). Inhibition of attachment of virus to its cell receptor is thought to be predominantly steric in nature, because most receptor-binding sites on viral attachment proteins are inaccessible to antibodies. After binding to cell receptors, extensive modifications occur in the conformation of viral glycoproteins or the capsid proteins of icosahedral viruses during the events leading up to release of viral nucleic acid into the cytoplasm, and it is thought that most neutralizing antibodies act to prevent successful completion of this phase of virus entry.

The very important role that neutralizing antibodies play in immunity to viral infection is highlighted by the observation that viruses use several distinct mechanisms to escape from neutralization by antibodies. Certain viruses decorate their surface proteins with N- or O-linked carbohydrates to evade neutralization by antibodies (248). The V2 loop of the human immunodeficiency virus (HIV) envelope glycoprotein appears to shield an as yet unidentified region of the protein that is rich in neutralization epitopes (281). It might be necessary to modify such carbohydrate or protein regions of a live or nonliving virus vaccine candidate to increase its immunogenicity, especially for viruses that are weak inducers of neutralizing antibodies such as HIV. Viruses such as the influenza A virus develop missense mutations in the neutralization epitopes of the HA (i.e., the attachment protein) in an attempt to evade herd immunity of the human population conferred by previous infection with influenza A viruses of the same subtype. In addition, influenza A virus can acquire an antigenically unrelated HA from an avian influenza virus source via gene reassortment. Escape of influenza A viruses from neutralization by either mechanism allows the antigenic variant to become the predominant viral strain circulating in the human population, because it displaces other previously dominant strains; this successful escape from antibody is the basis for the unique need for annual immunization against this viral pathogen. Adenoviruses have been found to undergo a similar, but slower, form of antigenic change by illegitimate recombination in the gene encoding a major protective antigen (60). A persistent virus such as HIV evades the humoral immune response in a single host by generating waves of antigenic virus variants that resist neutralization by antibodies induced by their progenitors (218). Finally, the neutralizing antibody response to an acute viral infection can be severely blunted by CTL-mediated lysis of neutralizing antibody–producing B cells that have been infected by virus via the membrane-associated antibody receptor present on the B cell (236).

Antibodies Active Against Virus-Infected Cells

Viruses that mature at the cell surface by budding or that insert viral glycoprotein(s) into the cell surface membrane render the infected cell susceptible to lysis by humoral (antibody-dependent, complement-mediated lysis) and cellular [antibody-dependent, cell-mediated cytotoxicity (ADCC)] mechanisms. Antibodies plus complement can lyse virus-infected cells and thereby decrease the amount of infectious virus released by the cells. Cytophilic antibodies can arm leukocytes in the ADCC reaction, which has been shown to be important in the resistance of infant mice to herpes infection and for clearance of a retrovirus (52,146). Some herpesviruses encode an IgG Fc receptor homolog, which enables the virus to evade ADCC, underscoring the importance of the ADCC effector mechanism *in vivo* (72). These mechanisms in which antibody acts cooperatively with cells or complement to exert antiviral effects *in vivo* represent, like CTLs, a second line of defense against infection because infection of cells must occur for these immune mechanisms to act effectively.

Nonneutralizing Antibodies with Antiviral Activities

Nonneutralizing antibodies can also mediate resistance to viral infections but are less effective than neutralizing antibodies (196). Nonneutralizing antibodies can be directed against antigens on the surface of virus particles or against virion or nonstructural proteins displayed on the surface of infected cells. *In vivo*, nonneutralizing antibodies mediate antiviral activities by several different mechanisms. First, virus particles coated with nonneutralizing antibodies can undergo accelerated clearance from the bloodstream. Second, nonneutralizing antibodies directed at surface glycoproteins such as the NA of influenza A virus or the hemagglutinin–esterase protein of coronavirus can decrease the level of virus replication in the target organ, presumably by inhibiting the release of virus from infected cells (29,334). Third, nonneutralizing antibodies can lyse virus-infected cells via an IgG Fc-dependent mechanism (266).

Antiviral Activity of Antibodies in Vivo

In the past, conventional wisdom discounted the importance of antibodies in resolution of virus infections. Instead, clearance of virus was thought to be mediated primarily by CTLs. However, several recent observations cast doubt on this generalization and indicate that antibodies do indeed participate in the resolution of virus infections and, in some instances, can independently bring about resolution of infection, even one occurring at a mucosal surface (14,89,122,195,314). For example, in SCID mice, a persistent influenza virus infection of the lungs or an alphavirus infection of the neurons in the brain can be cleared rapidly by parenteral inoculation of glycoprotein-specific monoclonal antibodies (195,314). The mechanism responsible for this dramatic effect in the brain is IgG-subclass independent but requires that the antibody be bivalent (314).

Other studies in mice indicate that antibody directed against the sigma 1 outer capsid protein of reovirus (the viral attachment protein) can interrupt the spread of established reovirus infection within the central nervous system (CNS) as well as infection that moves from the brain to the eyes (313). Secretory IgA antibodies have been shown to function

within cells of the mucosal epithelium. Dimeric IgA secreted by plasma cells present in submucosal tissues is transported from the basal layer of mucosal epithelial cells to their apical surfaces in association with the polymeric Ig receptor to which dimeric IgA initially binds. During its transport through Sendai virus–infected cells, virus-specific IgA can reduce the level of replication of infectious virus within the cell (173). The mechanism responsible for this effect is not clear at this time, but it is likely that the endocytic pathway used for IgA transport and the exocytic pathway used for transport of viral glycoproteins intersect at some location within the cell (94). Thus, antibodies play diverse roles *in vivo* and can act not only to prevent virus infection but also to modify an infection that develops in a partially protected host.

In light of the great diversity and complexity of the *in vitro* and *in vivo* actions of antiviral antibodies, it is unlikely that simple immunogens such as peptides or antiidiotype antibodies could induce the antibody repertoire that is required for the control of viral infections *in vivo.* This failure may limit the usefulness of such immunogens. Immunization can best be achieved by including as many of the protective antigens of the virus in the immunogen as feasible (21,102).

Antibodies Active on Mucosal Surfaces

Antibodies present in the systemic circulation protect internal organs against viruses that are introduced directly into the bloodstream (e.g., HBV, HIV) or that spread via the bloodstream from primary sites of replication such as the respiratory or gastrointestinal mucosa. As mentioned previously, diseases produced by viruses that fall into the latter category (i.e., measles, polio, hepatitis A, rubella, smallpox, and varicella) can be prevented or modified by Ig prophylaxis, often with small amounts of antibody that are difficult to detect in the blood of recipients (41), and such antibodies are relatively easy to induce by parenteral immunization with live or nonliving virus vaccines. In contrast, antibodies present in the systemic circulation do not provide efficient protection against viral diseases that are limited to mucosal surfaces unless these antibodies are present in high titer. This is because only a small proportion of such Ig molecules traffic from the plasma to the lumenal surface of the mucosal epithelium by transudation (41,198). Therefore, to prevent viral diseases that are limited to mucosal tissue, two different strategies can be employed. The first, and the preferred strategy, is to induce secretory IgA antibodies at the mucosal site by virus replication at that site. The second, and less efficient, strategy is to stimulate a high titer of serum IgG antibodies that can protect mucosal surfaces following transudation.

When IgG antibodies present in the blood are passively transferred by transudation to mucosal surfaces, where they can exert antiviral activity, there is a gradient regarding the ability of serum IgG–derived antibodies to restrict virus replication on mucosal surfaces. This gradient is lung > nasopharynx > lower intestinal tract (198). IgG antibodies, if present in the serum in high enough titer, can provide almost complete resistance to pulmonary replication of RSV, but resistance in the upper respiratory tract is more difficult to achieve (41). Immunization of the female genital tract with a live virus vaccine can induce the local synthesis of IgG antiviral antibodies such that the specific activity of mucosal IgG antibodies significantly exceeds that of serum, indicating that IgG antibodies present on a mucosal surface can come either from serum via transudation or from IgG antibody–secreting cells present in the submucosal tissues (227).

Although passively transferred IgG antibodies can provide mucosal immunity in the lower respiratory tract, the major mediators of resistance to viral infection of the upper respiratory tract, the larger airways of the lungs, and the gastrointestinal tract are IgA antibodies, which are selectively transported across mucosal surfaces to exert antiviral effects on the lumenal surface (198). Both nonneutralizing (32) and neutralizing (257) IgA antibodies have antiviral effects on mucosal surfaces, with the former active intracellularly during transcytosis and the latter active both intracellularly and on the lumenal side of the epithelium. Antiviral IgA antibodies function to clear viral infections, to modify the severity of disease on reinfection, and to prevent infection on reexposure to virus. The level of antiviral IgA antibodies, as well as the number of virus-specific IgA secreting cells, often correlates with resistance to viral infection (198,336). Since IgA antibodies recognize the same protective antigens as IgG antibodies, the greater role of IgA versus IgG antibodies in mucosal immunity is largely the result of the higher levels of Ig antibodies present on the lumenal surfaces, which results from their selective secretion via the polymeric-Ig receptor-mediated transport system.

The primary mucosal IgA response peaks within the first 6 weeks after infection and usually decreases to a low, often barely detectable, level by 3 months. The transient nature of the primary mucosal antibody response is a factor in the ability of many viruses to reinfect mucosal surfaces, and it underlies the need for two or more doses of vaccine to efficiently immunize mucosal surfaces. The virus-specific IgA antibody response is greater at the site of virus replication or of antigen administration than at distal sites, suggesting that mucosal immunity is best induced by antigenic stimulation of sites directly involved in replication of the wild-type virus. The appearance of IgA antibodies in mucosal secretions coincides with the cessation of virus excretion during infection in both the respiratory and gastrointestinal tracts (198).

Thus, to achieve optimal resistance to virus infection in mucosal tissues, immunization should induce IgA antibodies efficiently. This can be accomplished most effectively by infection of the mucosa with a live virus vaccine. It has also been recognized that the upper respiratory tract is an effective inductive site for stimulating IgA responses in distal mucosal sites such as the genital tract (12,98). In studies in which the intranasal and parenteral routes of immunization with a herpes simplex virus (HSV) type 2 glycoprotein D vaccine candidate have been directly compared for their efficacy against a genital challenge with HSV-2, the parenteral route of immunization was superior to the intranasal route (219). This observation indicates that parenteral immunization can provide superior immunity to a mucosal infection than can immunization at a distal mucosal site.

Adverse Effects of Antibodies

Antiviral antibodies are not always helpful in the elimination of virus infection and can, in certain circumstances, augment viral infectivity and participate in the potentiation of disease. For example, it has been proposed that heterotypic antibodies to the envelope glycoprotein of dengue virus play a central role in the severe clinical entity known as dengue hemorrhagic fever/shock syndrome (148). Dengue viruses replicate primarily in cells of the mononuclear phagocyte lineage, and subneutralizing amounts of dengue virus antibodies enhance dengue virus infection of these cells *in vitro* by increasing uptake of virus via IgG Fc receptors present on these cells (113). However, the mechanism by which augmented disease results from enhanced access of dengue virus into mononuclear cells remains unclear (256). It has

been proposed that antibody enhancement of infectivity also plays a role in the enhanced disease seen in immunized cats challenged with infectious peritonitis virus, a coronavirus that also infects cells of mononuclear lineage (57). These observations suggest that special attention should be given to the functional activity of antibodies induced against viruses that replicate in cells bearing receptors for the Fc fragment of IgG. Development of antibodies that bind to viral surface antigens but fail to neutralize infectivity effectively could render vaccinees more susceptible to infection as well as to enhancement of disease once infection has occurred.

OBSTACLES TO IMMUNIZATION IN EARLY LIFE

Viruses that cause disease in early infancy present special problems for the development of effective vaccines. One example is provided by RSV, which produces severe lower respiratory tract disease with highest frequency during the second month of life, generally causing disease in those infants possessing lower levels of maternally derived antibodies. For a vaccine to be effective against this virus, it must be administered to infants by 1 month of age. Because RSV is a ubiquitous pathogen and reinfection occurs commonly, most young infants possess a relatively high serum titer of passively acquired, maternally derived RSV-neutralizing antibodies. Both immunologic immaturity and a high level of maternally derived antibodies act to suppress the immune response of the young infected infant to the protective antigens of RSV (i.e., the F and G glycoproteins) (143,199). In experimental animals, passively administered RSV antibodies had adverse effects, both quantitative and qualitative, on the immune response to RSV glycoproteins expressed by a vaccinia-F (vac-F) or vac-G recombinant virus (203). For example, the frequency and magnitude of the serum antibody response to the F and G protective antigens was markedly suppressed when RSV immune serum was administered to animals the day before they were infected by a parenteral route with vac-F and vac-G (203). Furthermore, antibodies to the RSV protective antigens that did develop had abnormally low neutralizing activity. Immunized animals that had their immune response suppressed by passively transferred antibodies were more susceptible to challenge infection with RSV than were animals that received control serum lacking RSV antibodies. This form of antibody-mediated immunosuppression has been observed with purified protein or whole virus antigens, vector-expressed antigens, and antigens encoded by DNA (73,233,268,320). Fortunately, this form of immunosuppression can be overcome, in part, by immunization with a vaccine virus that actively replicates in the respiratory tract (73). Although virus-specific antibody responses to vector- or DNA-encoded viral antigens can be suppressed by passively acquired viral antibodies, T_H cell and CTL responses can be induced in such circumstances, and accelerated immune responses can occur upon subsequent boosting (268).

A second important effect of maternally derived antibodies on immunization is their ability to restrict replication of a live attenuated virus, thereby decreasing its immunogenicity. This is a well-known phenomenon that adversely affects the efficacy of parenterally administered live attenuated measles virus vaccine during infancy. It constitutes the basis for delaying immunization until after 12 months of age, by which time a sufficient decay of maternally acquired neutralizing antibodies has occurred to permit efficient replication of the live attenuated vaccine virus. Since maternally derived antibodies are less efficient at restricting replication of vaccine viruses administered mucosally rather than systemically, it is possible to successfully immunize neonates who possess maternally derived antibodies if the viral vaccine can replicate on a mucosal surface. For example, live attenuated poliovirus vaccines are effective immunogens in young infants because virus introduced into the gastrointestinal tract is not neutralized by the maternally derived serum IgG antibodies, which allows replication to high titer at this site.

The ability of maternally derived antibodies to restrict replication of live attenuated vaccine virus can be beneficial in some cases. The licensed live rhesus rotavirus vaccine exhibits mild reactogenicity for fully seronegative infants over 3 months of age (230). This effect can be abrogated significantly, without losing immunogenicity, by immunizing younger infants who possess passively acquired serum antibodies. In this instance, the passively acquired serum antibodies further restrict replication of the partially attenuated vaccine virus, and this restriction of replication of vaccine virus contributes to the overall attenuation of the vaccine for the young infant (134). This partial contribution of maternal antibody to the attenuation of the rotavirus vaccine is the basis for the recommendation that the vaccine not be given to older infants and children in whom maternally acquired antibodies have decayed to a low level.

GOALS OF IMMUNIZATION AGAINST VIRAL DISEASES

Prevention

The major goal of immunization against viruses is the prevention or modification of disease. Most viral vaccines prevent or modify disease without necessarily preventing infection. The ways in which this is achieved are diverse. Whereas most viral vaccines are administered before infection occurs, prevention of CNS disease in individuals inoculated with rabies virus by an animal bite can be achieved by administration of vaccine shortly after infection has occurred. This is possible because the long incubation period of the infection permits the development of an effective immune response in time to modify infection and prevent disease. Similarly, individuals exposed to smallpox virus can be protected against a fatal outcome if vaccinia virus vaccine is administered up to 4 days after initiation of smallpox virus infection.

The major goal of immunization against rubella virus is prevention of fetal abnormalities caused by intrauterine infection. To achieve this goal, both males and females are immunized. Immunization of males has little direct benefit to the vaccinee other than prevention of the relatively mild illness caused by the rubella virus. The fetus of a vaccinated female is protected by immunization of the mother before pregnancy. Herd immunity resulting from extensive immunization of males and females provides some protection to the fetus of an unvaccinated female by decreasing the circulation of virus in the community.

Some vaccines can prevent infection in individuals who have not been vaccinated, not only by engendering herd immunity but also by the spread of vaccine from recipients to contacts. This has been observed with oral live poliovirus vaccine, which spread from vaccinees to unvaccinated contacts (262). This resulted in immunization of a significant proportion of the population that had not been administered vaccine, markedly reducing the incidence of poliomyelitis in both vaccinated and unvaccinated individuals. Spread of vaccine virus has been viewed by many as a desirable property

because it confers the benefits of immunization on many individuals who were not vaccinated. Of course, this has been a mixed blessing because of the rare occurrence of vaccine-associated paralytic disease among contacts of vaccinees. Although live poliovirus vaccine is no longer recommended for use in the United States, immunization of the unvaccinated still appears to be a positive feature of the live poliovirus vaccine especially when viewed in the context of interruption of virus spread in the community and, more importantly, for eradication of poliovirus worldwide.

Although most vaccines in use today are effective in preventing disease, they are inefficient at preventing infection. Prevention of infection is a highly desirable property for specific vaccines such as HBV and HIV. Infection with HBV during the neonatal period is associated with a greatly increased risk of progression to the chronic carrier state that is strongly associated with the development of chronic liver disease and hepatocellular carcinoma later in life. Therefore, a major goal of an HBV vaccine is to prevent transmission of infection from persistently infected mothers to their infants during the neonatal period. Considerable success in this effort has been achieved through the use of HBsAg vaccine or hyperimmune HBV antiserum plus vaccine immediately after delivery (124). Since HIV can progress to acquired immunodeficiency disease (AIDS) many years after initial infection, prevention of infection would be desirable.

In addition to preventing the acute effects of viral infection, two vaccines, one licensed (HBV) and one under development [human papillomavirus (HPV)], have as their goal the prevention of the most serious long-term sequelae of viral infection, namely cancer of the liver or cervix, respectively (124).

Immunotherapy

HSV-1 and HSV-2, as well as VZV, produce latent infection in sensory ganglia that is periodically activated, resulting in development of new lesions and increased opportunity for transmission of virus. Therefore, a goal of immunization of persons previously infected with these viruses is to prevent or ameliorate recurrent disease caused by reactivation of their latent infection (21,156). This form of immunization is referred to as immunotherapy. Other illnesses targeted for immunotherapeutic vaccines include warts and cancer caused by HPVs (156), and chronic hepatitis caused by HBV (169). Effective immunotherapeutic vaccines for recurrent HSV will be difficult to develop because the vaccinees have been infected by a wild-type virus and will be effectively reimmunized during each recurrence. It will be difficult to augment an immune response in such repeatedly immunized hosts.

Eradication

Appropriate use of a highly effective vaccine can help eradicate a major disease when humans are the only natural host of the virus. During the 1970s, this goal of eradication was achieved for smallpox largely through the use of the live vaccinia virus vaccine, and this ranks as one of the major public health achievements of this century. Two other viruses have been similarly targeted for eradication, namely poliovirus and measles, and significant progress toward this goal has been made for both viral pathogens. Live virus vaccines have played and continue to play a central role in these current eradication efforts.

CURRENTLY LICENSED VIRUS VACCINES

This chapter will focus solely on active immunization, and the reader is referred to Chapter 45 on RSV for a discussion on the only widely used form of passive immunization, a monoclonal antibody to the F glycoprotein used for immunoprophylaxis of high-risk children.

The first vaccine used in humans, live vaccinia virus, was developed by Jenner more than 200 years ago for the control of smallpox. During the ensuing two centuries, vaccinia virus had a noble record of success in controlling this disease and played an essential role in the final eradication of smallpox. It is ironic that the origin of this most important vaccine virus strain has remained obscure. Attempts to determine the origin of vaccinia virus using modern molecular biologic techniques have yielded equivocal results. Vaccinia virus appears to be a distinct species, different from both variola and cowpox viruses (167).

Since the introduction of vaccinia virus, licensed vaccines have been developed for 21 other viral pathogens (Table 1). Several of these vaccines already have helped to control the diseases against which they are directed—notably, poliomyelitis, yellow fever, mumps, measles, and rubella.

TABLE 1. *Viral vaccines licensed in the United States*[a]

CURRENTLY LICENSED NONLIVING VIRUS VACCINES

Nonliving virus vaccines are available in the United States for the prevention of disease caused by 10 separate viral agents (Table 1). These vaccines are prepared from virus that is grown in eggs (influenza types A and B), a continuous monkey kidney cell line (poliovirus types 1, 2, and 3), human diploid fibroblasts (rabies, hepatitis A), or mouse brain (Japanese encephalitis virus vaccine). Virus is then inactivated with a chemical such as formalin or disrupted with a detergent (influenza). The level of efficacy of these vaccines differs: Inactivated poliovirus vaccine is highly effective in preventing disease, whereas influenza virus vaccine is only partially protective.

Semipurified influenza virus subunit vaccines have been developed in an attempt to increase purity and decrease toxicity associated with whole virus vaccines. Such vaccines containing the HA and NA surface antigens of the virus are less toxic than are inactivated whole virus vaccines, but there is no increase in protective efficacy (226). In fact, in unprimed individuals, influenza virus subunit vaccine appears to be less immunogenic than inactivated whole virus vaccine, and two doses are needed for effective immunization in immunologically naive persons (226).

Finally, one of the latest nonliving virus vaccines to be developed is a highly purified HBV subunit preparation that contains the 22-nm HBsAg virus-like particle (VLP). The initial version of this vaccine, designed to protect against type B hepatitis, was unusual because surface antigen was purified from the blood of persons persistently infected with HBV. An effective second-generation HBsAg vaccine was developed using a recombinant plasmid to express the gene for HBsAg in yeast. Yeast-produced HBsAg self-assembles into typical HBsAg VLPs and is immunogenic in humans.

Advantages of Nonliving Virus Vaccines

Inactivated virus vaccines offer the advantage of immunization with little or no risk of infection. Only rarely do such vaccines contain a contaminating adventitious agent or residual infectious virus that has resisted inactivation. An example was paralytic disease produced by some of the early lots of inactivated poliovirus vaccine that contained residual infectious virus (213,231). Contamination by an infectious adventitious agent was also detected retrospectively in some early lots of inactivated poliovirus. This was of some concern because the contaminating SV40 was oncogenic in hamsters (123). Fortunately, long-term follow-up of individuals who received SV40-contaminated vaccine parenterally during early infancy failed to show evidence of an oncogenic effect (191,286). Live vaccinia virus was present in a preparation of inactivated vaccinia–HIV recombinant virus used to augment immunity in HIV-infected subjects. Unfortunately, an immunodeficient recipient of this vaccine developed progressive vaccinia initiated by residual live virus in the inoculum (337). The use of purified viral proteins or synthetic peptides should eliminate both types of contamination. In addition, the preparation of vaccines free of nucleic acid precludes the possibility of long-term adverse effects associated with infection or integration of viral nucleic acid into the host genome.

Disadvantages of Nonliving Virus Vaccines

Several nonliving virus vaccines have potentiated disease rather than prevented it (95,140). This was first observed with formalin-inactivated measles virus vaccine (95). Initially, this vaccine prevented measles, but after several years vaccinees lost their resistance to infection. When subsequently infected with naturally circulating measles virus, the vaccinees developed an atypical illness with accentuated systemic symptoms and pneumonia (95,209,244). Retrospective analysis showed that formalin inactivation destroyed the ability of the measles fusion (F) protein to induce hemolysis-inhibiting antibodies, but it did not destroy the ability of the H (hemagglutinin or attachment) protein to induce neutralizing antibodies (216,217). When the immunity induced by the H protein had waned sufficiently to permit extensive infection with measles virus, an altered and sometimes more severe disease was seen at the sites of measles virus replication (16,33). This atypical disease is believed to be mediated in part by an altered cell-mediated immune response in which T_H2 cells were preferentially induced, leading to heightened disease manifestations at the sites of viral replication (238). Chemical inactivation of poliovirus for use in a vaccine results in modification of a major neutralization epitope. This indicates that inactivation of the infectivity of nonenveloped as well as enveloped viruses can modify the antigenicity of the vaccine (83).

Potentiation of disease also was observed after parenteral administration of an experimental formalin-inactivated RSV (FI-RSV) vaccine (140). In clinical trials conducted in the mid 1960s, an FI-RSV vaccine induced a measurable serum neutralizing-antibody response but did not protect the young vaccinees. Unexpectedly, upon subsequent natural infection with RSV, the FI-RSV vaccinees developed severe RSV lower respiratory tract disease significantly more often than did infants and young children who had received an inactivated parainfluenza virus vaccine (140). Speculation on the mechanism of disease potentiation by the inactivated RSV vaccine has centered on several possible aberrations of the immune response to vaccine that involve an imbalance between or within various compartments of the immune system (43). First, it is likely that the vaccine failed to induce appreciable local respiratory tract RSV secretory IgA antibodies, thereby leaving vaccinees susceptible to infection under conditions in which the adverse effects of a series of other unbalanced responses might exacerbate disease.

Second, vaccinees immunized with FI-RSV developed a high titer of serum antibodies to the F glycoprotein of the virus, but these antibodies exhibited a low level of neutralizing activity that was not sufficient to provide effective resistance (205). This observation was confirmed later in an experimental setting; passive transfer of antibodies with such low neutralizing activity failed to protect rodents from RSV infection (54). The young infant vaccinees also developed a low level of antibodies to the other major RSV protective antigen, the G glycoprotein (205).

Third, shortly after the immunization phase of the vaccine trials was completed, it was observed that lymphocytes from the young RSV vaccinees exhibited an exaggerated proliferative response to RSV antigens *in vitro* that was significantly greater than that detected after RSV infection (141). It is thought that the vaccine most likely induced a high level of virus-specific memory T_H cells, probably of the CD4+ lineage. Recent studies have shown that CD4+ T cells predominate in the pulmonary infiltrate that develops after RSV challenge of FI-RSV-immunized mice (56). On the other hand, studies

in mice indicate that FI-RSV vaccine does not induce an RSV-specific CD8+ CTL response (56). These observations suggest that the vaccinees also experienced an imbalance in their cell-mediated immune response, in which the CD4+ component predominated and the CD8+ component was deficient (43,56). Finally, an additional imbalance attributable to immunization with FI-RSV was identified recently, namely an alteration in the T_H1 and T_H2 components of the CD4+ T-cell response to RSV infection. Ordinarily, T_H1 cells predominate in the lungs of RSV-infected mice, but in animals previously immunized with FI-RSV the ratio of T_H1 to T_H2 CD4+ T cells in the lungs of RSV-infected mice appeared to be reversed and sharply skewed to favor the latter (55,104). Since CTLs promote the development of a T_H1 response, their absence in the FI-RSV vaccinees partially contributed to the skewing of the T_H cell response toward the T_H2 subset (280). The absence of a protective immune response in the presence of heightened T_H2 cell immunity resulted in increased inflammation at the sites of RSV replication in the lung, which translated clinically into a more severe form of bronchiolitis and pneumonia in the FI-RSV vaccinees. In many ways, this adverse effect of immunization with an FI vaccine is reminiscent of the potentiation of measles that occurred following the use of the licensed FI measles virus vaccine.

Several lessons were learned from the potentiation of disease by FI-RSV. First, the chemical treatment and physical purification procedures used for the preparation of each new inactivated vaccine should be evaluated for their effect on the immunogenicity of the major viral protective antigen(s). The ability of a candidate vaccine to induce a high titer of serum antibodies with relevant functional activity (usually neutralization of virus infectivity) that is equivalent to that induced by infection, would constitute a sign that the protective antigen(s) had not been perturbed significantly. Retention of immunogenicity of the major viral protective antigen(s) present in the vaccine should preclude an unbalanced immune response deficient in protective antibodies.

Second, evidence for an imbalance involving the CD4+ T-cell response to the vaccine should be sought in experimental animals. An exaggerated CD4+ response, especially in the absence of an adequate protective antibody response, would represent a danger signal suggesting that other methods for inactivation of virus infectivity or for purification of virus particles or proteins should be investigated before proceeding further in vaccine development.

Third, the potential dangers inherent in pursuing a strategy for selective induction of T-cell responses in the absence of a protective antibody response should be evaluated in experimental animals, if possible. Failure to do so could result in the preparation of an inactivated vaccine that causes potentiation of disease rather than its prevention or amelioration. This caution applies not only to CD4+ T_H cells but also to CD8+ CTLs because adoptive transfer of the quantity of polyclonal or cloned CTLs required for rapid resolution of RSV infection can cause disease in recipient mice, and in some circumstances may kill the host (36).

Potentiation of disease by an inactivated virus vaccine is not limited to vaccines containing measles virus or RSV. For example, administration of an inactivated caprine lentivirus vaccine has also been associated with an accelerated, more severe disease in animals subsequently challenged with virus (176). Also, immunization with a subunit vaccine, but not an inactivated whole virus vaccine, of another lentivirus, equine infectious anemia virus (EIAV), enhanced disease caused by subsequent challenge with a heterologous EIAV strain (128). The immunologic mechanisms responsible for these two examples of enhanced lentiviral disease have not been identified.

Another disadvantage of nonliving virus vaccines is that parenteral immunization against viruses that infect and cause disease that is limited primarily to a mucosal surface may not be completely effective because of the failure of parenterally administered antigen to stimulate a satisfactory local IgA antibody response (198). This means that resistance in the upper respiratory tract or in the intestines may be less complete than that conferred by local immunization or infection.

Inactivated virus vaccines also may be at a disadvantage in relation to live attenuated–virus vaccines with respect to induction of a CTL response. This type of response is induced most efficiently by infected cells in which processed peptides derived from endogenously synthesized viral proteins are presented to the immune system in association with MHC class I proteins. Inactivated influenza virus is considerably less effective than virus infection in stimulating a primary CTL response in mice. However, inactivated influenza A virus or purified surface glycoproteins derived from it can stimulate a secondary CTL response in sensitized mice or humans (2,79,80,322). As described earlier in this chapter, methods to induce effective durable immunity mediated by CTL epitopes are not currently available.

The Guillain-Barré syndrome was associated with widespread use of inactivated influenza A H1N1 (swine) virus vaccine during 1976 and 1977 (153), indicating that unanticipated, delayed, or untoward side effects can be induced by nonliving virus vaccines. Surprisingly, this syndrome has been associated only rarely with subsequent nonliving influenza virus vaccines, although these products were prepared in the same manner as the 1976 vaccine (153).

It has been recognized that antigenic changes can occur during selection and amplification of influenza viruses in the allantoic cavity of embryonated eggs, the substrate used to produce virus for the inactivated vaccine (252). The genetic basis for these mutations involve host cell selection of mutants that replicate more efficiently in eggs. These variants acquire a mutation in or near the receptor-binding pocket of the HA that increases their efficiency of replication in eggs but also alters their antigenicity and immunogenicity. However, the influenza viruses used to prepare inactivated vaccine for humans are grown in eggs, and such vaccines have been repeatedly shown to be protective. A similar situation has been described for the inactivated poliovirus vaccine (255). Poliovirus grown in tissue culture contains an uncleaved outer capsid protein VP1, which is usually cleaved in a natural infection by intestinal proteases. Thus, tissue culture–grown poliovirus has limited ability to induce antibodies that neutralize viruses containing a cleaved VP1. This creates a potential problem because the uncleaved VP1 antigenic site (site 1) of poliovirus type 3 appears to be immunodominant over antigenic sites 2 and 3. Thus, the major immune response to inactivated type 3 poliovirus vaccine is directed against intact antigenic site 1, a site not present on type 3 poliovirus that has been cleaved. Infection by attenuated vaccine or wild-type poliovirus type 3 induces antibodies capable of efficiently neutralizing virus with both cleaved and intact VP1. Presumably, during virus replication in the gastrointestinal tract, viruses with either cleaved or

uncleaved VP1 are present and induce antibodies to both forms of virus.

In humans, each of two inactivated poliovirus vaccines, one containing a cleaved VP1 of poliovirus type 3 and a second containing an uncleaved VP1, induced antibodies able to neutralize virus with either a cleaved or an uncleaved VP1, and each of the two induced a comparable level of resistance to replication of subsequently administered live attenuated poliovirus vaccine (234). These findings indicate that immunization of humans with an inactivated poliovirus bearing an uncleaved VP1 is efficacious. These observations suggest that inactivated virus vaccines derived from tissue cultures or eggs may not mimic the full array of virus forms generated during an infection of the host. Thus, immunization with such antigens may induce antibodies with diminished ability to efficiently neutralize the total repertoire of viruses produced during infection.

Immunization of monkeys with FI simian immunodeficiency virus (SIV) produced in human cells induces antibodies directed at antigens originating from the cells used to produce the virus (275). These anticellular antibodies can neutralize the infectivity of SIV produced in human cells, but not of virus produced in monkey cells, by interacting with human antigens incorporated into the virion's outer membrane. This form of neutralization, which results from complement-mediated virolysis, can yield an overestimate of vaccine immunogenicity. Hence, an effort should be made to avoid immunization with virions into which foreign host-cell antigens have become incorporated (275).

POTENTIAL SOURCES OF ANTIGENS FOR FUTURE NONLIVING VIRUS VACCINES

Major progress has been made using monoclonal antibody and recombinant DNA technology to produce large quantities of purified protective viral antigens for use in immunoprophylaxis. Monoclonal antibody immunoaffinity chromatography or lectin chromatography facilitates purification of viral antigens from infected cells, and recombinant DNA technology makes it possible to express viral proteins in eukaryotic cells of yeast, insect, or mammalian origin. The use of these techniques has yielded candidate vaccines encompassing a large array of viral proteins that are capable of inducing protective antibodies in experimental animals. The production of individual viral proteins in prokaryotic cells has been less successful, but VLPs have been made in bacteria (157). Other approaches to immunization involve the production of synthetic peptides representing immunologically important domains of viral surface antigens and the use of antiidiotype antibodies as antigens to elicit an antiviral antibody response. Conventional techniques for producing FI whole virus vaccines are still being actively pursued for various flaviviruses (242) and alphaviruses (1).

Production of Viral Proteins in Eukaryotic Cells

Before expression of viral proteins in eukaryotic cells can be used as a method for vaccine production, several obstacles must be overcome. First, it is essential to identify the correct immunogen. Second, it necessary to produce protein in a highly efficient manner to make this approach economically feasible. Strategies that have been pursued to enhance expression of viral proteins focus primarily on identification of strong promoters of gene expression and development of techniques for efficient gene amplification. Third, viral proteins must be effectively separated from host cell protein and DNA. This latter requirement is of special concern because continuous mammalian cell lines constitute the most feasible substrate for production of viral proteins; therefore, potentially oncogenic cellular DNA must be greatly reduced or absent from the final vaccine. Recombinant DNA techniques to promote secretion of viral glycoproteins into the medium have been developed to facilitate effective separation of viral proteins from host cell proteins. Fourth, the procedures used to produce and purify viral protein must be gentle enough to maintain the protein in its native state, thereby preserving the conformationally dependent neutralization epitopes needed to induce protective antibodies. Finally, because the purified proteins are relatively poor immunogens, adjuvants need to be developed to enhance their immunogenicity. The following discussion of these approaches is not intended to be exhaustive in scope but illustrative of current strategies in use or in development.

Recombinant DNA techniques have been used to express viral proteins in yeast, insect, and mammalian cells. The usefulness of yeast was described previously in the discussion about the production of the HBsAg vaccine; yeast is currently being used to express other VLPs such as HPV (161). However, it has proven difficult to produce purified viral proteins such as the rabies G protective antigen in a native conformation in yeast (263), and other expression systems are currently being developed using insect or mammalian cells.

A major advance in viral antigen production has been the development of baculovirus vectors to express foreign genes at high levels in insect cells under control of a strong baculovirus promoter such as the polyhedrin promoter (164). Protein can be produced in large quantity (1 mg/10^6 cells) using this system. The baculovirus expression system has been used to express the influenza A virus HA protein, which has been found to be as safe and as immunogenic as the licensed nonliving virus vaccine in humans (239). Hepatitis E virus (HEV) protective antigen produced in a baculovirus expression system protected rhesus monkeys against HEV challenge (312). The baculovirus system can also be used to express more complicated viral immunogens that require polyprotein processing to generate native immunogenic protective antigens. An example of this is expression of the entire structural protein region (C-E3-E2-6K-E1) of an alphavirus to generate authentic, processed viral proteins capable of inducing an efficient neutralizing antibody response in experimental animals (120).

Mammalian cells also have been used for the production of viral proteins that can be incorporated in a subunit vaccine. Mammalian cell cultures represent an optimal system for the production of viral proteins, because protein folding, transport, and processing closely approximate those that occur in the infected host. Viral proteins have been produced from mammalian cells infected with the virus of interest or with a recombinant virus expression system engineered for a high level of expression of the foreign viral antigen. Two such expression systems are the vaccinia/T7 recombinant virus system (93) and an alphavirus replicon expression system (92,99,307). In the former, cell cultures are infected with two vaccinia recombinant viruses: One recombinant expresses the foreign gene under control of the T7 bacteriophage promoter, and the second recombinant expresses the T7 polymerase protein under control of a vaccinia promoter (93). Expression of the T7 polymerase (controlled by the vaccinia promoter) results in a high level of expression of the foreign viral gene (controlled by the T7 promoter). As a consequence, doubly infected cells produce large quantities of the

protein encoded by the foreign gene. Infectious vaccinia virus must be removed from the final product.

Alphavirus replicons have also been used to produce large quantities of proteins in mammalian or insect cells. Their success, like that of the vaccinia/T7 recombinant virus system, results from the selective amplification of the mRNA for the foreign protein (92,99,133,307). The expression system is based on a self-replicating RNA, termed a replicon. The replicon vector consists of an RNA molecule with authentic alphavirus 5' and 3' genomic ends; it contains (a) an alphavirus packaging signal located within the coding sequences for the nonstructural proteins located toward the 5' end of the replicon, and (b) an alphavirus subgenomic promoter sequence located downstream of the genes encoding the nonstructural proteins but upstream of a cloning site into which the foreign gene is inserted. The foreign gene replaces the genes encoding the alphavirus structural proteins. This replicon RNA is transcribed *in vitro* and then transfected into cells where the transcriptase/replicase encoded by the nonstructural genes amplifies the vector RNA and the mRNA encoding the foreign protein of interest. Co-transfection of cells with the replicon RNA and a defective helper RNA that lacks the packaging signal but expresses the alphavirus structural proteins results in the production of a high titer of defective virus particles that contain only replicon RNA. These replication-defective viral particles are able to infect cells at a high multiplicity and induce a high level of expression of the foreign protein. This type of system can be used for the expression of proteins of viruses that (a) cannot be grown efficiently in cell culture, such as HBV or the parvovirus B19, (b) are poorly infectious, or (c) represent a significant biohazard and, hence, cannot be considered for use in an inactivated whole virus vaccine (e.g., certain lentiviruses, filoviruses, hantaviruses, and arenaviruses).

In each of the eukaryotic systems described before, recombinant DNA technology can be used to introduce mutations into the expressed viral glycoproteins that facilitate subunit vaccine production. For example, the cell membrane anchor domain of viral glycoproteins can be deleted, with the result that the viral glycoprotein is secreted into the medium (282), thereby greatly facilitating purification of the protein. Chimeric proteins containing the antigenic portions of two protective antigens fused to form one immunogen have been produced, but the advantage of a chimeric protein over other forms of the immunogenic proteins has not been established (54,121). To induce a protective immune response using purified proteins that form heterodimers in virions or in virus-infected cells, it may be necessary to immunize with the protein complex rather than with the individual proteins, as has been done for the gH-gL complex of HSV (229). For larger viruses such as HSV, which encodes over 10 protective antigens, it has proven difficult to successfully immunize with single purified virion proteins, and it may be necessary to administer a mixture of proteins to achieve satisfactory protection (21,102).

Immunoaffinity chromatography, lectin chromatography, and physical separation techniques have been used to purify a variety of viral glycoproteins that have induced partial to complete resistance in animals. When directly compared in animals, resistance induced by immunization is greatest when the purified viral glycoprotein is in its native conformation (316). For RSV, HSV-1, and HSV-2, the neutralizing antibody response of animals immunized with purified proteins has been less than that observed after virus infection (177,206). In the case of RSV and Epstein-Barr virus (EBV), purified glycoprotein vaccine induced antibodies that were able to bind to glycoprotein in an enzyme-linked immunosorbent assay (ELISA), but these antibodies had a very low level of neutralizing activity (206,330). The titer of neutralizing antibodies stimulated by the RSV or EBV proteins was less than that induced by infection. In contrast to purified protein immunogens, RSV glycoproteins expressed by a vaccinia virus RSV F or G recombinant induced a titer of neutralizing antibodies comparable to that developed by animals infected with the virus (54). Observations of this type underscore the need to use purification techniques that yield glycoproteins that retain the capacity to induce antibodies with a high level of neutralizing activity or other desirable functional characteristics.

Novel strategies are being explored to increase the level of expression and immunogenicity of expressed antigens that have not yet induced a satisfactory humoral immune response following infection or immunization, such as the gp160 of HIV. One such strategy being evaluated for gp160 is to increase protein expression in cell culture by modifying codon usage to match that used by mammalian cells rather than that encoded in the virus genome (111). A second strategy involves immunization with formalin-fixed whole cells expressing HIV virions bound to receptor-bearing cells to induce neutralizing antibodies to antigens that are uniquely exposed during the process of initiation of the virus–cell membrane fusion reaction (151). It remains to be determined whether such strategies will be useful in the production of future vaccines.

Plants have been genetically modified to express virus proteins, and it is possible that some future viral vaccines will use proteins purified from plants (40). Alternatively, it might be possible to be immunized by simply eating a plant containing expressed virus proteins or VLPs (329).

Production of Viral Proteins in Prokaryotic Cells

In general, production of immunogenic viral protective antigens in prokaryotic cells has met with little success because it has been difficult to express conformationally authentic viral glycoproteins in such cells due to differences in protein processing and in microenvironment. Several experimental vaccines have been prepared using viral antigens that self-assemble to form VLPs (see later) (157,211) or viral proteins that have linear B-cell epitopes such as certain picornavirus capsid proteins and the HSV gD protein (145,323).

Virus-like Particles

The development of nonliving virus vaccines has been greatly facilitated by the observation that protective antigens of a large number of enveloped and nonenveloped viruses can self-assemble into VLPs. The capsid of most nonenveloped viruses is composed of two or more proteins that assemble into one or more shells that surround the viral genome. In contrast to virions, VLPs consist of capsid proteins assembled into a similar shell-like structure, but viral nucleic acid is not present within the shell. These empty shells can display conformational epitopes that are not present on individual purified capsid proteins. Some of these epitopes are formed by the juxtaposition of parts of two different capsid proteins. VLPs offer several advantages as immunogens. First, VLPs present conformational epitopes to the immune system in the same way that native infectious particles do, so that neutralizing antibodies and other protective immune responses are

induced efficiently. Second, many of the viruses for which immunogenic VLPs have been developed replicate poorly or not at all in tissue culture (e.g., the B19 parvovirus and the papillomaviruses), thus precluding use of purified virus as immunogen. Third, because VLPs are noninfectious, inactivation with formalin is not required. For this reason, VLPs might prove to be better immunogens than FI whole virus vaccines because the deleterious effects of formalin on immunogenicity can be avoided. Fourth, the immune system responds better to a viral antigen presented as an assembled multimeric particle than to one presented as an individual monomeric protein. VLPs have been engineered successfully for viruses belonging to a wide range of virus families. The success of the first VLP vaccine in humans, the yeast-grown HBV vaccine, is encouraging for the development of additional VLP vaccines against other pathogens.

Initially, it was observed that picornavirus capsid proteins could self-assemble during the *in vitro* translation of viral RNA, to yield 75S to 85S particles (222). Later studies indicated that VLPs could form *in vitro* following translation of picornavirus vRNA lacking most of the 5' noncoding region (46). Next it was observed that expression of the open reading frames of capsid proteins of nonenveloped viruses by a baculovirus or vaccinia vector in appropriate eukaryotic cells resulted in generation of VLPs (47,144,338). For picornaviruses, particle assembly requires expression of the entire open reading frame to permit the proteolytic processing of the structural proteins by nonstructural viral-encoded proteases.

Currently, VLPs are being actively pursued as experimental virus vaccines for two viruses, HPV and parvovirus B19, largely because these viruses replicate poorly in cell culture and alternative vaccines do not exist. The two major diseases caused by HPVs in humans for which vaccines are being prepared are cervical cancer, which is most frequently associated with HPV-16 or HPV-18 infection, and genital warts, caused by HPV-6 and HPV-11. VLPs for HPV-16 and HPV-11 that induce neutralizing antibodies following parenteral or mucosal administration have been produced in prokaryotic and eukaryotic systems (12,157,211,254). VLPs have also been prepared against a variety of animal papillomaviruses, and prophylactic efficacy against a variety of these viruses causing cutaneous or mucosal tumors has been demonstrated (12). VLPs containing either the L1 capsid protein alone or both L1 and L2 capsid proteins have been efficacious. This VLP-induced immunity was shown to be mediated by antibodies, as protection could be readily conferred to naive animals by passive transfer of antibodies from animals rendered immune by vaccination. It is likely that immunization of humans with an HPV-16 or HPV-18 vaccine will restrict replication of HPV in the cervix sufficiently to decrease the frequency with which infection progresses to malignancy. An L1/E7 chimeric protein containing CTL epitopes present in the HPV E7 oncoprotein is able to assemble into a VLP and to induce antitumor immunity in an animal model (107). It is possible that such chimeric VLPs might be more effective as prophylactic vaccines than the L1 VLPs, and that the chimeric VLPs might be active immunotherapeutically. Bacterial vectors transformed with HPV L1 capsid protein can assemble VLPs, and infection of mice with live recombinant bacteria has resulted in the production of antibodies in serum and mucosal secretions that were directed against conformationally dependent antigens, indicating that it might be possible in the future to deliver VLPs by bacterial vectors (211).

Human parvovirus B19 causes erythema infectiosum, acute and chronic red cell aplasia, and other illnesses. A vaccine consisting of the human parvovirus B19 VP1 and VP2 capsid proteins that form VLPs is being developed (13). Immunization of humans with this vaccine induces neutralizing antibodies that achieve levels that are equivalent in magnitude and neutralizing activity to those seen following natural infection, indicating that this VLP also represents a promising vaccine candidate (24).

Synthetic Peptides as Immunogens

During the early 1970s, the use of synthetic peptides as immunogens was studied using a synthetic icosapeptide representing the immunodominant domain of the outer coat protein of bacteriophage MS-2 (152). This peptide, conjugated to a carrier and emulsified in adjuvant, induced antibodies in rabbits that neutralized the infectivity of the bacteriophage when goat anti–rabbit Ig antibodies were added to the mixture. Although synthetic peptides were subsequently shown to induce neutralizing antibodies that did not depend on the aggregating effect of anti-Ig antibodies and to stimulate immunity to certain animal viruses *in vivo* (22), the immunity induced was less than that achieved when full-length protein, inactivated whole virus, or live virus was used as immunogen. The decreased immunogenicity of synthetic peptides is a consequence of their failure to mimic the conformational epitopes of protective antigens. Strategies to augment the immunogenicity of synthetic peptides, such as (a) inclusion of both B and T_H cell epitopes in the peptide, (b) presentation of peptide in a noninfectious viral particle, or (c) expression of peptide by infectious virus, have not overcome the inherent deficiencies of this approach. Until these are achieved, it appears unlikely that a synthetic peptide vaccine will prove protective (289).

The recent demonstration that epitopes seen by CTLs consist of short peptides of about eight to 10 amino acids in length presented in the context of the MHC class I heterodimer suggested that it might be possible to produce peptide vaccines to induce CTL-mediated immunity (75). Success with such CTL-mediated vaccines has been achieved in several experimental systems. For example, a peptide, in adjuvant, induced CTLs and protected mice against Sendai virus infection (137). In addition, immunization with a vaccinia recombinant virus expressing a CTL epitope either in the context of the entire viral protein (115,149) or as a minigene (CTL epitope only) induced transient resistance *in vivo* (328). Immunization with vaccinia virus expressing a series of LCMV CTL epitopes induced resistance to LCMV in mice of different MHC haplotypes (328). However, immunization with CTL epitopes is fraught with obstacles (see section on CTLs in this chapter). It has yet to be demonstrated that a peptide-CTL-epitope vaccine induces immunity that is more effective and more durable than that induced by either a protein antigen or a VLP or by infection with an attenuated virus.

Antiidiotypic Antibodies as Immunogens

Another approach to induction of viral neutralizing antibodies involves the use of antiidiotypic antibodies as immunogens. Infection or immunization with a virus induces a neutralizing antibody (so-called antibody 1), which bears on its Fab variable region combining site a reverse image of the virion protein that is the target of that particular antibody. This unique region of the Fab is called an idiotype. Immunization with antiviral antibody (antibody 1) induces antiidiotype antibody (antibody 2), which has a conformation at its combining site that mimics the structure of the original viral epitope. This antiidiotype antibody can then be used instead of the viral antigen to elicit an immune response (antibody

3) to the viral protein. Immunization with antiidiotype antibody has induced a neutralizing antibody response to reovirus, poliovirus, rabies virus, coxsackievirus, or HBsAg (100,175,246,315), and protection of experimental animals has been demonstrated for poliovirus (315) and HBV (139). However, the level of neutralizing antibodies induced by these antiidiotype antibodies has been less than that elicited by infection or by immunization with inactivated viral particles. Thus, this approach to vaccine development does not appear to have an advantage over that of other, more conventional approaches used to induce protective antibodies.

Immunization with DNA Encoding Protective Antigens of Viruses

A new and potentially useful strategy for immunization involves direct intramuscular or intradermal inoculation of plasmid DNA that encodes viral protective antigens (290,331). Expression of the protective antigen is driven by a strong promoter capable of efficient activity in a variety of mammalian cell types. The feasibility of immunization with DNA was demonstrated by the induction of antibodies to human growth hormone in mice immunized with a plasmid encoding this foreign protein (290). Subsequently, immunization with DNA that encoded viral antigens, including antigens that can form VLPs, from a wide range of viruses has induced functional (i.e., neutralizing or syncytium-inhibiting) antibodies and/or resistance to viral infection (70). Immunization with DNA has several advantages over immunization with purified viral antigens. The most important advantage is that viral antigens such as viral glycoproteins can be expressed on the surface of transfected cells and are presented to the immune system in a native state. During the process of purification of viral proteins, purification and assembly of VLPs, or inactivation of viruses with chemicals, the integrity of epitopes on protective proteins can be adversely affected, resulting in altered and weakened immunogenicity. DNA immunization, which circumvents these problems, more closely resembles immunization with a live virus vaccine than with a nonliving viral antigen. Viral antigens encoded by DNA, whether entire proteins or minimal CTL epitopes, are presented efficiently in the context of class I MHC antigens and are able to induce T_H cells and CTLs (335). In this way, it is possible to induce a balanced immune response more similar to infection-induced immunity than immunity induced by administration of preformed viral antigens. A second advantage of immunization with DNA is its ability to transfect cells without interference by viral antibodies. Whereas live attenuated vaccine virus, such as that present in the measles virus vaccine, is effectively rendered noninfectious by maternal antibodies, DNA immunization should not be affected in this manner. Finally, it has been observed that the foreign antigen can be expressed *in vivo* for several months following DNA immunization (333). If transfected cells can present antigens over a longer period of time than live or nonliving virus vaccines, more durable B- and T-cell responses might result, but the rate of rise of immune responses following DNA immunization can be slow. Immunization with DNA encoding rabies G glycoprotein by gene-gun delivery of plasmid into skin (a delivery method considered highly efficacious) protected monkeys against challenge with virulent rabies virus. Nevertheless, the conventional vaccine induced a much more rapid rise to peak antibody titer, indicating that it would still be the preferred immunogen for postexposure prophylaxis (160). To date, immunization with DNA has induced lower titers of serum antibodies and less protective immune responses than that resulting from virus infection or from other more conventional forms of immunization (171,212,335). The major reasons underlying the weak immunogenicity of DNA vaccines are the paucity of cells that are transfected *in vivo* and the low level of expression of viral antigen in the transfected cell. Both of these deficiencies will need to be improved considerably if this form of immunization is to be useful in the next generation of vaccines.

The technology to improve the immunogenicity of DNA vaccines is evolving rapidly, and it is clear that this form of immunization has not yet been optimized. The immunogenicity of DNA vaccines has been significantly increased by a variety of methods (7,19,27,142,264,269), and it remains unclear which of these methods or which combination might bring DNA-based vaccines into the clinic. Recent success in augmenting the immunogenicity of DNA vaccines has been achieved using plasmid vectors based on the alphavirus replicon system, in which the plasmid vector expresses both the nonstructural alphavirus proteins and the foreign gene. The latter is selectively amplified in the cells transfected by the vector, as it is under control of the alphavirus subgenomic promotor (116).

The safety of DNA vaccines will require continued evaluation, but the likelihood of mutagenesis by integration of the vaccine DNA into the human genome appears at this time to be very small (27).

Adjuvants

A characteristic feature of purified viral proteins produced by recombinant DNA technology or peptide antigens is that they are weakly immunogenic in an immunologically naive host. This is because the immune system has evolved, in part, to respond most efficiently to viral antigens that are present on virus particles or on virus-infected cells—that is, the strongest immune responses are to multimeric, particulate antigens. An adjuvant is needed to increase the immunogenicity of recombinant viral antigens that are predominantly individual monomers or oligomers, but the only adjuvant licensed for human use is alum. This is a relatively weak but safe adjuvant. It is not surprising to find that VLPs, because of their particulate nature, can be highly immunogenic without an adjuvant. There is a considerable effort being made to develop safe and effective adjuvants for human use (4,59,220). Adjuvants function as antigen depots, as immunostimulants or immunomodulators, or as organizers of antigens into particulate forms. Many adjuvants combine two or more of these functions.

The depot function of adjuvants is designed to release antigen for a long period that exceeds that of an aqueous antigen suspension and that mimics an acute viral infection in which there may be sustained release of antigen for 2 to 4 weeks (59). Alum, an insoluble precipitate of aluminum hydroxide and aluminum phosphate, functions as a short-term antigen depot in which antigen that is electrostatically bound to alum is slowly released at the site of inoculation. A second type of depot is a water-and-oil emulsion from which antigen is slowly released as the biodegradable oil is metabolized or removed by macrophages. A third type of depot is that in which viral antigen is complexed with a synthetic polymer to form microparticles that can be degraded by tissue enzymes, thereby slowly releasing the viral antigen. Microparticles can be designed to release antigen over a long period of time.

The immunostimulatory and immunomodulatory functions of adjuvants serve to augment the antibody, CTL, and/or T_H cell responses to viral antigens. In addition, adjuvants can modify the T_H cell balance between the T_H1 and T_H2 subsets

achieved by immunization. For example, alum stimulates a T_H2 response, whereas monophosphoryl lipid A, a detoxified bacterial endotoxin, stimulates predominantly a T_H1 response. If the goal of immunization is to achieve a CTL response to the viral antigen, then one might choose to include in the adjuvant a saponin, which can form immunostimulating complexes (ISCOMs) (319). Various cytokines are also being explored as adjuvants (159). Bacterial toxins such as the cholera toxin and the *Escherichia coli* labile toxin, which have been molecularly engineered to exhibit greatly reduced toxicity *in vivo*, are potent systemic and mucosal adjuvants, but they can elicit an immune response to themselves that might limit their usefulness as general adjuvants (221). Last, it has recently been recognized that mammals have the capacity to recognize specific sequences, such as CpG sequences, in bacterial DNA, and to respond by augmenting the immune response to a viral protective antigen (64). For this reason, oligonucleotides containing CpG sequences have been incorporated into certain experimental adjuvant formulations.

Particulate adjuvants include (a) liposomes formulated to contain lipophilic or hydrophilic viral antigens; (b) ISCOMs, which are cagelike structures formed by a complex of a defined mixture of lipids and saponins, containing viral antigens; and (c) microparticles made from biodegradable polymers complexed with viral antigens (59).

Currently, one adjuvant formulation, designated microfluidized emulsion 59 (MF59), has been extensively tested in monkeys and humans, and its safety and immunogenicity profiles appeared sufficiently promising that it has been licensed in Italy for use with an inactivated influenza virus vaccine (4,220). MF59 consists of the biodegradable oil squalene and the surfactants sorbitan trioleate and Tween 80. Each of these three components has been previously used in human medicines. Squalene serves the depot function, but it remains unclear which component(s) functions as an immunostimulant. MF59 was originally developed as a vehicle for the immunostimulant MTP, a derivative of muramyl dipeptide, the active component of the *Mycobacterium* cell wall fraction in Freund's complete adjuvant. Clinical studies in humans indicated that MF59 itself was as immunostimulatory as MF59/MTP, with less toxicity (105). MF59 appears to be a safe adjuvant in nonhuman primates (308,318) and humans (105,184) but increased immunogenicity is accompanied by an increase in reactogenicity. The ability of MF59 to augment the humoral immune response appears to be greater in an unprimed host (308) than in a previously primed host (184).

CURRENTLY LICENSED LIVE VIRUS VACCINES

Except for vaccinia virus, each of the 16 currently licensed live vaccine viruses (Table 1) has a clear lineage. Vaccinia virus and the simian (rhesus) rotavirus are not of human origin. The orally administered enteric-coated adenovirus vaccine strains (types 4 and 7) are wild-type human viruses that produce an asymptomatic infection that is limited to the lower intestinal tract, in which disease with these types of adenovirus does not occur (42). One of the most widely used vaccine strains is a naturally occurring attenuated human poliovirus that was identified by its lack of virulence for the brain and spinal cord of monkeys (type 2 poliovirus, strain 712) (261). The quadrivalent rotavirus vaccine is composed of a simian rotavirus (serotype 3 specificity) and three reassortant viruses in which the VP7 gene (the determinant of serotype specificity) of the simian virus has been replaced by a human rotavirus gene with serotype 1, 2, or 4 specificity. Finally, the remaining vaccine viruses were derived from wild-type human viruses by serial passage in cell cultures prepared from an unnatural host, leading to the emergence of mutants that were partially restricted in humans at the portal of entry and/or the target organ(s). In this manner, attenuated mutants of rubella virus and types 1 and 3 poliovirus were selected after passage in monkey kidney tissue culture. Vaccine strains of yellow fever virus (YFV; 17D strain) and measles virus were generated by multiple passages in chick embryo cell culture, whereas embryonated eggs were used for this purpose for attenuation of mumps virus.

For the YFV and poliovirus vaccines, it was possible to identify promising vaccine strains by their attenuation for experimental animals. In monkeys, the 17D strain of YFV exhibited decreased tropism for the liver, and this served as a sign that this mutant might be suitably attenuated for humans (300). This was confirmed during subsequent clinical trials. In a similar fashion, naturally occurring and tissue culture–passaged strains of poliovirus were evaluated for neurovirulence in monkeys by intraspinal inoculation (260,261). This system was selected because a number of observations suggested that the spinal cord of monkeys was more permissive than that of humans to the neuronolytic effect of poliovirus (260,261). Viruses least neurovirulent for monkeys were identified, and these strains were then cloned and recloned by the plaque technique to yield progeny with the lowest possible level of monkey neurovirulence. These candidate vaccine strains were then subjected to additional cycles of selection, which led to the identification of mutants that replicated with high efficiency in the intestinal tract without significant increase in neurovirulence for nonhuman primates. These viruses were then evaluated in clinical trials and shown to be satisfactorily attenuated and immunogenic.

Experimental systems for evaluating virulence were not available for the other vaccine viruses. Hence, these viruses were tested for attenuation directly in humans. Initial candidate measles and rubella vaccines were not suitably attenuated, but further passage of rubella virus in monkey kidney cell culture and selection of a cold-adapted, temperature-sensitive mutant of measles virus yielded satisfactory vaccine strains. Attenuation of mumps virus passaged in eggs was also monitored in humans. Interestingly, the Jeryl Lynn strain of mumps virus vaccine has recently been found to be a mixture of two closely related strains of mumps virus (3).

Poliovirus, adenovirus, and rotavirus vaccines are administered orally, whereas yellow fever, rubella, measles, and mumps virus vaccines are given parenterally. It should be noted that, except for adenovirus and rotavirus vaccines, each of the currently licensed live-virus vaccines is directed against a virus that has a complex pathogenesis of infection in which virus is introduced by inoculation (yellow fever) or by implantation on a mucosal surface (measles, mumps, rubella, and poliomyelitis), with subsequent spread systemically to the target organ(s).

Basis for Attenuation

Mutants selected by passage in an unnatural host accumulate many mutations, often making it difficult to define in a precise manner the genetic basis for their attenuation. In a sense, these satisfactorily attenuated mutants are the product of a process of genetic roulette, followed by selection of mutants with the desired properties of attenuation and immunogenicity. The unpredictability of this process is illustrated by the failure of Theiler (299) to produce additional

attenuated mutants of YFV using the protocol that yielded the satisfactorily attenuated 17D strain of virus. The genetic basis for attenuation of measles, mumps, rubella, yellow fever, rotavirus, and vaccinia viruses is unknown, whereas the genetic determinants of attenuation of two of the three live poliovirus vaccine strains are better characterized. The net result of most attenuating mutations is to reduce the level of replication in the host, at the portal of entry or at internal sites, to a level that does not cause significant disease. For some viruses, the specific level of replication in humans or nonhuman primates that is associated with attenuation is known, although it is not known for most viruses (200,202,298).

The poliovirus vaccine strains are temperature sensitive with respect to replication and exhibit greatly decreased neurovirulence in monkeys after intraspinal administration of virus (260). Because the poliovirus vaccine viruses replicate efficiently in the gut of vaccinees and can produce viremia, it is likely that restriction of replication in neurons represents the basis of attenuation of these viruses for the CNS of humans, monkeys, and rodents. The genetic basis of this neuroattenuation of each of the three poliovirus vaccine strains has been partially defined (108). The identification of mutations contributing to neuroattenuation of the three vaccine viruses derives from a large series of studies involving (a) sequence analysis of virulent parental type 1 and type 3 viruses and their attenuated vaccine strain derivatives; (b) sequence analysis of neurovirulent “revertant” virus isolated from vaccineassociated cases of poliomyelitis (101); (c) *in vitro* generation of chimeric recombinant viruses produced from cDNA clones of virulent and attenuated viruses or viruses bearing site-specific mutations thought to be associated with neuroattenuation on the basis of sequence analysis of revertant viruses (25); or (d) evaluation of the neurovirulence of these naturally occurring or *in vitro*–generated viruses in monkeys, normal mice, or mice transgenic for the human poliovirus receptor. These analyses have identified an attenuating nucleotide substitution in the same region in the 5' noncoding sequence of each of the three vaccine viruses (nucleotide 480 in type 1 virus, 481 in type 2 virus, and 472 in type 3 virus) and other attenuating or *ts* mutations in the 3' noncoding region or in the structural or nonstructural coding regions of type 1, type 2, or type 3 polioviruses (25,101,249). The mutation in the 5' noncoding region (a) alters the predicted secondary structure of this important regulatory region, (b) is responsible in part for the *ts* phenotype of the vaccine viruses, and (c) decreases virus replication *in vitro* in cells of neural origin, presumably by altering the function of a neural tissue specific internal ribosomal entry site (108). These mutations can now be monitored during manufacture (45,249) and following replication *in vivo*. Importantly, reversion in several of these attenuating mutations has been detected during the *in vitro* passage of virus that is required for the production of vaccines (45) or after replication *in vivo*, even as early as 47 hours after vaccine administration. Specifically, the rare reversion of the attenuating mutation at nucleotide 472 of the 5' noncoding region of the Sabin type 3 vaccine strain that occurs during vaccine production can now be detected using sensitive polymerase chain reaction techniques. Vaccine lots with an increased frequency of reversion at residue 472 exhibit increased neurovirulence, and such lots can be discarded as unacceptable for human use (45). Thus, it is now possible to use molecular virologic techniques to control the manufacture of vaccines by identifying the presence of the desired attenuating mutations as well as the absence, or low frequency, of unwanted reversions (45).

A different approach was taken to develop the live adenovirus vaccines that are currently licensed for use in military personnel, where adenoviruses are the major cause of epidemic respiratory tract disease (42,74). Attenuation is achieved by limiting infection to an area of the body in which disease does not develop. The current vaccine contains wild-type virus that is administered orally in an enteric coated tablet. Virus is released when the tablet enters the intestines. There it establishes an asymptomatic, immunizing infection that does not spread to the respiratory tract, the region in which disease develops during natural infection. Although vaccine virus is shed in feces, spread to susceptible contacts occurs with a very low frequency. Selective enteric infection stimulates a vigorous systemic immune response that confers complete or almost complete resistance to adenovirus disease (74). Resistance to reinfection is also impressive (70%) but not complete (74,274).

The Jennerian approach to the development of live attenuated viruses involves the use of a virus strain of mammalian or avian origin to immunize humans against a human virus that is related antigenically to the animal or avian strain. Mammalian and avian viruses that are well adapted to their natural host often do not replicate efficiently in humans and hence are attenuated. At present, we lack a thorough understanding of the genetic basis for this form of host-range restriction. However, those mammalian or avian viral genes that have been identified as being responsible for host-range restriction in humans exhibit significant divergence of nucleotide sequence from that of the corresponding human viral genes. The recently licensed quadrivalent rotavirus vaccine is an example of the Jennerian approach to vaccine development in which a nonhuman rotavirus strain, the rhesus rotavirus (RRV), was found to be attenuated in humans and protective against human serotype 3 to which it is antigenically highly related (135). Since there was a need for a multivalent vaccine that would induce resistance to each of the four major human rotavirus serotypes, the Jennerian approach was modified by constructing three reassortant viruses, each of which contained 10 RRV genes plus a single human rotavirus gene that coded for the major neutralization antigen (VP7) of serotype 1, 2, or 4. The intent was to prepare single gene substitution RRV reassortants with the attenuation characteristics of this simian virus and the neutralization specificity of human rotavirus serotype 1, 2, or 4. The quadrivalent vaccine based on the host-range restriction of the simian RRV in humans induced a high level of resistance to human rotavirus disease in infants and young children (230). However, the licensed vaccine retains mild reactogenicity in older seronegative infants lacking maternal antibody, and second-generation Jennerian vaccines, based on strains of bovine rotavirus, is being developed to replace the RRV vaccine (48).

Advantages of Live Virus Vaccines

The major advantage of live virus vaccines is the activation of all components of the immune system yielding both a balanced systemic and local immune response, and a balanced humoral and cell-mediated response. This is particularly important for infections in which cell-mediated immunity plays an important role, and for mucosal infections in which both local and systemic immunity are required for optimal resistance. Mucosal infection with a live virus vaccine is usually more effective in stimulating a local response in the unprimed host than is a nonliving virus vaccine administered parenterally (198). Live virus vaccines also stimulate an immune response to each of the protective antigens of a virus, and this obviates the difficulties that arise from selective destruction of one of the protective antigens that may occur during preparation of a nonliving virus vaccine, which can result in disease potentiation. This is especially important for complex viruses encoding many protective antigens, as it is difficult to immunize economically with multiple purified proteins or to construct multivalent vectors. Furthermore, immunity induced by live virus vaccines is generally more

durable and more effective (132). It should be noted that there are also practical advantages to many live virus vaccines, such as low cost of production and ease of administration.

Disadvantages of Live Virus Vaccines

The major concerns with live virus vaccines are that they (a) can contain adventitious agents, (b) can cause illness directly or lose their attenuation during manufacture or during replication in vaccinees by reverion or by second-site compensatory mutations, (3) can spread to contacts (see preceding), and (4) can lose infectivity during storage, transport, or use. The potential for contamination with live adventitious agents always exists. Fortunately, this has rarely been a problem. Some of the early lots of live poliovirus vaccine were contaminated with live SV40, and the live YFV vaccine was initially contaminated with an avian leukosis virus. Follow-up of individuals who were given live vaccine contaminated with SV40 or avian leukosis virus has failed to identify any long-term adverse effect, including cancer, associated with exposure to these adventitious viruses (191,286,321). Current vaccines grown in chicken cells contain a presumably noninfectious retrovirus derived from the cell cultures, and this contaminating particle does not appear to be infectious for vaccinees (311). Nonetheless, prudence dictates that live virus vaccines should be free of such contaminants.

Some live virus vaccines, such as the measles virus, rubella virus, and YFV vaccines, retain a low level of residual virulence. The reactions produced by these vaccines are minor and have not interfered with acceptance and widespread use of these products. A more serious problem is that of restoration of a varying degree of virulence during infection by vaccine virus. This occurs with the poliovirus vaccine at an extremely low frequency i.e., about one in 10^6 to 10^7 immunizations) (215). Most vaccine-associated cases of paralysis in vaccinees or their close contacts occur after the first dose and involve the type 3 vaccine strain (215). A significant proportion of the paralytic illnesses associated with poliovirus vaccine occur in individuals who are immunocompromised, but this may not represent a manifestation of genetic alteration of vaccine virus (215). In most instances, however, vaccine virus appears to have regained neurovirulence by mutation, allowing it to produce disease in the vaccinee or a close contact (101). In addition to mutation, polioviruses with recombinant genomes have been isolated from vaccinees with paralytic disease, suggesting that restoration of virulence might occur by the process of interserotypic recombination as well as by mutation (96).

The genetic basis for the very rare increase in virulence of the poliovirus vaccine strains during replication *in vivo* is relatively well understood. However, a paradox exists, in that mutation toward a higher level of virulence for the CNS occurs rapidly and frequently during replication of type 3 poliovirus in the intestinal tract of vaccinees, but vaccine-associated paralytic disease is extremely rare (183,188). It is now clear that mutations that increase neurovirulence of the virus for primates can occur in each of the three Sabin vaccine strains during infection of vaccinees (165,293,296), but, fortunately, poliomyelitis in vaccinees or contacts is very rare. During manufacture of vaccine, the mutations that are associated with restoration of virulence can be detected at variable low frequency by sequence analysis, and neurovirulence of the final product can be held to a low level by rejecting vaccine lots that exceed the accepted standard for frequency of these mutations (45). Genetic instability was also a problem with the 17D YFV vaccine during early field trials. Encephalitis was observed in 1% to 2% of young vaccinees administered virus that had been passaged 20 times beyond the original seed lot (88,300).

The problem of genetic instability of live attenuated virus vaccines following replication *in vivo* is an even larger concern for viruses that can cause latent or persistent infection *in vivo*, such as herpes viruses or lentiviruses (e.g., HIV). Despite this concern, a successful vaccine has been developed for VZV, a herpes virus that causes chickenpox and zoster, indicating that a successful live attenuated vaccine can be developed for a virus that causes a lifelong infection in humans.

During studies of attenuated lentivirus mutants, SIV in monkeys and HIV in humans, the time required for expression of residual virulence proved to be very long (9,155). These mutants, constructed in the laboratory (SIV) or detected initially in persons with long-term inapparent HIV infection, contained multiple mutations including deletion of the *nef* gene as well as other regions of the viral genome. Nevertheless, immunodeficiency did develop (9,155). The long incubation period to disease and the development of additional second-site mutations that suppressed the attenuation phenotype of an SIV deletion mutant (20) emphasize the daunting challenge of the live attenuated vaccine approach to prevention of AIDS.

Because live poliovirus vaccines can cause persistent infection and paralytic disease in immunodeficient children (332), there is an increasing concern that, as the numbers of immunodeficient humans increase, other live attenuated virus vaccines might need to be phenotypically more stable in the future. Rubella virus can be recovered from the lymphocytes of immunologically normal individuals with arthritis up to 6 years after immunization or natural infection (44), but the rubella virus vaccine does not appear to be associated with chronic arthritis (245). Interestingly, persistence of measles vaccine virus has not been detected, nor has the vaccine virus been implicated in subacute sclerosing panencephalitis (182). Instead, widespread use of live measles vaccine has almost eradicated this rare but serious sequela of persistent wild-type measles virus infection.

Several other concerns have been identified for live attenuated virus vaccines. First, although there is a theoretical risk that infection of the fetus with rubella vaccine virus during the first trimester of pregnancy might lead to development of the congenital rubella syndrome, the actual risk appears to be negligible (225). Second, naturally occurring wild-type viruses may interfere with infection by a live virus vaccine, resulting in a decrease in vaccine efficacy. Such interference has been observed primarily with live poliovirus vaccine strains and is caused by a wide variety of enteric viruses. This phenomenon has also been seen with experimental live attenuated alphavirus vaccines (174). To overcome this virus–virus interference, multiple doses of polyvalent live virus vaccines are required to ensure a protective immune response to each component. Third, defective interfering particles have been identified in one preparation of live measles virus vaccine (35). The presence of such particles could modify the clinical response to vaccine and possibly produce variation in immunogenicity and level of attenuation among successive lots of vaccine. Fourth, live attenuated measles virus vaccine has been associated with a generalized immunosuppression that was observed to be directly correlated

with the level of immune response to the vaccine (126).

Finally, it should be noted that stability is a serious problem with labile vaccine viruses such as measles virus. The need for storage and transport of measles vaccine at low temperature (4°C) has limited its usefulness in some tropical areas, where maintenance of a “cold chain” for transport and storage is difficult.

DIRECTIONS FOR FUTURE DEVELOPMENT OF LIVE ATTENUATED VIRUS VACCINES

Conventional Approaches and Naturally Occurring Attenuated Mutants

Conventional techniques for attenuation of viruses, such as passage of virus at low temperature, mutagenesis followed by selection of mutants with the desired phenotype(s), or passage of virus in heterologous tissues, will continue to have a role in the development of live virus vaccines (17,168). These techniques are being used to generate candidate vaccine strains for cytomegalovirus, ortho- and paramyxoviruses, alphaviruses, flaviviruses, HAV, and arenaviruses. In the case of RSV, a candidate vaccine strain that was partially attenuated for susceptible young infants by multiple *in vitro* passages at low temperature in embryonic bovine kidney cells was subsequently subjected to chemical mutagenesis, and further attenuated derivatives containing attenuating temperature-sensitive (*ts*) or small plaque mutations were identified (201). In this way, two conventional approaches were combined to introduce different classes of attenuating mutations (i.e., host-range mutations introduced by passage in a heterologous host, and *ts* mutations introduced by chemical mutagenesis). This process of combining different attenuating mutations is thought to be desirable because the different mutations can have synergistic effects on the stability of the attenuation phenotype *in vivo* (204).

Variation in virulence of naturally circulating human viruses has been documented, but this phenomenon has not been studied systematically, nor have its implications for immunoprophylaxis been adequately explored. Almost 45 years ago, Sabin (259,260) observed that strains of poliovirus recovered from healthy individuals exhibited a wide range of neurovirulence as measured by intracerebral or intraspinal inoculation of monkeys. Approximately one fifth of these strains were highly attenuated. This suggests that systematic study of viruses recovered from healthy persons might identify naturally occurring attenuated mutants of viruses other than poliovirus. As indicated previously, the type 2 poliovirus strain of the live oral vaccine was identified in this manner.

The use of conventional methods for achieving attenuation will diminish as the newer techniques for construction of viruses with defined attenuating mutations are applied to development of live virus vaccines. Viruses bearing stable, defined, identifiable attenuating mutations or attenuating gene constellations represent the vaccine strains of the future because the genetic basis for attenuation will be known and can be monitored directly during all phases of vaccine development, manufacture, and utilization in humans.

Attenuating Mutations Introduced into Coding Regions

Missense Mutations

A missense mutation that specifies an amino acid substitution in an encoded viral protein can decrease its function *in vivo*, thereby attenuating the virus for its host. Three classes of missense mutants with easily identifiable phenotypes have been evaluated extensively for their level of attenuation and their potential usefulness in live attenuated viral vaccines: (a) *ts* mutants, (b) protease activation (*pa*) mutants (also designated as cleavage mutants), and (c) mutants with altered interaction with host cell receptors.

The *ts* mutants are conditional lethal viruses that replicate efficiently at permissive temperatures (32° to 34°C) but that are restricted in replication at the high end of the normal temperature range (37° to 39°C). The *ts* mutants can be grown efficiently *in vitro* at the permissive temperature for vaccine production because the attenuating *ts* mutations generally restrict replication only at elevated temperature. Attenuating *ts* mutations have been identified in most, if not all, genes of the viruses that have been mutagenized and then examined systematically (267). Also, multiple sites within a given protein can sustain *ts* mutation (154). Thus, it is possible to introduce a *ts* mutation into almost any gene of a candidate vaccine virus. Alternatively, several *ts* mutations can be introduced into the same gene using recombinant cDNA technology (288,327), and two nucleotide changes per codon can often be engineered to specify the desired amino acid substitution, thereby increasing the stability of the missense mutation. It is also possible to export an attenuating missense mutation that is present in a virus to the corresponding site of a member of a distantly related virus genus or subfamily, and in this way the number of mutations that are available for use to attenuate candidate vaccines can be significantly expanded (270). Thus, recombinant DNA technology offers new flexibility to add or subtract mutations in vaccine candidates to achieve the desired delicate balance between attenuation and immunogenicity that is needed to produce a successful vaccine.

The use of *ts* mutations to attenuate respiratory viruses is especially attractive because the *ts* lesion should restrict virus replication in the warmer lower respiratory tract (37°C), the major site of disease; however, sufficient replication should occur in the cooler upper respiratory tract (32° to 34°C) to immunize the host (250). Importantly, virus replication in the latter site is usually sufficient to immunize the host against infection with virulent virus (17,250). However, genetic instability has presented a problem for *ts* mutants because there is strong selection *in vivo* for ts^+ viruses that have undergone reversion to wild-type sequence or have sustained suppressor mutations that abrogate the *ts* phenotype (304). The phenotypic stability of candidate vaccines bearing *ts* mutations can be enhanced by increasing the number of *ts* mutations per virus or by combining *ts* and non-*ts* attenuating mutations, which can act synergistically to augment stability of the attenuation phenotype (204,271,327).

The second approach to producing missense mutations that specify attenuation involves the isolation of *pa* mutants. Proteolytic cleavage of the F glycoprotein of paramyxoviruses is required for activation of infectivity, and this process is thought to play an important role in tissue tropism and pathogenicity. Trypsin-like enzymes that are present in host tissues are required for the cleavage of the fusion protein precursor F0 to its disulfide-linked F1 and F2 subunits. The *pa*

mutants of murine parainfluenza virus type 1 (PIV-1; Sendai virus) were selected by growing virus in the presence of another protease such as chymotrypsin or elastase (294,295). The *pa* mutants selected in this manner were resistant to activation by trypsin but formed plaques in the presence of the selecting protease. These *pa* mutants, which sustained amino acid substitutions that abolished the cleavage site for trypsin and created a new site for cleavage by chymotrypsin or elastase (129), were attenuated and protective in animals. However, revertants did develop during replication *in vivo* (186).

Viral surface proteins can also undergo mutation that results in attenuation. This is not surprising because missense mutations affecting surface proteins can alter tissue tropism and pathogenesis of infection (277). This was shown most convincingly in studies in which mutants were selected by growing virus in the presence of a monoclonal antibody that neutralized virus infectivity and by isolating antigenic mutants that were no longer neutralized by the selecting antibody. These variants, which are referred to as monoclonal antibody-resistant (*mar*) mutants, generally sustain only a single amino acid substitution. Some *mar* mutants have been described that have properties desirable for a candidate vaccine—namely, they have a decreased ability to enter and infect cells in the target organ in which the virus produces disease, but they are able to replicate at other sites *in vivo* and in tissue culture (277,278). It has been possible to increase the stability of *mar* mutations by the introduction of multiple mutations sequentially into the capsid proteins of coxsackievirus B4 or the G glycoprotein of rabies (58,240).

Because it appears that attenuation can be achieved with even a small number of mutations in certain circumstances, it should now be possible using modern molecular techniques to introduce the requisite number of attenuating missense mutations into a virulent or partially attenuated virus to produce a vaccine virus that has a stable attenuation phenotype (327). Missense mutations can be combined with attenuating deletion mutations to fine-tune the level of attenuation while maintaining a high level of stability of the attenuation phenotype that will allow use even in immunocompromised persons.

Deletions

Deletion mutations that represent either partial or complete deletion of a given protein sequence can attenuate a virus for its host. Deletion mutations can be used in several ways to construct candidate vaccine viruses. First, deletion mutations can be produced in one or more genes that are not required for replication *in vitro* to attenuate the virulence of the virus for its host (67,166,276). Second, a protein that mediates a specific function in the host that would be undesirable in a vaccine virus can be deleted—for example, a gene encoding neurovirulence for a herpes virus or a gene encoding a protein involved in immune evasion. The use of deletion mutations as the basis for the attenuation of a vaccine virus has appeal because this form of mutation cannot be corrected directly as this would require restoration of deleted sequence. Although phenotypes specified by a deletion mutation can be modified by a suppressor mutation or by another genetic mechanism such as a sequence duplication (20,38,310), attenuation specified by an appreciable deletion is more stable than that specified by a single missense mutation.

To be useful in construction of live vaccine viruses, deletion mutations should restrict virus replication *in vivo* while permitting virus to grow efficiently *in vitro* during vaccine production. This is most easily achieved for poxviruses, herpesviruses, and adenoviruses, whose large genomes encode a number of functions that are not essential for virus replication *in vitro*, but it also has been accomplished for RNA viruses that bear genes that encode accessory functions (138,325). Furthermore, deletions have been introduced in noncoding regions of a viral genome to achieve attenuation without greatly restricting replication (178).

Attenuating deletion mutations can be designed to abrogate specific undesirable functions of a virus. The function of immune evasion genes can be deleted via mutation, resulting in attenuation *in vivo* (163) or in an increased susceptibility to immune mediators of protection (163,210). Deletion of specific genes of HSV can (a) reduce the number of latently infected neurons, (b) decrease the frequency of reactivation from latency, (c) or decrease neurovirulence while maintaining efficient replication *in vitro* (66,130,301).

Insertions

A virulent virus can be attenuated by the insertion of genes that encode proteins with known antiviral activities or with known immunoregulatory functions, such as interferons, interleukins (ILs), or tumor necrosis factor (31,84,147). Such recombinant viruses encode foreign proteins that function to restrict replication of the virus, and this results in attenuation of the virus for its host. Vaccine candidates possessing insertions that provide antiviral activity must be produced in cells that are refractory to this activity. Some DNA or RNA viruses bearing such attenuating foreign immunomodulatory proteins have been found to be satisfactorily attenuated in animals, with some recombinants even being highly attenuated for immunodeficient animals (31,84,147). It is also possible to augment immunogenicity of a candidate vaccine by inclusion of desired ILs—for example, inclusion of IL-5 or IL-6 in a vaccinia virus increased mucosal IgA responses to vaccinia virus (243). Usually, the restriction of replication imposed by the cytokine insertion decreases immunogenicity; however, for RSV, insertion of the interferon-g gene attenuated the virus while retaining a vigorous humoral immune response (31). Rapid attenuation of many viruses can now be achieved in a single step by the simple insertion of one or more specific attenuating cytokines. However, the genetic stability of the insert following manufacture and use in humans remains an issue.

Attenuating Mutations Introduced into Noncoding Regions

It is possible to attenuate a virus for its host by introduction of mutations into the 5' or 3' noncoding regions of the genome as well as into other cis-acting noncoding regions of the genome. These noncoding regulatory regions contain cis-acting signals required for efficient replication, transcription, and translation that represent target sites for modification of these functions by mutation. Attenuating mutations in these cis-acting regulatory regions can result in (a) a tissue-specific attenuation (108,339), (b) increased sensitivity to interferon (339), (c) temperature sensitivity (326), (d) a general restriction in level of replication (178,208), and (e) host-specific restriction of replication [e.g., a dengue virus that replicates in mammals but not in mosquitoes (34)]. These attenuating mutations can be achieved by point mutations,

exchanges of sequences between related viruses, or deletions.

Host-Range Mutations: The Jennerian Approach

The Jennerian approach to the development of live attenuated viruses has been successfully employed to develop the recently licensed rotavirus vaccines (see preceding) and is being explored to develop vaccines for PIV types 1 and 3 and for HAV (76,125,136). In each case, the animal virus is antigenically related to the human virus, and infection of experimental animals with the animal strain induces resistance to the human virus. The Jennerian approach to the development of live attenuated vaccines for influenza A viruses was attempted, but it failed to produce a consistently attenuated vaccine for use in humans (283).

Attenuation by Gene Incompatibility

The proteins of the PB2, PB1, and PA influenza virus polymerase complex function as a unit, performing a variety of biochemical activities. These proteins must be compatible with each other to function efficiently. Disruption of this compatibility can bring about attenuation. An example of the use of this strategy to produce an attenuated vaccine candidate is an influenza A reassortant virus derived by mating an avian influenza virus with a human influenza virus (287). This reassortant, which possesses a mixed polymerase complex, with the PB1 and PA genes derived from the human influenza A virus parent and the PB2 gene derived from the avian influenza A virus parent, was attenuated in humans. It replicated efficiently in avian tissue but grew poorly in mammalian cell culture and in the respiratory tract of humans. Incompatibility of polymerase genes also contributed to the attenuation of influenza A/PR/8/34 reassortants for humans (86). The phenomenon of gene incompatibility resulting in attenuation is also seen with DNA viruses. Intertypic recombinants between HSV-1 and HSV-2 often exhibit decreased neurovirulence for experimental animals compared with either parent (112,131,302).

Antigenic Chimeric Viruses

Live attenuated antigenic chimeric virus vaccines possess the protective antigens of a virus against which the vaccine is directed, plus the remaining coding and noncoding regions of another related virus that bears attenuating mutations. Live attenuated antigenic chimeric viruses comprise three of the four components of the quadrivalent licensed rotavirus vaccine. Each of the three antigenic chimeric viruses contains the attenuating backbone of 10 genes of the rhesus rotavirus plus the gene for a human VP7 serotype 1, 2, or 4 protective antigen. Similarly, the live attenuated influenza virus vaccine candidates are antigenic chimeric viruses that are antigenically updated annually by replacement of the HA and NA genes of the attenuated donor virus with those of a new epidemic or pandemic virus.

Recombinant DNA technology is actively being used to construct live attenuated antigenic chimeric virus vaccines for flaviviruses and for paramyxoviruses. For flaviviruses, a live attenuated virus vaccine candidate for Japanese encephalitis virus (JEV) has been made by the replacement of the premembrane (prM) and envelope (E) regions of the attenuated YFV with those from an attenuated strain of JEV. The JEV-YFV antigenic chimeric recombinant vaccine candidate was attenuated and immunogenic *in vivo* (110). Both components of this chimeric virus have come from an attenuated virus. Other strategies for developing live attenuated antigenic chimeric flaviviruses are also being pursued. Antigenic chimeric recombinant candidate vaccines have been made between a naturally attenuated tick-borne flavivirus (Langat virus) and a wild-type mosquito-borne dengue 4 virus, and the resulting recombinant was found to be significantly more attenuated than its tick-borne parent virus for mice (237). This is an example of an attenuating effect that stems from partial incompatibility between the two components of the chimeric virus.

A third strategy is being pursued for the production of a quadrivalent dengue virus vaccine in which a dengue 4 backbone containing an attenuating deletion mutation in the 3' noncoding region is used to construct antigenic chimeric viruses containing the protective antigens of dengue 1, 2, or 3 viruses (28,178). An antigenic chimeric virus containing the HN and F protective antigens of PIV-1 substituted for those of an attenuated PIV-3 virus has been constructed and shown to be attenuated and protective in experimental animals (292). This strategy is currently being pursued to make vaccines effective against PIV-1, -2, and -3.

VIRAL VECTORS

Replication-Competent Viruses as Vectors

Stable attenuated viruses, some of which have been used as vaccines in humans, are being used to construct viable recombinants that express the protective antigens of other viruses. The use of a viral vector for immunization has the general advantage that the foreign viral antigens are expressed naturally in the context of an infected cell, thereby inducing cellular as well as humoral immune responses. To date, the most success has been achieved using vaccinia virus as the recombinant vector (193). This virus has a large genome into which a variety of foreign viral genes can be inserted and expressed without seriously compromising the capacity of vaccinia virus to replicate. Recombinant vaccinia viruses expressing the protective antigen (or antigens) of a large number of viruses have been constructed and have been shown to be protective in experimental animals. Polyvalent live vaccinia virus recombinants have been used to successfully immunize experimental animals, even in the presence of immunity to one of the foreign viral antigens (85), and vaccinia–rabies virus recombinants are being used to control rabies in foxes (228). Unfortunately, vaccinia virus recombinants are not sufficiently attenuated for use in an immunocompromised host such as persons with HIV infection (82,247), and hence more attenuated poxvirus vectors were sought. A modified vaccinia virus Ankara (MVA), which was derived by more than 500 passages in chick embryo cells (181), has been evaluated as a vaccine vector for a variety of viral antigens. MVA is a highly attenuated host-range mutant that replicates well in avian cells but not in most mammalian cells, including those of monkeys and humans (23,39,71). MVA is nonpathogenic in immunocompromised hosts and has been administered to large numbers of humans without incident (172,285,324). Attenuation of the MVA recombinant resulted from the extensive deletions that the viral genome sustained during its many passages in embryonated eggs (8), and in this regard it resembles other further attenuated derivatives of vaccinia virus that have been attenuated by

extensive targeted deletions (223). Use of avian poxviruses, referred to as avipox viruses, as vectors represents a second type of host-range restricted poxvirus vector. Avipox viruses are naturally occurring host-range restricted viruses that are deficient in replication in mammalian cells and mammal hosts (223). Each of these poxvirus vectors has the property of efficient replication *in vitro* in avian cell culture but restricted replication in primates.

Although each of these poxvirus vectors is safe for immunodeficient persons, they, and most other viral vectors, have two other additional obstacles to overcome. The first obstacle is that vaccinees eventually develop immunity to the vector backbone itself, which restricts use of the vector to a limited number of immunizations (224). It is possible in certain circumstances to overcome this immunity (induced by previous parenteral immunization with a poxvirus) by readministration of vaccine by a mucosal route rather than a parenteral route (18). The second obstacle is that the immunity induced in primates by poxvirus vectors is often less than optimal (61), and additional research is required to optimize immunogenicity by coexpressing various cytokines and immunostimulatory molecules. The role that these poxvirus vectors will have in virus vaccines of the future remains to be defined, but it will depend in part on the success of efforts to augment immunogenicity.

A variety of other viruses that are being considered for use as vectors include adenoviruses (30,185) and rhabdoviruses (251), each of which has one or more features that offer specific advantages for its use as a replication-competent vector. It is likely in the future that such vectors will find use in immunization against viruses to achieve defined goals in immunization against specific diseases.

Replication-Defective Viruses as Vectors

Replication-defective virus vectors have had genes deleted that are essential for replication *in vitro* or *in vivo*. Replication-defective viruses can replicate to high titer in cell lines engineered to express the protein encoded by the deleted gene. The viruses produced in such complementing cells can infect cells *in vivo* but are unable to support multicycle replication. Such vectors undergo an abortive infection *in vivo* but express the foreign protein during this abortive infection and can thereby present antigens efficiently to both the humoral and cellular arms of the immune response. Such nonreplicating vectors would be expected to be safe in the immunosuppressed host.

Adenoviruses that lack the EIA gene replicate to high titer in the 293 cell line that constitutively expresses the EIA-encoded proteins (185,303). This type of defective adenovirus recombinant is prepared by inserting a foreign gene encoding viral protective antigens into the EIA region and then growing the adenovirus recombinant in 293 cells. Immunization of experimental animals with replication-defective recombinant adenoviruses has protected the animals against viral challenge (185,303).

Replication-defective HSVs have been produced in a manner analogous to that of the EIA-deficient adenoviruses—that is, they have had one or more genes deleted that are essential for replication, but replication *in vitro* is supported in a cell line that constitutively expresses the essential protein (26,62,63,119,189). In contrast to the EIA-deficient adenoviruses, the replication-defective HSVs are primarily being developed as vaccines to protect against disease caused by HSV itself rather than as a vector of foreign viral proteins. An immune response is induced not only to the antigens present in the input virus but also to the viral gene products expressed during the abortive infection *in vivo*. Such a replication-defective HSV could also be used as a vector of foreign viral proteins.

Replication-deficient alphavirus particles that cannot undergo multicycle replication *in vivo* have been generated (see preceding section on eukaryotic expression systems). Importantly, the high efficiency of the replicon amplification system *in vivo* permits a high level of expression of foreign protein *in vivo*, which induces a strong and effective immune response. The *in vitro* expression system has been modified to include the replicon along with two helper RNAs engineered to minimize the possibility of generating replication-competent alphavirus through recombination (241,273). Cell lines are being engineered to express various components of this tripartite system to increase the quantity of replication-defective virus generated *in vitro*. Replication-defective alphavirus vectors have induced a significant immune response, both cell-mediated and humoral, to a variety of viral proteins (118,241). Importantly, successful immunization to multiple pathogens has been achieved by sequential immunization (241). These replication-deficient alphavirus vectors offer promise for the development of future vaccines.

COMBINED USE OF LIVE AND NONLIVING VIRUS VACCINES TO ACHIEVE OPTIMAL PROTECTION

Sequential immunization with inactivated poliovirus vaccine followed by live attenuated virus vaccine was previously recommended for use in the United States to replace the three doses of the live virus vaccine that were in use. Several factors have contributed to this change. The live poliovirus vaccine causes paralytic disease very rarely in vaccinees or contacts, but since polioviruses have been eradicated from the Americas (except for the sporadic occurrence of imported cases), the vaccine-associated cases have received much more scrutiny. Since the vaccine-associated cases are seen predominantly following the first dose of vaccine, it was hoped that the use of the enhanced-potency inactivated poliovirus vaccine for the first several doses would induce sufficient immunity to abrogate even the rare cases of vaccine-associated polio caused by the live virus vaccine. Thus, the inactivated vaccine is used to protect against the rare cases of CNS infection caused by the live virus vaccine. The live virus is used because even the enhanced potency vaccine, in contrast to the live virus vaccine, provides relatively weak protection in the gastrointestinal tract (187,234). The live-virus vaccine is needed to optimize immunogenicity in the individual and to provide herd immunity to the population by inducing sufficient mucosal immunity to prevent the spread of imported strains of poliovirus. Currently, only the inactivated poliovirus is recommended for use in the USA.

Simultaneous administration of two different influenza virus vaccines to elderly subjects, namely, an intranasally administered live attenuated influenza A virus candidate vaccine and a parenterally administered licensed nonliving virus vaccine, induced greater resistance to illness than did administration of the inactivated virus vaccine alone (309). In this situation, the greater immunogenicity of the live virus vaccine in the respiratory tract coupled with the greater efficiency of

the inactivated virus vaccine in stimulating systemic immunity appear to act in concert to optimize efficacy. Sequential immunization with a live attenuated virus alphavirus vaccine candidate followed with a boost with an inactivated virus vaccine induced higher levels of antibody than live virus alone (235). A replication-defective HSV vaccine was found to be most immunogenic when administered by both parenteral and mucosal routes, indicating that the same virus preparation can be given by a combination of routes to achieve optimal protection (189).

For viruses that are relatively weak immunogens, such as HIV, various strategies are being explored to optimize immunogenicity by employing different types of immunogens in a sequential immunization regimen referred to as a prime-boost immunization schedule. The components of this strategy include vectored antigens or DNA vaccines, followed, in one scenario, by a boost with a purified protein vaccine (49,114,162,253). This varied-component, sequential immunization schedule is designed to stimulate multiple components of the immune system using different forms of the immunogen to attain a protective immune response.

SUMMARY

Over the next decade, it is likely that a large number of new viral vaccines will be successfully introduced. This increase will stem largely from the contribution that recombinant DNA technology has made to the generation of many candidate live and nonliving virus vaccines currently being evaluated in experimental animals and in humans. Vaccinologists of the future will have a greatly expanded choice of vaccine strategies, including the use of various combinations of different vaccines to achieve optimal protection.

CHAPTER 17 Virus Vectors and Their Applications

Alexander Pfeifer and Inder M. Verma

Gene therapy is a novel form of molecular medicine that is likely to have a major impact on human health in the coming century. Rarely has a medical technology elicited so much excitement, although that excitement is tempered by unfulfilled expectations. Excitement originates from the simplicity of the concept—introduce the gene and its product should have the ability to correct a genetic disorder and slow the progression of a disease. Disappointment stems from the inability to execute this task. How does one deliver genes into a wide variety of cells, organs, and whole animals? How long is the foreign gene expressed in its new milieu? Are there adverse immunologic consequences of both the delivery vehicle and its cargo? The quest for the perfect delivery vehicle is still incomplete!

The currently available delivery vehicles fall into two categories: The first consists of viral vectors, which take advantage of a variety of naturally occurring viruses to shuttle the foreign cargo either to be integrated permanently into the host's chromosome or to masquerade as an autonomous unit. The second category of delivery vehicles is made up of the nonviral vectors, which rely on direct delivery of either naked DNA or a mixture of genes with cationic lipids (liposomes). In this chapter, the currently available and widely used viral vectors, and their advantages and limitations, will be discussed.

RETROVIRAL VECTORS

Retroviruses can be classified into two categories (160): Simple retroviruses, encompassing the murine leukemia–related viral group [e.g., murine leukemia virus (MuLV)], and a group of complex retroviruses such as lentiviruses [e.g., human immunodeficiency virus (HIV)]. Gene therapy vectors have been developed from both groups of retroviruses and will be covered in separate sections.

Retroviral vectors based on MuLV were the first viral vectors to be used in a gene therapy trial that started a decade ago, with the aim to treat two children suffering from severe combined immunodeficiency (SCID) (16). Although the efficacy of this treatment and whether the disease was indeed cured by gene therapy could not be clearly ascertained because the patients received supportive conventional therapy during the trial, the retroviral gene transfer into the target cells (T cells) was partially successful.

Further underlining the potential of this class of gene delivery vehicles is the success of a clinical trial that resulted in the full correction of a disease phenotype (24). In this trial, CD34+ bone marrow cells were isolated from SCID patients and infected *ex vivo* with a MuLV-based retroviral vector carrying the cytokine receptor gene, which is mutated in these SCID patients. Cavazzano-Calvo et al. (24) were able to demonstrate expression and function of the transgene over a 10-month period, and most important, they showed the development and sustained function of the immune system, resulting in clinical improvement of the patients receiving gene therapy.

In principal, gene therapy vectors are either replication competent or they are rendered replication defective by deletion of essential viral genes from the vector. Replication-defective vectors are able to perform only one initial infectious cycle within the target cell. Although replication-competent retroviral vectors have been designed—especially in the early days of vector development—that are able to productively infect the target cell (106), replication of the viral vectors is unwanted in most gene therapy approaches, to avoid spreading of the recombinant virus.

Replication-Defective Retroviral Vectors

Most of the retroviral vectors (106, 176) presently used in gene therapy approaches are derived from MuLV. To generate replication-defective MuLV, all of the protein-encoding sequences are removed from the virus and replaced by the transgene of interest (Fig. 1A, Fig. 1B). However, the sequences required for encapsidation of the vector RNA [i.e., a packaging signal (Y)] have to be included in the vector construct. The absolute minimal MuLV packaging signal has been narrowed down to a region encompassing bases 215 to 355 (96, 97). In addition, the 5' end of the *gag* gene has been shown to carry sequences that are required for efficient encapsidation of the vector RNA. Inclusion of this region

[nucleotides 215 to 1,039 (10)] resulted in so-called Y^+ or gag^+ vectors with a 50- to 200-fold increase of vector titers (7,10) compared to vectors containing only the minimal Y signal. To ensure reverse transcription and integration of the vector DNA into the host genome, the long terminal repeats (LTRs), the primer transfer RNA (tRNA) binding site (PBS), and the polypurine tract (PPT) have to be incorporated into the vector construct (see Fig. 1B). The proteins needed for production of infectious viral particles can be supplied in trans in packaging/producer cells (see next section, Packaging of Retroviral Vectors).

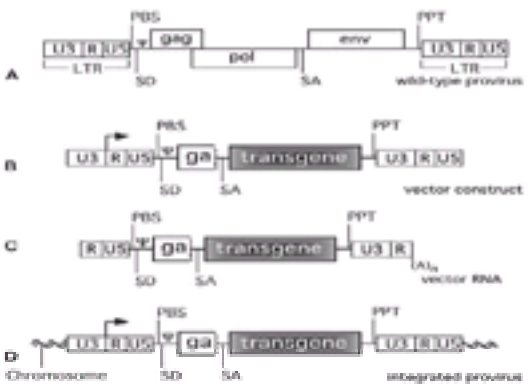

FIG. 1. Retroviral vectors. **A:** Schematic representation of the retroviral provirus. PBS, primer binding site; SD, splice donor; Y, packaging signal; SA, splice acceptor; PPT, poly purine tract; LTR, long terminal repeat. **B:** Retroviral vector. The transgene replaces the viral genes and is flanked by the retroviral LTRs. Apart from the minimal packaging signal (Y), portions of 5' *gag* sequences are included to increase packaging efficacy. **C:** Vector RNA packaged into virions in the producer/packaging cells. **D:** Integrated provirus. The transgene of interest is transcribed from the promoter/enhancer region within the U3 of the 5' LTR (*arrow*).

Although the retroviruses and their genomic organization is described in detail in Chapter 57, Chapter 58, Chapter 59, Chapter 60, Chapter 61 and Chapter 62 the life cycle of a retroviral vector is briefly summarized here (see Fig. 1B,Fig. 1C and Fig. 1D). The vector DNA is transcribed into RNA in the producer cells and packaged into viral particles. The promoter/enhancer regions of the 5' U3 region are not transcribed, and the U5 sequences of the 3' LTR are replaced by a polyadenylation [poly(A)] tail as a result of the presence of a poly(A) signal in the R region (see Fig. 1C). In the infected cell, the vector RNA genome is reverse transcribed and the provirus DNA integrates into the host genome. The U3 regions of the 5' and the 3' LTR of the provirus are derived from the U3 regions of the 3' LTR originally present in the vector RNA, and both U5 regions are derived from the 5' LTR originally present at 5' end of the vector RNA (see Fig. 1C,Fig. 1D). This has important practical implications for the vector design. The transgene should not contain a poly(A) signal sequence, as this would lead to the replacement of the 3' U3/R region with a poly(A) tail during transcription of the vector RNA (106). Furthermore, the duplication of the 3' U3 region during reverse transcription is also the basis for the development of self-inactivating vectors (see later).

Several changes of the 5' as well as the 3' LTR region have been introduced into the retroviral vectors to increase vector yield and to improve the biosafety of the vectors, respectively. Among the most important changes concerning the efficacy of virus production is the replacement of the U3 region of the 5' LTR with the immediate-early region of the human cytomegalovirus (CMV) enhancer-promoter (Fig. 2A), which results in a CMV/LTR hybrid that has a high transcriptional activity when introduced into the appropriate cell line (47), such as human embryonic kidney (HEK) 293 cells. This cell line expresses the adenoviral E1 gene products (59), which have been shown to superactivate the CMV promoter (55). After transient transfection of CMV/LTR vectors (47,120) together with CMV-driven packaging constructs (47,120) in 293 cells, this vector system yielded titers that were 100-fold higher than those obtained with retroviral vectors carrying the parental MuLV 5' LTR.

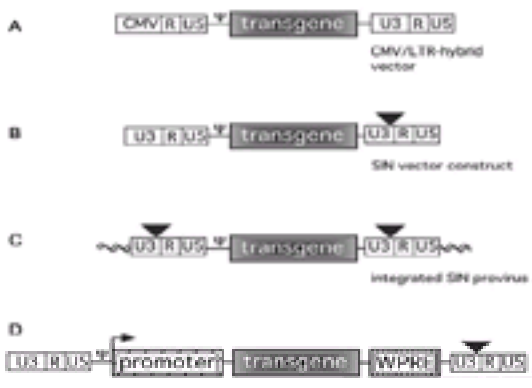

FIG. 2. Retroviral vector development. **A:** The CMV/LTR-hybrid vector system [e.g., r*kat* or pCL vectors (47,120)] allows a high-titer vector production in 293 cells. **B,C:** Retroviral SIN (self-inactivating) vectors with deletions (*black triangle*) of the promoter/enhancer regions of the 3' LTR of the vector construct, which replaces the 5' U3 region in the final integrated SIN provirus. **D:** An internal, heterologous promoter can be included in the vector construct to increase transgene expression in the target cell and/or to restrict transgene expression to certain cell types and tissues. To avoid interference with the promoter/enhancer of the viral LTRs, a SIN vector can be used. Incorporation of the WPRE into the vector enhances transgene expression.

To improve the biosafety of the retroviral vectors, deletion mutations were introduced into essential regions of the 3' LTR. Because the U3 promoter/ enhancer region of the 5' LTR of the integrated provirus is derived from the 3' LTR of the vector construct, deletion of promoter activity from the 3' LTR should be carried over to the 5' LTR during reverse transcription in the target cell (see Fig. 2B, Fig. 2C). This concept of transcriptional inactivation of the provirus is also termed self-inactivation, and these vectors are known as SIN (self-inactivating) vectors (178,182). Because the transcriptional activity of wild-type LTRs can affect the expression of host proto-oncogenes, the SIN strategy is a major improvement in the biosafety of the vectors. The drawback of the inactivation of the transcriptional regulatory elements of the proviral LTRs is a substantial loss in viral titer, which was at least 10- to 100-fold lower than the parental retroviral vector (178,182). On the other hand, partially disabled vectors (178) with an intact TATA box still exhibit a low level of LTR-driven transcription (0.1% to 1%).

The use of SIN vectors may be necessary to avoid interference of the viral promoter and enhancer regions with internal promoters of the vector in the target cells. In the most simple vector design, the 5' LTR of the integrated provirus drives the expression of the transgene (see Fig. 1D). To achieve a higher level of transgene expression and/or specific expression in certain cell types and tissues, heterologous promoters can be placed internally in the retroviral transcription unit to drive transgene transcription (see Fig. 2D). However, the transcriptional activity of the proviral 5' LTR can interfere with the activity of internal promoters (42). Thus, elimination of the promoter and enhancer functions of the proviral 5' LTR may be necessary, and this can be achieved by using SIN vectors (see Fig. 2D).

Another improvement of transgene expression can be achieved by inclusion of cis-acting posttranscriptional regulatory elements (PRE) (186). PREs are present in herpes simplex and hepatitis B virus, and the latter has been shown to enhance expression of a heterologous cDNA (e.g., b-globin cDNA). Incorporation of the PRE of the woodchuck hepatitis virus (WPRE) 3' of the transgene (see Fig. 2D) increased gene expression at least fivefold in MuLV-derived vectors (186). Interestingly, the enhancement of transgene expression by the WPRE was independent of the cell type or the cell cycle status of the target cells (186). The precise mechanism of WPRE function remains unknown.

Packaging of Retroviral Vectors

To package the replication-defective vector into virions, the viral proteins required are provided in trans in the packaging cell (Fig. 3 and Fig. 4). Retroviral packaging constructs are either transfected transiently into the packaging cells, or a cell line is established that stably expresses the viral proteins. The first-generation packaging cell lines (such as Y-2) carried a mutant MuLV virus with deletion mutations of the essential Y sequence (97) (see Fig. 3B). Deletion of Y results in a dramatic reduction of encapsidation of MuLV. In addition, the host range of vector particles produced by this packaging cell line was rather small. The tropism of MuLV is defined by Env and the species distribution of its receptor (see Chapter 57). Ecotropic viruses—such as MuLV—can infect only murine cells that express the receptor for Env [a sodium-independent cationic amino acid transporter (2)]. Since Y-2 cells carry the ecotropic *env* of MuLV, only murine cells could be infected with viral vectors produced by these cells. The host range of the vectors can be expanded by replacing the MuLV *env* gene with envelope sequences from amphotropic viruses (see Chapter 57; and refs. 32,108). These chimeric retroviruses contain *gag* and *pol* sequences from MuLV and the *env* gene from the amphotropic viruses (e.g., 4070A) (see Fig. 3B). Transfection of NIH3T3 with these chimeric packaging constructs, which lack the encapsidation signal, together with a retroviral vector, resulted in the production of high-titer [>10^5 transducing units (T.U.)/mL] stocks of helper-free recombinant retrovirus with amphotropic host range, able to infect murine and human cells (32).

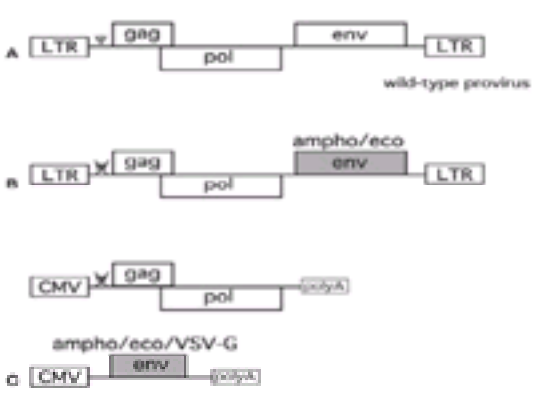

FIG. 3. Retroviral packaging system. **A:** Schematic representation of the wild-type retroviral provirus. **B:** First-generation packaging strategy with deletion mutations of the packaging signal (Y). Replacement of the wild-type *env* gene (*eco*) with, for example, amphotropic *env* (*amph*) results in a broadened host range. **C:** Split-genome packaging strategy: *gag*/*pol* and *env* are encoded on separate plasmids.

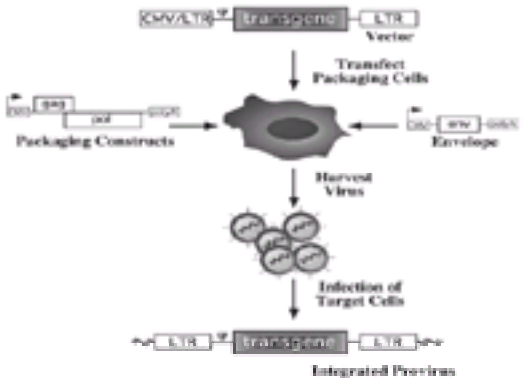

FIG. 4. Production of retroviral vector particles. Retroviral vectors can be produced by transient co-transfection of the vector plasmid (containing a hybrid CMV-LTR promoter/enhancer at the 5' LTR position) with packaging constructs (coding for *gag* and *pol*) together with the envelope plasmid (a total of three plasmids are transfected) into packaging cells (e.g., 293 cells). The CMV promoter drives the expression of the different expression cassettes in the packaging cells. After infection of the target cells, the integrated provirus containing the foreign gene is transcribed from the 5' LTR.

An important biosafety issue of these early generations of packaging systems was contamination with replication-competent recombinants (RCRs), also called helper viruses. This problem was addressed by introducing further deletions into the packaging construct: the 3' LTR and the PPT site (see Fig. 1A) were replaced with the simian virus 40 (SV40) poly(A) signal (107). Thus, in the rare case of encapsidation of the packaging construct into infectious virions, the packaging RNA will not be completely reverse-transcribed because it lacks the site for initiation of second-strand DNA synthesis. In addition, the 5' end of the 5' LTR that contains the cis-acting signal sequence required for integration (also called *att* element; see Chapter 57 for details) was removed. This deletion mutation should prevent integration of recombinant viruses that contain the 5' part of the packaging construct. However, there was still a considerable amount of homology between the packaging construct and the retroviral vector, which could lead to the production of helper virus after a single recombination event between the two plasmids. Therefore, a packaging strategy based on split packaging constructs, one containing the *gag* and *pol* genes and the other carrying the *env* gene, was introduced (see Fig. 3C) (36,98). Splitting the packaging genome into multiple units not only increases the safety of retroviral vectors, but also facilitates pseudotyping of retroviral vectors with the envelope of other viruses, because different envelope genes can be included in the packaging cells by a simple exchange of the envelope construct.

A major hurdle for the use of retroviral vectors in human gene therapy was that virions, which incorporated ecotropic or amphotropic envelope proteins, could be concentrated only with a very low efficiency and labor-intensive protocols. Importantly, these virions could not withstand the shear forces of ultracentrifugation. It was previously shown that MuLV could be pseudotyped with the G protein of the vesicular stomatitis virus (VSV-G) (43). VSV-G mediates viral entry by membrane fusion via the interaction with phospholipid components of the cell membrane, and therefore it has a broad host range. Additionally, VSV-G-pseudotyped vectors can be concentrated 100- to 300-fold by ultracentrifugation to titers above 10^9 infectious units (IU)/mL (21). The major disadvantage of using VSV-G as an envelope is its toxic effects in the packaging cells, especially as high levels of VSV-G expression are required for high-titer virus production (21). The packaging cells express the VSV-G protein also on their cell surface, which leads to the formation of syncytia and cell death after several days of transfection with the VSV-G plasmid (21). Because of the toxicity of VSV-G, attempts to produce retroviral vectors from cell lines stably expressing VSV-G failed until inducible expression strategies (26,124) were developed using the tetracycline-repressed regulatable system (TrRS) (57).

The TrRS is based on the tetracycline resistance operon of *Escherichia coli* and combines the specificity of the tet repressor (tetR) for the tet operator sequence (*tet*O) with the activity of the herpes simplex virus transactivator (VP16) in eukaryotic cells. A conditionally active tetracycline transactivator (tTA) was created by fusion of the C-terminus of VP16 to the C-terminus of the tetR protein. Alternatively, tetR can also be fused to the ligand-binding domain of the estrogen receptor, leading to hormone-dependent function of the fusion protein (26). In the absence of tetracycline, the tetR domain of tTA binds to a tetracycline-regulated promoter (tRP), consisting of seven *tet*O repeats placed upstream of a minimal CMV promoter, and activates transcription of the transgene. Binding of tetracycline to tTA leads to a conformational change and highly reduced affinity of tTA for tRP, and the transgene expression is switched off. This strategy is also known as tet-off system (see Fig. 5D). The tetracycline system exhibits an impressive degree of regulation and can be turned off and on within 24 hours (77). The two components of this regulatory system, the transactivator tTA and the regulated promoter tRP, together with the VSV-G expression cassette were transfected into 293 (HEK) cells that stably express *gag* and *pol* [293GP cells (21)], and stable clones were selected (26,124). Finally, the retroviral vector is introduced into the stable packaging cell clones, either by infection with a recombinant virus (SIN vectors cannot be used for this purpose) or by transfection of the vector construct. Withdrawal of tetracycline induces a VSV-G expression in the packaging cells (26,124), with maximal virus production between 48 and 96 hours after removal of tetracycline (124).

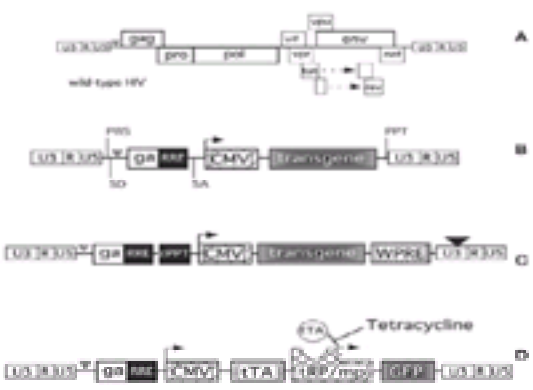

FIG. 5. Lentiviral vectors. **A:** Schematic representation of the wild-type HIV provirus. **B:** Lentiviral vector containing the lentiviral LTRs, a packaging signal (Y), the primer tRNA binding site (*PBS*), and a polypurine tract. 5' *gag* sequences and the Rev-responsive element (*RRE*) are included to increase packaging efficacy and to allow efficient transcription and cytoplasmic export of full-length vector transcripts. **C:** The most advanced lentiviral vector construct with improved performance is a result of the incorporation of a central polypurine tract (*cPPT*) to enhance nuclear translocation of the vector in the target cell. In addition, the WPRE is included to improve transgene expression in the target cell and deletions in the U3 region of the 3' LTR (*triangle*) to achieve self-inactivation of the vector in the target cell. **D:** Lentiviral vector incorporating the tetracycline-regulated system. The vector contains the tetracycline transactivator (*tTA*) (a fusion of tetR and VP16) and the tetracycline-regulated promoter (*tRP*), consisting of *tet*O repeats placed upstream of a minimal

CMV promoter (*mp*). Expression of the tetracycline responsive elements is driven by a CMV promoter. Binding of tetracycline to tTA inhibits tRP-dependent gene expression; the transgene (e.g., GFP) expression is switched off.

Taken together, the recent improvements of the retroviral vector and packaging system are important steps toward using retroviral vectors for gene therapy trials in humans. The stable packaging cell lines allow the standardized production of retroviral vectors that can be screened for the presence of helper virus contamination. The split-genome approach to packaging (see Fig. 4) is an important safety feature that reduces the risk of such contamination. Pseudotyping of the virions with VSV-G broadens the host range and allows concentration of the virus with easy ultracentrifugation protocols. The toxic effects of the VSV-G protein in the packaging cells can be controlled by inducible expression strategies (e.g., the tetracycline-regulated system). The development of human-derived packaging cell lines (based on 293 cells) allows the production of clinical-grade virus preparations and offers several advantages over the—so far—frequently used NIH3T3 cells: Human-derived cells do not harbor a large number of endogenous retroviral genomes that could participate in recombination events to generate replication-competent viral mutants (147). Retroviral vectors produced from murine cells have been shown to be inactivated by human serum (natural antibodies and complement). The use of vectors that carry a CMV–LTR hybrid (see Fig. 2A) and CMV-driven packaging constructs (see Fig. 3C and Fig. 4) in 293 cells makes use of the fact that 293 cells express the adenoviral E1A protein, which stimulates of CMV-dependent transcription.

Furthermore, transient transfection of the viral vector, the packaging construct (carrying *gag* and *pol*), and the envelope construct (e.g., VSV-G) into 293 cells is a suitable way to generate high-titer (>10 ^{9} IU/mL) preparations of many different viral vectors for laboratories that work on animal models for gene therapy (177).

LENTIVIRAL VECTORS

Lentiviruses belong to the family *Retroviridae*, whose characteristics—virion structure, genome, replication strategy, and host spectrum—are described in detail in Chapter 59, Chapter 60 and Chapter 61. An important genetic difference between simple retroviruses and lentiviruses is the presence of regulatory (*tat* and *rev*) and auxiliary genes (*vpr*, *vif*, *vpu*, and *nef*) that have important functions during the viral life cycle and are relevant for lentiviral pathogenesis.

In contrast to simple retroviruses, lentiviruses are able to infect nondividing, terminally differentiated mammalian cells. This feature of lentiviruses makes them a very attractive tool for gene delivery (119,159).

The development of lentiviral vectors is based on the techniques and strategies developed for vectors studied in simple retroviruses. Previous experiences with retroviral vectors proved to be very helpful in the development of lentiviral vectors.

Replication-Defective Lentiviral Vectors

Like murine retroviral vectors, replication-deficient lentiviral vectors were designed by splitting the viral genome into cis- and trans-acting components necessary for gene transfer into the target cells (Fig. 5 and Fig. 6). The viral proteins required for the infection of the target cells are provided in trans by producer/packaging cells, which package the transfer vector that contains the transgene into infectious viral particles. In the vector constructs, the transgene is flanked by viral LTRs that contain cis-acting sequences necessary for packaging, integration, transcription, and polyadenylation (see Fig. 5).

FIG. 6. HIV-derived packaging constructs. **A:** HIV-1 provirus. **B:** First-generation packaging plasmid. The reading frames of *env* and *vpu* are blocked, and the 5' and 3' LTRs are replaced with the CMV promoter and a polyadenylation [poly(A)] site, respectively [e.g., pCMVDR9 (118)]. **C:** Deletion of *env*, *vif*, *vpr*, *vpu*, and *nef* resulted in the second generation of packaging construct [e.g., pCMVDR8.91 (188)]. **D:** Tat-free, nonoverlapping split genome packaging system. In this third generation of an HIV-based packaging system, *gag* and *pol* are encoded on one plasmid [e.g., pMDLg/pRRE (40)], and *rev* is expressed in trans from another plasmid [e.g., RSV-REV (40)]. **E:** The envelope of the lentiviral vector is provided by a plasmid containing the VSV-G coding region flanked by the CMV promoter and a poly(A) signal [e.g., pMD.G (118)]. Y, packaging signal; RRE, Rev-responsive element; SD, splice donor.

As in the MuLV-based vectors, inclusion of sequences extending further into the *gag* gene (up to 722 nucleotides) significantly increased vector propagation and gene transfer efficiency (19,128). In addition, incorporation of the Rev-responsive element (RRE) of *env* (see Fig. 5B) increases encapsidation and transfer efficacy (128,137). Analysis of the ratio of unspliced to spliced cytoplasmic vector RNAs in packaging cells showed a significant reduction of unspliced

RNA in the HIV-based vectors lacking the RRE compared to vectors containing the RRE (128).

The ability of lentiviruses to infect nondividing and terminally differentiated cells has been extensively studied, but the precise mechanism by which lentiviruses transduce nondividing cells remains elusive. The preintegration nucleoprotein complex (PIC) is recognized by the nuclear import machinery of the target cell and actively transported through the nucleopore (see Chapter 59, Chapter 60, and Chapter 61). HIV-1 contains multiple nucleophilic determinants that allow the nuclear entry of the lentiviral PIC. Three karyophilic proteins have been identified in HIV-1: the *gag*-encoded matrix protein (MA) (20), integrase (IN) (52), and Vpr (69). The MA contains two nuclear localization signal (NLS) motifs (65), and inactivation of both of them renders the mutant virus defective in nuclear transport, even in the presence of Vpr and IN. IN also harbors sequence homologies to NLS (51,130), and mutation of these regions has caused nuclear exclusion of IN but not of the HIV PIC (130). Both MA and IN are included in the HIV-based lentiviral vectors, but the multiply attenuated lentiviral vectors produced with the second- (see Fig. 6C) (188) or third-generation packaging systems (40) (see Fig. 6D) lack Vpr (see later section, Development of Lentiviral Packaging Systems). At least for the gene transfer into the central nervous system, Vpr is completely dispensable, as Vpr-deficient (Vpr^-) vectors transduce a similar number of adult rat neurons as Vpr-positive vectors (75,188). In addition, quiescent human and murine hematopoietic stem cells are transduced by Vpr^- vectors (23,99). However, the requirement of lentiviral accessory genes for the transduction of other cells such as macrophages may differ, as Vpr can rescue the ability of MA NLS-mutant viruses to infect nondividing macrophages (69).

Apart from these karyophilic viral proteins, HIV-1 genomic cis-acting sequences have recently been found to enhance the nuclear DNA import (50,183). In addition to the 3' PPT, located just 5' of the U3 region of the LTR (see Fig. 5B), all lentiviruses contain a central copy of the PPT (cPPT), at which synthesis of the downstream plus strand is initiated (183). Inclusion of the upstream cPPT element (see Fig. 5C) enhances nuclear import of the HIV-1-derived vector genome (50,183). Because the cPPT element is situated in the *pol* gene, the HIV-based gene transfer vectors devoid of *pol* lack this sequence, and the nuclear import of these vectors should be retarded as compared to wild-type HIV-1. Interestingly, *pol*-deficient lentiviral vectors are able to transduce terminally differentiated, nondividing cells such as neurons (118), muscle (75), hepatocytes (75), retinal photoreceptors (112,156), and hematopoietic stem cells (23,111), showing that at least in these cell types the cPPT is not necessary for nuclear import. An important difference between the $cPPT^-$ and $cPPT^+$ vectors is the time course of the transgene expression *in vitro* and *in vivo* and the total amount of protein expression achieved (50): After intravenous injection of $cPPT^+$ vectors carrying a CMV-driven expression cassette encoding human factor IX into SCID mice, the plasma level was twice as high as that achieved after injection of the $cPPT^-$ vector. Interestingly, inclusion of a cPPT has also been shown to enhance two- to threefold the transduction efficacy of simian immunodeficiency (SIV)-based vectors (95). Thus, the inclusion of a cPPT-element into lentiviral vectors improves their performance *in vivo* (50,183).

Enhancement of Lentiviral Transgene Expression

Vector performance can also be improved by increasing transgene expression after integration of the recombinant lentivirus into the host genome using cis-acting transcriptional regulatory elements. Inclusion of the posttranscriptional regulatory element of WPRE in HIV-derived vectors increased the reporter gene (green fluorescent protein [GFP] and luciferase) expression five- to eightfold after transduction of both dividing and arrested 293T cells (186). The WPRE has to be present within the transgene transcript in sense orientation, and it is placed 3' of the transgene cDNA upstream of the 3' LTR (see Fig. 5C).

SIN Lentivectors

As in all retroviruses, the U3 and U5 LTR regions of the lentiviral provirus are derived by duplication of the 5' U5 and the 3' U3 regions of the viral RNA during reverse transcription. Therefore, the same principal used to generate retroviral SIN vectors (see earlier and Fig. 1 and Fig. 2) can be employed for the production of lentiviral SIN vectors. SIN lentivectors (see Fig. 5C) were designed by incorporating extensive deletions (133 to 400 bp) in the 3' U3 region of HIV-1 LTR, leaving intact the *att* element at the 5' end of the U3 that is required for integration into the host genome (110,187). The deleted U3 regions include the TATA box, the three SP1 binding sites, the NFkb sites (110) up to the NF-ATc sites located further upstream, and the so-called negative response element (187). Co-transfection of the SIN vectors with packaging constructs resulted in titers that were similar to those obtained with the original vector plasmid without U3 deletions (110,187). Analysis of the effect of the U3 deletions on SIN lentivirus–derived RNA production in the target cells revealed an almost complete loss of the LTR promoter activity (187). Importantly, using a sensitive virus rescue assay, it was shown that the amount of virus rescued from SIN vector–infected cells was 10,000-fold lower than from cells infected with the parental vector without SIN mutations (110). Thus, the use of SIN vectors reduces the risk of mobilization of integrated provirus by replication-competent virus, minimizing the risk of vector virus spread.

Furthermore, after one round of viral replication, the U3 regions in both LTRs are derived from the U3 region of the 3' LTR (see Fig. 1), thus allowing the replacement of the U3 region of the 5' LTR with the CMV promoter in the vector plasmid (110,187). This modification of the 5' LTR is important because SIN vectors combined with hybrid CMV-LTR contain only one U3 region (with deletions). Thus, recombination to generate a wild-type U3 region is not likely. In addition, replacement of the U3 region of the 5' LTR with the CMV promoter resulted in Tat-independent transcription (110,187). This allows the production of HIV-derived vectors in the absence of Tat (see later).

Regulated Gene Expression

Spatial and temporal regulation of transgene expression would be a highly desirable feature of gene therapy vectors. Among the different regulatory systems that have been developed for use in gene therapy vectors (1), the TrRS (57) offers many advantages and is one of the best characterized regulatable systems (see also Packaging of Retroviral Vectors).

Because lentiviral vectors can package and deliver large transgenes, such as human factor VIII cDNA, a

tetracycline-regulatable lentiviral vector system has been developed (77). In this system (see Fig. 5D), the two regulatory components of the TrRS [i.e., the tTA (tetR/VP16 fusion) and the tRP (*tet*O/minimal promoter)] are encoded on a single vector that also carries the transgene (77). After transduction of 293 cells with the regulatable lentiviral vector carrying a GFP transgene (pCL-CTIG), GFP expression was 500- to 1,000-fold induced by withdrawal of doxycycline from the culture medium (77). Maximal suppression of GFP transcription was achieved within 24 hours of addition of the tetracycline analog. In addition, after transduction of adult rat brain with pCL-CTIG, tetracycline-regulated GFP expression was achieved *in vivo*: Only a low level of GFP expression in a few cells could be detected in the brains of doxycycline-treated animals, whereas the nontreated or doxycycline-removal group demonstrated a very high level of GFP, as far as 2 to 3 mm from the site of virus injection.

So far, only the tetracycline-regulated system has been used in combination with lentiviral vectors, but studies are underway that employ the insect hormone ecdysone (121) or other nuclear hormone receptors as regulatory elements in the context of lentiviral vectors. Also, the rapamycin (FK506) system (138), which has been shown to function in an adeno-associated viruses (AAV)-inducible system (139,175), holds great promise, because it exhibits low baseline expression and a high induction ratio, as well as control by an orally bioavailable small-molecule drug.

Development of the Lentiviral Packaging System

Like retroviral packaging cells, all lentivirus proteins necessary for virus production are provided in trans by packaging plasmids, and virus particles are assembled by expressing viral proteins in producer/packaging cells (see Fig. 4). As a result of biosafety concerns, the packaging constructs lack cis-acting sequences required for the transfer of the viral genome to target cells (see Fig. 6). The aim is to identify the minimal number of viral genes required for efficient virus production and to minimize the number of lentiviral genes present in the packaging plasmids.

The first genuine lentiviral packaging constructs (19,128,133,149) carried a deletion mutation of Y, and/or lacked the 5' and 3' LTRs (which were replaced by the CMV promoter and a polyadenylation signal, respectively). Although deletion of LTR and Y eliminated the sequences crucial for packaging—reverse transcription and integration of transcripts derived from the packaging plasmids—these packaging constructs still contained more than 90% of the HIV genome. Because these initial packaging systems incorporated the endogenous HIV envelope, the host range of these vectors was restricted to CD4-positive cells, and there was a risk of generating wild-type HIV. In addition, only low infectious titers [in the range of 10^1 to 10^2 IU/mL (19,128)] were obtained, and the vector particles could not be efficiently concentrated.

A crucial step for the advancement of lentiviral gene transfer was the incorporation of envelope proteins of other viruses. Dual infection of cells with HIV and a murine amphotropic retrovirus led to the production of HIV virus that carried the amphotropic envelope, demonstrating that HIV-1 can be pseudotyped with heterologous envelopes (151). By using replication-defective HIV-1 mutants that carry deletions of gp160, it was shown that the HIV enevelope can be provided in trans (125). Expression of the envelope gene of an amphotropic virus or of the human T-cell leukemia virus in cells transfected with the gp160-deficient HIV mutant resulted in the production of infectious viral particles (88,125).

Replacement of the HIV envelope glycoprotein with VSV-G (see Fig. 6B,Fig. 6E) expanded the host range of the HIV vectors (117,136). After transient co-transfection of packaging and vector plasmids, the virus can be harvested by collection of the culture medium of the 293T producer cells and concentrated to titers of up to 10^8 IU/mL by using a facile ultracentrifugation procedure (117,136). First-generation, VSV-G pseudotyped lentiviral vectors (see Fig. 6B, Fig. 6E) were able to transduce nondividing, G1/S- and G2-arrested HeLa cells (118). Furthermore, comparison of the transduction efficiency of MuLV-based with HIV-based VSV-G pseudotyped vector in unstimulated human peripheral blood CD34+ cells, which are highly enriched for G0/G1 cells, revealed an eightfold higher number of transduced cells after infection with the lentiviral vector (136). More importantly, lentiviral vectors (10^8 IU/mL) were able to transduce terminally differentiated, nondividing neurons *in vivo* (118).

With an approach similar to that used for HIV-1-based vectors, packaging systems for vectors based on feline immunodeficiency (FIV) (132), SIV (95), HIV-2 (131), and equine infectious anemia virus (123) have been developed, achieving titers (after concentration by ultracentrifugation) in the range of 10^7, 10^7, 10^8, and 10^6 IU/mL, respectively. Because HIV-1-based vectors have been exploited more extensively, we have used them as a model system for discussion of lentiviral vectors.

The initial packaging plasmids contain most of the lentivirus genes except for *env* (see Fig. 6B). In an effort to improve safety, a second version of the packaging system was introduced with extensive deletions of the viral genome (see Fig. 6C). Because it was shown that accessory genes of HIV-1 (*vpr*, *vpu*, *vif*, and *nef*) are not required for efficient production of viral particles (188), a packaging system containing only the *gag*, *pol*, *tat*, and *rev* genes of HIV-1 was developed (75,188). Thus, these packaging constructs are devoid of all the accessory genes required for efficient replication in human cells. HIV-based vectors packaged with this system are able to deliver genes into dividing and nondividing cells *in vitro*, and to transduce adult neurons and muscle *in vivo* (75,188).

In the latest, third generation of packaging strategies, the *tat* gene is deleted (40) (see Fig. 6D). Tat is a strong transcriptional activator of the HIV-1 LTR promoter element and is essential for viral replication (34,41). Tat expression in the packaging cells is necessary for the production of high-titer HIV-vectors (40), because interaction of Tat with the LTR promoter region is essential for the transcription of the vector plasmids in the packaging cells. Transcription from the HIV LTR in the absence of Tat was 10- to 20-fold reduced compared to the levels obtained in the presence of Tat in the first and second generation of packaging systems. This limitation of the Tat-free system was overcome by the inclusion of strong constitutive promoters, such as CMV (40,110) or respiratory syncytial virus (RSV) promoters (40), in the U3 region of the 5' LTR of the vector constructs, resulting in CMV/RSV–HIV hybrid LTRs.

Another prominent feature of the third-generation packaging system is a split genome strategy (40). Initially, only the *gag* and *pol* genes (without the sequences upstream of the *gag* initiation codon) were cloned into one plasmid. However, transfection of this construct resulted in almost no detectable expression (40). Efficient expression was achieved after

Dull et al. (40) inserted the HIV RRE 3' of *pol* (see Fig. 6D) and included the *rev* gene—on a separate plasmid—in the packaging system. This minimized HIV-genome, split-genome packaging strategy is a significant improvement of the biosafety of the viral vectors.

Stable Packaging Cell Lines

Most of the studies using lentiviral vectors published so far rely on transient transfection of packaging and vector plasmids for vector production. Using the highly transfectable 293T cells, one routinely obtains titers of 10^{9} to 10^{10} IU/mL after transient transfection with the latest generations of packaging (containing VSV-G) and vector constructs followed by concentration of the virus particles by ultracentrifugation. However, standardization of the virus production is not easily achieved with transient transfections. Given the problem of possible contaminations of the lentivirus preparations with RCRs and cellular debris (e.g., proteins and lipids shed by apoptotic producer cells), stable producer cell lines may be necessary to address biosafety concerns before HIV-derived vectors are used in clinical trials.

The development of a packaging cell line for lentiviral vectors was curtailed by the fact that VSV-G and some lentiviral proteins inhibit cell proliferation (e.g., Vpr) and/or exhibit cytotoxic effects (Vpr, Gag, and Tat). Because a long-term, stable expression of these proteins is not feasible, cell lines that carry deletion mutations of most of the accessory genes and that do not contain the VSV-G envelope gene were developed (22,33,181). However, these cell lines produced only low-titer virus with a limited host range. A very promising approach to address this problem is the development of cell lines that express the toxic components from inducible plasmids (78,181). The first inducible packaging cell line for the production of HIV-based vectors was described by Yu et al. (181). In this cell line, the expression of HIV genes is regulated by a dual system: HIV *rev* and *env* are encoded on a plasmid that carries the tetracycline-regulated system (see preceding section, Packaging of Retroviral Vectors), whereas the HIV late transcripts Gag, Pol, Tat, and Vif are expressed from a second plasmid that lacks the 3' LTR, Y, and the other HIV proteins. Only in the absence of tetracycline, is Rev expressed, which in turn up-regulates the expression of the other HIV proteins (i.e., Gag, Pol, Tat, and Vif). In the presence of tetracycline, no infectious particles were detected (by measuring reverse transcriptase activity after stable transfection with the vector plasmid) (181), because of the regulatory function of Rev for the expression of late HIV transcripts.

In the packaging cell line developed by Kafri et al. (78), all HIV-1 genes (except the HIV envelope) are transcribed from a single expression cassette that is regulated by the tetracycline-regulated promoter. In addition, the VSV-G gene too is under the control of the tetracycline-responsive system. Withdrawal of tetracycline after transduction with the vector constructs results in the production of vector particles at titers greater than 10^{6} IU/mL for 3 to 4 days, after which cell viability declines dramatically (78). Recently, a third-generation lentiviral packaging cell line has been generated (82) (T. Kafri, personal communication, 2000).

Transduction of Nondividing Cells

VSV-G pseudotyped lentiviral vectors derived from HIV-1 have been shown to transduce a broad spectrum of terminally differentiated, nondividing cells *in vivo*, such as neurons (118) and retinal (110,156), hepatic (75), and muscle cells (75). The absence of a cellular immune response at the site of injection, as measured by staining for CD4+ T lymphocytes or macrophages, after injection of lentiviral vectors (1 to 3×10^{7} IU/mL) into the liver and muscle of the rat, indicates that lentiviral vectors might constitute immune-tolerated vectors. However, higher vector concentrations (>10^{9} vector genomes) and different tissues have to be tested, especially in higher mammals, and also the humoral immune response has to be assessed.

The fact that lentiviral vectors transduce human CD34+ hematopoietic stem cells *in vitro* without cytokine prestimulation is of high clinical relevance and a clear advantage in comparison to MuLV-based retroviral vectors (23,50,111). The transduced CD34+ cells provided long-term repopulation and were capable of engrafting and differentiation into multiple hematopoietic lineages after transplantation into nonobese diabetic (NOD)/SCID mice (111).

The correction of several human genetic diseases by gene therapy will require the delivery of large DNA fragments. For instance, sickle cell anemia and b-thalassemia, two genetic disorders of the b-globin gene, will require high-level expression of the b-globin gene in hematopoietic and erythroid (31) cells. To achieve this, introns of the b-globin gene and parts of the locus control region (LCR) of the human b-globin gene (122) will have to be included in the vector. Viral vectors based on simple retroviruses exhibit genetic instability if genomic fragments, such as introns, are included in the vector DNA. Therefore, retroviral vectors containing b-globin transcription units and LCR fragments are very unstable, with multiple rearrangements on transmission of the provirus (91,122). Genetic instability of retroviruses occurs by (a) inappropriate splicing or polyadenylation of the viral genome, and/or by (b) rearrangements during reverse transcription (91). In contrast, lentiviruses such as HIV-1 have the ability to package unspliced viral genomes, and Rev has been shown to permit the nuclear export of unspliced or incompletely spliced HIV-1 RNAs (94). Because RRE is included in HIV-based lentiviral vectors (118), it was speculated that lentiviral vectors might overcome the problem of retroviral instability.

It has recently been shown that the use of HIV-based viral vectors enables the efficient transfer and faithful integration of the human b-globin gene together with large parts of its LCR into hematopoietic stem cells (99). The high efficiency of the lentiviral gene transfer, together with an optimized b-globin-LCR configuration and the absence of vector rearrangements, yielded human b-globin expression in the therapeutic range in a mouse model of b-thalassemia after bone marrow transplantation of transduced stem cells. In summary, lentiviral vectors clearly fulfill many of the promises of a suitable gene delivery vehicle.

ADENO-ASSOCIATED VIRUS

Adeno-associated viruses are nonpathogenic, nonenveloped DNA viruses that belong to the parvovirus family. AAV virions contain a single-stranded DNA genome of only 4,680 bases, which is flanked by two inverted terminal repeats

(ITRs). Because productive (lytic) infection with AAV normally requires co-infection with an unrelated helper virus, either adenovirus or herpesvirus, these viruses were also termed dependoviruses (for a detailed description, see Chapter 69 and Chapter 70). In the absence of helper virus, AAV establishes a latent infection and integrates into a host chromosome via its ITRs. The ITR consists of 145 nucleotides, with the first 125 bases forming a palindromic sequence that forms a Y- or T-shaped structure. The ITR plays a crucial role in the AAV life cycle: It is involved in integration of the AAV genome and its rescue from the integration site. Latent infection in human cells with wild-type AAV results in site-specific integration into the AAV-S1 region of chromosome 19 (86,146). The integration sites are clustered, and they show microhomologies between the host DNA and the ITR (173). Because the integrated AAV provirus can be mobilized by subsequent superinfection of the host with a helper virus, latent infection seems to be a mechanism for ensuring the survival of AAV in the absence of helper virus. On the other hand, the helper-free life cycle of AAV is the basis for the development of AAV-based gene therapy vectors (12,61,113,114,145,152).

Adeno-Associated Viral Vectors

So far, six serotypes of AAV have been found in primates (AAV-1 to AAV-6). Type 2 is the best-characterized primate serotype, and it was the first AAV used for the development of vectors for gene transfer (103,144). Most of the vectors currently in use are derived from AAV-2, but vectors based on AAV-1 have been recently described (169).

In contrast to retro- and lentiviral vectors, in which vector development not only resulted in different versions but also achieved significant improvements of transduction efficacy and biosafety, the original design of AAV vectors has not changed over the last decade. The AAV-2-based vectors contain only the left and right ITRs, and 139 (103) or 45 (144) nucleotides of nonrepeated AAV sequences adjacent to the right terminal repeat, respectively. Samulski et al. (143) were able to show that all the cis-acting AAV functions required for replication and virion production are located within the ITR and the immediately adjacent 45 nucleotides. In the AAV-based vectors, the two viral open reading frames (ORFs), which code for the capsid proteins (VP1, 2, and 3) and the four nonstructural Rep proteins (Rep78/68 and Rep52/40) are replaced with the transgene of interest and its promoter (Fig. 7B,Fig. 7C) and then transfected into the producer cells, where the viral genes necessary for virus production and packaging of the vector genome are provided in trans by packaging plasmids and helper viruses/plasmids (see next section, AAV-Vector Packaging Strategies).

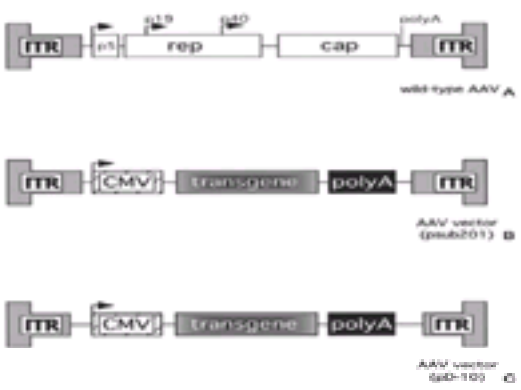

FIG. 7. Adeno-associated viral vectors. **A:** Scheme depicting wild-type AAV. The inverted terminal repeats (*ITRs*) and the promoters (*p5*, *p19*, and *p40*) of the *rep* gene are indicated. **B:** Recombinant AAV vector [e.g., p*sub*201 (143)]. The viral *rep* and *cap* genes are replaced with the transgene of interest, its promoter (e.g., CMV) and a polyadenylation signal sequence [*poly(A)*]. **C:** AAV vector carrying deletion mutations of the ITRs [e.g., pD-10 (164)] to minimize recombination between the vector and packaging/helper plasmids carrying adenoviral terminal repeats.

One disadvantage of AAV-based vectors is their size limitation: The optimal size for AAV vectors lies between 4.1 and 4.9 kb (37). Although larger genomes can be packaged, the packaging efficacy is sharply reduced and the maximal size of the vector genome (including the two ITRs) is 5.2 kb (37). Because of this size limitation, a dual vector, trans-splicing AAV vector system was developed (39,116,155,172), which allows the transduction of target cells and tissues with two AAV vectors that contain a split expression cassette. This promising approach to AAV-based gene transfer is based on the finding that episomal recombinant AAV (rAAV) genomes form circular multimers that concatamerize in a head-to-tail orientation (38). The dual-vector strategy functions as follows: After co-infection of the target cells, the two AAV vectors that carry the split genome form head-to-tail heterodimers through sequence homology of the ITRs, thereby rejoining the split gene into one continuous DNA molecule. Although such rejoining leads to the disruption of the gene-coding sequence by the AAV ITR, this problem can be overcome by inclusion of eukaryotic splicing signals to remove the ITR sequences during RNA maturation. With this novel dual-vector approach, the *E. coli lacZ* transgene (116,155), a luciferase reporter gene (39), and the human erythropoietin (172) gene were successfully delivered *in vitro* and *in vivo* (to muscle and liver of the mouse). Although the efficacy of gene delivery in the dual-vector system was consistently reported to be lower than in the unsplit, conventional AAV vector system, the individual efficacies vary between 16% (155) and 70% (116) as compared to unsplit vectors.

AAV-Vector Packaging Strategies

The basic principal of the AAV packaging system is the same as in other vectors: The vector plasmid contains the required cis-acting viral sequences necessary for packaging and integration and the transgene, while the packaging plasmids provide the viral components required for virus production in *trans.* However, because AAV is a dependovirus, its propagation depends on the functions provided by a helper virus (adenovirus or herpesvirus). Although replication has been described to occur in a helper-independent fashion if the host cells are stressed with genotoxic agents such as irradiation, adenovirus infection is still the most efficient way to induce AAV replication.

The initial studies with AAV vectors revealed that both the AAV *rep* and *cap* genes can be provided in trans in producer cells (103,144), and this resulted in the first generation of packaging systems (103,144). In this system, the packaging plasmid [pAAV/Ad (144)] encodes the *rep* and *cap* genes, and the essential helper functions are provided by the adenovirus (Fig. 8). Transfection of the AAV packaging construct together with the vector plasmid into adenovirus-infected packaging/helper cells results in excision of the ITR-flanked transgene from the vector plasmid, followed by its amplification and packaging into AAV capsids. This first generation of AAV packaging yielded up to 102 rAAV particles per cell, but there is a major disadvantage: the coproduction of wild-type adenovirus along with the AAV vector particles. Although these AAV preparations can be purified [e.g., by centrifugation in multiple cesium chloride (CsCl) gradients] and/or the adenovirus contamination can be inactivated (e.g., by heating the preparations for 30 minutes at 56°C), a complete removal of adenoviral capsid components is not always possible. In addition, this may lead to a loss in the activity of the AAV particles. Given the fact that viral proteins derived from inactivated adenovirus preparations elicit a cytotoxic T lymphocyte (CTL) immune response at the site of injection (76), it is clear that this packaging system is suboptimal, at least for clinical use.

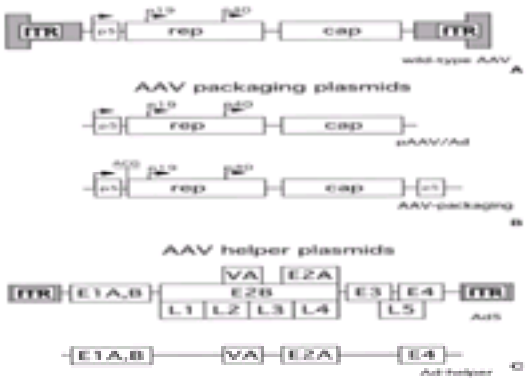

FIG. 8. AAV packaging/helper constructs. **A:** Wild-type AAV**. B:** AAV packaging constructs of the first [e.g., pAAV/Ad (144)] (*top*) and of the second generation [e.g., pXX2 (171)] (*bottom*); the latter contains a mutation of the start ATG to ACG, and two p5 promoter/enhancer elements to optimize *rep* and *cap* expression. **C:** Ad5 (*top*) can be used as an AAV helper virus. The use of adenovirus-derived helper plasmids [e.g., pXX6 (171)] that contain the required viral genes minimizes the risk of helper-virus contamination.

To overcome this problem, a packaging system was developed (171) that is free of adenovirus. The adenoviral genes that provide essential helper functions during the productive life cycle of AAV are the E1A, E1B, E2A, E4, and VA RNA genes (reviewed in Chapter 69 and ref. 114). E1A functions as a transactivator of AAV *rep* and *cap* transcription. Interaction of E1B with E4 stabilizes AAV mRNAs and/or facilitates the mRNA transport to the cytoplasm. A similar role has been described for E2A and VA RNA. By cloning of the E2A, E4, and VA RNA genes into a high-copy plasmid, Xiao et al. (171) generated a helper plasmid (pXX6) that contains all the essential helper genes but lacks the adenovirus structural and replication genes and the adenoviral terminal repeats (see Fig. 8C). The missing E1 gene products are provided by using 293 producer cells (59). Surprisingly, supplying the adenoviral helper functions from a plasmid that resulted from deleting most of the adenoviral genome significantly increased AAV vector production (171). This is presumably the result of the lack of competition between the AAV and adenovirus for adenoviral gene products in the packaging cells, in addition to the removal of the lytic action of the helper virus (145).

A further, major improvement of AAV vector production was the development of a second generation of packaging constructs (171): Because *rep* expression has been shown to cause a paradoxical inhibition of rAAV production if the Rep68/78 proteins are overexpressed in the producer cells (92), the ATG translation start codon of the *rep* gene was mutated into an inefficient ACG codon to achieve attenuation of Rep68/78 synthesis (see Fig. 8B). Because the p5 promoter exerts positive effects on p19 and p40 but negatively regulates its own transcription (100,129), Xiao et al. (171) reasoned that inclusion of a second copy of the p5 promoter/enhancer element 3' of the *cap* gene might have positive effects on AAV vector production (see Fig. 8B). Indeed, these changes increase vector yields approximately 15-fold over the conventional packaging plasmid pAAV/Ad. Thus, co-transfection of 293 cells with this second-generation packaging system, containing three plasmids (the vector, the pXX2 packaging plasmid, and the pXX6 helper construct) results in viral titers of up to 10^{10}/10-cm plate (171).

A problem with this packaging system is that the adenoviral terminal repeats present in pAAV/Ad and pXX2 have been shown to be involved in illegitimate recombination with the AAV ITRs. This recombination between the AAV vector and the packaging plasmids can lead to the production of wild-type AAV-2 particles in the range of 4% of the total physical titer (164). However, removal of the distal 10 nucleotides (in the D sequence of the ITR; see also Chapter 69) of the AAV vector ITRs [pD-10 vector construct (164)] reduced the amount of wild-type AAV contaminants to below the detection level, when a packaging plasmid was used that lacked adenoviral ITRs (164). The elimination of replication-competent wild-type AAV and helper virus (e.g., adenovirus) contaminations from the rAAV preparations is an important step toward the generation of clinical-grade vectors.

Packaging Cell Lines for AAV

Adeno-associated-virus vector production in stable cell lines has to overcome several problems associated with the toxicity of viral proteins and the viral life cycle. The Rep proteins exert an antiproliferative effect on mammalian cells (174), and they have a negative effect on heterologous gene expression (92). Therefore, it was not surprising that initial attempts to establish a stable cell line containing AAV-2 *rep* and *cap* (30,157) were not very successful. The initial AAV cell lines gave titers of 30 IU/cell (30), whereas transient transfection of the second generation of packaging/helper

system yields up to 1,000 IU/cell (171). Recently, a number of promising inducible cell lines have been developed, in which the expression of Rep and Cap proteins is regulated by the tetracycline-inducible system (73) (see earlier section, Packaging of Retroviral Vectors). Infection of the cell line with adenovirus after the addition of tetracycline or doxycycline to the medium resulted in AAV vector production with titers 10 times higher (i.e., 10,000 IU/cell) than those obtained by transient transfection. However, after 3 to 4 days in doxycycline, the number of particles per cell dropped dramatically (73).

A major drawback of the presently available packaging cell lines is the requirement for the infection with a helper virus, and an extensive purification procedure has to be applied to minimize the amount of helper virus contamination. In addition, an important problem with stable cell lines for AAV vector production is that expression of the helper viral genes leads to the excision of the vector genome from the integration site, and thus prolonged expression of helper virus genes might disturb the genomic stability of the packaging/producer cells.

Purification of Recombinant AAV and Titering

In contrast to retroviral vector particles that are secreted into the culture medium of the packaging/producer cells, rAAV accumulates intracellularly and has to be purified from the producer cells. Lysis of the producer cells (e.g., by freeze/thaw cycles) is necessary if a packaging/helper system is used that is devoid of lytic helper-viruses. The conventional purification protocol involves a step-wise precipitation of AAV particles with ammonium sulfate, followed by up to three rounds of CsCl density gradient centrifugation (170). After each round of CsCl centrifugation, the gradient is fractionated and the active fractions are identified by dot-blot hybridization or polymerase chain reaction analysis. Because this purification method is labor intensive and often results in substantial loss of viral particles, new methods have been developed to purify rAAV using gradient media other than CsCl or column chromatography (29,157,185). A major improvement of AAV purification is the iodixanol method developed by Zolotukhin et al. (185), which decreases toxicity from rAAV aggregates and avoids the toxicity of residual hyperosmotic CsCl. Iodixanol is an iso-osmotic, inert x-ray contrast reagent that has been extensively tested. Crude producer cell lysates can be purified at least 100-fold, and 70% to 80% of the starting infectious particles are recovered. With this method, lysates obtained from 2.5×10^{9} cells can generate 10^{14} virus particles or 10^{12} IU/mL (185).

An important further step toward clinical-grade virus preparations was the development of ligand affinity chromatography purification techniques. Two laboratories have developed heparin affinity chromatography procedures using commercially available heparin columns (29,185). This approach exploits the fact that heparan sulfate proteoglycan acts as a cellular receptor for AAV-2 (154). Furthermore, it appears to be superior to earlier attempts to purify AAV using ion exchange or size-exclusion columns (29,157). The combined iodixanol/heparin chromatography procedure results in 50% to 70% recovery of virus that is better than 99% pure and is more infectious than the CsCl method (particle-to-infectivity ratios are less than 100:1 for iodixanol/heparin, versus 1,000:1 for the traditional purification strategies) (185). Recently, an immunoaffinity column chromatography approach to AAV purification has also been explored (60).

Host Range and Infection of Nondividing Cells

AAV-2-derived viral vectors exhibit a broad host range and infect a wide variety of tissues and cells. Furthermore, AAV is a nonpathogenic virus and is able to transduce nondividing cells such as muscle cells (170), hepatocytes (150), and neurons (101). These cells are terminally differentiated, and progression through the cell cycle seems not to be a prerequisite for transduction, as indicated by analysis of 5'-bromo-2'-deoxyuridine (BrdU) labeling of livers infected with rAAV (104). However, it has been reported that transduction efficacy is influenced by the cell cycle phase of the target cells and that the transduction frequency is significantly higher in cells in S phase (142). In addition, there appears to be a preference of rAAV for certain cell types: For example, rAAV infects neurons, but no transgene expression was found in astrocytes or microglia after infusion of AAV vectors into the adult rat brain (9). Furthermore, neuronal AAV infection was reported to be restricted to certain areas of the brain (e.g., the hippocampus), whereas neurons in the cerebral cortex were not transduced (101). Possible explanations are that rAAV might require a certain metabolic state, or that the receptors needed for AAV attachment and entry are not expressed on cells refractory to AAV transduction. The latter notion received further attention when the cellular receptor and coreceptors for AAV were identified. Heparan sulfate proteoglycan has been identified as the primary receptor for AAV (154) that mediates attachment of AAV-2 to the cell membrane of the target cell. In addition, integrin a_vb_5 and the fibroblast growth factor receptor 1 (FGFR1) have been identified as coreceptors for AAV infection (134,153). Interestingly, coreceptors have been identified for both adenoviruses (Chapter 67 and Chapter 68) and herpes simplex viruses (Chapter 72 and Chapter 73). Thus, AAV may have acquired coreceptor dependency as a mechanism for co-infection with its helper viruses that allows the optimal production of progeny virions (153).

Apart from the cell cycle phase and the requirement for AAV receptor, expression of helper virus genes (46) and exposure to agents that induce genotoxic stress (e.g., irradiation) and DNA repair (46,140) can significantly increase transduction efficiency. Not only does adenovirus help wild-type AAV to initiate productive infection, it also enhances rAAV transduction (reviewed in ref. 145). It has been shown that the E4 protein is directly involved in this process, and that the E4- and genotoxic stress-induced increase in rAAV transduction is caused by enhanced second-strand synthesis (46). The latter is of importance for AAV-based gene delivery, because the conversion of the single-stranded AAV genome to duplex is the rate-limiting step for rAAV transduction in many cell types (145).

Integration Versus Episomal Persistence of rAAV

Site-specific integration would be a highly desirable feature of a gene therapy vector, as it would ensure long-term (theoretically even life-long) expression of the transgene and minimize the mutagenic and carcinogenic potential—major drawbacks of random integrating vectors based on retroviruses. Although the ITRs are the only genomic elements necessary for integration, efficient integration and site specificity require the presence of the viral Rep protein (165). Because AAV vectors lack the Rep expression cassette, it comes as no surprise that AAV vectors integrate with low efficacy and low specificity into the host genome. Integration of rAAV has been observed in dividing cells (e.g., HeLa

cells) (173), as well as in nondividing cells *in vitro* (human neuronal cell lines) (168). Nakai et al. (115) provide direct evidence for integration of rAAV into the mouse genome. Further analysis by pulse-field electrophoresis and fluorescence in-situ hybridization (FISH) showed integration of the rAAV in approximately 5% of liver cells (105).

Apart from integration into the host genome, the presence of episomal forms of rAAV has been demonstrated *in vivo* (38,49,115). Several studies demonstrated the presence of AAV vector DNA in an episomal circular form in muscle and brain tissue transduced with AAV vectors (38,115). Because this form of episomal AAV DNA persists for up to 9 months (38,115), the episomal AAV DNA might be a major contributor to the long-term expression of transgenes delivered with AAV vectors. The characteristic feature of these circular genomes is that they contain two viral ITRs in a head-to-tail orientation, which appears to confer an increased persistence of episomal DNA at least in certain cell types (e.g., HeLa cells) (38). Presently, not much is known about the exact mechanisms that lead to the formation of these concatamers, but it appears to involve recombination events between separate viral genomes. This inherent ability of AAV to form concatamers fusing the 5' and 3' ends of two genomes of two viruses is the basis for the development of trans-splicing, dual-vector systems (39,116,155,172).

In summary, completion of second-strand synthesis appears to be the rate-limiting step of rAAV infection (recently reviewed in refs. 113,141), and it is associated with an increase in transgene expression, which can take several weeks after administration *in vivo*. Long-term (i.e., several months) transgene expression could be achieved by integrated concatamers, or by stable concatameric episomes, or both.

Immune Response Against AAV in Humans

Single administration of rAAV into the muscle of immune-competent mice does not result in a detectable cellular immune response as determined by staining for CTLs (170). However, a detailed analysis of the immune response in mice that received rAAV via intramuscular (i.m.), intraperitoneal (i.p.), intravenous (i.v.), and subcutaneous (s.c.) injection revealed that all these different routes of administration elicited a humoral response (17). Interestingly, a potent transgene-specific CTL response was detected after i.p., i.v., and s.c. injection, whereas only a minimal CTL activity was observed after i.m. administration (17).

The preexisting humoral immunity against AAV in humans is likely to be a hurdle for many gene therapy approaches in humans. A recent study by Chirmule et al. (27) showed that virtually all patients had antibodies to AAV-2, and in 32% of the cases neutralizing antibodies were found. In addition, 5% of the subjects had peripheral blood lymphocytes that proliferated in response to AAV-2 antigens. All patients enrolled in the first clinical trial of intramuscular injection of an AAV vector carrying human factor IX in patients with hemophilia B (79) had detectable titers of neutralizing antibodies against AAV before treatment. However, factor IX expression was demonstrated in muscle biopsies even in the patient with the highest pretreatment antibody titer. Administration of the AAV vector elicited a 10- to 1,000-fold increase in the neutralizing antibody titer.

Therefore, especially if vectors are readministered, efforts to overcome the humoral immunity against AAV have to be considered. Temporary block of CD4 T cell function to inhibit memory B cells (28), and the selective modification of the AAV capsid (54) are additional approaches. The latter is also a way to alter AAV-2 tropism and may be employed for targeting of AAV vectors *in vivo*.

ADENOVIRAL VECTORS

Adenoviruses are medium-sized DNA viruses that have been isolated from avian and mammalian species. Their genomic organization and virion structure are described in detail in Chapter 67 and Chapter 68. The double-stranded linear DNA genome is 36 kb long and is flanked by two ITRs that contain the origin of replication (Fig. 9A). The Ad genome is packaged in a nonenveloped icosahedral protein capsid. On infection of permissive cells, the viral genome is replicated and transcribed in two major stages: an early and a late phase. The boundaries of the two phases are delineated by viral replication. The early genes lie in five noncontiguous regions designated as early region 1A (E1A), E1B, E2, E3, and E4. Most late transcripts are initiated from the major late promoter and are subsequently processed to generate five families of transcripts (L1 to L5) that share the same carboxyl terminus.

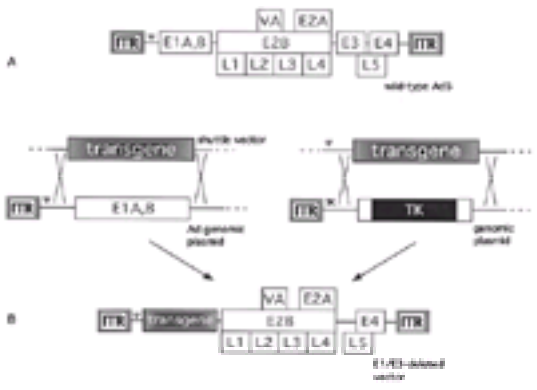

FIG. 9. Adenoviral vectors. **A:** Wild-type adenovirus (Ad5) **. B:** First generation of adenoviral vectors. *Left:* Homologous recombination of the shuttle vector that carries the transgene flanked by adenoviral genomic sequences with the genomic plasmid results in the replacement of the E1 region with the transgene in the recombinant Ad vector (*bottom*). *Right:* Deletion of the packaging signal and/or insertion of a selection marker such as thymidine kinase (TK) reduces the amount of contamination with unrecombined parental virus.

Development of Adenoviral Vectors

Of the approximately 50 known serotypes of human adenovirus, which are categorized into six subgroups, most adenoviral vectors (63,71,166) have been derived from serotype 5 (Ad5) of subgroup C. An important finding for the development of adenoviral vectors was that Ad5 carries a cis-acting DNA encapsidation signal at the end of the viral chromosome, and that recombinant viral genomes lacking these signal sequence cannot be packaged into viral particles, although normal levels of viral proteins were synthesized from these mutants (68). Two other important findings are (a) that Ad DNA can circularize in infected cells and that circular Ad genomes can be propagated as bacterial plasmids (reviewed in ref. 13), and (b) that co-transfection of two plasmids with overlapping sequences can generate infectious viral particles via homologous recombination *in vivo*.

Based on these findings, the first generation of Ad-derived vectors were designed by replacing adenoviral coding regions E1 and/or E3 with foreign genes. Because the E1A proteins are essential for transcription of other early viral genes and promote the expression of host cell proteins needed for DNA replication, deletion of the E1 region should render the vector replication-defective. The E1-deleted vectors can be propagated in 293 cells, which express 11% of the Ad5 genome and complement for E1 function (59). Thus, nearly all the E1 coding sequences (up to 3,181 nucleotides) can be removed (13), as long as the packaging signal and the coding sequence of protein IX, which is colinear with E1B but uses a different promoter (see Chapter 67), is not affected. Because the packaging capacity of Ad5 virions is 105% of the wild-type genome (14), transgenes of up to 4.7 to 4.9 kb can be accommodated in E1-deleted adenoviral vectors. The capacity of the viral vectors can be further increased by deletion of the E3 region (11,66), which is not essential for viral replication and growth in cell culture. However, for gene therapy vectors, the E3 protein is of relevance, as it has immunosuppressive functions (71): From the seven proteins encoded by the E3 region, the gp 19-kd protein binds to MHC class molecules and the 14.7/10.4-kd proteins inhibit apoptosis. The largest viable E3 deletion described so far is 3.1 kb (13). A combination of both E1 and E3 deletions in one mutant virus results in a cloning capacity of 8.3 kb.

Several strategies have been developed to insert the transgenes of interest into the Ad vectors. The most commonly used strategy relies on homologous recombination in the 293 producer cells (see Fig. 9). The transgene is inserted into a shuttle vector that contains adenoviral genomic sequences that flank the recombination target site (i.e., the E1 coding region) in the recipient Ad genomic plasmid. Through homologous recombination in the 293 cells, the transgene sequence is integrated into the Ad vector DNA, replacing the E1 gene. This E1-deleted Ad vector is able to replicate in the 293 cells because of their E1 helper function, and it is possible to produce up to 10^{11} viral particles per 10-cm cell culture dish.

A drawback of this first generation of Ad vectors is the contamination with wild-type virus. Two major changes have been incorporated into the Ad genomic plasmids to solve this problem (see Fig. 9): (a) removing the packaging signal (13), or increasing its size beyond the maximum that can be packaged (102), thereby inhibiting packaging of the parental genome, and (b) incorporating a selection marker (e.g., by replacing the E1 region with the thymidine kinase gene) that allows for the selection against wild-type virus (72). In addition, strategies have been designed for the production of recombinant viral DNA that do not rely on recombination with parental infectious viral genomes in 293 cells. Instead, Ad genomic DNA can be manipulated in yeast (80) and bacteria (25). The recombinant Ad genome can then be purified from these hosts and used to produce virus in 293 cells.

A recurrent problem with the first generation of Ad vectors is the generation of replication-competent adenovirus (RCA). To address this problem, further deletions of viral genes were introduced into the vector backbone, resulting in the second generation of Ad vectors. Reduction of the number of viral genes present in the Ad vector should also reduce the immune response against the vector and vector-infected cells. These second-generation vectors (71,161) are based on deletion of the E2 and/or E4 regions within the E1-deleted vectors. The E2 region encodes proteins required for the replication of the viral chromosome: the precursor terminal protein, DNA polymerase, and DNA-binding protein (DBP). The first attempts to delete the E2 region were hampered by the fact that the production of the E2-deleted vectors require expression of E2 in trans, which is not easily achieved because of the toxicity of the E2 protein (83). Therefore, Engelhardt et al. (44) constructed an E1-deleted adenoviral vector that harbors a temperature-sensitive mutation of DBP. This mutation reduces the ability of the virus to replicate at 39°C. Because of the “leakiness” of this system and the conflicting results regarding persistence of transgene expression [especially at a later time (beyond 7 days) (44,45)], vectors with deletions of DBP (56), of adenoviral DNA polymerase (5), and of the precursor terminal protein (148) were designed that can be produced in packaging cell lines that complement for the deleted protein (4,56,89,184).

E4 is the other genomic region that has been targeted for the development of second-generation vectors. Located at the right end of the Ad genome (see Fig. 9A), E4 encodes proteins that are required for viral DNA replication, mRNA splicing and accumulation, late protein synthesis, and inhibition of host cell protein synthesis. Deletion of the entire E4 region is theoretically possible; however, in practice such vectors have been shown to result in a significant drop in vector yield (18). The mechanism for this decrease in viral titer of E4-deleted vectors is not completely understood, but it was shown that total deletion of E4 causes a reduction in the expression of late region 5 (L5) mRNA. It was postulated that the spatial organization of E4, L5, and the right ITR itself might be of importance for the regulation of L5. The defect of E4-deleted vectors was overcome either by insertion of spacer sequences into the E4 locus (18) or by only partially deleting the E4 region (53,162,179). To propagate the E1/E4-deleted vectors, E4-complementing cell lines have been developed. An important aspect of E4 function is the discovery that the product of ORF6 can substitute for the entire E4 region. Because expression of E4 ORF6 together with E1B is detrimental to the packaging cells, inducible E4 expression systems have been developed (87,163). Although deletion of the majority of E4 should decrease the host immune response and increase the cloning capacity of the Ad vector, the E4 region may be required for long-term expression, especially if the CMV promoter is used as internal promoter in the vector construct (6,8).

High-Capacity, Helper-Dependent Vectors

The third-generation Ad vectors (63,71,84) have been termed, according to their characteristics, high-capacity,

helper-dependent, mini, and “gutless” adenoviral vectors. They were designed to minimize the amount of Ad viral genes present in the vector. This would increase the cloning capacity of the vector and should reduce the host immune responses against the Ad vector-transduced cells.

Earlier attempts (48,64,109) to divide the adenovirus genome into separate cis- and trans-acting functions to establish clearly separated vector and packaging/helper constructs were successful. However, two major problems were encountered (71): The vector preparations were highly contaminated with up to a 1,000-fold excess of helper virus (48). Vectors that are significantly below the size of the wild-type Ad genome proved to be unstable and undergo DNA rearrangements (48,64). Parks and Graham (127) analyzed the size constraints of Ad vectors: The optimal DNA packaging length ranges from 75% to 105% of the wild-type (36-kb) genome. Vectors smaller than 75% were packaged with a much lower efficacy, and were unstable (127).

An important step in the production of helper-dependent vectors was the introduction of the Cre/ *loxP*-strategy in the Ad system to remove viral DNA sequences (67,93,126). The Cre-recombinase of bacteriophage P1 excises DNA sequences that are flanked by *loxP* recognition sites and has been successfully used for gene targeting experiments in mice (62). The Cre/*loxP* systems allows even the manipulation of mammalian chromosomal regions (up to 3 to 4 cM) (135). Insertion of *loxP* sites so that they flank the genomic region to be deleted is a promising way to restrict the Ad genome (Fig. 10). Lieber et al. (93) deleted 25 kb of adenoviral genome encompassing the pIX, the E2, and the L1 to L4 regions by infection of 293 cells stably expressing the Cre recombinase (293-cre) with an Ad vector that contained *loxP* sites flanking the region to be deleted. These authors (93) introduced the *loxP* sites into an E1-deleted vector backbone that carried a transgene in the place of the E1 region, and the final result after Cre-mediated excision was a 9-kb vector that contained only the transgene, a *loxP* site, the packaging signal, and the E4 region flanked by ITRs (see Fig. 10). Unfortunately, this vector was unstable, presumably because of its size, and it provided only limited transgene expression *in vivo*.

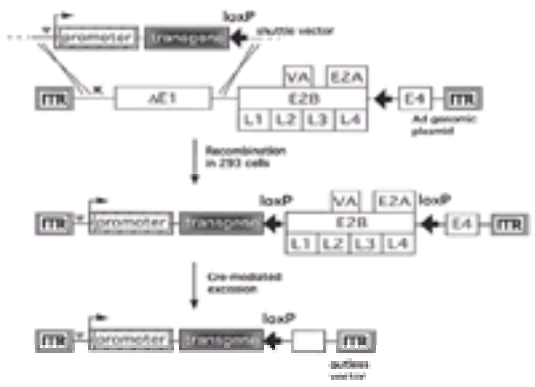

FIG. 10. High-capacity adenoviral vectors. High-capacity, adenovirus vectors can be obtained by introduction of two *loxP* sites (*black arrows*) into an Ad genomic plasmid that carries deletions in the packaging signal, in the E1 region, and in the E3 region (93) (*top*). Infection of 293-cre cells that express the Cre recombinase leads to the excision of the sequences flanked by the *loxP* sites (*middle*), thereby deleting almost all viral sequences. The resulting “gutless” vector contains only the ITRs, the packaging signal, the viral E4 region, and the transgene and the internal promoter.

An alternative Cre/*loxP* system was designed that targeted the sequences essential for packaging of the helper virus to prevent its packaging (67,126). Previous studies (85) had shown that using a helper virus that carried a deletion of 91 bp of the Ad packaging signal, together with a helper-dependent Ad vector, resulted in a considerable improvement of the helper virus contamination, reducing it to less than 1% after CsCl purification. The helper virus with the *loxP*-flanked packaging signal can be easily propagated in conventional 293 cells. After infection of 293-cre cells with this helper virus, the packaging signal is excised, and the helper virus retains its capability to provide the Ad functions required for replication and packaging of the helper-dependent virus. With this system, Parks et al. (126) obtained about 10^{10} IU, with less than 0.01% of total virus being helper virus.

The principal advantage of helper-dependent vectors over first- and second-generation Ad vectors and other gene therapy vectors is their enlarged cloning capacity: If all viral genes are deleted, up to about 35 kb of DNA could be packaged in the Ad5 virion. The cis-acting elements required for replication and packaging (i.e., the packaging signal and the ITRs) of the vector are contained within 500 bp at the end of the Ad genome (58). In addition, the removal of viral genes from the vector is a promising way to avoid the host immune response.

Replication-Competent Adenoviral Vectors

Although replication of Ad vectors is unwanted in most gene therapy approaches, viral replication, virus assembly, and release of the progeny virus by lysis of the infected cell can be exploited for cancer gene therapy. To use adenoviruses for oncolytic gene therapy, conditionally replicative adenoviruses have been developed that replicate exclusively in tumor cells (3). An example of such a virus is an Ad mutant that replicates selectively in p53-deficient cells (called dl1520 or ONYX-015) (15,70). The dl1520 is a human subgroup C Ad that carries an 827-bp deletion and a point mutation in the E1B region that prevents expression of the E1B-encoded 55-kd (E1B-55K) protein. E1B-55K normally binds and inactivates the tumor suppressor p53 (180) and contributes to oncogenic transformation by Ad. Because p53 function must be blocked to allow efficient virus replication, it was hypothesized that replication of the E1B-55K-deficient Ad virus would be suppressed in normal cells, whereas cancer cells that lack p53 would support viral replication. Indeed, the E1B-55K-deficient virus was subsequently shown to productively infect a broad spectrum of human tumors with p53 abnormalities (e.g., p53 mutations and/or deletions) and to exert a replication-dependent cytopathic effect in these tumors *in vitro* and *in vivo* (70). On the other hand, human cells with functional p53 were highly resistant to the

E1B-55K-deficient virus (70). Given this promising result, a phase II clinical trial was started with intratumoral administration of E1B-55K-deficient Ad mutant in combination with standard i.v. chemotherapy in patients with recurrent squamous cell carcinoma of the head and neck (81). The combined therapy caused a more than 50% decrease in tumor volume in 63% of the patients, and none of the responding tumors progressed for 6 months, whereas all tumors treated with chemotherapy alone did progress. Thus, the approach of using specially engineered replication-competent Ad vectors in the treatment of cancer is a promising direction for gene therapy.

Immunologic Impediments

The ability to generate high-titer (10^{14} particles/mL) recombinant Ad vectors (RAd) and their efficient transduction of both dividing and nondividing cells boded well for a very successful vector. Unfortunately, length of expression of the transgene was transient (7 to 10 days) (35). It soon emerged that transient expression was caused by an immune response, because in immunocompromised animals, expression in slow-turnover cells such as muscle and neurons is observed for long periods of time. It is now generally accepted that cells transduced by RAd vectors are eliminated by CTLs generated against viral proteins or the transgene (76,158). It was for this reason that a number of investigators generated second- and third-generation vectors in which chances of synthesis of viral proteins are minimized. Unfortunately, RAd vectors present a unique problem because even the inactivated RAd vector can elicit potent CTLs against viral proteins (76). Furthermore, the RAd vectors elicit a potent humoral response that will effectively eliminate all subsequent transduction. This is even more pertinent to adenoviral vectors because they do not integrate, and hence they suffer loss by cell division and by DNA degradation, necessitating a repeat infection with the vector. Because there are scores of adenoviral serotypes, one strategy to overcome this problem might be to use different serotypes.

The high-titer recombinant adenoviruses are potentially toxic, even though the precise mechanism associated with this toxicity remains uncertain. The death of a patient directly associated with recombinant adenoviruses is a tragic warning sign that signals the need for further improvement of viral gene therapy. The RAd vectors will, however, continue to be utilized in situations where a high-level but transient expression of the foreign gene is required—for example, restenosis and cancer.

OTHER VECTORS

Our emphasis in this chapter was on most commonly used viral vectors, but there are other viral vectors based on SV40, Sindbis virus, herpes viruses, and others. Among these, the herpes virus–based vectors have the best potential for clinical applications. The presently available herpes viral vectors, where viral immediate-early genes have been deleted, appear to be nontoxic and therefore likely to be useful for clinical applications. We refer the reader to excellent reviews on the subject of emerging vectors (74) and herpes viral vectors (90,167).

The last two decades have witnessed the birth of the field of gene therapy, which has generated great hopes and great hypes. The promise of influencing the outcome of a vast array of diseases, ranging from birth defects to neurological disorders and from cancer to infectious disease, although far-reaching, is not beyond reach. With the completion of the sequence of the human genome, over 50,000 genes will be available to the practitioners of gene therapy. The potential benefits for human health are vast. Gene therapy has many challenges and hurdles ahead, but they are surmountable. It will continue to remain an exciting field of research.

CHAPTER 18 Diagnostic Virology

Gregory A. Storch

PERSPECTIVE

Until recently, diagnostic virology was outside of the mainstream of clinical laboratory medicine. The reasons were clear: virology laboratories depended on tissue or cell culture techniques that were slow and expensive, commercial availability of reagents was very limited, and few treatments were available for viral infections. Consequently, most hospitals did not have clinical virology laboratories. Those that existed were usually associated with children's hospitals, having been established to assist in the diagnosis of poliomyelitis.

In contrast, diagnostic virology is presently integrated into routine medical practice. The expanded role of diagnostic virology has several explanations. First, the human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS) epidemic and the success of organ transplantation have greatly increased the pool of patients at risk for serious opportunistic viral infections. Second, an increasing number of antiviral agents are available, and their use often depends on establishing a laboratory-based diagnosis. Third, technologic developments such as monoclonal antibodies and the polymerase chain reaction (PCR) have made rapid viral diagnosis a reality. It is still true that diagnostic virology laboratories as distinct entities are by and large limited to large hospitals, especially tertiary referral centers that are often within academic medical centers.

An important characteristic of modern diagnostic virology is the use of multiple methods for detecting viral infections. Viral culture, detection of viral antigens and nucleic acids, and detection of viral antibodies are all used to diagnose current viral infection. Light microscopy is used to detect the effect of viral infection in tissue and to define the role of viral infection in producing disease. Serologic techniques are used to define the presence of specific antiviral immunity. Tests using these methods may be carried out in a number of different clinical laboratories, including serology, blood bank, surgical pathology, chemistry, molecular diagnosis, and retrovirology laboratories in addition to traditional diagnostic virology laboratories. Several books on diagnostic virology provide more detailed treatment than is permitted by the scope of this chapter (97,112,184).

Diagnostic virology is much more important in some areas of clinical medicine than in others. Patient groups whose care often involves the use of diagnostic virology tests include immunocompromised patients, especially recipients of solid organ or bone marrow transplants and those with HIV or AIDS; patients with sexually transmitted diseases, acute respiratory infections, gastrointestinal infections (especially children but increasingly adults as well), infectious mononucleosis-like illnesses, acute or chronic viral hepatitis, serious ocular infections; and infants (and fetuses) suspected of having congenital infections. The management of antiretroviral drug therapy in patients with HIV or AIDS is based on assays to measure plasma HIV RNA plus genotypic and phenotypic assays to detect HIV drug resistance. The approaches developed for HIV are establishing new paradigms for the care of patients with chronic viral infections in which viral diagnostic tests are used to direct and monitor ongoing antiviral therapy.

Diagnostic virology has also been important in public health. For example, viral culture surveillance of patients with acute respiratory infections is crucial for the recognition of new strains of influenza. Specific diagnosis of cases of measles or rubella may initiate aggressive emergency immunization programs. Recognition of cases of arboviral encephalitis may set in motion mosquito control programs. Detection of Norwalk agent or other caliciviruses may be important in

understanding and controlling food- and water-borne gastroenteritis.

HISTORY OF DIAGNOSTIC VIROLOGY

The modern era of medical virology began in 1898 with the discovery by Loeffler and Frosch that foot and mouth disease of cattle was caused by a filterable agent referred to as a virus. Viral inclusions had been noted previously in 1892 by Guarneri (81), who described intranuclear and intracytoplasmic inclusions at the base of smallpox lesions. Knowledge of viruses as causes of human disease increased rapidly in the first quarter of the 20th century. The earliest methods that were widely used for diagnosing these infections were serologic, directed at the detection of viral antibodies or antigens. The complement fixation test described by Bedson and Bland in 1929 was first used to detect antibodies to smallpox, vaccinia, and varicella zoster viruses (VZV) (18). Serologic testing for antiviral antibodies is still widely employed to diagnose acute viral infection as well as to define specific antiviral immunity.

Diagnostic virology leaped forward in 1948 with the report by Weller and Enders of the first growth of pathogenic human viruses in tissue culture (197). Because the newly developed techniques for maintaining tissue cultures were beyond the scope of existing clinical laboratories, virology laboratories were established as distinct entities. Cell culture, the growth of defined populations of cells not formed into discrete tissues, was a refinement of tissue culture that formed the basis of diagnostic virology for many years. It is now being gradually replaced by nonculture techniques based on immunologic or molecular methods.

The first application of fluorescent antibody (FA) staining to diagnostic virology was the detection of influenza virus antigen in nasal smears by Liu (114). The method was further pioneered by Gardner and McQuillan (72). The development of monoclonal antibodies in the 1970s (101) greatly increased the availability of immunologic reagents with well-defined specificity for individual viruses. Rapid viral diagnosis became a practical reality during the 1980s as diagnostic virology laboratories implemented monoclonal antibody–based assays to detect a wide variety of viral antigens directly in clinical specimens. The introduction of molecular techniques into the diagnostic virology laboratory accelerated with the development of PCR, described in 1985 (169), and led to a period, still ongoing, of rapid evolution of diagnostic virology laboratories.

SPECIMENS FOR VIRAL DIAGNOSIS

The quality of viral diagnosis can never exceed the quality of the specimen that is received in the laboratory. Important variables include the timing of the specimen in relation to the patient's illness, the type of specimen, the quality and amount of specimen material obtained, and the time and conditions of transport to the laboratory. Although this concept is so basic as to seem trivial, optimizing the variables listed requires knowledge on the part of the physician and attention to logistic considerations that can present substantial barriers.

For the diagnosis of acute viral infections, the best specimens are usually obtained from the site of disease. For example, in the patient with suspected viral meningitis, cerebrospinal fluid (CSF) is the best specimen. In infections involving skin or mucosal surfaces, specimens obtained from that surface are usually the only ones required. Viral titers are highest early in the illness, so that specimens obtained within the first few days after onset are most likely to be positive.

Viral culture requires more attention to conditions of transport than specimens submitted for detection of viral antigens or nucleic acids because the viability of the virus must be preserved. A number of clinically important viruses are labile and will not survive prolonged transport. General instructions for transporting specimens for viral culture are shown in Table 1. These conditions are usually also suitable for detection of viral antigens and nucleic acids, but consultation with the laboratory performing testing is advised. Specimens other than blood should usually be kept at 4°C during transport, especially if transport will require more than 1 hour. If a delay of more than 24 hours is anticipated, the specimen should be frozen at a temperature of –70°C or lower. The recovery of some viruses, such as respiratory syncytial virus (RSV) and human cytomegalovirus (CMV), is seriously compromised by freezing. Blood specimens can be transported at room temperature, but recovery of CMV by culture is unlikely if the time of transport is 24 hours or greater, regardless of whether the blood is at room temperature or 4°C (160).

Specimen	Instructions
Blood	Usual volume required is 3–10 ml. The appropriate tube is determined by the test to be performed, the blood component on which the test is performed (whole blood, leukocytes [buffy coat], plasma, or serum), and the preference of the laboratory. Whole blood, leukocytes, and plasma require collection into a tube containing an anticoagulant. The most commonly used anticoagulants are EDTA (purple-top tube), heparin (green-top tube), and acid-citrate-dextrose (ACD). Note that heparin is inhibitory for some polymerase chain reaction (PCR) procedures, especially those performed on plasma. Some nonculture tests performed on blood may have specific collection tube requirements that can be determined through communication with the laboratory. Most serologic procedures, some cultures (e.g., for enteroviruses), and some PCR assays (e.g., for parvovirus B19) are performed on serum. Serum specimens require collection into a tube that does not contain an anticoagulant (red-top tube). Blood specimens do not have to be placed on ice if transport requires less than 1 day. Note that prolonged transport can severely compromise the ability to recover cytomegalovirus in culture from blood specimens.
Swab	Swabs with Dacron or rayon tips are preferred. If available, swabs designed specifically for collection of viral specimens should be used. Swabs can also be place in viral transport media. In this case, the shaft of the swab may have to be cut to allow the top of the transport vial to be securely closed. The swab or tube of transport media should be placed on ice if transport will require more than 1 hour.
Fluid	Place in a sterile container.
Tissue	Place in a sterile container with a small amount of viral transport media, sterile saline, or phosphate-buffered saline to maintain moisture.
Stool	Obtain at least 4 g of stool. Place in a clean or sterile container.

[a]Specimens other than blood should be transported on ice if more than 1 hour is required for arrival at the laboratory. If a delay of more than 24 hours is anticipated, specimens should be frozen at –70°C and transported on dry ice. Note that some viruses, such as respiratory syncytial virus and cytomegalovirus, are unlikely to retain viability with freezing. Specimens should not be frozen at –20°C.

TABLE 1. *Instructions for obtaining and transporting specimens for viral culture*[a]

For serologic diagnosis, an acute-phase serum specimen should be obtained within the first few days of illness and a convalescent phase specimen 2 to 4 weeks later. If a virus-specific immunoglobulin M (IgM) assay is available, the acute-phase specimen may be sufficient by itself. Immunoglobulins are stable in serum or plasma. Proper handling of specimens for serologic diagnosis begins with separation of serum or plasma. If testing is performed within several days, the serum or plasma can be stored at 4°C. If a longer delay is involved, the specimen should be frozen at –20°C or

–70°C. For certain viral infections, serologic tests can be performed on saliva or urine.

METHODS USED IN DIAGNOSTIC VIROLOGY

Viral Culture

Viral culture is the procedure that sets diagnostic virology apart from other areas of diagnostic microbiology. Because viruses require cellular machinery for replication, living systems must be used. Historically, inoculation of animals and eggs was used to cultivate and propagate viruses, but these techniques have been largely supplanted by cell culture in virtually all diagnostic virology laboratories. Viral culture has important advantages and disadvantages compared with other diagnostic methods. By its very nature, culture is an amplification method that increases the amount of the putative pathogen, facilitating detection and characterization. Viral culture is unique among detection methods in that it provides an isolate of viable virus that can be further characterized as necessary and can be stored for future studies. Another important feature is that culture methods allow the detection of many different viruses, including some not suspected at the time the culture is established. Even viruses not previously known can be discovered. This is in contrast to immunologic or nucleic acid–based diagnostic tests, which ordinarily detect only the specific virus to which the diagnostic reagent is directed. Viral culture also has significant disadvantages as a diagnostic method, including requirement for specialized facilities and expertise, expense, relatively prolonged time to detection, and relatively limited range of viruses that can be detected.

Growth of Cell Cultures

Cells are grown in the laboratory using the appropriate nutrient media, temperature, and atmosphere of incubation. A number of defined basal media are commercially available and are often supplemented with additives such as glutamine, fetal bovine serum, and antibiotics to counteract bacterial or fungal contamination. Most cell cultures used in diagnostic virology laboratories grow as cell monolayers that are adherent to glass or plastic surfaces. Most commonly, cultures are planted in individual glass tubes, but other vessels, including plastic flasks and microtiter trays, can be used. Some cell culture types do not adhere and are grown as suspension cultures. No one type of cell culture can grow all medically important viruses, and therefore diagnostic virology laboratories must use several different types of cell culture. Cell cultures can be maintained and propagated within the laboratory, or alternatively, they can be purchased from commercial suppliers who maintain supplies of a wide variety of cell culture types.

Types of Cell Culture

Cell cultures can be divided into four distinct categories. Primary cell cultures are derived directly from the source animal. Examples include primary monkey kidney cells and primary rabbit kidney cells. Viruses endogenous to the source can occasionally be propagated in these cells, and care must be taken to distinguish these viruses from viruses derived from the clinical specimen. Diploid or semicontinuous cells are capable of a limited number of passages before undergoing senescence. The most widely used semicontinuous cells are human fibroblast cell cultures such as MRC-5 and WI-38. Continuous or transformed cell lines are immortalized cells that can be “passaged” without limit. Examples include HEp-2, HeLa, A549, and Madin-Darby canine kidney cells. Hematopoietic cells, such as peripheral blood mononuclear cells or umbilical cord mononuclear cells, are required for the growth of viruses such as Epstein-Barr virus (EBV), human herpesviruses types 6 to 8, and HIV. These cultures are grown in suspension and must be set up from the source material within a few days before inoculation of the specimen. Although necessary for growth of the viruses mentioned, hematopoietic cell culture systems are not used routinely in most diagnostic virology laboratories. Table 2 lists commonly used cell cultures and the medically important viruses that grow in those cultures.

Culture type	Examples	Viruses Supported
Primary	Monkey kidney	Influenza virus, parainfluenza virus, enteroviruses
	Rabbit kidney	Herpes simplex virus
	Human embryonic kidney	Adenovirus, enteroviruses
Diploid	Fibroblast	Cytomegalovirus, varicella zoster virus, herpes simplex virus (HSV), rhinovirus, enteroviruses (some), adenovirus, respiratory syncytial virus (RSV)
Continuous	HEp-2	RSV, adenovirus, HSV, parainfluenza virus (some), enteroviruses (some)
	A549	HSV, adenovirus, enterovirus
	MDCK	Influenza virus
	LLC-MK2	Parainfluenza virus
	Rhabdomyosarcoma (RD)	Echoviruses
	Buffalo green monkey	Coxsackieviruses

TABLE 2. *Cell culture types used for the detection of medically important viruses*

The determination of which cells to use for a given specimen is based on the viruses likely to be present in that specimen. Thus, communication between clinicians and the laboratory is essential to maximize yield. When specific communication does not take place, cell cultures should be selected based on the viruses likely to be present in a given specimen type.

Specimen Processing and Inoculation

Performing a viral culture requires the following steps: processing of the specimen and inoculation onto the cell culture, maintenance of the inoculated cell culture, and detection of viral growth. Normally sterile body fluids, such as CSF, may be inoculated directly onto cell cultures. Urine specimens should have the pH adjusted toward neutrality before inoculation. Specimens from body sites typically contaminated with bacteria, such as respiratory or genital specimens,

are treated with antibiotics before inoculation to prevent bacterial or fungal overgrowth. After inoculation, cultures are incubated at 35° to 37°C and inspected periodically, for example, once daily or every other day. Respiratory cultures directed at detection of influenza or rhinoviruses may be incubated at 33°C.

Detection of Viral Replication

Viral growth in cell cultures is most often detected based on the development of microscopically visible cytopathic effect (CPE). Some viruses, however, can grow to high titer without producing visible CPE and must be detected by other means.

Cytopathic Effect

When viruses grow in cell culture, they often produce changes in the infected cells, or CPE. A number of viruses reveal distinctive morphologic changes resulting from CPE that can be visualized microscopically and that allow their recognition in the culture with considerable confidence. Important characteristics of CPE include which cell culture types are affected, the timing and rate of progression, the distribution (focal, diffuse, limited to the margins of the cell culture), and the nature of the morphologic changes. Several examples of CPE caused by common viruses are shown in Figure 1. The CPE may be sufficiently distinctive to allow unequivocal identification of the virus, but in other cases, techniques such as FA staining performed on cells scraped from the cell culture are used to confirm the presence of the suspected virus.

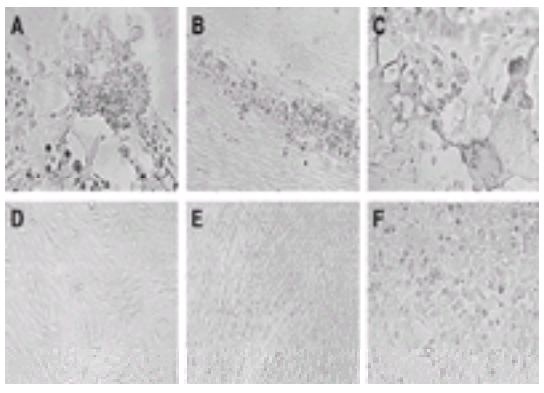

FIG. 1. Cytopathic effect caused by viruses growing in cell culture. Herpes simplex virus growing in primary rabbit kidney cells (**A**); uninfected primary rabbit kidney cells (**D**). Cytomegalovirus growing in human embryonic lung fibroblast cells (**B**); uninfected human embryonic lung fibroblast cells (**E**). Respiratory syncytial virus growing in HEp-2 cells (**C**); uninfected HEp-2 cells (**F**).

Hemadsorption

Paramyxoviruses, including influenza, parainfluenza, and mumps viruses, may produce only minimal visible CPE and instead are routinely detected by testing the inoculated cell culture for hemadsorption. Hemadsorption occurs because infection of cell cultures with certain viruses brings about the expression on the cell surface of viral proteins that bind to erythrocyte membranes. The binding is specific for the erythrocytes of certain species, such as guinea pig, rat, or monkey. To test for hemadsorption, a suspension of guinea pig erythrocytes is introduced into the cell culture previously inoculated with a clinical specimen. After a 30-minute incubation period, the culture is inspected microscopically to detect attachment of the erythrocytes onto the cells in culture. If hemadsorption is detected, the causative virus can be identified by FA staining of cells from the culture.

Interference

The interference assay is based on the phenomenon that a cell culture infected by one virus may be rendered resistant to infection by other viruses to which it was originally sensitive. To carry out this assay, a culture previously inoculated with a specimen is “challenged” with a test virus to which it is ordinarily susceptible. A companion culture of the same type that was not inoculated with a clinical specimen is challenged simultaneously to demonstrate viability of the challenge virus. Interference is present if the challenge virus grows in the companion tube but does not grow in the tube inoculated with the clinical specimen. When interference is demonstrated, the virus responsible can be identified by FA staining of cells from the culture.

Other Detection Methods

A variety of other methods can be used to detect viral growth in cell culture when CPE is not visible. A particularly important one is electron microscopy to detect viral particles. Electron microscopy is especially useful when there is uncertainly regarding the identity of the virus that might be present, precluding the use of immunologic or nucleic acid reagents. When a specific virus is suspected, its presence in the culture can be detected using virus-specific antibodies or nucleic acid assays.

Shell Vial Culture

Shell vial culture refers to a modified cell culture in which the specimen is centrifuged onto the cell monolayer and viral growth is detected by antigen detection procedures, whether or not CPE is visible. The method was developed originally

for CMV (77,79) but has subsequently been applied to many other viruses, including herpes simplex virus (HSV), VZV, respiratory viruses, and enteroviruses. The main advantage of the shell vial culture method is that it can decrease the time required to detect the presence of the virus being sought. For a slow-growing virus such as CMV, this difference can be dramatic. A diagram of the method is shown in Figure 2. For some viruses, either the centrifugation step or the antigen detection component of the full shell vial procedure can be omitted, although for CMV, inclusion of both components is required to maximize the sensitivity of the method.

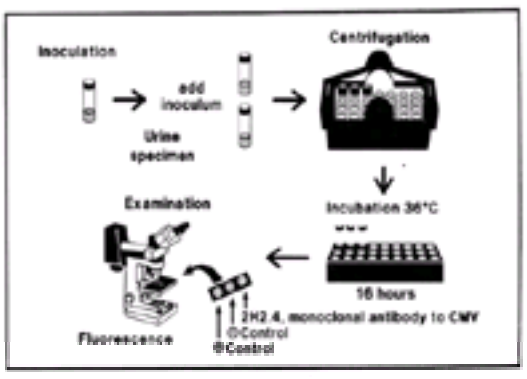

FIG. 2. Shell vial assay for cytomegalovirus. (From Shuster EA, Beneke JS, Tegtmeier GE, et al. Monoclonal antibody for rapid laboratory detection of cytomegalovirus infections: characterization and diagnostic application. *Mayo Clin Proc* 1985;60:577–585, with permission.)

In a common application of the shell vial method, human fibroblast cells are grown on a cover slip that is placed at the base of a 1-dram vial (these thin-walled vials are also known as shell vials). After inoculation of the specimen, the vial is centrifuged at low speed (i.e., 700 × g for 45 minutes) and then incubated for at least 16 hours. After the incubation period, the cover slip is removed and subjected to FA staining using a monoclonal antibody specific for an immediate early antigen of CMV. The presence of one or more fluorescent nuclei is evidence of the presence of CMV in the specimen. The sensitivity of the method varies among laboratories and is affected by a number of technical variables, including the age and condition of the fibroblasts, the timing of the staining, the monoclonal antibody used, and the quality of the fluorescent microscope (7). In some laboratories, the sensitivity of the method exceeds that of conventional viral culture (7,78).

Genetically Engineered Cell Lines

Techniques of genetic engineering have been used to modify cell lines to either make them susceptible to viruses that they are not otherwise susceptible to or create novel means of detecting viral growth. For example, HeLa CD4 cells are HeLa cells that have been transfected with the gene encoding the CD4 molecule. Expression of CD4 on the cell surface renders the cells susceptible to HIV (162). Another example is a cell line developed by Stabell and Olivo for the detection of HSV (181,182). This cell line, shown in Figure 3, consists of baby hamster kidney cells that have been transfected with the b-galactosidase gene from *Escherichia coli* under the control of a promoter from the HSV gene *UL39.* The promoter is activated by exposure to HSV proteins ICP0 and VP16. Exposure of the cells to a specimen containing HSV specifically activates the promoter, causing production of b-galactosidase, which can be detected by a simple histochemical stain of the culture, performed 16 to 24 hours after inoculation. A commercial version of this system called *ELVIS HSV* is marketed by Diagnostic Hybrids (Athens, OH) and has been shown to have sensitivity comparable to conventional viral culture for detection of HSV in clinical specimens (182). The system has also been adapted to the performance of HSV susceptibility assays (188).

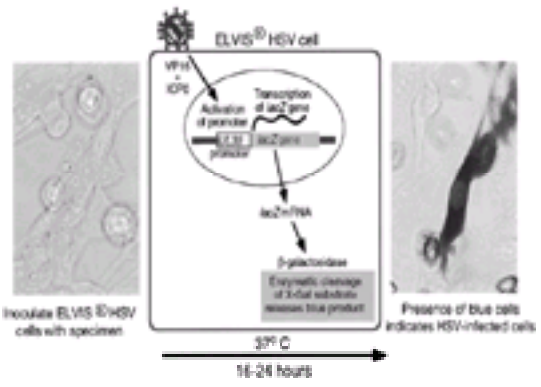

FIG. 3. ELVIS herpes simplex virus (HSV), a genetically engineered cell line for the detection of HSV in clinical samples. ELVIS cells are baby hamster kidney cells that contain a b-galactosidase gene under the control of the HSV promoter UL39. If HSV is present in the specimen, viral particles enter the cells, and the HSV proteins ICP0 and VP16 activate the UL39 promoter, leading to synthesis of b-galactosidase. The presence of b-galactosidase is detected by adding X-gal, a substrate for the enzyme. The activity of b-galactosidase on X-gal results in blue staining of ELVIS cells, visible microscopically.

Electron Microscopy

Viral infections can occasionally be diagnosed using electron microscopy for the direct visualization of viral particles in specimens. Advantages include speed, lack of requirement for viral viability, and the fact that many different kinds of viral particles can potentially be seen. Thus, like viral culture, electron microscopy is an “open” procedure. Disadvantages include the cost and complexity of maintaining an electron microscope, the need for a skilled operator, and relative lack of sensitivity related to the fact that a relatively high concentration of viral particles (10^5 to 10^6 per milliliter) is required for visualization (128).

Direct Specimen Examination

The main area in which electron microscopy has been used in diagnostic virology is the evaluation of stool specimens from patients with suspected viral gastroenteritis (93). None of the major viral causes, including rotaviruses, enteric strains of adenovirus, caliciviruses, and astroviruses, is readily cultivable. However, all can be seen by transmission electron microscopy of material that has been negatively stained using phosphotungstic acid or uranyl acetate. Rotaviruses and adenoviruses are easily seen, but most laboratories rely on immunoassays rather than electron microscopy for diagnosis of gastroenteritis caused by these agents. Detection of caliciviruses such as the Norwalk agent is enhanced by preincubation with immune serum (immune electron microscopy) to create viral aggregates that are more easily visualized than individual viral particles. Other applications of electron microscopy to the direct examination of specimens include examination of blister fluid to discriminate between herpesvirus and poxvirus particles and detection of filoviruses (e.g., Marburg and Ebola viruses) in clinical samples such as serum or urine.

Examination of Fixed Tissue

Electron microscopy can also be used to detect and classify viral particles in fixed tissue obtained by biopsy or at autopsy. Screening of tissue samples by electron microscopy is not useful because of the small area of tissue that can be examined. Thus, electron microscopy is best employed when it is directed by evidence of viral infection detected by routine histology.

Examination of Infected Cell Cultures

Finally, electron microscopy can be used to identify viruses growing in cell culture when they cannot be identified by other methods. Although identification to the species level is not possible, identification of a virus family based on morphology can provide a starting point for more detailed identification.

Light Microscopy

Although viral particles, with the exception of poxviruses, cannot be directly visualized by light microscopy, indirect evidence of viral infection may be detected. The most characteristic signs of viral infection are inclusion bodies (composed of masses of virions), multinucleated cells, and syncytial cells. These findings may be present in cytologic specimens or in tissue examined after histologic staining. Viral inclusions can be found in the nucleus or cytoplasm of infected cells. The location is characteristic of the responsible virus. The location of viral inclusions is summarized in Table 3. Microscopy for detection of the effects of viral infections in clinical specimens is generally carried out in surgical pathology, rather than diagnostic virology, laboratories.

Virus	Nuclear	Cytoplasmic
Herpes simplex virus	X	
Varicella zoster virus	X	
Cytomegalovirus	X	X
Adenovirus	X	
Polyomaviruses (JC and BK)	X	
Parvovirus B19	X	
Poxviruses		X
Measles	X	X
Parainfluenza virus		X
Rabies		X

TABLE 3. *Viral inclusions*

Cytology

Cytologic examination for evidence of viral infection can be performed on smears prepared by applying a specimen directly to a microscope slide, on slides prepared by cytocentrifugation of fluids such as bronchoalveolar lavage fluid, and on touch preps prepared from pieces of unfixed tissue. Viruses that may produce cytologic evidence of infection in respiratory specimens include HSV, CMV, adenovirus, and measles virus (Warthin-Finkeldey cells). Cytologic examination is usually not a sensitive method for detection, but it provides strong evidence for tissue involvement. Examples of cytologic findings suggestive of viral infection are shown in Figure 4.

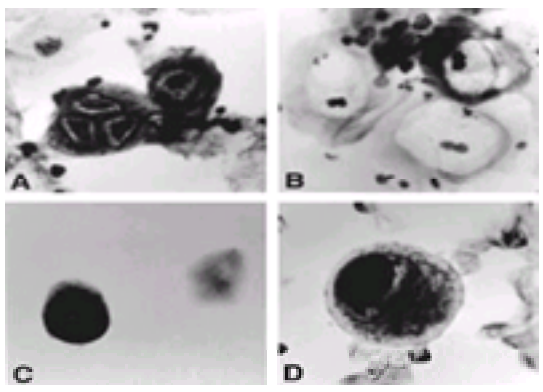

FIG. 4. Cytologic findings suggestive of viral infection. **A:** Cervical smear showing multinucleated cells and the Cowdry type A intranuclear inclusions of herpes simplex infection. **B:** Papanicolaou smear showing binucleate squamous epithelial cells with distinct perinuclear halos. These characteristics are described as *koilocytosis* and are the cellular features associated with human papillomavirus infection. **C:** Urinary epithelial cell containing an enlarged nucleus with smudgy chromatin and a small pale “glassy” intranuclear inclusion indicative of polyomavirus infection. **D:** Cell from bronchoalveolar lavage with a large intranuclear inclusion with a perinuclear clear space (“owl's eye” cell) indicative of cytomegalovirus infection. (Photographs provided by Dr. Leslie Boucher, Department of Pathology, Washington University, St. Louis.)

Tzanck Smear

A specific example of cytologic staining for viral infection is the Tzanck smear, first described in 1949 (193). The Tzanck smear has been used for the rapid detection of HSV or VZV infection in skin lesions. Tzanck smears are prepared by applying material from the base of a lesion on a microscope slide, followed by air drying, fixation in acetone, and staining with Wright stain, Giemsa stain, or a variety of other stains. The presence of multinucleated giant cells or intranuclear inclusions suggests the presence of HSV or VZV virus. The technique does not distinguish between the two viruses. For VZV, the Tzanck smear is more sensitive than culture but less sensitive than FA staining (174). The main advantages of the technique are that it is rapid and does not require sophisticated equipment.

Papanicolaou Staining

Another application of cytology for viral diagnosis is Papanicolaou staining of cells obtained from the uterine cervix. Human papillomavirus (HPV) infection produces characteristic changes in keratinocytes, including a condensed nucleus with a prominent perinuclear clear zone referred to as *koilocytosis.* More specific evidence of the presence of HPV can be provided by histochemical stains or molecular techniques.

Urine Cytology

Cytologic staining of cells present in urinary sediment may reveal intranuclear inclusions indicative of infection with either CMV or the polyoma viruses JC and BK. Culture for CMV and PCR for polyoma viruses are more sensitive techniques. Cytology does not distinguish between JC and BK viruses.

Histology

Histologic examination of stained tissue can provide unique information about the role of viral infection in producing tissue inflammation or injury and can be useful in distinguishing between asymptomatic viral shedding and clinically significant infection. This is particularly useful for CMV infections, in which prolonged viral shedding can occur without producing disease. For example, the presence of cytomegalic inclusion cells in tissue obtained by biopsy or at autopsy is often considered to be the gold standard for diagnosing clinically significant CMV infection. Histopathology can be enhanced by immunohistochemistry (IHC) to detect specific viral antigens and by *in situ* hybridization (ISH) to detect specific viral nucleic acids. These methods can enhance the sensitivity of detection and allow identification of the presence of a specific viral agent. IHC can often be performed on formalin-fixed tissue, but for some antigen–antibody combinations, sensitivity is better on fresh-frozen tissue. ISH can usually be performed on formalin-fixed tissue. The technique of *in situ* PCR has been developed to allow the PCR to be performed directly on tissue. *In situ* PCR can allow exquisitely sensitive detection of viral nucleic acid in tissues but is currently available only in a limited number of laboratories with a special interest in the technique.

Antigen Detection

The detection of viral antigens directly in clinical specimens has become an essential component of the methodologic repertoire of diagnostic virology. Antigen detection methods can provide diagnostic information within a few hours of the receipt of the specimen in the laboratory. The lack of requirement for virus viability is another important advantage over viral culture, especially when specimen transport time is prolonged or otherwise suboptimal.

Antigen detection methods can be applied when the following conditions are met: (a) viral antigen is expressed and is present in an accessible specimen, (b) an appropriate antibody (usually, but not necessarily, monoclonal) is available, (c) antigenic variability does not preclude recognition by immunologic reagents of different strains of the target virus, and (d) the antigen being detected is sufficiently stable that it does not degrade during transport and processing of the specimen. Methods used for viral antigen detection include FA staining, immunoperoxidase staining, and enzyme immunoassay (EIA). The latter can be subdivided into solid-phase and membrane immunoassays. The viruses for which antigen

detection assays are in widespread use are shown in Table 4.

Specimen	Viruses detected
Respiratory (nasopharyngeal swab or aspirate, nasopharyngeal wash, tracheal aspirate, bronchoalveolar lavage)	Respiratory syncytial virus Influenza virus A, B Parainfluenza virus 1-3 Adenovirus Measles
Skin or mucous membrane scraping	Herpes simplex virus Varicella zoster virus
Conjunctival or corneal scrapings	Herpes simplex virus Adenovirus
Stool	Rotavirus Adenovirus (enteric serotypes)
Blood	Cytomegalovirus (pp65) Hepatitis B (surface antigen) Human immunodeficiency virus (p24)

TABLE 4. *Viral antigen detection: specimens used and viruses detected*

Fluorescent Antibody Staining

FA staining is widely employed for detection of cell-associated viral antigens. In the direct format, a fluorescent label, usually fluoroscein isothiocyanate (FITC) is conjugated directly to the antibody that recognizes the viral antigen. In the indirect format, the antiviral antibody is unlabeled and is detected by a second antibody that recognizes immunoglobulins from the animal species of origin of the antiviral antibody. The second antibody carries the fluorescent label. After staining, the specimen is viewed with epiillumination using ultraviolet light of the wavelength needed to excite the fluorescent label. The direct method is simpler to use but requires conjugation of each antiviral antibody with the fluorescent label. The indirect method is slightly more sensitive and more versatile because only the antiimmunoglobulin antibody has to be conjugated with the fluorescent label.

The main applications of FA staining have been for the detection of respiratory, ocular, cutaneous, and bloodstream pathogens. Many different respiratory specimens can be used, including nasopharyngeal swabs or aspirates, nasal washes, tracheal aspirates, and bronchoalveolar lavage fluid. In each case, the specimen is processed in the laboratory to prepare a pellet of cells, which is spotted onto one or more microscope slides. The cells are air dried, fixed in acetone, and stained with monoclonal antibodies to one or more viruses. For ocular infections, material is scraped from the conjunctiva or cornea, placed on microscope slides, and processed as described for respiratory specimens. Staining is usually directed at detection of HSV and adenovirus antigens. For cutaneous infections, the lesion is scraped with a scalpel blade or swab, and cellular material obtained is placed directly on one or more microscope slides. Alternatively, the base of the lesion can be rubbed vigorously with a swab and the swab submitted to the laboratory, where cellular material is washed from the swab and spotted onto a microscope slide. The use of cytocentrifugation to prepare the slides has been shown to improve the results (110). Staining is directed at detection of HSV and VZV. In the CMV pp65 antigenemia assay, peripheral blood leukocytes are separated from anticoagulated blood, spotted onto a microscope slide, usually by cytocentrifugation, and stained using a monoclonal antibody specific for the CMV pp65 antigen.

Immunoperoxidase Staining

Immunoperoxidase (IP) staining is similar in principle to FA staining except that horseradish peroxidase is used in place of a fluorescent label. After the peroxidase-labeled antibody is incubated with the specimen, a substrate for peroxidase is added that changes color when acted on by the peroxidase. The advantage of this method is that the staining can be viewed by light microscopy, thus obviating the need for a fluorescent microscope. IP staining is particularly advantageous when performed on intact tissue because the tissue can also be stained by histochemical stains, allowing examination of the spatial relationship between viral antigens and cellular structures. The disadvantages of the IP method are that it is more cumbersome than FA staining, and endogenous peroxidases in some specimens can produce background staining.

Enzyme Immunoassay

EIA is a versatile and widely used method that can be applied to the detection of antigens regardless of whether they are cell associated or in fluid phase. Because intact cells in the specimen are not required, specimen integrity is less important than for FA or IP staining. This may be advantageous when specimen transport time is prolonged. A common assay format for antigen detection is the double antibody sandwich, shown in Figure 5. In this assay, a “capture” antibody specific for the viral antigen being sought is bound to a reaction surface; for example, the wells of a plastic microtiter tray or the surface of a plastic bead. When the specimen is added, viral antigen present in the specimen binds to the capture antibody. Bound antigen is detected using a second antiviral antibody, the “detector” antibody. The detector antibody can be labeled with an enzyme or can be detected by the addition of an enzyme-labeled third antibody with specificity for immunoglobulin of the species from which the second antibody was derived. The addition of an enzyme substrate produces a color change or light emission if the enzyme is present. Thus, color change or light emission indicates that viral antigen was present in the specimen being tested. Advantages of EIA include applicability to diverse specimens and potential for automation. Laboratory instruments are now available that can perform EIAs for the detection of either antigens or antibodies. Viruses for which antigen EIAs have been widely used are RSV, influenza, rotavirus, enteric adenoviruses, HSV, hepatitis B virus (HBV), and HIV.

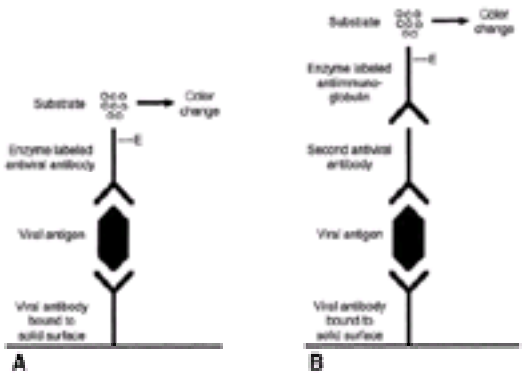

FIG. 5. Enzyme immunoassay (EIA) for antigen detection. **A:** Direct. **B:** Indirect.

Membrane Immunoassays

The membrane immunoassay is a variant of EIA in which antigens or antigen–antibody complexes are captured directly on membranes. An assay called the Directigen test (Becton-Dickinson, Cockeysville, MD) is commercially available, and versions exist for detection of influenza A and B and RSV. Membrane immunoassays are manufactured as self-contained cassettes that are convenient for testing single specimens. They are simple enough to be used in physician's offices or in other outpatient facilities.

Assay Performance

For certain applications, especially RSV and CMV, the sensitivity of antigen detection exceeds that of viral culture (148,190). For the other respiratory viruses and a number of other targets, however, the sensitivity is often less than culture and is certainly less than PCR and other nucleic acid amplification techniques. Overall performance of FA and IP staining techniques is affected by many variables, including the source, timing of acquisition, and transport of the specimen; the quality of the reagents and microscope in use; and the skill of the microscopist. EIA techniques tend to be less affected by the skill of the individual performing the assay and are more suitable for automation.

Nucleic Acid Detection

Diagnostic virology is being revolutionized by the application of nucleic acid detection techniques. These techniques detect specific nucleic acid sequences and can be applied to the detection of virtually any virus. Depending on the target sequence, the assays can be specific for a single virus species or for a group of related viruses. The latter characteristic is particularly advantageous because it allows nucleic acid detection techniques to be applied to groups of viruses, such as the enteroviruses, for which antigenic diversity has precluded successful application of antigen detection techniques. In the case of the enteroviruses, highly conserved sequences in the 5' nontranslated region of the genome have been exploited to develop reverse transcription–polymerase chain reaction (RT-PCR) assays that can simultaneously detect almost all enterovirus serotypes (31,164).

The earliest attempts at nucleic acid–based diagnosis involved direct hybridization of nucleic acid probes to viral nucleic acids present in clinical specimens. Direct hybridization was never widely adopted because it lacked adequate sensitivity, requiring the presence of 10^4 to 10^5 copies of the target nucleic acid. The development of PCR (169) and other nucleic acid amplification techniques overcame that sensitivity barrier and has led to the development of nucleic acid–based diagnostic tests for many viruses. Nucleic acid amplification assays are particularly attractive for viruses that are difficult or impossible to cultivate, viruses that grow slowly in culture, and viruses for which antigen detection cannot be applied because of antigenic diversity or because the level of viral antigen in clinical specimens is too low to permit successful detection. Because nucleic acid amplification techniques can often be performed on a small volume, they are also uniquely useful for specimens such as CSF or ocular fluid that may be available only in small amounts. Still another advantage of nucleic acid detection as a diagnostic method is the stability of DNA, so that detection of viral nucleic acids can be done even when conditions lead to loss of virus viability.

Nucleic Acid Amplification Assays

Nucleic acid amplification assays can be divided into those that amplify target nucleic acid, those that amplify the probe itself, and those that amplify the detection signal.

Target Amplification Assays

PCR is the prototype of target amplification assays. PCR employs short oligonucleotide primers and a thermostable DNA polymerase, such as Taq polymerase, to amplify a segment of target DNA that is typically 100 to 1000 base pairs in length. The PCR itself includes 25 to 40 cycles, each consisting of denaturation, primer annealing, and extension steps that take place at different temperatures. Progression through the steps of the cycle is controlled by an instrument called a *thermal cycler* that controls the temperature of the reaction. After PCR amplification, the PCR product, or *amplicon,* is detected by gel electrophoresis or one of several probe-hybridization techniques, such as Southern blot. The analytic sensitivity of PCR can be as low as 1 to 10 copies of target DNA. Because of its simplicity and broad applicability, PCR has been widely used in viral diagnosis.

Another important target amplification technique is called *transcription-based amplification* (82,105) (Fig. 6). These techniques use three enzymes: reverse transcriptase (RT), RNase H, and T7 RNA polymerase to amplify a target RNA sequence, employing a series of reactions that mimic the retrovirus replication scheme. An advantage of

transcription-based amplification assays is that they are isothermal and do not require complicated instrumentation. The assays begin with synthesis of a DNA strand that is complementary to the RNA target, using a primer that contains a T7 polymerase–binding site. The resulting DNA–RNA hybrid is converted to double-stranded DNA by the action of RNase H and a second primer that also contains a T7 polymerase–binding site. The double-stranded DNA product then serves as a template for transcription brought about by T7 RNA polymerase. The newly synthesized RNA transcripts serve as templates for additional cycles of the reaction. The assay is being developed commercially as the NucliSens assay (Organon-Teknika Corp., Durham, NC) for the detection of HIV and CMV RNA.

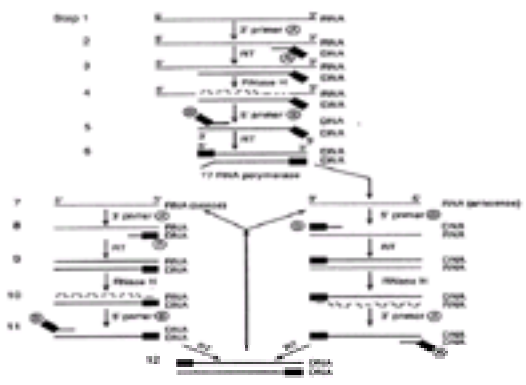

FIG. 6. Transcription-mediated assay, also called 3SR. The 3SR reaction depends on a continuous cycle of reverse transcription and transcription reactions to replicate an RNA target by means of cDNA intermediates. Oligonucleotides A and B prime DNA synthesis and encode the promoter sequence for the T7 RNA polymerase (*black boxes*). Steps 1 to 6 depict the synthesis of a double-stranded cDNA, which is a transcription template for T7 RNA polymerase. Complete cDNA synthesis is dependent on the digestion of the RNA in the intermediate RNA:DNA hybrid (step 4) by RNase H. Transcription-competent cDNAs yield antisense RNA copies of the original target (step 7, *right*). These transcripts are converted to cDNAs containing double-stranded promoters on both ends in an inverted repeat orientation (steps 7 to 12). These cDNAs can yield either sense or antisense RNAs, which can reenter the cycle. Thin lines, RNA; thick lines, DNA; RT, reverse transcription. (From ref. 82, with permission.)

Signal Amplification Assays

Examples of signal amplification assays include the branched-chain DNA (bDNA) assay (54) and the hybrid capture assay (88). The bDNA assay (Fig. 7) was originally developed by Chiron Corporation (Emeryville, CA) and is being applied to the detection of HIV and hepatitis C RNA. The assay uses short branched-chain oligonucleotides to capture the target nucleic acid sequence. Other branched-chain oligonucleotides link multiple molecules of detector enzyme to the captured target. A chemiluminescent substrate allows detection of the target, and measurement of the intensity of emitted light makes it possible to quantitate the input target accurately. Because the target itself is not amplified, this reaction is less susceptible than PCR to carryover contamination (see later).

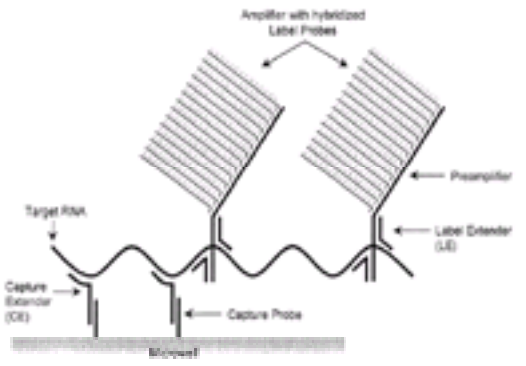

FIG. 7. Branched-chain DNA assay as used for ultrasensitive detection of human immunodeficiency virus (HIV). After liberation of viral nucleic acid from the clinical specimen by a lysis buffer, viral nucleic acid is hybridized with two sets of bifunctional oligonucleotide probes, each of which contains sequences complementary to the target. One set of probes also contains a generic sequence complementary to a capture probe, which is bound to the surface of a microtiter tray, and serves to bind the target to the solid surface. The other set of probes contains a sequence complementary to preamplifier molecules. Additional specificity is achieved because two of the target-specific probes must be juxtaposed in the correct orientation to stabilize the binding of the preamplifier molecule. Each preamplifier molecule binds numerous amplifier molecules, each of which bind many subsequently added alkaline phosphatase-labeled probes. A chemiluminescent substrate is added, and generated light is read by a luminometer. The cascade effect results in amplification of the signal generated from initial binding of probes to the target and allows for detection and quantitation of nucleic acid present in the specimen. (Courtesy of Bayer Diagnostics, Emeryville, CA.)

The hybrid capture assay (Fig. 8) is another signal amplification assay that is being developed commercially for viral diagnosis (Digene Corporation, Beltsville, MD) (116,124). The assay involves a liquid hybridization reaction between the denatured DNA target and RNA probes specific for the viral DNA sequence of interest. If the viral DNA is present, DNA–RNA hybrid molecules are formed and are captured and detected using an antibody specific for DNA–RNA hybrids. This assay can be used as either a qualitative or quantitative assay. The hybrid capture assay is being developed for

detection of the HPV, CMV, and HBV DNA.

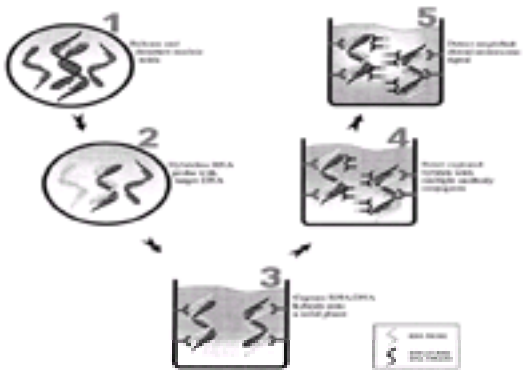

FIG. 8. Hybrid capture assay. In step 1, target DNA is released and denatured. In step 2, RNA probe hybridizes with target DNA. In step 3, RNA:DNA hybrids are captured by an antibody to RNA:DNA hybrids that is bound to the sides of the reaction vessel. In step 4, an enzyme-conjugated antibody that recognizes RNA:DNA hybrids binds to the hybrids. In step 5, a chemiluminescent substrate is added, and light is emitted if hybrids have been formed. (Courtesy of Digene Corporation, Beltsville, MD.)

Contamination

A general concern regarding highly sensitive nucleic acid amplification assays is the occurrence of false-positive results resulting from contamination of the reaction with exogenous nucleic acids. The source of contaminating nucleic acids can be either amplified product from previous reactions or viral nucleic acids present in a different specimen, especially one containing a high level of the intended target. Prevention of contamination requires fastidious attention to procedural detail within the laboratory. A number of specific preventive techniques are widely used to prevent carryover contamination after PCR, including the use of positive displacement pipettes or plugged pipette tips to block aerosol production, ultraviolet irradiation of reaction components (not including Taq polymerase and PCR primers that can be inactivated by ultraviolet irradiation), use of small working aliquots, and frequent cleaning of equipment and laboratory surfaces with 10% bleach. An important precaution is the physical separation of the laboratory into sections where (a) the specimen is prepared, (b) the PCR reaction is set up, (c) the PCR amplification reaction takes place, and (d) the detection of amplification products is carried out. After PCR has taken place, the reaction tube is only opened in the section of the laboratory devoted to product detection.

Two other specific methods have been developed to prevent PCR carryover contamination. The first is the use of uracil-*N*-glycosylase (145). In this method, the original amplification reaction is carried out with deoxyuracil triphosphate substituted for deoxythymidine triphosphate, leading to incorporation of deoxyuracil residues into any amplified nucleic acid. Subsequent PCR reactions are set up including uracil- *N*-glycosylase in the reaction mixture. The action of this enzyme cleaves deoxyuracil residues from DNA. The sites where deoxyuracil residues have been cleaved are susceptible to scission during any subsequent PCR reaction, rendering the DNA unsuitable for amplification and eliminating any risk related to carryover contamination. The second method involves the use of furocoumarin compounds such as psoralens and isopsoralens (145). These agents bind to DNA when exposed to ultraviolet light of the proper wavelength. DNA to which the furocoumarins have bound cannot be amplified by Taq polymerase. In this method, the furocoumarin compound is included in the PCR reaction mixture. After amplification but before the reaction tube is opened, the mixture is subjected to ultraviolet irradiation to allow binding of furocoumarin to DNA. The cross-linked DNA cannot serve as the target for additional PCR amplification, thus eliminating danger of carryover contamination.

RNA Detection

Because Taq polymerase uses only DNA as a template, the use of PCR to detect viral RNA sequences requires the inclusion of an RT step before PCR. This can be done in the same reaction tube in which PCR will take place, and the combined reaction is called RT-PCR. The RT reaction can be performed using a devoted enzyme such as Moloney murine leukemia virus RT or avian myeloblastosis virus RT. Alternatively, heat-stable multifunctional enzymes, such as recombinant *Thermus thermophilus* DNA polymerase, are available that can carry out RT as well as DNA polymerase reactions. Special care must be used in specimen processing because of the susceptibility of RNA to digestion by ribonucleases that may be present in clinical samples. RT-PCR has been applied to the detection of numerous RNA viruses, including HIV, hepatitis C, enteroviruses, RSV, influenza and parainfluenza viruses, rotavirus, and other RNA viruses that cause gastroenteritis. RT-PCR can also be applied to the detection of viral messenger RNA (mRNA). This may be particularly useful in the diagnosis of infection caused by viruses that have a latent phase in their life cycle. For these viruses, detection of viral DNA might not distinguish between latent and productive infection, whereas detection of an mRNA expressed only in productive infection would be evidence of active viral infection. Transcription-based amplification assays (see Fig. 6) are ideally suited for amplification of RNA.

Multiplex Polymerase Chain Reaction

Multiplex PCR refers to PCR reactions in which more than one primer set is included, allowing the detection of multiple targets. This can be an efficient means for detecting within the same reaction multiple agents that can produce the same clinical syndrome. For example, a multiplex assay has been described to allow the simultaneous detection of enteroviruses, HSV-1 and HSV-2, and VZV in specimens of CSF from patients with encephalitis or meningitis (149). The agents detected do not have to be only viruses; for example, a PCR reaction has been described for the simultaneous detection of EBV and *Toxoplasma gondii* in CSF from immunocompromised patients with mass lesions within the brain

(161).

Quantitative Polymerase Chain Reaction

A variety of methods can be used to allow PCR and other amplification methods to quantitate the amount of target nucleic acid present in a specimen. A widely used method is the quantitative-competitive PCR reaction, in which an alternative target (referred to as the *competitor*) which has the same primer binding sites as the legitimate target is included in the reaction mixture. The competitor must be different from the legitimate target in some way, such as size or partial sequence difference, that allows the amplified competitor to be distinguished from the amplified legitimate target. After amplification, the amount of legitimate target in the original specimen is determined from the ratio of amplified target to amplified competitor.

Real-Time Polymerase Chain Reaction

Several new PCR assays have been developed in which the synthesis of the PCR product is detected as it occurs (75,89). These assays have been termed *real-time PCR.* Two specialized instruments are available for carrying out real-time PCR assays, and more are under development. The two instruments currently available are the Prism 7700 manufactured by Perkin-Elmer (Foster City, CA) (also known as the *Taqman* instrument), and the Light Cycler, manufactured by Roche Diagnostics (Mannheim, Germany). The two instruments have important differences and are adapted to run different real-time PCR assays, including the 5'-exonuclease assay, the hybridization probe assay, and the SYBR Green DNA-binding assay. All three formats can be run on the Light Cycler, whereas the Prism 7700 is currently configured to run the 5'-exonuclease and SYBR Green assays.

The unique feature of the Light Cycler is very short PCR cycle times, achieved by using very small-volume capillary tubes whose surface area is large in proportion to the volume. This feature, combined with an air-based thermal system, achieves rapid heating and cooling of the PCR tubes, allowing amplification reactions to be completed in as little as 20 to 30 minutes. Reaction products are detected with a fluorescence detection system consisting of a light-emitting diode that delivers excitation light to each reaction tube and an optical unit with three detection channels to record emitted light of three different wavelengths. The instrument can accommodate 32 capillary tubes, all of which can be analyzed simultaneously.

The Prism 7700 is based on a Perkin-Elmer 9600 thermal cycler with a laser-based optical system that delivers excitation light to each of 96 wells of a microtiter tray and reads emitted fluorescent light from the same wells. The PCR cycle characteristics are similar to those used in conventional PCR. The Prism 7700 is particularly advantageous for applications requiring high throughput.

The simplest system for detection of real-time PCR products uses the DNA-binding dye SYBR Green, which fluoresces when it binds to double-stranded DNA. When SYBR Green is included in a PCR reaction, the intensity of fluorescence is proportional to the amount of PCR product. Because SYBR Green binds nonspecifically to any double-stranded DNA, signal is generated by undesired amplification products, such as primer-dimers, as well as by intended amplicons. Discrimination among different amplification products can be achieved through the use of dissociation curves (also referred to as *melting-point analysis*). Melting-point analysis is performed after completion of the amplification reaction by recording fluorescence as the temperature of the reaction mix is gradually increased. When the dissociation temperature (melting point) of the double-stranded DNA reaction product is reached, SYBR Green is released, and fluorescence decreases. Because the melting point is affected by both length and sequence of the PCR product, intended and unintended amplification products can usually be readily distinguished.

The other two detection systems are based on the use of oligonucleotide probes that are labeled with fluorescent dyes that interact with one another according to principles of fluorescence resonance energy transfer. The hybridization probe assay format requires two oligonucleotide probes that are homologous to adjacent portions of one of the strands of the amplified DNA. The probes are chosen so that the 5' end of one probe is within a few nucleotides of the 3' end of the other probe. These adjacent ends are each labeled with a fluorescent dye. The dye on the 3' end is termed the *donor dye* and the dye on the 5' end is termed the *accepter* dye. The required property of these dyes is that when they are in close proximity to one another (within a distance of several nucleotides), excitation of the donor dye leads to emission of light by the accepter dye. When both probes bind to their target sequences, the two dyes are within the proximity required for excitation of the accepter dye, and fluorescence occurs. The fluorescence intensity is proportional to the amount of PCR product.

The other detection system based on interacting fluorescent dyes is the fluorogenic 5'-exonuclease assay (also referred to as the *Taqman* assay). This assay uses a probe that is complementary to a segment of the intended PCR product located between the PCR primers. This probe is labeled with two fluorescent dyes, one called the *reporter,* which is linked to the 5' end of the probe, and the other called the *quencher,* which is linked to the 3' end. When they are in close proximity (i.e., bound to opposite ends of an oligonucleotide probe), the quencher prevents fluorescence by the reporter. During the annealing step of PCR, the probe labeled with both dyes binds to the PCR product. During extension, the 5'-exonuclease activity of Taq polymerase cleaves nucleotides from the bound probe, releasing the reporter dye, which allows it to emit light upon excitation. As in the hybridization probe assay, the intensity of fluorescence is proportional to the amount of PCR product.

Real-time PCR assays have several important advantages over conventional PCR. Because the accumulation of PCR product is monitored in the reaction tube, no separate detection method, such as gel electrophoresis, is required, thus shortening the effective assay time markedly. In addition, the chance of contamination by amplified PCR product is decreased because the systems are closed, with no handling of the reaction contents after completion of PCR. The use of multiple fluorescent dyes with different emission wavelengths makes it possible to perform multiplex reactions with simultaneous amplification of more than one product. Quantitation of PCR targets is readily achieved because the

generated fluorescence is proportional to the amount of PCR product.

Polymerase Chain Reaction and Nucleotide Sequencing

Sequencing of PCR amplification products can provide valuable information about the identity of a virus whose nucleic acid was amplified or the presence of viral mutants associated with resistance to antiviral drugs. The process of obtaining nucleotide sequence data from PCR reactions is achieved through the use of the cycle sequencing reaction, which uses Taq polymerase and dideoxynucleotides in the PCR reaction mixture (98). The resulting reaction products can be analyzed by polyacrylamide gel electrophoresis followed by automated laser scanning and sequence assembly. The main application in diagnostic virology is for the detection of antiviral resistance in HIV directly from patient plasma specimens (94). Similar assays have also been used to detect antiviral resistance in CMV (37).

Other uses of nucleotide sequencing in diagnostic virology are restricted to highly unusual circumstances. For example, rapid sequencing was used to determine the identity of the hantavirus, sin nombre virus, when it was discovered as the cause of hantavirus pulmonary syndrome (138). In this case, because of clinical and laboratory suspicion that a hantavirus was the cause of the syndrome, PCR reactions were carried out using primers that matched conserved sequences of previously discovered human hantaviruses. Nucleotide sequencing of the amplification product of PCR performed on clinical specimens from patients with hantavirus pulmonary syndrome revealed the presence of a new hantavirus.

Chip Technology

It is now possible to bind precisely hundreds or thousands of oligonucleotide probes to a small silicon chip and to carry out hybridization reactions directly on the chip. Confocal microscopy is used to scan the chip, detecting fluorescent signals that reveal hybridization at precise locations on the chip. Use of probes representing all possible nucleotide sequence variations within a target sequence allow rapid determination of nucleotide sequence (144). Chip technology has the potential to allow simultaneous detection of multiple infectious disease pathogens, viral and nonviral. The first application in diagnostic virology has been for rapid sequencing to detect HIV mutations associated with resistance to antiretroviral drugs (102).

Applications of Nucleic Acid Amplification Techniques

PCR has been used to detect numerous viruses and is increasingly used to assess prognosis, monitor response to treatment, and assess progression of infection. Some of the more widely used diagnostic applications are listed in Table 5. Widespread use of nucleic acid amplification techniques is limited because few assays are available as commercial kits. The only nucleic acid amplification assays currently licensed by the Food and Drug Administration are the Amplicor assay for HIV plasma RNA (Amplicor HIV-1 Monitor Test, Roche Molecular Systems, Mannheim, Germany) and the NucliSens assay for CMV pp65 messenger RNA (Organon-Teknika, Durham, NC). Other assays have been developed by individual laboratories as “home-brew” assays. This situation has resulted in a proliferation of different assays that are not uniformly standardized and thus are not directly comparable. Performance of home-brew assays varies widely among laboratories, and interlaboratory proficiency testing is still in its infancy. In addition to variation in the PCR assays themselves, varying approaches to the choice of specimen, technique used to process the specimen within the laboratory, and technique used to detect the products of the PCR reaction can have important effects on the performance of PCR. Thus, it is important for the user of PCR to be familiar with the laboratory performing the assay. It may be appropriate to request data that the laboratory used to validate a specific PCR reaction.

Target	Specimen(s)	Application(s)
Human immunodeficiency virus (HIV) (DNA)	Leukocytes from infant born to HIV-infected mother	Perinatal infection
HIV (RNA)	Plasma	Viral load (prognosis, response to treatment)
Herpes simplex virus	Cerebrospinal fluid (CSF), ocular fluid	Encephalitis, meningitis, retinitis
Varicella zoster virus	CSF, ocular fluid	Encephalitis, meningitis, retinitis
Cytomegalovirus	Leukocytes, plasma, whole blood, CSF, ocular fluid, amniotic fluid	Diagnosis of systemic infection after organ transplantation, encephalitis, radiculomyelitis, retinitis, congenital infection
Epstein-Barr virus	CSF, leukocytes	Primary central nervous system lymphoma in acquired immunodeficiency syndrome (AIDS), posttransplantation lymphoproliferative disorder
Parvovirus B19	Serum, amniotic fluid	Chronic parvovirus B19 infection, aplastic crisis, congenital infection
JC virus	CSF	Progressive multifocal leukoencephalopathy
BK virus	Urine	Hemorrhagic cystitis
Human papillomavirus	Genital secretions	Detection of viral types associated with cervical carcinoma
Enteroviruses	CSF	Meningitis
Hepatitis C virus (qualitative)	Plasma	Diagnosis of infection
Hepatitis C virus (quantitative)	Plasma	Prognosis, monitoring response to therapy
Hepatitis B virus	Serum	Monitoring response to therapy

Serology

The measurement of antiviral antibodies was one of the first methods used for the specific diagnosis of viral infections and remains an important tool in the diagnostic virology laboratory. The role of serology may be for the diagnosis of acute or current infection or for the determination of immune status to specific viruses. Serologic diagnosis is important for viruses that cannot be readily cultured or for which culture is slow or otherwise impractical. Viruses for which serology is useful in diagnosing acute infection are shown in Table 6. Serology is uniquely useful for defining immunity with respect to specific viruses. It is important to use sensitive assays, such as EIA, for this purpose because antibody levels indicative of past infection may decline to low levels years after the infection. The specific assay used must also be selected with care to ensure that it measures antibodies that correlate with immunity. Viruses for which serologic testing is used to determine immune status are shown in Table 7.

Epstein-Barr virus[a]
Cytomegalovirus (mononucleosis syndrome)[a]
Hepatitis viruses (A–E)[b]
Measles[a]
Rubella[a]
Mumps[a]
Parvovirus B19[a]
Encephalitis viruses[a]
Rabies
Hemorrhagic fever viruses[a]
Dengue[a]
Human immunodeficiency virus
Human T-cell lymphotrophic virus types I and II

[a]Virus-specific immunglobulin M (IgM) assays are used.
[b]Virus-specific IgM assays are used for hepatitis A and B (IgM anti-HBc).

Kinetics of the Antibody Response

Serologic diagnosis is based on the kinetics of the antibody response to viral infection. Virus-specific antibodies are absent in a susceptible individual but typically become detectable several weeks after the onset of infection. Virus-specific IgM antibodies are often detectable for a short period before virus-specific IgG antibodies. The IgM response tends to decline within about 1 to 2 months, although low levels may persist for 1 year or more in some viral infections. IgG antibodies are much more long-lasting and may persist for the life span of the individual. According to this model, the absence of virus-specific IgG and IgM antibodies signifies susceptibility to infection; the presence of virus-specific IgM antibodies, with or without virus-specific IgG antibodies, signifies current or very recent infection; and the presence of virus-specific IgG but not IgM antibodies signifies past infection. The latter pattern often indicates immunity to subsequent infection.

The relationship between the onset of clinical manifestations of infection and the presence of virus-specific antibodies depends on the incubation period of the infection. In infections with short incubation periods, such as acute respiratory infections, antibodies are absent at the onset of symptoms. In viruses with incubation periods of 1 month or longer, however, virus-specific IgG and IgM antibodies are typically present at the onset of symptoms.

Serology in Reinfection and Reactivation

The serologic diagnoses of reinfection and reactivated infection are more complicated than is the diagnosis of initial infection. In both of these cases, the infection occurs in an individual with preexisting virus-specific IgG antibodies. In reinfection, there may be an anamnestic response that results in an increase in the level of virus-specific IgG antibodies with continued absence of virus-specific IgM antibodies. Reactivation of latent infection, for example, in the case of herpesvirus infection, may result in the appearance of virus-specific IgM as well as IgG antibodies.

Serology in Chronic Infections

The interpretation of serology is unique for viruses that typically cause chronic infection, such as HIV and the related retroviruses human T-cell lymphotrophic virus (HTLV) types I and II. For these agents, the detection of antibodies of any isotype to these viruses (in the absence of artificial immunization) virtually always signifies current infection. In the case of hepatitis C virus, the confirmed presence of antibodies to the virus corresponds to active infection in about 85% of individuals.

Serologic Assays

Binding Assays

The most widely used assays are those that directly measure binding of antibodies to viral antigens. Examples of binding assays include EIA, radioimmunoassay (RIA), and the indirect immunofluorescent antibody assay (IFA). Binding assays can be used in many different formats. In one common format, a viral antigen (which may consist of virally infected cells, a purified viral preparation, or a recombinant viral protein) is attached to a solid surface such as the inner surface of the well of a microtiter tray, a plastic bead, or a microscope slide in the case of IFA. Serum is added, allowing the binding of

antiviral antibodies that might be present in the serum. After an appropriate incubation period, the serum is removed, and the well is extensively washed. The next step is the addition of a second antibody (also referred to as a *detector* antibody) with specificity for human immunoglobulins. The second antibody is typically a mouse monoclonal antibody or a polyclonal antibody from a nonhuman species. It is linked to an enzyme such as horseradish peroxidase. The second antibody binds to any human antibody present (ideally because of specific binding to the viral antigen). The well is again extensively washed, and the presence of the second antibody is detected based on a colorimetric, radiometric, or fluorescent signal. An important advantage of binding assays is that they can be modified to detect IgM- or IgA-specific antiviral antibodies through the use of isotype-specific detector antibodies.

Separated Antigen Assays

The Western blot and related recombinant immunobinding assays are binding assays that allow the identification of antibodies to specific viral proteins. In the Western blot assay, viral antigens present in infected cells are denatured, separated by gel electrophoresis, transferred to a membrane, and allowed to react with the serum specimen. Binding of antiviral antibodies is detected through the use of labeled detector antibodies. The Western blot is cumbersome but provides a high level of specificity because of the ability to identify binding to individual viral proteins and the production of a characteristic blot fingerprint. Thus, its main application in diagnostic laboratories is the confirmation of screening assays, such as EIA, that are less specific. For example, the Western blot is widely used to confirm a positive HIV EIA. Western blot is also considered the gold standard for determining the type specificity of HSV antibodies. The recombinant immunobinding assay differs from the Western blot in that specific viral antigens are produced in *in vitro* expression systems and are artificially attached to membranes in a predetermined configuration, often in dots or in bands. The membranes are then incubated with serum, and bound antibodies are detected as in the Western blot. Because the antigens used in the immunobinding assay are not denatured as they are in routine Western blots, these assays may have advantages in detection of antibodies to conformational epitopes. A recombinant immunobinding assay is widely used to confirm positive hepatitis C EIA results.

Functional Assays

Functional assays are based on detection of specific activities resulting from the binding of specific antibodies to viral antigens. An important example is the neutralization assay, which measures the ability of antibodies to block viral infectivity. In neutralization assays, serial dilutions of the serum to be tested are incubated with a standardized quantity of infectious virus. After a short incubation period, the serum–virus mixtures are added to cells that support the growth of the virus, in parallel with a similar inoculum of virus that has not been incubated with serum. The neutralizing antibody titer is the highest serum dilution that prevents infection of the cells. The neutralization assay correlates well with protection from infection and is sometimes considered the standard against which other serologic assays should be measured. Because it is cumbersome and expensive, the neutralization assay is now rarely used in routine diagnostic laboratories. Other examples of functional assays are the hemagglutination-inhibition assay, in which the presence of antiviral antibodies is detected by their ability to block virus-induced hemagglutination, and the complement fixation assay, which measures the ability of antiviral antibodies to fix complement, preventing the complement from lysing indicator erythrocytes. Although the hemagglutination-inhibition and complement fixation assays have been widely used in the past, they are increasingly being replaced by binding assays.

Agglutination Assays

Viral antigens can be bound to a variety of particles, including fixed erythrocytes and latex particles. Agglutination assays are performed by mixing dilutions of serum with a suspension of antigen-coated particles. The agglutination titer is the highest serum dilution that results in visible agglutination of particles. The advantage of agglutination assays is simplicity; they are rapid and do not require sophisticated equipment. Therefore, they are well suited to “stat” testing and for use under field conditions. For example, a rapid latex agglutination assay for varicella antibodies may be employed for rapid determination of the varicella immune status of health care personnel who are exposed to a patient with VZV.

Virus-Specific Immunoglobulin M Assays

Assays for virus-specific IgM antibodies are important because they often allow a specific diagnosis to be made based on analysis of a single serum specimen obtained during the acute phase of illness. These assays are most likely to be useful in diseases with incubation periods that are sufficiently long that virus-specific IgM levels are present at detectable levels at the onset of illness. Hepatitis A provides an excellent example; because of its incubation period of 1 to 6 months, hepatitis A IgM antibodies are virtually always detectable at the time patients seek medical care.

A number of methods are used to measure virus-specific IgM antibodies. Two older methods include (a) separating IgG and IgM fractions before performing the virus-specific antibody assay and (b) performing the virus-specific assay before and after procedures, such as treatment with b-mercaptoethanol, that selectively destroy IgM antibodies. Many modern virus-specific IgM antibody assays use IFA or EIA with a detector antibody that binds only to human IgM. The IgM capture assay is an alternative approach in which IgM antibodies present in the serum sample being tested are first “captured” using an antibody specific for human IgM. A preparation of viral antigen is added, followed by an enzyme-labeled antibody specific for the viral antigen. Binding is detected by the addition of the appropriate enzyme substrate.

Virus-specific IgM assays have several potential pitfalls and must be interpreted in conjunction with clinical findings. False-positive results can occur if the serum being tested contains rheumatoid factor (IgM antibodies to human IgG) and virus-specific IgG antibodies that form complexes that may be falsely detected by the assay as virus-specific IgM antibodies. This problem can be avoided by pretreatment of the serum to remove either rheumatoid factor or IgG antibodies. One or the other of these pretreatment methods is included routinely in many commercial virus-specific IgM antibody assays. False-negative results can occur if the serum being tested contains high levels of virus-specific IgG antibodies that may compete with the virus-specific IgM antibodies. The IgM-capture assay configuration avoids this

problem, as does serum pretreatment to remove IgG.

Complexities in the nature of the IgM antibody response must also be considered when interpreting virus-specific IgM antibody tests. In some patients, the IgM antibody response is transient or low level, leading to failure to detect virus-specific IgM antibodies, whereas in others, low levels of IgM antibodies may persist for 1 year or longer, decreasing the specificity of the assay as an indicator of recent infection. In herpesvirus infections, IgM antibodies can sometimes be detected in reactivations as well as in primary infection.

Saliva and Urine Assays

Virus-specific antibodies can often be detected in saliva and urine. These body substances are attractive for use in serologic assays because they avoid the need for phlebotomy. Assays for HIV antibodies in these fluids are commercially available and have performance characteristics similar to assays carried out on serum (71,194).

Cerebrospinal Fluid Serology

Serologic testing can be applied to CSF for the diagnosis of central nervous system (CNS) infection. For unusual viruses, such as rabies, the presence of any virus-specific antibodies within the CSF is diagnostic of active infection. For the diagnosis of encephalitis caused by the alphaviruses, bunyaviruses, or flaviviruses, the presence of virus-specific antibodies in CSF is highly suspicious, and the presence of virus-specific IgM antibodies in CSF is diagnostic. For more common viruses, such as the herpesviruses or the common respiratory viruses, the mere presence of virus-specific antibodies in CSF is not diagnostic of CNS infection because antibodies produced in the blood are present in the CSF even in the absence of CNS infection. The problem is further complicated by the fact that defects in the blood–brain barrier that may occur during many neurologic diseases can increase the passage of antibodies from blood to CSF. Therefore, for the common viruses, intrathecal synthesis of specific antiviral antibodies must be demonstrated to provide evidence of CNS infection.

Intrathecal synthesis of a specific antiviral antibody is evaluated by determining the quotient of two ratios: (a) the ratio of specific antiviral antibody level in CSF to the level in serum ($CSF_{\text{specific antibody}}/serum_{\text{specific antibody}}$ ratio), and (b) the ratio of total IgG in CSF to total IgG in serum ($CSF_{IgG}/serum_{IgG}$). A quotient greater than 1.5 is evidence of intrathecal antibody synthesis of the specific antibody. The antibody assay used to measure the specific antiviral antibody must have certain special characteristics. First, it must be very sensitive because CSF antibody levels are usually low (about 1000-fold less than serum levels). Second, it must be capable of providing a quantitative result that allows calculation of the CSF/serum ratio of specific antibody level. EIAs are usually used, but testing of a series of dilutions of CSF and serum is required to obtain linear quantitative estimates of antibody level suitable for calculating the necessary ratio. Because of the complexities involved, accurate determination of intrathecal antibody synthesis of specific antiviral antibodies is performed in only a limited number of reference laboratories.

Measurement of intrathecal antibody synthesis has been used in a variety of CNS infections. The application for which experience is most extensive is HSV encephalitis. In HSV encephalitis, the utility of determinations of intrathecal antibody synthesis is limited because intrathecal antibody synthesis may not be detectable until 7 to 10 days after the onset of illness. Interestingly, intrathecal antibody synthesis may persist for years after the acute infection (150). Therefore, the main utility is in cases in which specimens were not available early in the illness to allow a definitive diagnosis based on PCR. A caveat concerning diagnosis by demonstration of intrathecal antibody synthesis is that nonspecific polyclonal intrathecal antibody synthesis may occur in some diseases, such as multiple sclerosis (150). This pitfall can be avoided by evaluating intrathecal synthesis of antibodies to at least one other virus other than the one of primary interest.

Antiviral Susceptibility Testing

In recent years, antiviral drugs have been licensed for the treatment of infections caused by HSV, VZV, CMV, influenza A and B, RSV, and HIV. Not surprisingly, increasing use of these drugs has been accompanied by the appearance of antiviral drug resistance. Testing for resistance may be required for optimal patient management, particularly in infections caused by HSV, CMV, VZV, and HIV, for which resistance testing can guide the choice among several potentially effective drugs. Antiviral drug susceptibility testing is performed in some diagnostic virology laboratories.

Phenotypic and Genotypic Assays

Antiviral susceptibility testing is divided into phenotypic and genotypic methods. Phenotypic methods analyze the effect of antiviral drugs on the growth of virus, which can be measured by infectivity, viral antigen production, or viral nucleic acid production. Phenotypic assays are attractive because they directly measure the effects of antiviral drugs on viral growth. However, they tend to be labor intensive and slow. They have also been difficult to standardize, and results can vary based on the test system used. Table 8 shows recommended cutoffs that define resistance to several drugs used for HSV and CMV infections.

Virus	Drug	Susceptible	Intermediate	Resistant
Herpes simplex virus[195]				
	Acyclovir	<6 μM		≥6 μM
	Foscarnet	<200 μM		≥200 μM
Cytomegalovirus[9]				
	Acyclovir	≤6 μM	6–12 μM	>12 μM
	Foscarnet	≤400 μM		>400 mM
	Cidofovir	≤6 μM		>6 μM

Source: Data on herpes simplex virus from ref. 167, with permission; data on cytomegalovirus from ref. 58, with permission.

TABLE 8. *Cutoffs for antiviral susceptibility testing for herpes simplex virus and cytomegalovirus using the plaque reduction assay*

Genotypic assays test for the genetic basis for resistant phenotypes and can involve detection of restriction fragment length polymorphisms, differential hybridization assays, or nucleotide sequencing. Genotypic assays are informative only when the genetic basis for resistance is known, and they are most attractive when the resistance being evaluated is accounted for by a limited number of genetic changes.

Plaque Assay

The plaque assay is a traditional infectivity-based method that measures the inhibitory effect of an antiviral drug on the production of viral plaques in cell culture. In this assay, a standardized viral stock is inoculated into multiple identical cell cultures, usually grown in wells of a cluster plate. A solidifying agent such as agarose is added to the cultures to minimize spread of virus through the media. The viral titer of the stock is previously determined and is adjusted to yield a countable number of plaques in each well. Increasing concentrations of the antiviral drug being evaluated are incorporated into a series of wells. The effect of the drug is often expressed as the 50% inhibitory concentration (IC_{50}), defined as the lowest concentration of drug that results in a 50% decrease in the number of viral plaques compared with control wells with no antiviral drug. The IC_{90} can be similarly determined and is of additional interest because it better reflects the presence of minority resistant subpopulations. The plaque assay is considered the gold standard for antiviral susceptibility testing but is labor intensive and time-consuming. Completing the assay requires initial growth of the virus, titration of the viral stock, and the assay itself. For a slow-growing virus such as CMV, the time involved is often more than 6 weeks. For HSV, the assay can be completed in less than 2 weeks.

Other Phenotypic Assays

Assays measuring viral antigen or nucleic acid production are alternatives to infectivity-based assays. A variety of assays have been used in individual laboratories, but only two assays are commercially available. The Hybriwix assay (Diagnostic Hybrids, Athens, OH) uses ^{125}I-labeled probes to measure viral DNA that has been bound to nylon wicks placed in the culture wells. The IC_{50} is the minimal concentration of drug that results in a 50% decrease in viral DNA. The results of the Hybriwix assay for HSV and CMV correlate well with those measured by the plaque reduction assay (50,186). The ELVIS assay illustrated in Figure 3 has also been adapted for the performance of antiviral susceptibility testing (188).

Recombinant phenotypic assays have recently been developed for HIV. These assays involve insertion of the polymerase and protease genes of HIV from a patient being evaluated into a vector consisting of a rapidly replicating laboratory strain of HIV that also contains a reporter gene, such as luciferase, that is used to measure viral growth (142). These assays allow relatively rapid testing of the susceptibility of HIV to multiple drugs as well as to drug combinations.

Genotypic Assays

Genotypic assays have been most widely used for CMV and HIV, since phenotypic assays for involving these viruses are slow or expensive. A relatively limited number of mutations in the CMV *UL97* gene account for resistance to the antiviral drug ganciclovir in about 80% of resistant CMV isolates (35,36). The most important of these are mutations at *UL97* codons 460, 594, and 595, which can be detected using an assay based on PCR amplification followed by digestion of the PCR product with restriction endonucleases that differentiate between wild-type and mutant sequences. In many cases, this assay can be carried out directly on patient specimens, providing a result within 2 days. If a resistant pattern is not detected, nucleotide sequencing of the regions of the *UL97* and polymerase genes that have been implicated in resistance is required for complete detection of resistance (59). Resistance to the drugs foscarnet and cidofovir has been localized to mutations in the polymerase gene, and nucleotide sequencing is the only method available for detecting these mutations (59).

Genotyping testing for resistance is increasingly used for antiretroviral drug management of patients with HIV. This testing involves RT-PCR amplification of regions of the polymerase and protease genes, followed by nucleotide sequencing. Certain mutations are highly associated with phenotypic resistance and drug failure, whereas the significance of other mutations found in drug-resistant strains is less clear. Interpretation of HIV genotypic testing is complicated because of the diversity of mutations and the evolving knowledge base regarding the interaction of multiple mutations in determining the viral phenotype and response to therapy (94).

Genotypic testing for HSV is less useful than phenotypic testing because of the diverse genetic loci within the HSV thymidine kinase and polymerase genes that can account for resistance (73,168).

DIAGNOSTIC APPROACHES TO SELECTED CLINICAL PROBLEMS

Herpesviridae Infections

The diagnosis of infections caused by members of the family Herpesviridae is complex because of the diversity of clinical syndromes, frequently involving immunocompromised individuals. Additional complexities are related to the life cycle of the members of the family. After primary infection, herpesviruses become latent, with periodic reactivations. Reactivations are typically associated with the presence of infectious virus but may or may not be clinically significant. The following

discussion is subdivided according to the three Herpesviridae subfamilies.

Alphaherpesvirinae

The members of the alphaherpesvirinae subfamily that are human pathogens are HSV and VZV. B virus (also known as *Cercopithecine herpesvirus 1* or *Herpesvirus simiae*) is a virus that infects Old World macaques and can cause severe human disease when it is introduced by the bite of an infected monkey or through other exposures to infected secretions or animal products, including cell cultures. These viruses are characterized by rapid replication, efficient destruction of infected cells, and tendency to establish latency in sensory ganglia. Most clinical infections with HSV and VZV involve vesicular lesions of the skin and mucous membranes. Both viruses can also infect the CNS and produce encephalitis, meningitis, or myelitis. Likewise, B virus produces severe infection of the CNS. Visceral infection with HSV and VZV can also occur but is unusual.

Herpes Simplex Virus and Varicella Zoster Virus

Mucocutaneous Infections

The main diagnostic approach to mucocutaneous HSV and VZV infections involves direct detection of the virus, either by culture or antigen detection. Virus can be cultured during either primary or reactivated infection with either virus, although titers are higher with primary infection. Specimens are obtained by unroofing a vesicle and using a swab to soak up vesicular fluid as well as to scrape the base of the lesion. Calcium alginate swabs should not be used because this material inhibits the growth of HSV (48). HSV grows well in cell culture, usually producing CPE in 1 to 3 days (25). A variety of cell culture types can be used, but rabbit kidney, mink lung, and guinea pig embryo cells are particularly susceptible (111). Some laboratories use shell vial culture techniques or the ELVIS genetically engineered cell line (Diagnostic Hybrids, Athens, OH) (181,182). The sensitivity of cell culture techniques for HSV is strongly influenced by the stage of the lesion, with higher sensitivity for vesicular and pustular lesions than for lesions that are crusted (106). The overall sensitivity of culture for the diagnosis of genital HSV is about 80% (133). HSV-1 and HSV-2 grow equally well in culture. They can be differentiated by FA staining of the infected cell culture.

VZV is more difficult than HSV to grow in culture. This virus grows only in human fibroblast cells and monkey kidney cells and typically requires 4 to 8 days to become detectable. The sensitivity of culture detection is lower than for HSV but can be enhanced through the use of the shell vial technique (174).

Rapid Diagnosis

Rapid diagnosis of both HSV and VZV infections can be accomplished by FA staining. For this technique, cells from the base of a lesion are obtained by scraping the base with a scalpel blade or rubbing vigorously with a Dacron or rayon swab, and placing the material obtained on one or more microscope slides. This material is air dried, fixed with acetone, and then stained with fluorescent-labeled monoclonal antibodies to HSV and VZV. This technique is particularly advantageous for VZV because of the difficulty of culturing that virus (174). FA staining is preferable to a Tzanck smear because it allows specific viral identification and is more sensitive. PCR can be used to detect HSV or VZV DNA in cutaneous lesions with greater sensitivity than cell culture (87,165).

Serology

Serology has little role in the diagnosis of acute HSV infection because viral culture or antigen detection is usually successful, because serology requires acute and convalescent phase specimens, and because of difficulties in interpretation related to cross-reactions as well as asymptomatic reactivations. VZV serology is occasionally useful for diagnosis of acute VZV if appropriate specimens were not obtained for culture and antigen detection or if those tests were negative despite a clinical impression that VZV was the true diagnosis. Detection of seroconversion is the strongest serologic evidence of infection, although detection of VZV-specific IgM antibodies also supports the diagnosis of recent infection. Virus-specific IgM antibodies can be present with reactivation (zoster) as well as with primary infection (12,47).

Serology is widely used for determination of immune status, especially to VZV. The reference test for this purpose is the fluorescent antibody to membrane antigen test (199), but EIA, IFA, and latex agglutination assays are more widely used. None of these assays has optimal sensitivity for detection of VZV antibodies produced in response to varicella immunization. Latex agglutination is more sensitive than EIA or IFA for this purpose (183), although it is less sensitive than an EIA that uses purified glycoproteins as antigen (146). The latter assay is not commercially available at the current time.

Assays have become available that accurately distinguish antibodies made in response to HSV-1 or HSV-2 infection (13). These assays detect antibodies to type-specific glycoproteins, such as glycoprotein G. These assays may be useful in several settings. For example, in individuals with recurrent genital lesions who have never had a positive culture, detection of HSV-2 antibodies suggests that the genital lesions are probably herpetic. Type-specific antibody testing may also be useful for counseling couples. For example, if one partner is known to have HSV-2 infection, testing the other partner may reveal prior infection, suggesting no risk of transmission, or alternatively, absence of infection, indicating susceptibility and highlighting the need for precautions to prevent transmission. Testing of pregnant women may be helpful in identifying those who are seronegative but have a seropositive partner. These couples should take precautions to avoid transmission during the pregnancy. Pregnant women who are seropositive should be monitored with particular care taken to identify the presence of active lesions at the time of delivery. The issues involved in the use of type-specific HSV serology are complex and require much further evaluation.

B Virus

Most cases of human B virus infection have occurred after a bite or other exposure to infectious secretions or excretions

from a monkey infected with B virus. Symptomatic disease may not be apparent in the monkey. Typically, a vesicular lesion develops at the site of the bite, leading to lymphangitis and regional lymphadenopathy, followed by ascending encephalomyelitis. Recommendations for evaluation and treatment of suspected cases have been published by an expert working group (95). When B virus infection is suspected, specimens should be obtained from mucocutaneous lesions using a Dacron or cotton swab. CSF and conjunctival and pharyngeal swabs can also sometimes yield the virus, which grows in several types of primary and continuous monkey kidney cell cultures. Attempts to isolate the virus should be carried out only by appropriate reference laboratories with the necessary biologic safety capabilities (see later for listing of qualified laboratories). PCR may also be used to detect B virus. Acute and convalescent serum specimens should also be obtained, although cross-reactions with HSV can make interpretation difficult.

The following laboratories provide consultation as well as testing for B virus:

•Julia K. Hilliard, Ph.D
Southwest Foundation for Biomedical Research
Department of Virology and Immunology
7620 Northwest Loop 410
San Antonio, Texas 78228
Telephone (210) 674-1410 extension 280; or (210) 673-3269
Pager 1-800-443-7243; ID 011422
•Seymour S. Kalter, Ph.D.
Virus Reference Laboratory
7540 Louis Pasteur Drive
San Antonio, Texas 782229
•David Brown, M.R.C. Path.
Virus Reference Division
Central Public Health Laboratory
61 Colindale Avenue
London NW9 5HT, England
Telephone 081-200-4400

Betaherpesvirinae

The betaherpesvirinae include CMV, HHV-6, and HHV-7. These viruses are characterized by restricted host range, slow growth in culture, enlargement of infected cells, and latency in secretory glands and lymphoreticular cells. These viruses are widespread in the population, usually causing asymptomatic infection, but sometimes causing serious disease, especially in immunocompromised patients. The diagnosis of infection with these viruses is complicated by the frequent presence of these viruses in the absence of clinically significant manifestations. Thus, the presence of the virus, particularly in saliva or urine, is not diagnostic of disease. General approaches to this problem involve detection of the virus in less usual sites, such as blood; detection of the viruses in tissue, along with histologic examination to provide evidence that the infection is associated with pathologic findings; and quantitation of the level of virus present. For CMV, a number of laboratory methods are well established, including culture, antigen detection, nucleic acid detection, and serology.

Cytomegalovirus

Culture

CMV can be readily cultured in the diagnostic virology laboratory, although the virus is labile, and rapid transport to the laboratory is important (160). CMV grows only in human fibroblast cells and typically requires 7 to 21 days to exhibit CPE. For this reason, the shell vial technique is important because it provides results within 24 to 48 hours. Its sensitivity compared with that of conventional culture varies widely among individual laboratories but can be comparable or greater (7,78). The interpretation of CMV cultures can be difficult because of frequent shedding of the virus in saliva and urine in symptom-free individuals. Cultures of blood are more helpful diagnostically because asymptomatic CMV viremia does not occur in nonimmunocompromised hosts. In the immunocompromised patient, positive blood cultures indicate active infection but may occur in the absence of symptoms. Culture of CMV from urine or saliva usually has little diagnostic significance.

pp65 Antigenemia Assay

The pp65 antigenemia assay (154,195) is commercially available in both FA and IP formats and is widely used for the rapid diagnosis of CMV infection. In this assay, leukocytes are separated from other blood elements, spotted onto a microscope slide, and stained using a monoclonal antibody to pp65, the CMV lower matrix phosphoprotein. The assay has a number of desirable attributes, including potential availability of results within a few hours of receipt of the blood sample in the laboratory, sensitivity exceeding that of culture, capability of providing quantitative data, and a strong although not perfect correlation with the presence of clinically significant infection (190). A concern in the use of the assay, particularly for quantitative purposes, is that the antigen is labile, and results may be inaccurate if transport to the laboratory takes more than 24 hours (109,139).

Nucleic Acid Detection Assays

Detection of CMV DNA can be accomplished using PCR or the Digene hybrid capture system (Digene Corporation, Beltsville, MD). An assay for CMV pp65 RNA is also commercially available (NucliSens, Organon-Teknika, Durham, NC). PCR assays can be performed on any body substance or tissue but are usually performed on blood for the diagnosis of active CMV infection. Detection of CMV DNA in blood of normal, CMV-seropositive individuals is unusual and strongly suggests clinically significant infection either currently or in the recent past (155). In immunocompromised patients,

however, detection of CMV in blood is much more common and is poorly correlated with the presence of clinically significant CMV disease. Increasing evidence suggests that quantitative tests that measure the amount of CMV DNA in peripheral blood will be more useful in clinical decision making about the need for antiviral therapy (21,43,159,179). Further studies are required to define whether the optimal specimen is plasma, leukocytes, or whole blood.

Serology

CMV serology is of less value for the diagnosis of infections in immunocompromised patients than are direct tests for the virus (121). It is useful, however, for the diagnosis of CMV infection in the normal host (see later) and for defining CMV immune status, for example, in blood donors or in transplant donors and recipients. EIA is the assay format most widely used for detection of CMV antibodies and is more sensitive than the complement fixation test, which was widely used in the past.

Cytomegalovirus in the Normal Host

The most common disease manifestation of CMV in the normal host is a mononucleosis-like illness. In these cases, the heterophile antibody test is negative, as are tests for EBV IgM antibodies. Because these are primary infections, detection of CMV IgM antibodies is a convenient approach that usually provides a diagnosis (96). Acute EBV infection can also produce a false-positive CMV IgM test; therefore, acute EBV infection should be excluded before a positive CMV IgM test is considered diagnostic (86,96). In patients with CMV mononucleosis, CMV is regularly detected in the urine by culture and often in the blood by culture, the pp65 antigenemia, or PCR (155). Of these, PCR is the most sensitive, reaching 100% sensitivity in one study (155).

Cytomegalovirus in the Immunocompromised Host

CMV is the most common cause of opportunistic infection in patients who have received either solid organ or bone marrow transplants. It is also the most common virus that causes opportunistic infection in patients with AIDS. A common manifestation of CMV infection, especially after transplantation, is a systemic syndrome without specific organ localization. Involvement of specific organs can also occur, either along with a systemic syndrome or without systemic manifestations. The availability of antiviral drugs, such as ganciclovir and foscarnet, that are effective both for prevention and treatment of CMV infections has created a variety of viral diagnostic needs that affect the choice of test used.

Diagnosis of Systemic Cytomegalovirus Infection

No available diagnostic test is perfect for the diagnosis of current systemic CMV syndrome after transplantation. Detection of CMV in the blood correlates better with the presence of systemic disease than does detection in urine or saliva. Detection by culture of peripheral blood leukocytes suggests that a systemic syndrome can be attributed to CMV but is not absolutely diagnostic because CMV viremia also occurs in asymptomatic transplant recipients (121,127). The sensitivity of blood cultures for the diagnosis of systemic CMV infection is also imperfect because not all patients with a systemic CMV syndrome after transplantation have positive blood cultures. The pp65 antigenemia assay is both more sensitive and more specific than blood culture for identification of current disease. High levels of antigenemia or increasing levels in sequential specimens increase the positive predictive value (190). PCR is even more sensitive, but less specific. Failure to detect CMV DNA in blood by PCR virtually excludes CMV as a cause of a systemic syndrome, but a positive test has a low predictive value. High levels of CMV DNA detected by quantitative PCR may have a higher predictive value.

Diagnosis of Localized Disease

Patients with localized CMV infection are not always viremic. The diagnosis of CMV pneumonitis or gastrointestinal tract disease is best made by histologic examination of tissue from the site of disease. The diagnosis of CMV CNS infection is best made through the use of PCR to detect CMV DNA in CSF (10). The diagnosis of CMV retinitis is usually a clinical diagnosis made by ophthalmologists, but in cases with atypical features, CMV PCR can be performed on vitreous or aqueous humors (125).

Diagnosis of Impending Disease

Detection of CMV in blood by culture, pp65 antigenemia assay, hybrid capture assay, or PCR can be used as a trigger to initiate antiviral therapy before symptoms have occurred. Transplant programs that use preemptive therapy regimens typically evaluate patients for evidence of CMV viremia every 1 to 2 weeks during the first 4 months after transplantation, when the risk for disease is highest. In general, PCR is the most sensitive test, detecting CMV DNA in the blood of virtually all transplant recipients before the onset of symptoms, but also detecting CMV DNA in recipients who never develop symptoms, thus having a low positive predictive value. The hybrid capture assay and the pp65 antigenemia assay become positive several days to 1 week after PCR and occasionally fail to detect CMV antigenemia before the onset of symptoms, but they have higher positive predictive values (20,175). Culture is the least sensitive and often the last test to become positive. The proper choice of test depends on the vulnerability of the patient population being monitored, with more sensitive tests generally recommended for more vulnerable patients. It is likely that quantitative testing of blood will improve the predictive value of CMV detection assays (43,159). The level of CMV DNA in plasma as measured by quantitative CMV PCR correlates with the likelihood of subsequent CMV infection in patients with AIDS (179).

Monitoring of Patients During Antiviral Therapy and Prediction of Relapse

After the initiation of antiviral therapy, cultures become negative within a few days, followed by the pp65 antigenemia assay, followed by PCR (74). Further study is required to define whether persistence of antigenemia or CMV DNA during therapy is associated with relapse. Quantitative assays may be useful in providing a measure of response to therapy,

with rising levels potentially providing an early warning of antiviral drug resistance (159).

Congenital Cytomegalovirus Infection

Congenital CMV infection can be readily diagnosed by culture or PCR performed on urine within the first week of life. It is important to perform testing during this period because later cultures may not distinguish congenital infection from infection acquired in the peripartum period (156). *In utero* CMV infection can be diagnosed by culture or PCR performed on amniotic fluid. False-negative results have occurred when amniotic fluid was obtained too early in gestation or too early after maternal infection (27,55,56). Repeated sampling is suggested for maximal sensitivity when the level of clinical suspicion is high.

Human Herpesvirus Types 6 and 7

HHV-6 is the cause of roseola in infants. It has also been suggested as the cause of cases of encephalitis, febrile seizures, hepatitis, and secondary bone marrow failure after bone marrow transplantation. One study has suggested a role for HHV-6 as a cause of multiple sclerosis (29). HHV-7 has also been implicated as a cause of some cases of roseola. The diagnosis of these infections is difficult because both are ubiquitous, and asymptomatic viral shedding is common. HHV-6 DNA has been detected in the CSF of infants with acute HHV-6 infection, but the clinical significance of this finding in individual cases is unclear (26). HHV-6 DNA has also been detected in brain in the absence of neurologic disease (118).

Culture of HHV-6 and HHV-7 presents practical difficulties because it requires the use of umbilical cord lymphocytes, which are not available in most diagnostic virology laboratories. Furthermore, no criteria exist for the interpretation of diagnostic tests for HHV-6 and HHV-7 in immunocompromised patients. In infants, seroconversion is diagnostic of acute infection. Other findings suggestive of acute infection are a positive PCR performed on peripheral blood mononuclear cells in conjunction with a negative antibody titer (33) and the presence of HHV-6 in peripheral blood mononuclear cells but not in saliva because salivary shedding has later onset than viremia (41). In unusual cases, tissue should be examined by IHC and ISH whenever possible to assist in understanding the relationship of HHV-6 to the patient's pathologic process.

Gammaherpesvirinae

The members of the gammaherpesvirinae subfamily that infect humans are EBV and HHV-8, also known as Kaposi's sarcoma virus. The characteristics of these viruses are replication in lymphoid and epithelial cells, latency in lymphoid cells, and a proliferative effect on latently infected cells. EBV is the cause of infectious mononucleosis. HHV-8 has been linked to Kaposi's sarcoma in patients with HIV-related immunosuppression.

Diagnostic Tests for Epstein-Barr Virus

The cultivation of EBV requires immortalization of umbilical cord lymphocytes with demonstration of the presence of EBV antigens in the immortalized cells. This procedure is not practical for routine diagnostic laboratories, and accordingly, most diagnosis of EBV infections is based on serologic testing. Most cases of infectious mononucleosis are diagnosed based on the presence of atypical lymphocytes in peripheral blood plus the presence of heterophile antibodies, which are IgM antibodies that agglutinate the erythrocytes of sheep, oxen, and horses. The classic Paul-Bunnell-Davidson test has been largely replaced by slide agglutination tests that use horse erythrocytes and do not require differential absorption with beef erythrocytes and guinea pig kidney. Failure to produce heterophile antibodies is common in children, especially those younger than 4 years of age (185), and occurs occasionally in adults as well. Specific EBV antibody tests are used for diagnosis in these patients.

Specific Epstein-Barr Virus Serology

EBV serology consists of tests to measure antibodies to the viral capsid antigen (VCA), early antigens (EA), and nuclear antigens (NA). In some laboratories, tests for anti-EA distinguish between antibodies to diffuse and restricted components, based on the location of fluorescent staining and the differential sensitivity of the two components to acetone and methanol fixation. Testing for IgM antibodies to VCA is useful in defining acute infection because IgM anti-VCA is usually detectable with the onset of clinical manifestations and remains detectable for only several months (60,91). Testing for IgG VCA is useful in defining EBV immune status because these antibodies are detectable for the life of the individual. Anti-EA arise within a few weeks of infection but are not detected in all patients with acute infectious mononucleosis (91,92). The presence of antibodies to the diffuse component is more specific for recent infection because these antibodies do not persist for more than a few months. In contrast, antibodies to the restricted component may persist for several years after infection. Antinuclear antibodies arise later after infection than anti-EA and persist for life (90,91). Thus, measurement of anti-EA (especially the diffuse component) and anti-NA is occasionally useful for determining the timing of infection. The use of EBV antibodies for the diagnosis of chronic fatigue syndrome is of no value because the link once thought to exist between EBV infection and this syndrome has been disproved.

Epstein-Barr Virus Infections in Immunocompromised Patients

Like other herpesviruses, EBV can produce serious disease in immunocompromised patients. In patients with AIDS, EBV is associated with primary CNS lymphoma. PCR to detect EBV DNA in CSF is useful for making this diagnosis (9,38,51). EBV is also associated with the syndrome of posttransplantation lymphoproliferative disorder (PTLD) seen in solid organ and bone marrow transplant recipients. EBV serology is not useful for making this diagnosis. PTLD is confirmed by detecting EBV antigens (201) or nucleic acid (115,147) in lymphoid tissue showing the appropriate histologic findings. Several reports suggest that using PCR to monitor EBV DNA levels in peripheral blood mononuclear cells may be useful for the early recognition and clinical management of this syndrome (99,117,158).

Respiratory Viral Infections

The viruses that are common causes of respiratory infection include influenza and parainfluenza viruses, RSV, adenovirus, rhinovirus, coronavirus, and enteroviruses. All but the coronaviruses are frequently identified in routine diagnostic virology laboratories. Testing involves viral culture and antigen detection techniques. The preferred specimens are nasopharyngeal aspirates, washes, and swabs. Tracheal aspirates and specimens obtained through a bronchoscope, especially bronchoalveolar lavage fluid, are also suitable specimens. Antigen detection techniques, such as FA staining, are widely used to achieve rapid diagnoses.

Culture for Respiratory Viruses

Culturing for respiratory viruses is complicated because of the diverse growth and detection requirements of the different viruses that might be present. The influenza and parainfluenza viruses replicate best in primary monkey kidney cells, although continuous cell lines can be used, such as Madin-Darby canine kidney for influenza viruses and LLC-MK2 for parainfluenza viruses. Serum-free medium is used for incubating these cells for recovery of influenza and parainfluenza viruses, and some strains of influenza virus replicate best at 33°C. Trypsin is included in the media when Madin-Darby canine kidney cells are used. The influenza and parainfluenza viruses may replicate without producing CPE, and hemadsorption with guinea pig erythrocytes is used for detection. Early detection of viral replication can be accomplished by hemadsorption as early as 24 hours after inoculation (130). RSV replicates optimally in HEp-2 cells. This virus is very labile, and delayed transport to the laboratory may result in failure to isolate RSV. Adenoviruses replicate optimally in human embryonic kidney cells (104). Rhinoviruses replicate only in human diploid fibroblast cells, and they replicate better in some fibroblast cell lines than in others. Incubation at 33° to 34°C is required for optimal rhinovirus recovery. Coronaviruses do not replicate in currently available cell culture systems, but require tracheal organ cultures for cultivation in the laboratory.

Antigen Detection for Respiratory Viruses

Antigen detection techniques can be used to achieve rapid diagnosis of RSV, influenza, parainfluenza, and adenovirus respiratory tract infection. Viral antigens are visualized by FA staining of respiratory epithelial cells obtained by nasopharyngeal aspirate, wash, or swab. Aspirates and washes provide a higher cellular yield and have higher viral titers than swabs (2,84,123), but nasopharyngeal swabs are convenient and are used successfully by many laboratories (2,66). Tracheal aspirate and bronchoalveolar lavage specimens are also suitable for examination. On arrival in the laboratory, a cell pellet is prepared, spotted on a microscope slide, air dried, fixed, and stained. The entire procedure takes about 2 to 3 hours. Staining can be performed using monospecific antibodies or pools of monoclonal antibodies that can detect multiple respiratory viruses. Convenient membrane immunoassays that can be performed by personnel with less training than is required for FA staining are now commercially available for RSV and influenza. These assays can be performed in an emergency unit or physician's office. Other new rapid assay formats for detection of influenza viruses include an optical immunoassay for influenza antigens (45) and an assay for direct detection of neuraminidase activity.

A consistent finding is that the sensitivity of antigen detection methods exceeds that of culture for RSV (148). For influenza, parainfluenza, and adenovirus, some laboratories have reported sensitivities comparable to culture (72), but many laboratories find lower sensitivity compared with culture for these viruses (148). Rhinoviruses and coronaviruses are not detected by antigen detection methods because of antigenic diversity and lack of availability of appropriate antibodies. In general, antigen detection methods have higher sensitivity in children than in adults. The sensitivity of antigen detection methods to detect RSV in adult patients is particularly poor (61).

Nucleic Acid Amplification for Respiratory Viruses

PCR and RT-PCR have been applied to the detection of respiratory viruses (32,40,62,63,67,76,132,137,143,196). These techniques are probably more sensitive than either antigen detection or culture, but whether the increased sensitivity justifies the increased cost and complexity requires further evaluation. An intriguing concept is the use of multiplex PCR to detect multiple respiratory viruses simultaneously (63). Nucleic acid amplification may be most useful for detection of viruses that are not optimally detected by current methods, such as coronaviruses, rhinoviruses, influenza C virus, and parainfluenza virus type 4. It may also be useful for special patient groups, including adult patients with low levels of virus, immunocompromised patients, and perhaps asthmatic patients.

Need for Specific Viral Diagnosis

There is ongoing debate about the need for specific viral diagnosis of patients with acute viral respiratory infection. Proponents argue that specific diagnosis is useful for establishing prognosis, limiting antibiotic usage, and cohorting hospitalized patients to prevent nosocomial transmission (1,103). Skeptics argue that in the absence of specific antiviral therapy, patient management is not changed. There is little doubt that making a specific diagnosis is helpful in patients with unusual clinical manifestations and in immunocompromised patients.

Gastrointestinal Viral Infections

Viruses that are important causes of gastrointestinal infection are rotaviruses, enteric adenoviruses (especially serotypes 40 and 41), caliciviruses, astroviruses, and possibly toroviruses. Interestingly, none of these viruses is readily cultivable, and laboratory diagnosis has depended on electron microscopy and antigen detection techniques. Nucleic acid amplification techniques have also been applied.

Electron Microscopy

Electron microscopy was instrumental in the discovery of each of these agents (6,64). Negative staining with uranyl

acetate or phosphotungstic acid can be performed directly on stool specimens with minimal preparation. Some of the viruses, especially the caliciviruses, are better visualized using immune electron microscopy, in which viral particles are agglutinated using a specific antiserum before negative staining. Electron microscopy is not in widespread use in diagnostic virology laboratories but is used with excellent yield in selected laboratories with a special interest in the technique.

Antigen Detection

Antigen detection methods are widely used in the laboratory diagnosis of viral gastroenteritis. Many commercial assays that use a variety of EIA and particle agglutination formats are available for rotavirus detection, and at least one commercial adenovirus assay is available. Because the amount of rotavirus antigen present in fecal specimens is as high as 10^{11} particles per gram of stool during rotavirus gastroenteritis, the sensitivity of rotavirus antigen detection tests tends to be high. EIAs tend to be somewhat more sensitive than agglutination tests (53), although the latter may have advantages in convenience. There is some variation in specificity among the various commercial assays (53). Antigen detection assays for astrovirus have been used in investigations (131) but are not commercially available.

Nucleic Acid Amplification

RT-PCR and PCR assays have been developed for the main viral agents of gastroenteritis, but their use is restricted to research laboratories. These assays are unlikely to replace antigen detection assays for rotavirus because of the adequate sensitivity and greater simplicity of antigen detection assays. Likewise, at least one investigation of astrovirus infections showed no advantage in sensitivity for RT-PCR compared with EIA (70). The diversity of the caliciviruses is so extensive that no single primer set is yet available to amplify all pathogenic caliciviruses. Nucleic acid amplification methods may be especially useful for environmental studies and studies of molecular epidemiology (14,140,198).

Viral Meningitis and Encephalitis

A diverse group of viruses cause meningitis and encephalitis. No single diagnostic test method detects all possible suspects, and clues from the patient's history of exposure and clinical findings must be used to guide the choice of tests. The likelihood of making a specific diagnosis has been greatly increased by the application of nucleic acid amplification methods. Different diagnostic approaches are required for patients with (a) meningitis, (b) encephalitis, and (c) opportunistic viral infection of the CNS. Multiplex PCR assays are potentially applicable to each of these clinical problems and are likely to be an important approach in the future (149,161).

Meningitis

Enteroviral Meningitis

The echoviruses and coxsackieviruses are the most common viral causes of meningitis. RT-PCR assays that amplify a segment of the 5' nontranslated region of the enterovirus genome that is conserved among most enteroviral types are rapidly becoming the standard for diagnosis (31,163,171). These assays improve on viral culture of CSF, which has a sensitivity of 70% or less, is not successful for some coxsackie A virus strains, and requires at least several days to detect viral growth. Several studies have suggested that RT-PCR assays can improve patient management and may be able to decrease length of hospital stay for children with enteroviral meningitis (3,85,176).

Herpes Simplex Virus Meningitis

Most HSV meningitis is associated with HSV-2, which may cause recurrent episodes of meningitis. Some episodes are accompanied by genital lesions. Laboratory diagnosis using techniques other than PCR can be difficult because viral cultures are uniformly negative in recurrent cases (19). PCR appears to be both sensitive and specific for HSV meningitis. Use of PCR has revealed that many cases of recurrent meningitis of unknown etiology, previously referred to as *Mollaret's meningitis,* are actually caused by HSV (189).

Varicella Zoster Virus Meningitis

VZV can cause meningitis as a complication of either primary or reactivation infection. PCR can be used to amplify VZV DNA from the CSF of these cases. Experience is not yet adequate to provide data regarding sensitivity and specificity. The results of VZV PCR performed on CSF must be interpreted with the knowledge that VZV DNA is present in some cases of zoster without neurologic complications (83). PCR may be uniquely useful in recognition of cases of VZV meningitis without cutaneous lesions (58). A recent study that used a multiplex RT-PCR and PCR assay to detect simultaneously the nucleic acids of enteroviruses, HSV, and VZV indicated that VZV meningitis in the absence of skin lesions may account for a substantial proportion of cases of viral meningitis, especially in adults (149).

Encephalitis

Herpes Simplex Virus Encephalitis

PCR performed on CSF has revolutionized the approach to the diagnosis of HSV encephalitis, which previously required a brain biopsy for laboratory diagnosis (15,107). The sensitivity and specificity of HSV PCR for the diagnosis of HSV encephalitis were found to be 96% and 99%, respectively, in a metaanalysis of published studies (187). HSV DNA is still detectable in CSF for several days after initiation of acyclovir therapy (107). Laboratory performance may vary widely because an HSV PCR assay is not currently available as a commercial kit.

Arbovirus Encephalitis

Diagnosis of arboviral encephalitis is best accomplished by serologic testing. Either EIA or IFA assays can be used to detect arboviral specific IgM antibodies, which are diagnostic of recent infection when detected in either CSF or serum. About 40% of patients have arboviral IgM antibodies detectable in serum or CSF by 4 days after onset, and this percentage increases by about 10% per day, so that by day 10, nearly all cases are positive. It is important to be aware that low levels of arboviral IgM antibodies can persist in serum for up to 1 year after infection (191).

Rabies

The diagnosis of rabies is accomplished by a variety of methods depending on the stage of the infection. In the earliest phase, diagnostic tests are directed at detection of the virus by culture, antigen detection using FA staining, or nucleic acid amplification. Important specimens include saliva and CSF for culture and RT-PCR, and skin (usually from the nape of the neck) for FA staining. A brain biopsy is not indicated for the diagnosis of rabies, but if brain tissue is available, it should be analyzed for rabies antigen by FA staining. After the 8th day of illness, rabies antibodies may be present and are diagnostic if the patient had not received rabies immunization. The presence of rabies antibodies in CSF is always diagnostic of rabies (178).

Other Causes of Meningitis or Encephalitis in Immunocompetent Hosts

A wide variety of other viruses can cause meningitis or encephalitis in immunocompetent hosts, including EBV, HHV-6, B virus, lymphocytic choriomeningitis virus, measles, mumps, rubella virus, influenza virus, and adenovirus. These cases can be diagnosed by a combination of culture, serology, and nucleic acid amplification. Viral diagnostic studies other than serology are negative in cases that represent postinfectious demyelination.

Opportunistic Viral Infections of the Central Nervous System

Several viruses are important causes of CNS infection in immunocompromised patients. CMV is an important cause of encephalitis and radiculomyelitis in patients with advanced AIDS. The virus can only rarely be cultured from CSF in these cases but is detectable by PCR (10). Quantitation of the level of CMV DNA is useful to distinguish between clinically significant CMV CNS infection and cases with asymptomatic or presymptomatic infection (8). EBV is strongly associated with primary CNS lymphoma in patients with AIDS. PCR performed on CSF can detect EBV DNA in most cases, with a reported sensitivity of 83% to 100% and reported specificity of 88% to 100% (9,38,39,51). PCR for JC virus is useful for diagnosing progressive multifocal leukoencephalopathy, although the sensitivity in most laboratories is less than 100% (39).

Viral Hepatitis

Six hepatitis viruses (A to E and G) are currently known. Of these, A to E are known to cause clinical hepatitis. Because these viruses are difficult or impossible to culture, diagnosis has been based primarily on serologic tests.

Hepatitis A

Acute hepatitis A is diagnosed using assays for hepatitis A IgM antibodies. This test is virtually always positive when symptoms develop and remains positive for several months. Assays for total antibodies to hepatitis A virus are used to define previous exposure and immunity.

Hepatitis B

HBV infection is diagnosed using several different serologic tests. The test for hepatitis B surface antigen (HBsAg) defines current active infection with HBV. This test is usually positive with the onset of symptoms of acute HBV. Persistence of a positive HBsAg test beyond 6 months defines the HBV carrier state. Antibodies to hepatitis B surface antigen (HBsAb) and core antigen (HBcAb) develop after HBV infection. Anti-HBc is the first antibody to appear and is always present during the symptomatic phase of illness. Anti-HBs develops later. Both antibodies may persist for many years. A test for HBc IgM antibodies is used in the diagnosis of acute HBV infection. It is regularly present at the onset of symptoms and is particularly useful because occasional patients with acute HBV may be in the window period when they are negative for both HBsAg and anti-HBs. Only anti-HBs is produced in response to hepatitis B vaccine, and its presence indicates HBV immunity. Hepatitis e antigen is a component of HBc. It is detectable in the serum during active infection, and its presence signifies active viral replication. Anti-HBe is produced in response to HBe, and its presence in HBsAg carriers, generally indicates a less active state of infection. A quantitative assay for HBV DNA polymerase is also used to define active infection. PCR for HBV DNA is the most sensitive test for HBV. HBV DNA is sometimes detectable in serum by PCR when all other HBV markers are negative (24).

Hepatitis C

The screening test for HCV is the hepatitis C EIA. This assay may not become positive for months after infection. Because false-positive tests are common, especially when the test is used to screen low-risk populations such as blood donors, a positive HCV EIA must be confirmed by an additional test. In blood donor testing, the additional test is usually the radioimmunobinding assay. This test detects antibodies to the same antigens as the EIA, but because antibodies to individual antigens are visible, it is helpful in the recognition of false-positive tests. In high-risk patients, the additional test is often a test for HCV nucleic acid. These tests, including RT-PCR and the bDNA assay performed on plasma, define the presence of active HCV infection. Quantitative HCV RNA tests are used to assess the likelihood of response to antiviral therapy and to monitor the response when treatment is given. Molecular techniques, including hybridization or

nucleotide sequencing, are used to define the HCV genotype, which may be important because it affects the likelihood of response to interferon therapy and is used to determine the duration of treatment.

Hepatitis D, E, and G

Infection with hepatitis D virus (HDV) (also known as the delta agent) is diagnosed by the detection of antiviral antibodies. HDV produces infection only in patients who are also infected with HBV. HDV RNA can be detected by RT-PCR and may also be useful for defining active infection (170). Hepatitis E is diagnosed using an EIA that measures antibodies to HEV. The presence of anti-HEV IgM antibodies indicates recent infection. Tests for hepatitis G virus are not used in diagnostic virology laboratories because of uncertainty regarding the pathogenicity of this virus.

Human Papillomaviruses

The HPVs are important because of their close association with cervical cancer. They also cause the common wart and several other conditions affecting the skin and mucous membranes. Multiple types exist and differ in their relationships to various disease manifestations. Some types, such as 16, 18, 31, and 45, are considered high-risk types in relation to cervical cancer. HPV cannot be grown in cell culture; therefore, laboratory diagnosis depends on other techniques. Characteristic cytologic findings on cervical Papanicolaou smear (i.e., koilocytosis) are indicative of HPV infection. PCR and the hybrid capture assay have been used to detect HPV DNA in patient specimens. The most widely used PCR assay detects a segment of the gene encoding the L1 major capsid protein that is common to all HPV types (173). Typing is accomplished by differential hybridization of the PCR product with DNAs from individual types. The hybrid capture assay is a commercial system (Digene Corporation, Beltsville, MD) usually applied to swabs obtained from the cervix. This assay is configured to detect pools of HPV types designated as high risk or low risk. It is less sensitive than PCR but more sensitive than Southern blot (44). It also can provide quantitative data on the amount of HPV DNA present.

The indications for HPV testing are not well defined. One situation in which it may be helpful is the case of cervical lesions that are mildly atypical or have low-grade dysplasia. In these cases, the presence of high-risk HPV may justify more aggressive management (46). The question of whether HPV testing should be part of routine cervical cancer screening is still under study (49,120).

Human Polyomaviruses

Two polyomaviruses, the JC and BK viruses, are linked to human disease. Both are common human viruses that cause disease in only a tiny minority of infected individuals. JC virus is the cause of progressive multifocal encephalopathy, most commonly seen in patients with AIDS. BK virus is the cause of hemorrhagic cystitis, which occurs most often in bone marrow transplant recipients. Neither virus is routinely cultured in diagnostic virology laboratories. BK virus grows in human embryonic kidney cells, and a shell vial culture method has been described (122). JC virus grows only in human fetal brain cultures and a human fetal cell line called SVG (119). PCR assays are available for both viruses and are usually used on CSF for the detection of JV virus and on urine for detection of BK virus (11).

Exanthematous Viral Diseases (Measles, Rubella, Mumps, Parvovirus B19, Enteroviral Infection)

Measles, mumps, and rubella have become rare because of the success of immunization programs. Curiously, this increases the need for laboratory diagnosis of individual cases because many physicians trained in the vaccine era are not skilled in recognizing the diseases. In addition, specific diagnosis is important because extensive public health control measures may be implemented based on the occurrence of even a single case. All of the viruses discussed in this section, with the exception of parvovirus B19, can be cultured, but other laboratory methods are more important because of their potential for rapid diagnosis.

Measles

Measles virus can be grown in a variety of human and simian cells. Specimens from which the virus can be recovered include nasopharyngeal and conjunctival secretions, blood, urine, and CSF. Cultivation of the virus is slow and not always successful. Rapid diagnosis can be accomplished by FA staining of nasopharyngeal secretions or urine for measles antigen (69,129). An alternative approach for rapid diagnosis is to test for measles-specific IgM antibodies, which are always detectable within several days of appearance of the rash (192). The diagnosis can also be made by comparing measles antibody titers in acute and convalescent phase specimens, with seroconversion or a four-fold rise taken as diagnostic of recent infection. The presence of measles virus IgG antibodies in serum is evidence of measles-specific immunity. Subacute sclerosing panencephalitis, a late sequela of measles virus infection, is diagnosed by the demonstration of high levels of measles antibodies in CSF (42). Other CNS complications of measles may be diagnosed by using RT-PCR to detect measles virus RNA in CSF (136).

Rubella

Rubella virus can be cultured from specimens of nasopharyngeal or throat secretions, urine, stool, blood, and joint fluid. African green monkey kidney, Vero, or RK-13 cells can be used to grow the virus. Culturing for rubella virus is complicated by the fact that the virus may grow without producing CPE and must be detected by using the interference assay, in which the culture is “challenged” with a virus to which it is ordinarily susceptible. Failure of the challenge virus to grow is evidence of the presence of an interfering virus, whose identity can be confirmed by specific FA staining or nucleic acid detection techniques. Because this technique is cumbersome and time-consuming, serology is the preferred approach for the diagnosis of rubella. A rapid diagnosis can be accomplished by testing for rubella virus–specific IgM antibodies, which are usually detectable within a few days of onset of the rash. Rubella virus antibody titers can also be compared in acute and convalescent specimens, with seroconversion or a four-fold rise taken as diagnostic of recent infection. The presence of rubella virus IgG antibodies in serum is evidence of rubella-specific immunity.

Mumps

Mumps virus can be grown from specimens of saliva, urine, and CSF. Rhesus monkey kidney cells and human embryonic kidney cells can be used. The virus grows slowly and often requires hemadsorption with guinea pig erythrocytes for detection. A rapid diagnosis can be made by detecting mumps virus–specific IgM antibodies, which are usually present in serum at the time of clinical illness. Mumps virus antibody titers can also be compared in acute and convalescent specimens, with seroconversion or a four-fold rise taken as diagnostic of recent infection. Cross-reactivity with parainfluenza viruses can complicate the interpretation of serologic tests but is not usually a major issue because of differences in the clinical presentation of disease caused by the mumps and parainfluenza viruses.

Parvovirus B19

Parvovirus B19 produces diverse clinical manifestations depending on the stage of infection and the immune status of the host. The diagnostic approach is different for the different clinical manifestations. The virus cannot presently be cultured in routine diagnostic virology laboratories; therefore, diagnosis is based on serologic and nucleic acid testing. Acute parvovirus B19 infection causes fifth disease, also known as *exanthem subitum.* The optimal approach for documenting acute parvovirus B19 infection is to test for parvovirus B19–specific IgM antibodies, which are present within several days of the onset of symptoms (5). Parvovirus B19–specific antibody titers can also be compared in acute and convalescent specimens, with seroconversion or a four-fold rise taken as diagnostic of recent infection. The presence of acute parvovirus B19 infection in an individual with chronic hemolytic anemia may produce hemolytic crisis (177). Hemolytic crisis occurs earlier after infection than fifth disease, and parvovirus B19 antibodies may not be detectable for about 1 week after the onset of crisis. However, parvovirus B19 DNA is regularly present in serum at this time and can be readily detected by PCR (166). Parvovirus B19 infection in immunocompromised patients may result in chronic infection of erythroid progenitor cells, resulting in chronic red blood cell aplasia (68,100). Patients with chronic parvovirus B19 infection may fail to develop parvovirus B19–specific antibodies, but the diagnosis can be established by detecting parvovirus B19 DNA in serum by PCR or other DNA detection assays (100). Finally, parvovirus B19–specific immunity can be demonstrated by testing for parvovirus B19–specific IgG antibodies.

Enteroviruses

The enteroviruses include coxsackie A and B viruses, echoviruses, polioviruses, and several viruses classified only as enteroviruses. This group of viruses can produce a wide variety of clinical syndromes, including meningitis, encephalitis, nonspecific febrile illness with or without a rash, pharyngitis, hand-foot-and-mouth disease, upper respiratory tract infection, hemorrhagic conjunctivitis, myocarditis, pericarditis, and pleuritis. CNS infections are best diagnosed using RT-PCR to detect enteroviral RNA in CSF.

Enteroviral infections of body sites other than the CNS are best diagnosed by culture. The best specimens are stool and nasopharyngeal or throat secretions. The coxsackie B viruses grow well in primary monkey or human embryonic kidney cells as well as in a number of continuous monkey and human cell lines. Many of the coxsackie A viruses require newborn mouse inoculation for growth. The echoviruses grow in human fibroblast cells as well as in primary monkey or human embryonic kidney cells. Cultures often become positive in 2 to 8 days. Viruses growing in culture can be classified to group by FA staining using group-specific monoclonal antibodies, but type-specific identification requires the laborious neutralization test. Enteroviruses can typically be cultured from respiratory tract specimens for 1 to 2 weeks after infection, and from stool specimens for 4 to 6 weeks. Because of the prolonged shedding, the significance of positive cultures is not always clear, and clinical judgment is required. Rapid recovery of enteroviruses from patients with compatible clinical syndromes is highly suggestive of a causal relationship. Serologic testing is not widely available because of the antigenic diversity of the enterovirus group.

Congenital and Neonatal Infection

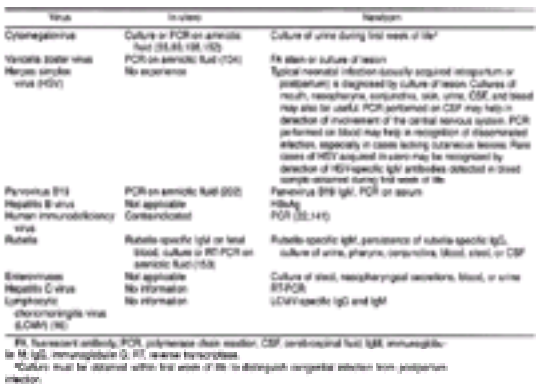
A variety of viruses can infect the fetus, resulting in congenital infection. Some of the same viruses, as well as others, may cause infection in the peripartum or immediate newborn period, resulting in neonatal infection. The possibilities for diagnosing congenital and neonatal viral infections have increased dramatically because of the convergence of several developments: (a) improvement and very widespread use of intrapartum ultrasound examination, which can detect morphologic evidence of *in utero* infection; (b) improved techniques for obtaining fetal samples; and (c) molecular techniques that can be used to analyze small sample volumes.

Diagnosis of infection *in utero* depends on acquisition of fetal samples. Techniques that are employed include chorionic villus sampling, amniocentesis to obtain amniotic fluid, and cordocentesis to sample fetal blood (200). Important considerations include the volume of specimen obtained and the timing during the pregnancy in relation to (a) acquisition of fetal infection and (b) the synthesis of antibodies by the fetus. Chorionic villus sampling provides a fetal sample from the first trimester of pregnancy, whereas amniocentesis and cordocentesis are usually performed during the second or third trimesters.

Viral diagnostic tests that are employed for the diagnosis of *in utero* or neonatal infection include viral culture, viral nucleic acid amplification assays, and tests for virus-specific IgM antibodies. Because IgM antibodies are not passively transferred across the placenta, the detection of virus-specific IgM antibodies in the fetus or newborn is presumptive evidence of congenital infection. The capability of synthesis of IgM antibodies is present starting at about 20 weeks of gestation (4). Assays for virus-specific IgM antibodies used to diagnose congenital infection must include procedures to prevent false-positive results from rheumatoid factor, which can be present either in the fetus or in the young infant and can cause nonspecific test results (151,180). The use of batteries of IgG serologic assays, such as TORCH titers (antibody titers to *Toxoplasma gondii, Treponema pallidum,* rubella virus, CMV, and HSV), are not useful for diagnosis of fetal or congenital infection because the presence of virus-specific IgG titers may represent passive transfer of maternal

antibodies rather than fetal infection.

The specific tests used depend on the virus and the period of gestation or age of the newborn. Table 9 provides a summary of approaches to the diagnosis of viral infections of the fetus and newborn. The reader is referred to chapters on the individual viruses and to other sources (200) for additional information.



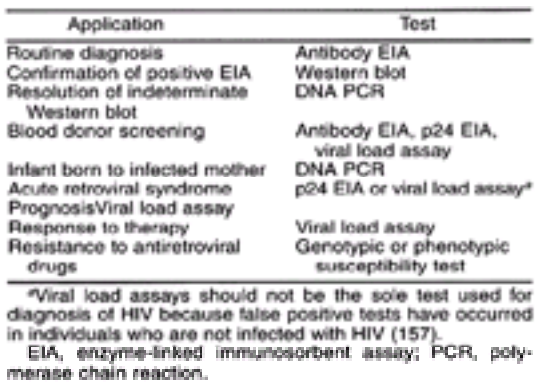
Virus	In utero	Newborn
Cytomegalovirus	Culture or PCR on amniotic fluid (68,69,108,152)	Culture of urine during first week of life[a]
Varicella (latent virus	PCR on amniotic fluid (124)	
Herpes simplex virus (HSV)	No experience	Typical neonatal infection (usually acquired intrapartum or postpartum) is diagnosed by culture of lesion. Cultures of mouth, nasopharynx, conjunctiva, skin, urine, CSF, and blood may also be useful. PCR performed on CSF may help in detection of involvement of the central nervous system. PCR performed on blood may help in recognition of disseminated infection, especially in cases lacking cutaneous lesions. Rare cases of HSV acquired in utero may be recognized by detection of HSV-specific IgM antibodies detected in blood sample obtained during first week of life
Parvovirus B19	PCR on amniotic fluid (202)	Parvovirus B19 IgM, PCR on serum
Hepatitis B virus	Not applicable	HBsAg
Human immunodeficiency virus	Contraindicated	PCR (32,141)
Rubella	Rubella-specific IgM or fetal blood, culture or RT-PCR on amniotic fluid (153)	Rubella-specific IgM, persistence of rubella-specific IgG, culture of urine, pharynx, conjunctiva, blood, stool, or CSF
Enteroviruses	Not applicable	Culture of stool, nasopharyngeal secretions, blood, or urine
Hepatitis C virus	No information	RT-PCR
Lymphocytic choriomeningitis virus (LCMV) (96)	No information	LCMV-specific IgG and IgM

RIA, fluorescent antibody; PCR, polymerase chain reaction; CSF, cerebrospinal fluid; IgM, immunoglobulin M; IgG, immunoglobulin G; RT, reverse transcriptase.
[a]Culture must be obtained within first week of life to distinguish congenital infection from postpartum infection.

TABLE 9. *Tests used for the diagnosis of viral infection of the fetus and newborn*

Human Retroviruses

Essentially all patients who are truly seropositive for HIV have active infection. This concept forms the basis for the use of the HIV antibody test as the standard approach to the diagnosis of HIV infection. Other assays, such as the p24 antigen assay, DNA PCR, plasma RNA, and genotypic and phenotypic susceptibility assays, are used for a variety of specialized purposes, described subsequently and summarized in Table 10.



Application	Test
Routine diagnosis	Antibody EIA
Confirmation of positive EIA	Western blot
Resolution of indeterminate Western blot	DNA PCR
Blood donor screening	Antibody EIA, p24 EIA, viral load assay
Infant born to infected mother	DNA PCR
Acute retroviral syndrome	p24 EIA or viral load assay[a]
PrognosisViral load assay	
Response to therapy	Viral load assay
Resistance to antiretroviral drugs	Genotypic or phenotypic susceptibility test

[a]Viral load assays should not be the sole test used for diagnosis of HIV because false positive tests have occurred in individuals who are not infected with HIV (157).
EIA, enzyme-linked immunosorbent assay; PCR, polymerase chain reaction.

TABLE 10. *Laboratory tests used for the diagnosis and management of human immunodeficiency virus (HIV) infections*

Human Immunodeficiency Virus Antibody Assays

Virtually all HIV antibody testing is performed using EIA. A number of assays are commercially available, with sensitivity and specificity often exceeding 99%. These assays detect all serotypes of HIV-1, with the exception of some group O viruses (172). Some commercially available assays, including all of those used for screening of blood donors, are designed to detect both HIV-1 and HIV-2. The remaining HIV-1–specific assays detect about two-thirds of cases of HIV-2 (52). Current HIV EIAs typically become positive about 22 days after infection (23).

Despite the high specificity of the HIV EIA, when it is used for screening purposes in low to moderate risk populations, a high proportion of all positive results detected are false-positive results. Therefore, Western blot testing is required to confirm positive EIA results. The two-step algorithm of EIA followed by Western blot if positive has extremely high sensitivity and specificity. The major difficulty with this approach is that occasional Western blot results are indeterminate. These troublesome situations can often be resolved by molecular tests (see later) or by repeating the EIA and Western blot after several months.

HIV antibody testing can be performed on oral transudate (71) or urine (194). Use of oral transudate and urine tests can facilitate screening in situations in which it is not practical to draw blood. Particle agglutination assays that can be performed on serum to provide results within minutes of collection are also commercially available, and the U.S. Public Health Service has recommended the use of such tests in selected situations for testing individuals who may not return to learn of test results (28).

p24 Antigen Assays

Assays for HIV p24 antigen in serum can detect HIV infection about 6 days earlier than the antibody EIA (23). These assays are used by blood banks for screening all collected blood units and are occasionally used for the diagnosis of the acute retroviral syndrome. Other uses have been replaced by plasma HIV viral load assays.

Nucleic Acid Amplification Assays

HIV DNA PCR assays that detect proviral DNA are used to detect infection in infants born to HIV-infected mothers. HIV antibodies are present in these infants as a result of transplacental transfer from the infected mother and do not indicate infection of the infant. Current estimates are that HIV DNA PCR is positive in about 40% of these infants within the first few days of life and in more than 90% by 2 weeks of age (22,141).

Assays for plasma HIV RNA, also referred to as *viral load assays,* have become an essential tool for the management of HIV. The level of HIV RNA provides information about the prognosis of HIV (126) and is used to evaluate the response to treatment. Methodologies that are employed include RT-PCR, branched-chain DNA, and transcription-mediated amplification. Each of these methods is able to provide accurate quantitation of HIV RNA in plasma over a very large range. Ultrasensitive modifications of these assays can detect as few as 40 copies of HIV RNA per milliliter of plasma. Because these assays provide the earliest detection of HIV after infection, they are now being evaluated for screening of blood donor units as well as for the diagnosis of individuals with the acute retroviral syndrome. Viral load assays should not be the sole test used for diagnosis of HIV because false-positive tests have occurred in individuals who are not infected with HIV (157).

Antiretroviral Susceptibility Testing

The availability of multiple therapeutic agents for HIV and the potential for the virus to become resistant to these agents has created a need for tests to measure the susceptibility of HIV to antiretroviral agents. These tests are classified as genotypic and phenotypic (94). Genotypic assays are based on nucleotide sequencing of HIV RNA amplified directly from plasma. The presence of specific mutations correlates with specific drug resistance. Use of these assays has been shown to be useful in minimizing HIV viral load (17). Phenotypic assays assess the effect of antiretroviral drugs on the growth of HIV in culture. Recombinant assays are commercially available in which the polymerase and protease genes of a patient's virus are inserted into a standardized molecular clone that is used to carry out viral growth assays. The role of genotypic and phenotypic assays in clinical practice is evolving rapidly.

Human Retroviruses Other Than Human Immunodeficiency Virus Type 1

HIV-2, HTLV-I, and HTLV-II share with HIV-1 the characteristic that essentially all infected individuals are chronically infected. This means that assays for antiviral antibodies can be used to diagnose active infection. Antibody assays are available for each of these viruses and are used to screen all blood donor units in the U.S. Western blot and radioimmunoprecipitation assays are also available to provide supplemental testing. PCR can also be used to confirm infection and to discriminate among the various human retroviruses.

When evaluating patients for HIV infection, the possibility of HIV-2 infection must be considered in individuals who may have acquired infection in West Africa or from an individual infected in that area. Commercially available HIV assays, including antibody EIA, p24, PCR, and viral load assays, vary in their ability detect HIV-2. In cases in which HIV-2 is a possibility, consultation with the laboratory performing the testing is recommended to determine whether the tests in use detect HIV-2.

Exotic Viral Infections

In the era of global travel, infections may become symptomatic far from where they were acquired. Therefore, it is important for virology laboratories to be able to provide assistance in the diagnosis of these infections. Some agents, such as the filoviruses and the arenaviruses, can be hazardous to laboratory personnel, and all testing must be performed in Biosafety Level 4 facilities. Consultation with State Health Departments and personnel at the Centers for Disease Control and Prevention is important when exotic viral infections, especially the hemorrhagic fevers, are diagnostic considerations. Table 11 provides a summary of exotic viral infections, geographic locations, and diagnostic tests.

Virus or syndrome	Location	Tests*
Sin nombre virus (hantavirus pulmonary syndrome)	Western U.S.	Virus-specific IgM, RT-PCR
Other hantaviruses	Asia, Europe	Virus-specific IgM
Colorado tick fever	Western U.S.	Culture of blood clot, IFA stain of erythrocytes, RT-PCR
Dengue	Asia, Central and South America	Virus-specific IgM, RT-PCR
Hemorrhagic fevers (filoviruses [Ebola and Marburg], arenaviruses [Lassa and South American hemorrhagic fevers], yellow fever, Congo-Crimean hemorrhagic fever)	Africa, South America, Asia	Virus-specific IgM, culture of serum, RT-PCR, EM of urine or blood (Ebola and Marburg), antigen detection assays
Rift valley fever	Africa	Virus-specific IgM, culture, RT-PCR
Alphaviruses (Chikungunya, Chyorg nyorg, sindbis, Mayaro, Ross River)	Africa, Europe, Asia, Central and South America, Australia	Virus-specific IgM, culture, RT-PCR

*Performed on blood unless otherwise specified.
IFA, fluorescent antibody; IgM, immunoglobulin M; RT-PCR, reverse transcriptase polymerase chain reaction.

TABLE 11. *Exotic viral infections*

DISCOVERY OF NEW VIRAL AGENTS

In recent years, numerous new viral agents have been discovered. In some instances, conventional viral culture techniques have yielded new viruses. For example, detection of Hendra virus, a new paramyxovirus that causes infection

of horses and humans, was based on growth of the virus in cell cultures in use in diagnostic virology laboratories (135). In other cases, powerful nucleic acid–based techniques have been applied to detect viruses that could not be cultivated. Application of these techniques is likely to yield additional new viruses in coming years. Short descriptions of the culture-independent discovery of three human pathogenic viruses follow.

The first outstanding example of culture-independent virus discovery is hepatitis C virus. This virus was discovered through molecular cloning of plasma known to be infectious for chimpanzees. Serum from a person with non-A, non-B hepatitis was used to screen an expression library of about 1 million candidate clones, resulting in discovery of one clone expressing an HCV gene product. Nucleic acid sequencing provided the identification of the new virus as a flavivirus and led to the development of a blood test used for screening of donated blood units (34). Cultivation of HCV has still not been achieved.

The discovery of sin nombre virus, the cause of hantavirus pulmonary syndrome, began with the detection of antibodies in the serum of affected individuals that cross-reacted with known human hantaviruses. Based on that clue, an RT-PCR assay was designed using primers based on sequences conserved in the four hantaviruses previously known to be human pathogens. Sequencing of a product amplified from specimens obtained from human cases revealed the presence of a new hantavirus (138). That discovery has led to the discovery of numerous additional hantaviruses (57). Laboratory cultivation of sin nombre virus and related viruses remains extremely difficult.

Kaposi's sarcoma virus (HHV-8) was discovered as the cause of Kaposi's sarcoma through use of the technique of representational difference analysis (113). This technique involved the use of DNA extracted from Kaposi's sarcoma tissue, which was used along with DNA extracted from normal tissue. Unique sequences were detected that were homologous to known gammaherpesviruses (30). The new virus was subsequently shown to be highly associated with Kaposi's sarcoma as well as with multicentric Castleman's disease and AIDS-related body cavity–based lymphoma. Cultivation of the virus in cell culture has subsequently been achieved (65).

CHAPTER 19 Plant Viruses

Sondra G. Lazarowitz

HISTORY

The oft cited color variegation in tulip flowers, caused by tulip breaking virus, is probably the most splendid example of disease symptoms produced by a viral infection of plants. Tulips, with their naturally solid colored flowers, acquired this infection when introduced from Constantinople to the Netherlands in 1551. The spectacular floral patterns that resulted were so highly coveted that a tulip bulb could command an astonishingly high price: 5,200 guilders were reportedly paid for a tulip bulb in 1637, whereas Rembrandt's fee for his masterpiece “The Night Watch” in 1642 was a mere 1,600 guilders (59). Given the tulip mania that seized the Netherlands, the affected tulips were reproduced in great numbers by noted 17th-century Dutch painters and growers alike (Fig. 1). Although considered an example of the beneficial consequences of some virus infections, most plants do not fare as well in the face of virus infection. Indeed, viruses are currently responsible for severe losses in crop plants of every type worldwide (Table 1). It is difficult to place a precise dollar figure on the total losses annually, but a single virus, such as tomato spotted wilt virus (TSVW), is estimated to cause annual crop losses in excess of $1 billion.

FIG. 1. “Study of Tulips” by the Dutch botanical artist Jacob Marrel (1614–1681). Reprinted with permission of the Metropolitan Museum of Art, New York, Rogers Fund, 1968 (66,68).

Virus disease	Geographic distribution	Host crop
Sugarcane mosaic	Worldwide	Sugarcane, corn
Cassava mosaic	Africa	Cassava
Citrus quick decline (tristeza)	Africa, Americas	Trees[a]
Swollen shoot of cocoa	Africa	Cocoa (heavy losses)
Plum pox (sharka)[b]	Europe	Plums, peaches, apricots
Barley yellow dwarf	Worldwide	Grains
Tomato yellow dwarf	Mediterranean, Caribbean	Tomatoes, beans
Tomato spotted wilt	Worldwide	Tomatoes, tobacco, peanuts, ornamentals, others[c]

[a]Tens of millions of trees infected as of 1997.
[b]Severe, spreading epidemic.
[c]Extremely broad host range.

TABLE 1. *Viruses that cause severe crop losses worldwide*

The origins of the science of virology in general are rooted in research at the end of the 19th century on tobacco mosaic disease, caused by what came to be called tobacco mosaic virus (TMV). The interest in TMV at the time was economic: the diseased tobacco leaves were not suitable for making cigars. Adolf Mayer, Director of the Agricultural Research Station at Wageningen, was investigating this tobacco mosaic syndrome and in 1886 showed that he could transfer the disease by injecting healthy tobacco plants with leaf extracts from diseased plants (222). Thus, he had established the

infectious nature of this disease, but he failed to identify the pathogenic agent. In 1892, Dmitrii Ivanowski, working in the Crimea, reported that such extracts from mosaic-diseased tobacco, when passaged through candle filters that would exclude bacteria, were still infectious (157), thereby establishing the cause of this disease as a “filterable agent.” However, despite this and additional evidence from his own work, he wrongly concluded that the causal agent was a toxin or bacterial agent that could still pass through the filters. It was Martinus Beijerinck at the Technical School of Delft, repeating and extending these filtration studies, who made the conceptual leap to report in 1898 (22) that this mosaic disease of tobacco was caused by a “contagium vivum fluidum”—a contagious living fluid. Thus, TMV was the first of the new class of “filterable agents” of disease, which eventually would simply be called *viruses,* to be identified, in the same year that Loeffler and Frosch reached similar conclusions for the cause of foot-and-mouth disease in livestock.

During the first half of the 20th century, TMV remained a central player in the development of modern virology, in general, and plant virology in particular. This was due in part to the ease of infecting and propagating a virus in plants (as opposed to obtaining human volunteers as did Reed and Carroll in their studies of yellow fever) and largely to the stability of TMV and the large amounts of virus that could readily be purified from infected tobacco plants. TMV was the first virus to be purified in a crystalline state and shown to consist of ribonucleoprotein (RNP) particles (19,325), and the first for which the architecture of the particles was revealed by electron microscopy and x-ray diffraction (25,44,107,168). It was the first virus shown to reassemble into infectious particles *in vitro* from viral RNA and coat protein (105) and the first for which the intrinsic infectivity of the virion RNA was demonstrated (118). As studies became more molecular, TMV has continued to be in the forefront of the development of techniques and concepts in modern plant virology. Techniques to prepare plant protoplasts and infect these with TMV were a major technical breakthrough in plant virology (15,338). The concept that plant virus movement between cells was an active process facilitated by a viral-encoded “movement protein” was established based on studies of temperature-sensitive mutants of TMV (244). The first successful example of pathogen-derived resistance was the engineering of transgenic plants resistant to TMV infection based on the expression of the viral coat protein gene (270), and much of our current thinking about the function of virus movement proteins derives from the initial demonstration that the TMV movement protein could alter the gating properties of plasmodesmata (376). Just as for animal viruses, research on plant viruses has been both applied and basic, with very similar goals: to understand how plant viruses cause diseases so as to prevent these and their impact economically and in terms of human and animal nutrition, and to use them as models to investigate plant cell biology and gene expression. In contrast to animal viruses, this latter goal has taken longer to realize because of technical limitations in investigating plant viruses.

REVERSE GENETICS AND THE MODERN ERA OF PLANT VIROLOGY

From the mid-1950s on, the availability of animal cell tissue culture systems meant that clonal isolates of animal viruses, essential for genetic studies, could be readily obtained and that synchronous infections could be done to dissect viral multiplication cycles. Thus, investigations of animal viruses became more molecular, and our knowledge of animal virus–host interactions advanced. Lacking appropriate tissue culture systems, plant virus studies relied on the ability to infect plants by mechanical means—rubbing a suspension of virus particles onto a leaf with a finger or spatula, often in the presence of an abrasive agent such as fine-grade carborundum—or using appropriate vectors, usually insects. For a number of plant viruses, protoplasts (isolated plants cells from which the walls had been enzymatically removed) could be transfected with the viral genome or, in some cases, virions. However, this advance did not occur until 1968, at which point plant virus studies began to focus more on virus replication and on the synthesis and translation of viral messenger RNAs (mRNAs). In particular, advances were reported for positive-sense RNA plant viruses (including TMV) that could be readily propagated because the purified viral genome was infectious, often multipartite (i.e., segmented), and could be translated *in vitro* using available rabbit reticulocyte and wheat germ extracts, or when injected into oocytes from frogs or toads. Thus, from the 1970s to the early 1980s, knowledge about virus replication was advanced for those positive-sense RNA viruses that accumulated to high levels in infected plants and could be easily purified. The coat proteins of brome mosaic virus (BMV) and TMV were shown to be translated from a subgenomic mRNA (152,317). Protoplast studies began to identify nonstructural proteins encoded by these viruses and other viruses, and genetic studies began to identify specific viral genes through the study of temperature-sensitive mutants and genetic reassortment studies for viruses having segmented genomes.

Against this background of technical limitations, the impact of reverse genetics on the investigation of plant viruses in the early 1980s was immense, ushering in the current era of research on plant virus–host interactions at the cellular level. Ahlquist and colleagues (8) were the first to report the generation of infectious plant virus transcripts from cloned complementary DNA (cDNA) of the genome of BMV. Their success was facilitated by the fact that the BMV genome consists of three segments of positive-sense RNA, the largest being 3.2 kb. Their approach was to clone each of the three BMV cDNAs behind a modified bacteriophage lambda P_R promoter such that transcription would correctly initiate at the first nucleotide of the inserted sequence. Transcripts of each segment with correct 5' and 3' ends were generated *in vitro* using *Escherichia coli* RNA polymerase, and these proved to be infectious when mechanically inoculated onto susceptible host plants or transfected into plant protoplasts. Generating full-length cDNAs that could be transcribed into an infectious transcript for the larger (at least in terms of contiguous nucleotides) genomes of RNA plant viruses like TMV (6.4 kb) and the potyviruses tobacco vein mottling virus and plum pox virus (~10 kb) proved to be more difficult, but followed within a few years (83,288).

It was more straightforward to clone infectious DNA copies for plant viruses with DNA genomes like the geminiviruses with their single-stranded DNA (ssDNA) genomes, or the pararetrovirus cauliflower mosaic virus (CaMV) with its double-stranded DNA (dsDNA) genome. However, here the problem was how to efficiently infect plants with these cloned DNAs. The same issue in principle existed for positive-sense RNA viruses like the luteoviruses that could not be mechanically transmitted to plants, and for the negative-sense plant rhabdoviruses and tospoviruses (in the *Bunyaviridae*), in which the genome alone would not be infectious. The earliest solution was developed in studies of CaMV and the geminivirus tomato golden mosaic virus (TGMV) and took advantage of the ability of *Agrobacterium tumefaciens,* the bacteria that causes crown gall tumors on plants, to transfer its tumor-inducing (Ti) plasmid into plant cells by a mechanism that resembles bacterial conjugal DNA transfer (126). In crown gall tumor, bacterial Ti plasmid sequences are integrated into the plant chromosome, and studies to define the mechanism by which this occurs led to the development of vectors that are commonly used to generate transgenic plants. In the agroinfection procedure that

was developed, the CaMV or TGMV genomes were each cloned into vectors that would autonomously replicate in *A. tumefaciens.* These would be transferred into plant cells by the same mechanism as Ti plasmid transfer when the bacteria were either injected into the plants or introduced at wounded sites (Fig. 2). Once inside the plant cells, infection was initiated when inserted viral sequences would replicate or recombine out of the bacterial vector to reform the virus genome. This same general approach can be used to infect plants with the cloned cDNA copies of RNA virus genomes and viroids, as well as to generate transgenic plants that contain specific viral sequences (126). The introduction of biolistic bombardment in the early 1990s to "shoot" cloned DNAs into plant cells provided an alternative approach to using *A. tumefaciens* to transform plants, as well as to infect them with cloned plant virus genomes or introduce reporter gene constructs for transient expression assays.

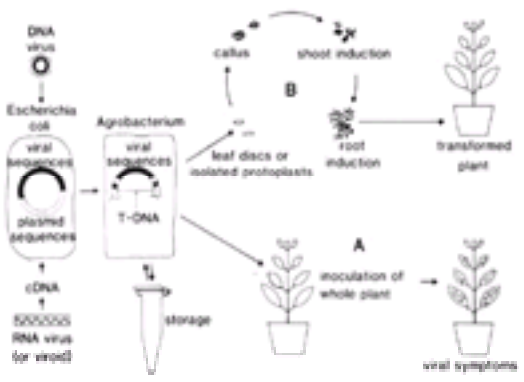

FIG. 2. Agroinfection: transfer of a viral genome or viroid RNA to plants. The gene or genome of interest is cloned into a plasmid that can replicate in *Agrobacterium tumefaciens*. It contains at least the Ti plasmid right border sequence; thus, it can be transferred into plant cells by the action of the bacterial *Vir* genes. The outcome of infection, or integration to create a transgenic plant, is determined by the Ti plasmid having a left as well as a right border sequence (integration) and on whether the introduced plasmid contains a viral sequence that can autonomously replicate when released from the plasmid in the plant. (From Grimsley N, Bisaro DM. Agroinfection. In: Hohn TH, Schell J, eds. *Plant DNA infectious agents.* New York: Springer-Verlag, 1987:87—107, with permission.)

The impact of reverse genetics on plant virology cannot be overstated. Having clonal isolates of plant virus genomes and the techniques in place to introduce these back into plants in the absence of a vector meant that defined mutations could be introduced and studied for their effects on the virus replication, transcription, and host interactions. Thus, individual viral genes could be readily identified and functions assigned to these. Viral genomes and genes were used for *in situ* hybridization to track virus multiplication and infection in the plant and were expressed in *E. coli* to generate antisera for identifying and localizing individual virus-encoded proteins in infected plants. Sequence analysis and hybridization studies established the relationships among viruses and, extended through the use of the polymerase chain reaction (PCR), have produced a veritable growth industry in the identification and cloning of new plant viruses, which has profoundly affected studies on plant virus epidemiology. b-Glucuronidase (GUS) and the jellyfish green fluorescent protein (GFP) expressed from plant virus genomes have provided visual reporters to trace the path and tissue specificity of virus infection in the plant and, fused to individual plant virus proteins, are identifying the cellular components and pathways used by plant viruses. Given the relative ease with which a number of plant species can be transformed, the functions of individual plant virus genes and their role in pathogenesis are being studied in transgenic plants. Indeed, plant virus genomes themselves have been termed a veritable "tool box" for plant genetic engineering and crop protection (374), being the source of strong promoters and translational enhancers that are routinely used to express foreign genes in plants, and of individual virus genes to confer resistance against virus infection. For example, it is almost impossible to read about transgenic plants without coming across reference to the strong CaMV 35S promoter (24). What we have learned is that plant viruses are not fundamentally different from animal viruses in their basic replication and gene expression strategies, which is logical because they are after all eukaryotic viruses. However, because of fundamental differences in the structure of plant and animal cells and in the physiology of plants and animals, plant viruses are fundamentally different in how they enter and exit from cells and systemically invade their hosts, and they have evolved some clever strategies to deal with these problems.

In the previous edition of this textbook, it was noted that interactions between plant viruses and their vectors or the earliest events in the infection process were poorly understood, that detailed information about plant virus replication and cell-to-cell movement was just beginning to accumulate, and that the mechanisms by which plant viruses induce disease responses had not been determined (313). Yet, John Shaw in writing this was optimistic that it seemed "certain that the increasingly powerful techniques of molecular and cellular biology should provide us with explanations of these phenomena within a relatively short period of time." His optimism was not misplaced. Since 1996, when the last edition of this text was published, we have made major advances in all of these areas. This chapter focuses on the molecular and cellular details of plant virus replication and pathogenesis, highlighting the studies of a number of representative model plant viruses that have advanced our understanding of how plant viruses interact with their insect vectors, how different plant viruses replicate and regulate their gene expression, how these viruses move from cell to cell to systemically infect the host, and the interplay between virus and plant that results in disease or resistance of the host. An excellent overview of the families and genera of plant viruses, with descriptions of representative viruses within each group, can be found in the third edition of this book (313). The *Seventh Report of the International Committee on Taxonomy of Viruses* (ICTV) (347) and the *Encyclopedia of Virology* (123) present more detailed descriptions of all known viruses and viroids and their current classification. Additional excellent texts and reviews that describe the diseases caused by and the epidemiology of different plant viruses, as well as subviral agents (viroids and satellites) that infect plants, are also available (5,73,294).

THE PLANT VIRUS FAMILIES

According to the latest ICTV report (347), the number of recognized viruses is 3,618, of which ~25% (957) are plant viruses. In addition, there are subviral agents (formerly called *unconventional agents*) that can infect plants, namely viroids and satellites. Satellites are analogous to the d-agent of hepatitis B virus, being encapsidated RNAs that are not essential for the infectivity of a particular plant virus “partner” but can modulate the pathogenicity of that virus (294). Viroids, now classified in seven different genera, are small (~250 to 370 nt), highly structured RNAs that are responsible for a number of important diseases in plants, including potato spindle tuber disease, coconut cadang-cadang, and avocado sunblotch.

As for animal viruses, a system based on the use of Latin names has been adopted to classify plant viruses into families and subfamilies. Genera within these are based on running together the first few letters of the name of the virus that is considered to be the “type member” for that group. For example, *Tobamovirus* comes from *tobacco mo*saic virus, *Potexvirus* from *pot*ato virus *X*, and *Tospovirus* from *to*mato *spo*tted wilt virus (Fig. 3). This approach to classification has at times led to vigorous debate because the genera designations are not necessarily intuitive for the nonexpert, and even those in the field can find them difficult to remember. As is the case for animal viruses, researchers generally use common names to refer to individual viruses.

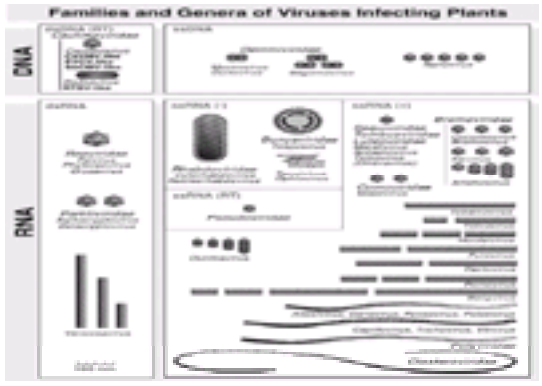

FIG. 3. Classification of plant viruses. (From ref. 347, with permission.)

Figure 3 illustrates several important points about plant viruses in relation to animal viruses. The vast majority of plant viruses are nonenveloped positive-sense ssRNA viruses. There are few enveloped plant viruses, and these are negative-sense (the rhabdoviruses) or ambisense (the tospoviruses and tenuiviruses) ssRNA viruses. There are few DNA plant viruses, and none of these are true dsDNA viruses. Thus, there are no simple dsDNA viruses corresponding to the papovaviruses, and there are no dsDNA viruses of the complexity of the adenoviruses, herpesviruses, or vaccinia viruses. The caulimoviruses and badnaviruses have dsDNA genomes of ~7.2 to 8.2 kb in size but employ a reverse-transcribing replication strategy through a positive-sense ssRNA intermediate, as do the hepadnaviruses (see Chapter 86). The geminiviruses and the nanoviruses have small multicomponent circular ssDNA genomes (one or two genome segments of ~2.6 to 2.9 kb for geminiviruses, and at least six genome segments of ~1.0 to 1.2 kb for nanoviruses) and, like the parvoviruses, replicate through dsDNA intermediates. In contrast to animal viruses, in which segmented genomes are encapsidated in a single particle, the majority of plant viruses (positive-sense ssRNA, and ssDNA) have segmented genomes (referred to as *multicomponent*), with each genome segment encapsidated in a distinct particle. Only a few plant viruses belong to recognized families of animal viruses: *Reoviridae, Rhabdoviridae,* and *Bunyaviridae.* The diversity of plant virus families and genera classified according to the scheme in Figure 3 is striking. Yet despite this diversity, sequence analyses have revealed striking similarities, both among the RNA plant viruses and between plant and animal RNA viruses, as well as among caulimoviruses, retroviruses, and hepadnaviruses. Such comparisons have led to the grouping of plant and animal RNA viruses into “superfamilies” that share common sequence arrangements in their RNA-dependent RNA polymerases (RdRp), helicases, methyltransferases, genome-linked viral-encoded protein (VPg) or encoded proteinases, and common strategies of gene expression (see Chapter 13). Several of these points are discussed further in the following sections in the context of functional studies on specific plant viruses and the differences between plants and animals.

CONSEQUENCES OF THE PLANT CELL WALL

The production of a rigid cell wall by plant cells is one of the two fundamental alterations that account for most of the differences between plants and animals (the other is carbon dioxide [CO_2] fixation through photosynthesis). Thus, perhaps it is not surprising that most of the basic differences between plant and animal viruses can be traced to plant cells being surrounded by this wall of long cellulose microfibrils (extensive polymers of b1®4–linked glucose residues) embedded in a matrix of branched polysaccharides (hemicellulose) and pectins, and the resultant rather sedentary lifestyle this imposes on plants. The plant cell wall is an effective barrier to virus entry and spread within the plant. External surface layers composed of cutin and waxes provide an additional protective barrier for the plant as a whole. Thus, to enter the plant initially and establish infection in a cell, a virus must mechanically breach these barriers. In addition, the virus will have to be delivered to the plant.

Plant-to-Plant Transmission

Although in nature a few plant viruses have been reported to be transmitted by direct plant-to-plant contact, and some can be introduced by mechanical abrasion with contaminated implements, most plant viruses are transmitted to their hosts through the action of a vector. In the vast majority of cases, this involves introduction into the aerial parts of the plant by the action of insects feeding on leaves and stems (124) (Table 2). The insect acquires the virus by feeding on infected plants and then transmits it when feeding on uninfected plants. These insect vectors include aphids, whiteflies,

leafhoppers, mealy bugs, thrips, mites, and beetles. The type of insect vector is specific for a particular genus of plant viruses. The insect-transmitted form is the virion itself, as suggested by genetic studies that show the plant virus coat or capsid protein (CP) is invariably required for insect transmission. The virus may simply become associated with the insect cuticle (noncirculative), or it may have to be altered by passing through tissues of the insect (circulative) before it is transmitted back to plants (Table 3). Because insects feed multiple times on a given plant, viruses are usually introduced at high multiplicities. This could explain the prevalence of multipartite plant viruses having separately encapsidated genome components.

	Aerosols (airborne) or ingestion (waterborne or foodborne)	Fluids (direct contact)	Parent to offspring	Vectors
Animal viruses	Most	Few	Few	Many
	Picorna	Hepadna	Retro	Toga
	Orthomyxo	Retro	Herpes	Flavi
	Corona	Herpes	Arena	Bunya
	Reo	Papilloma		Rhabdo
Plant viruses	None	Few	Many	Most
		Tobamo	Hordei	Poty
		Tombus	Ilar	Potex
		(water, mechanical)	Poty (seeds, pollen, bulbs, cuttings)	Gemini
				Luteo
				Tospo (Bunya) (insects, nematodes, fungi)

[a]Examples indicate that some, not necessarily all, viruses within the family are transmitted by the given mode. (Based on ref. 124.)

TABLE 2. *Transmission of viruses between hosts*[a]

	Noncirculative (cuticle associated)		Circulative (tissue associated)	
	Stylet borne (nonpersistent)	Foregut borne (semipersistent)	Nonpropagative (persistent)	Propagative (persistent)
Example	Potyviruses	Caulimoviruses	Luteoviruses	Tospoviruses
Acquire[a]	Seconds	Minutes	Hours	
Inoculate[b]	Seconds	Minutes	Hours	
Retain[c]	Hours	Days	Days	
Latent period[d]	No	No	Yes	

[a]Minimum feeding time required for an insect to acquire[a] or transmit[b] a virus.
[b]Period of time for which an insect retains the ability to transmit a virus.
[c]Lag between the time an insect acquires a virus and the time it becomes competent to transmit that virus.
Based on ref. 124.

TABLE 3. *Modes of plant virus insect transmission*

Viruses that are closely related are transmitted by the same type of vector and in a similar manner. For example, luteoviruses and potyviruses are both transmitted by aphids, but their relationships to the aphid differ. For potyviruses, the aphid is similar in principle to a flying syringe, although the interaction is more specific. The virus binds to a receptor(s) in the aphid stylet (the feeding probe), but the aphid is not a host for the virus: it simply serves to inject the virus into a plant during feeding, probably by a process of ingestion and salivation (124). This type of transmission mode has been termed *nonpersistent* and is now referred to as *stylet borne.* It is characterized by rapid insect acquisition and inoculation times (on the order of seconds), and the insect retains the ability to transmit the virus for only a few hours (see Table 3). In contrast, luteoviruses have to circulate through the aphid, passing from the insect midgut to the hindgut and crossing the hindgut wall to enter the hemocoel. From the hemocoel, the virus moves to the salivary glands and then enters the salivary canal, from which it will be inoculated into plants during aphid feeding. Thus, there is an obligatory biological relationship between the luteovirus and the aphid, one in which the acquired virus is altered in preparation for transmission. There is evidence to suggest that this alteration may involve proteolytic cleavage of a proline-rich extension in a subset of the viral CP subunits that make up the viral capsid. Although luteoviruses do not in fact multiply in the aphid, the insect is referred to as a “host,” but a nonpropagative one (see Table 3), and it is considered “infected” with the virus. This circulative mode of transmission is characterized by long acquisition and plant inoculation times, on the order of hours. It was formerly referred to as “persistent” because the insect can transmit the virus for many days, and potentially throughout its life, once it has acquired the virus.

A number of plant viruses that are transmitted by the circulative mode have been shown to multiply in their insect vector, thus infecting the insect in the more conventional sense. The insect in these cases is termed a *propagative host* (see Table 3). Perhaps not surprisingly, most of these plant viruses, which when viewed from their ability to multiply in the insect could be considered to be “animal viruses,” belong to well-recognized animal virus families— *Reoviridae, Rhabdoviridae,* and *Bunyaviridae*— although some apparently do not (marafiviruses) (see Table 3). The tospoviruses, named for the type member TSWV, are a genera within the *Bunyaviridae,* and TSWV illustrates at least some of the adaptations a plant virus may evolve to achieve this dual lifestyle.

TSWV, like the animal-infecting *Bunyaviridae,* has a tripartite ssRNA genome encapsidated in three nucleocapsids, which are surrounded by an envelope. The envelope contains heterodimeric spikes composed of the viral-encoded G1 and G2 glycoproteins. TSWV is transmitted by thrips in a circulative and propagative manner. The virus, once ingested, passes to the thrip midgut, where it may bind to a receptor(s) (17), and crosses the midgut wall, apparently by endocytosis. TSWV multiplies in the infected thrip, eventually reaching the salivary glands and salivary canal, from which it is transmitted to other plants. Comparison of the TSWV genome organization with that of the animal-infecting *Bunyaviridae* shows that its M segment, which encodes G1 and G2 in all *Bunyaviridae,* is uniquely ambisense, being transcribed into a subgenomic RNA that is translated into a plant virus-specific NSm protein (see Chapter 48). Both the glycoproteins and

NSm are needed for TSWV to exit from an infected cell, but in very different ways. G1 and G2, indeed the entire enveloped structure, are required for multiplication in and transmission by thrips, but are completely dispensable for infecting plants. This was graphically shown by the studies in which TSWV was serially passaged in tobacco plants by mechanical abrasion in the complete absence of the insect vector (285). After a number of passages, virus was obtained that was highly infectious when mechanically inoculated on plants but could not be transmitted by thrips. This mutated TSWV would still react with antinucleocapsid antisera but was no longer recognized by either anti-G1 or anti-G2 antisera, suggesting that the glycoproteins were absent. This was confirmed and extended in electron microscopic studies that showed these mutant TSWV preparations consisted of the typical viral RNPs, with no enveloped particles being present. Molecular studies in insect cells and gel overlay assays with tissue extracts from thrips suggest that the glycoprotein spikes are required for attachment and penetration in the thrips vector (17,171). NSm is not required for insect transmission or replication of the viral genome (272). Rather, it is a unique plant virus protein—a movement protein—that is needed for the virus to cross the cell wall and systemically infect the plant.

The specificity of the virus–insect interaction requires virus-encoded protein and presumably a receptor protein(s) in the insect, although few such candidate receptors have been identified. As shown for the geminiviruses, in nonenveloped viruses, the CP can be the only virus-encoded protein required for the specificity of interaction with the insect vector. There are different genera of geminiviruses, and the begomoviruses, such as African cassava mosaic virus (ACMV), are transmitted by whiteflies, whereas the curtoviruses, such as beet curly top virus (BCTV), and the mastreviruses, such as maize streak virus, are transmitted by different leafhopper species (see Fig. 3). When ACMV was engineered to express the BCTV CP in place of its own, the recombinant ACMV genome encapsidated in the BCTV CP was now transmitted by leafhoppers, and not by whiteflies, which demonstrated a direct role of the geminivirus CP in insect recognition (31). However, for some nonenveloped plant viruses, a virus-encoded transmission accessory or “helper” factor is required, in addition to the CP, for the specific interaction with receptors in the insect. This is the case for the potyviruses and their aphid vectors, where it has been suggested that a dimeric form of the viral-encoded helper factor (helper component, the HC domain of HC-Pro) acts as a bridging molecule between the virion capsid and receptor(s) in the cuticle lining the aphid stylet (264). The viral spikes in TSWV appear to bind directly to candidate receptor proteins in thrips (17,171), and it is reasonable to think that this may be generally true for all enveloped plant viruses that are transmitted by insects. Our understanding of plant virus attachment to and passage through, or replication in, the insect vector is currently rudimentary owing to the general lack of stable virus mutants that are defective in insect transmission, and of cultured insect cells in which to study plant virus attachment and replication. The functions in virus penetration or circulation of the few candidate receptor molecules that have been identified remains to be defined. Recent technical advances, such as the establishment of cultured thrips and leafhopper cell lines for replication studies, and genetic approaches to generate stable virus mutants (172,241,279) should aid in addressing these questions and increase our knowledge of how virions are altered as they pass through their insect vectors.

Elementary as our knowledge is about insect transmission of plant viruses, we understand even less about the transmission of plant viruses by fungi or nematodes, or their horizontal transmission through seed or pollen (see Table 2). In those instances in which it has been is studied, both virus-encoded and host-encoded components appear to be important in these modes of transmission. As for insect transmission, the evidence suggests that virus particles are transmitted by nematodes and fungi because, in the few cases in which it has been investigated, at least the viral CP is required for transmission by these vectors (125,212). About 18% of plant viruses can be transmitted through seeds in at least one host, a process that is more significant in terms of economic and epidemiologic impact than this number might imply once one considers the number of infected seeds that can be produced by a field of plants. In all cases, except for TMV, seed transmission requires that the embryo be infected either directly or indirectly through infection of the gametes prior to fertilization (221). Molecular studies of barley stripe mosaic virus (a hordeivirus), the potyvirus pea seed-borne mosaic virus, and the tobravirus pea early browning virus indicate that the process is complex. Nevertheless, in two of these cases, a viral-encoded protein that is a “pathogenicity determinant” has been identified as a determinant of seed transmission (96,162,362). This suggests that perhaps efficient systemic invasion of the host is a factor in the ability of some plant viruses to overcome tissue barriers and invade the developing embryo.

Adaptation to the Cell Wall: The Fundamental Difference Between Plant and Animal Viruses

Once mechanically introduced into a plant, by insect feeding or other means, plant viruses will initiate infection of the inoculated cells, most commonly within a leaf. However, the problem of the plant cell wall does not end here because it is an effective barrier to plant viruses exiting from as well as entering a cell. The virus must do this to spread from cell to cell within the inoculated leaf and then invade the growing plant, a process termed *systemic infection.* A fundamental distinction from bacteriophage, which also have to negotiate their way across cell walls, is that plant viruses infect and invade an integrated multicellular host, not a population of autonomously functioning walled cells. Plant cells, although surrounded by walls, are connected by transwall channels termed *plasmodesmata,* the formation and function of which can be developmentally regulated. Through these channels, all plant cells are potentially in communication with each other through the passage of solutes and small molecules, and recent studies suggest that even rather large proteins may pass through plasmodesmata at certain developmental stages (252,291). The term *symplasm* was coined to reflect this potential cytoplasmic continuity among plant cells. The spaces between plant cells constitute the *apoplasm.* If plant viruses were to adapt the solution of most phage (except f1/M13) of encoding the equivalent of a lysozyme function (a “cellulase”) to dissolve the wall of the infected cell, they would find themselves in the apoplasm facing the next cell wall. Worse yet, the “cellulase” could digest the walls of the surrounding cells, which, given their high internal hydrostatic pressure, would burst—not a useful outcome for the virus.

Although the cell wall presents a barrier, the plasmodesmata present an opportunity for the plant virus to move directly from cell to cell without having to go through an extracellular phase. This is similar in principle to cell-to-cell spread of vaccinia virus or human immunodeficiency virus (HIV), but in a manner that is potentially less destructive to the plant cells. All plant viruses encode a unique class of proteins termed movement proteins (MPs), which modify or alter plasmodesmata so that the virus genome can spread directly from cell to cell, effectively “tunneling” through the cell wall in a nondestructive way. The MP is essential for this process, as indicated by the name, which originates from the genetic studies that first identified the genes encoding such proteins. A plant virus that is mutated in the gene encoding this MP will still replicate in individual plant cell protoplasts and assemble virus particles, but this virus will be defective in

spreading within the inoculated leaf and systemically infecting the host. The classic studies on the TMV temperature-sensitive *Ls1* mutant (245) were among the first to show that such MPs exist. TMV *Ls1* can systemically infect tomato plants at 22°C but will not do so when the plants are grown at 32°C, although it replicates well at both temperatures. When tomato plant leaflets mechanically inoculated with this *Ls1* mutant were grown for 24 hours at 22°C or 32°C and stained with fluorescently tagged antivirus antibody that would detect TMV CP, fields of large numbers of adjoining infected cells that accumulated viral CP could be seen at the permissive temperature of 22°C. This was also true for leaflets at both temperatures inoculated with wild-type TMV. In contrast, only individual single cells were found to accumulate CP in the *Ls1*-inoculated leaflets grown at 32°C. This demonstrated that the *Ls1* mutant could replicate at the nonpermissive temperature because it was synthesizing viral CP. However, the fact that only individual single cells were seen to be infected, rather than fields of contiguous cells, showed that this *Ls1* mutant was defective at the high temperature in moving from the inoculated cell into neighboring cells within the leaf. As described in more detail later, we now know that this *Ls1* mutant has a missense mutation in the 30-kd MP of TMV (71).

Although the MP is essential for this cell-to-cell movement, the viral CP may or may not be required. TMV and several other positive-sense RNA viruses do not require CP to move locally from cell to cell within the infected leaf. Neither do the ssDNA bipartite geminiviruses (begomoviruses). As discussed later, although the mechanisms differ, the genomes of these viruses can move from cell to cell in a complex with a movement protein. Other plant viruses, such as TSWV, CaMV, and potato virus X (PVX), require CP in addition to movement proteins to move locally from cell to cell, moving as virions or subviral particles. Thus, although plant viruses are transmitted from plant to plant in the form of virus particles, virions are not necessarily the form in which the plant virus genome is transmitted directly from cell to cell, at least within an infected leaf (194). This is in stark contrast to animal viruses and phage. This does not mean that virus particles do not play a role in systemic infection of the plant. For most plant viruses, movement out of the inoculated leaf to distant parts of the plant to establish systemic infection occurs through the nutrient transport system of the plant, the phloem, by way of companion cells connected to the sieve elements or “tubes” that form the conduits for long distance transport of nutrients. Evidence suggests that most plant viruses require CP for this long-distance movement, although whether this occurs in the form of stable assembled virions in all cases remains to be shown.

As suggested from the preceding considerations, an additional distinct feature of plant viruses when compared to animal viruses and phage is that there is no evidence for the attachment of virus particles to specific receptors on the surface of plant cells to initiate infection. Such virus–receptor interactions do appear to be important for recognition of plant viruses by their insect vectors, and perhaps other agents, for transmission. It also seems likely that within the vector, receptor-mediated endocytosis or receptor binding, followed by cell surface fusion, will be used by plant viruses that infect their insect vectors such as the topsoviruses and plant rhabdoviruses. Whether this represents another plant virus adaptation to the presence of the plant cell wall or the physiology of the plant, such an interaction has not been demonstrated to play a role in virus infection of a plant host. Few studies have focused on the mechanism by which plant virus particles or the genome in some other packaged form moves out of phloem sieve elements to penetrate plant cells when invading a new leaf, or on the uncoating of the plant virus genome, and we understand little about these processes.

PLANT VIRUS GENE EXPRESSION AND REPLICATION STRATEGIES

Given the relatively compact nature of their genomes, plant viruses, like animal viruses, have devised a variety of strategies to expand their coding capacity and regulate their gene expression while adhering to the rules for the translation of mRNAs in their eukaryotic hosts. These strategies, and the viral replication schemes, are all found among the animal viruses. Plant viruses with ssRNA genomes each replicate through an antigenomic or complementary strand, which serves as template for the synthesis of progeny strand genome ssRNA: the antigenomic replication template is negative-sense for a positive-sense RNA virus and the same polarity as mRNA (positive) for a negative-sense ssRNA virus, but it is not translated. Thus, exactly like ssRNA animal viruses, plant ssRNA viruses have to reconcile their genome structure with the requirement for monocistronic mRNAs in eukaryotic cells. In doing so, positive-sense ssRNA plant viruses regulate their gene expression at the level of transcription, through the production of subgenomic RNA (sgRNA); and at the level of translation, through polyprotein synthesis, leaky ribosome scanning, suppression of termination (called *readthrough translation*), ribosomal frameshifting, or internal ribosome entry (see Chapter 5). The production of sgRNA is the most common strategy employed; however, most positive-sense ssRNA plant viruses use more than a single strategy to regulate and optimize their gene expression. The ambisense tospoviruses, in the *Bunyaviridae* (see Chapter 48), regulate their expression at the transcriptional level through cap snatching and the production of sgRNA, and by a polyprotein strategy at the translational level. The negative-sense plant rhabdoviruses probably employ a strictly monocistronic transcriptional strategy, as do the animal rhabdoviruses (see Chapter 38). Reinitiation of translation and RNA editing, strategies employed along with these others by different animal ssRNA viruses, have not been reported for ssRNA plant viruses.

In terms of plant DNA viruses, geminivirus circular ssDNA genomes are replicated through dsDNA intermediates by a rolling circle mechanism, as has been shown for the replication of the ssDNA genome of bacteriophage fX174 and proposed for the replication of herpesvirus dsDNA (see Chapter 22 and Chapter 72). The geminivirus dsDNA forms are also templates for the transcription of viral mRNAs, and gene expression is temporally regulated through transcriptional cascades, as it is in animal DNA viruses, such as the papovaviruses, adenoviruses, and herpesviruses, and in DNA bacteriophage. Alternative splicing of transcripts, as is found in many DNA animal viruses and the retroviruses, also regulates gene expression in some geminiviruses and in the caulimoviruses, such as CaMV and figwort mosaic virus (FMV). For these latter viruses, and the badnaviruses, the dsDNA genome is replicated by a reverse-transcribing mechanism through a positive-sense ssRNA in a manner similar to the hepadnaviruses (see Chapter 86). CaMV also regulates its gene expression through ribosome shunting (also used by adenovirus type 2) and the use of two promoters, and a virus-encoded transactivator acts to couple the translation of genes so that the viral 35S transcript is translated as a polycistronic mRNA even though it uses the eukaryotic translation machinery.

These strategies and principles are illustrated in the following sections by examining in detail the multiplication of plant viruses within several genera in an attempt to present the current state of our knowledge and highlight the experimental approaches being used. The particular viruses are not necessarily the most important in terms of disease potential and economic impact, but rather were chosen because they have been extensively characterized at the molecular,

biochemical, and/or cellular levels and each illustrates particular points about the regulation of gene expression and virus interactions with plant cells. All plant viruses that have been sequenced and characterized to date employ some combination of the strategies that are discussed in these sections. Unsegmented (monopartite) positive-sense ssRNA viruses are presented first, chosen to illustrate the spectrum of positive-sense RNA virus strategies in a variety of combinations. These are followed by an example of a positive-sense ssRNA plant virus with a segmented genome, enveloped plant viruses, and plant DNA viruses. All of the RNA viruses in the following sections, except for some of the rhabdoviruses, are cytoplasmic viruses. In addition, all of the viruses that are presented, save for the *Luteoviridae* and *Geminiviridae*, infect and replicate in mesophyll cells (the cells between the veins that make up the bulk of a leaf). Viruses in the family *Luteoviridae* are limited to infecting the phloem tissue within the veins, and this is also true for a number of the *Geminiviridae*.

Positive-Sense Single-Stranded RNA Viruses

Potyviruses: Polyprotein Strategy

The largest of the plant virus families, the *Potyviridae,* encompasses the potyviruses, rymoviruses, and bymoviruses, along with several other genera (347). The potyviruses themselves constitute the largest genus of known plant viruses (~30%) and as a group are responsible for the highest losses of crop plants worldwide (5). Although *pot*ato virus *Y* is the type member for this genus (hence “poty”), other potyviruses, such as tobacco etch virus (TEV), tobacco vein mottling virus (TVMV), and plum pox virus (PPV), have been better characterized at the molecular level. The virions are flexuous filamentous rods 11 to 15 nm in diameter and 680 to 900 nm in length (see Fig. 3) and are transmitted by aphids. The capsid is assembled from subunits of a single protein, the viral-encoded coat protein (CP). The potyviral genome is an unsegmented (monopartite) positive-sense ssRNA of ~10 kb that has a viral-encoded protein (VPg) covalently linked to its 5' end and is polyadenylated at its 3' end (reviewed in 290). With the initial complete sequencing of the genomes of TEV, TVMV, and PPV, it became clear that the potyvirus genomic RNA encodes a single open reading frame (ORF), which could be translated into one large polyprotein of 340 to 370 kd, similar to the animal picornaviruses. This, and similarities with picornaviruses and flaviviruses, as well as plant nepoviruses and comoviruses, in predicted amino acid sequence motifs, and the organization of proteins potentially involved in RNA replication, eventually led to the proposed superfamily of picorna-like plant and animal viruses (120) (see Chapter 13).

Prior to the availability of complete genome sequences and infectious clones, several of the potyvirus-encoded proteins were identified by a combination of biochemical and immunological studies of virions, insect (aphid) transmission, and infected plant tissue, and their names reflect these original associations. Thus, the viral CP was originally “Cap” for capsid protein, VPg is the genome-linked viral protein, and HC is the “helper component” N-terminal domain of HC-Pro (found in amorphous cytoplasmic inclusions) that is required as an accessory factor for insect transmission of virions (this has been extensively characterized, as reviewed in 264). Three additional viral proteins were associated with characteristic inclusions in infected cells: CI with cytoplasmic *cylindrical inclusions,* and NIa and NIb with *nuclear inclusions*.

The single polyprotein encoded by the potyvirus genomic RNA is cotranslationally and posttranslationally cleaved to produce all of the mature viral proteins by the action of three viral-encoded proteinases: P1, HC-Pro, and NIa (39,40,116,135,353) (Fig. 4). P1 and HC-Pro are responsible for two distinct autoproteolytic (*cis*) cleavages within the N-terminal region of the polyprotein. NIa, which resembles the picornavirus 3C proteinase, carries out the remaining cleavages (both in *cis* and in *trans*) within the C-terminal two-thirds of the polyprotein. NIa is composed of an N-terminal VPg domain and a C-terminal proteinase domain. This proteinase domain, and the C-terminal proteinase domain of P1, are both structurally related to the chymotrypsin class of serine proteinases. HC-Pro, also having a C-terminal proteinase domain, is a papain-like cysteine proteinase. P1, HC-Pro, and NIa are not only required for the correct proteolytic processing of the viral-encoded polyprotein: each proteinase is a multifunctional protein with additional roles in the virus life cycle. This multifunctionality appears to be true for most of the potyvirus proteins.

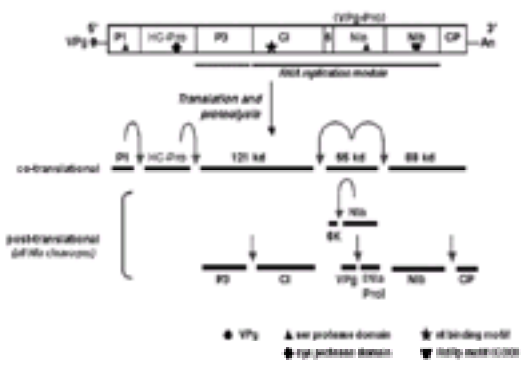

FIG. 4. Genome organization and polyprotein processing of tobacco etch virus (TEV). (Adapted from refs. 287 and 290, with permission.)

P1 autoproteolytically separates itself from HC-Pro (see Fig. 4). This proteolytic cleavage is essential for virus infectivity, but P1 proteolytic activity *per se* is not. This was shown in studies with TEV using mutants that were nonviable because each encoded a processing-defective P1 proteinase. Each mutant could be restored to infectivity by the insertion of an NIa cleavage site between P1 and HC-Pro (350). P1 can bind ssRNA *in vitro* (30,352), and based on this and sequence comparisons, it was long speculated that P1 might be an MP. To address this point, a modified strain of TEV was engineered to express the bacterial *GUS* gene (TEV-GUS) as a reporter. When protoplasts prepared from tobacco plants are transfected with TEV-GUS RNA, the level of virus replication can be determined based on a fluorometric assay to

detect GUS activity, produced from the viral genome, in cell extracts. When plants are inoculated with TEV-GUS, in addition to quantitating GUS activity in leaf extracts using this assay, intact leaves can be fixed and stained for GUS activity using a histochemical substrate (X-gluc) that will stain GUS-expressing cells blue (Fig. 5). Thus, using this GUS-expressing virus, mutations in P1, or in any other viral protein, can be directly assayed in plants for their effects on virus movement as well as virus replication. A mutant in which the P1 coding sequence was deleted from TEV-GUS replicated to low levels in protoplasts (~3% wild-type levels), suggesting that while P1 was not essential for replication, it did play an accessory role. Despite this poor replication, this mutant was capable of cell-to-cell and leaf-to-leaf (systemic) movement in inoculated plants (351). The level of replication in protoplasts could be increased if the protoplasts were prepared from transgenic plants engineered to express P1. Thus, P1 is not an MP but may be a *trans*-acting accessory factor that stimulates viral genome amplification. P1 could exert this effect directly by interacting with viral RNA or proteins in the replication complex, or more analogous to the 2A proteinase of picornaviruses, could indirectly affect genome amplification by stimulating viral RNA translation (351) (see Chapter 23).

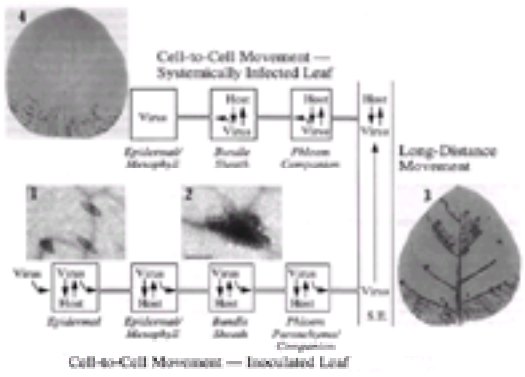

FIG. 5. Path of virus local and long distance movement as visualized in plants infected with tobacco etch virus (TEV) expressing a *GUS* reporter gene. Virus that is mechanically inoculated onto a leaf first moves from the surface epidermal cells to the underlying mesophyll cells. It then moves from cell to cell in the mesophyll to reach bundle sheath cells, from which it enters phloem parenchyma and companion cells. Long distance movement to enter a distal leaf occurs through the sieve elements of the phloem. At each stage, the virus is interacting with host factors (indicated by *boxes*). (From ref. 43, with permission.

The CI-6K-NIa-NIb region of the potyviral polyprotein is similar in sequence and organization to the 2C-3A-3B-3C-3D region of the picornavirus polyprotein, which led to its original designation as the RNA replication module (290) (see Fig. 4). Molecular genetic and biochemical studies have established that this similarity extends to function as well, with NIa (VPg-proteinase) playing an essential regulatory role similar to that of the picornavirus 3C proteinase (see Chapter 23). Potyvirus replication occurs in the cytoplasm, apparently in association with endoplasmic reticulum (ER)-derived membranes (Fig. 6). Several lines of evidence suggest that the 6K protein, probably in the form of the 6K-NIa polyprotein (see Fig. 4), may act to target and anchor replication complexes to these membrane sites. TEV infection causes a collapse of the ER network into aggregated structures, and 6K appears to be associated with these ER-derived membranes. This was shown by expressing a fusion of 6K and the jellyfish green fluorescent protein (GFP:6K) in living cells from plasmids or the TEV genome, which could be introduced into leaf cells by biolistic bombardment, transfected into protoplasts, or inoculated onto plants. Using confocal microscopy and immune staining for marker proteins known to be located in the ER or Golgi, the GFP:6K was shown to localize to ER-derived membrane vesicles, and subcellular fractionation studies showed that both replication complexes and the 6K protein were associated with ER-like membranes (304).

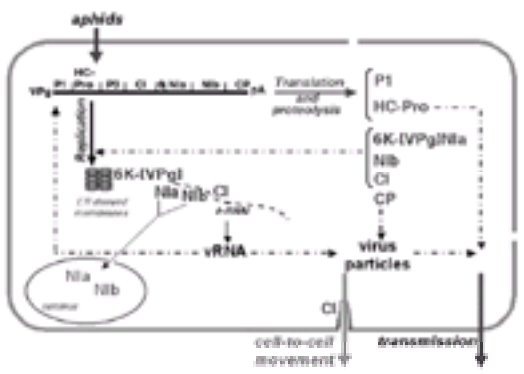

FIG. 6. Multiplication of tobacco etch virus (TEV). See Fig. 4 for the proteolytic events catalyzed by P1, HC-Pro, and NIa to process the TEV polyprotein into the individual encoded proteins.

Proteolytic processing by NIa, as well as NIa interacting with NIb, the viral RdRp (100,207), appear to be critical in orchestrating these events, with NIa acting in *cis* and NIb in *trans* (see Fig. 6). The latter conclusion is based on the finding that NIa mutants cannot be rescued for replication when transfected into protoplasts prepared from transgenic plants that express NIa, but NIb mutants can be rescued in transgenic protoplasts that express NIb (206,303). NIa can bind RNA *in vitro* (58), and TEV and TVMV NIa have also been shown to interact with NIb in yeast two-hybrid and *in vitro* binding assays (100,146,207). Genetic studies indicate that NIa–NIb interaction is essential for virus replication (57). TEV NIa cleaves sites that contain the consensus heptapeptide motif Glu-X-X-Tyr-X-Gln¯Gly/Ser at differing rates, and it

shows *cis*-preferential cleavage at a number of sites in the polyprotein, including those at CI/6K, 6K/NIa, and NIa/NIb. Whether NIa is retained in the cytoplasm or transported to the nucleus appears to be regulated by its association with 6K: the 6K-NIa polyprotein is retained in the cytoplasm, apparently because 6K masks the nuclear localization signal (NLS) which is present in NIa. However, after cleavage to produce the two separate proteins, NIa itself is efficiently transported to the nucleus mediated by its NLS, which is located in the VPg domain of the NIa (287). A suboptimal site that is slowly processed separates the VPg and proteinase domains of NIa itself. Mutants altered at this site to accelerate autocleavage by NIa are defective in amplifying the viral genome, as are mutants in the VPg linkage site (Tyr-62), the NIa (VPg) NLS, or the proteinase active site (303). Thus, nuclear targeting of NIa and slow internal processing between the VPg and proteinase domains, as well as VPg (or NIa) linkage to the viral genome and NIa proteinase activity, are required for viral RNA replication. The model that is consistent with these findings is that the 6K-NIa polyprotein bound to viral RNA by its NIa (VPg-proteinase) domain is anchored to ER-derived membranes through the 6K domain. NIb (RdRp) would be recruited to these replication complexes through a protein–protein interaction with NIa, which would position it next to the VPg domain to stimulate polymerase activity and protein priming of RNA synthesis (57), analogous to what has been proposed for picornavirus RNA replication. Whether VPg acts as a protein primer in potyvirus replication remains to be demonstrated. CI, which *in vitro* has been shown to have the properties of a helicase (95,188), is also required for genome replication (42,177). Such helicase activity is generally needed by large RNA viruses for their replication.

Given the functions of NIa and NIb in replication, why are both found to accumulate in the nucleus? It may be a consequence of the viral polyprotein strategy. CP is needed in large amounts to encapsidate the genome for insect transmission as well as for cell-to-cell movement (see below). Thus, very large amounts of NIa and NIb, as well as the other viral-encoded proteins, will also be made. It has been proposed that targeting NIa to the nucleus may be a way to down-regulate the level of NIa proteinase activity in the cytoplasm by, in essence, removing NIa to a separate compartment. This could be mediated by the NLS within the VPg domain of NIa, or an association with NIb, which itself has two NLSs (57,207,303). Independently, NIb targeting to the nucleus would be a mechanism to decrease the amount of RdRp in the cytoplasm late in infection to favor encapsidation of viral genomes for movement and transmission. It has also been suggested that NIa might act in the nucleus to affect host cell functions such as transcription (303,363).

The reported multifunctional nature of the potyvirus proteins is striking, and whether this to some extent reflects the polyprotein strategy of these viruses is an interesting point to ponder. At least CI and CP are not so different in this regard from other plant virus–encoded proteins as their multifunctional nature may reflect the particular requirements for virus movement. As discussed in the section on movement proteins, studies during the past several years have broadened our view beyond these simply being proteins that move the virus genome across the cell wall: movement proteins coordinate replication of the viral genome with its directed movement within and between plant cells (194). Genetic and ultrastructural studies suggest that CI, the virus-encoded helicase, is the potyvirus MP, associated with cone-shaped structures that align with plasmodesmata in infected cells (42,293). CP is also required for movement apparently because the viral genome is transported either as virus particles or in an RNP-complex with CP (81). Its role in aphid transmission is similarly explained by the fact that virus particles are the form transmitted, in a process that requires the helper component N-terminal domain of HC-Pro (reviewed in 264). Genetic studies suggest that the VPg domain of NIa, as well as HC-Pro, are “factors” involved in virus long distance (systemic) movement as well as genome amplification (55,166,177,282,305), but such studies do not distinguish between these proteins directly or indirectly affecting these processes. For HC-Pro, the effects seem to be the consequence of its role as a “pathogenicity factor,” and indeed HC-Pro may be the most impressive example of a truly multifunctional protein (277,316). It is undoubtedly the helper component for aphid transmission and a proteinase for viral polyprotein processing. However, its effects on virus replication and systemic movement are now known to reflect an additional role of HC-Pro as a viral counterstrategy against a host RNA–mediated defense response (see Plant Responses to Virus Infection). Sorting out the effects of VPg mutations on long distance movement will require a better understanding of the forms in which the potyvirus genome moves, both from cell to cell and from leaf to leaf, and the mechanism of systemic movement.

Similar to the picornaviruses, the coding region of the potyvirus genome is flanked by untranslated sequences at its 5' and 3' ends. These regions appear to contain structural elements that regulate virus translation and replication. Similar to the picornaviruses, mutational analysis of PPV suggests that the 5'-untranslated region (5'-UTR) contributes to viral pathogenesis (211). However, whether there is an internal ribosome entry site (IRES) within this region, as there is in picornaviruses, remains unclear. Studies with PPV suggest that translation is initiated at the second in-frame AUG codon by a leaky-scanning mechanism (289). However, this region in TEV and pea seed–borne mosaic virus contains an AU-rich region that acts as a translational enhancer, and it has been suggested that this might contain an IRES (41,243). To date, there is no definitive evidence for this. The potyvirus 5'-UTR is less than 200 nt in length, much shorter that that found in picornaviruses, and it is predicted to be less structured (214). The 3'-UTR of the genome is predicted to contain secondary structures, and mutational studies with TVMV suggest that these may contribute to viral pathogenesis. Studies that compared the effects on virus replication of frameshift-stop codon mutations and deletions within the CP coding sequence of TEV suggest that translation through at least the first half of the CP coding sequence was required for efficient replication to occur (213), perhaps because passage of the translational apparatus alters secondary structure, which facilitates initiation of replication at the 3' end of the genome. These studies also identified a structural element within the 3' end of the CP coding sequence that was essential for replication, although whether this element interacts with *cis* or *trans* factors involved in genome replication or promotes stability of the viral genome remains to be determined (213).

Potexviruses: Subgenomic RNA and Leaky Ribosome Scanning

There are about ~30 viruses in the genus *Potexvirus,* of which PVX is the type member and one of the best characterized at the molecular level. In addition to its role in defining the potexvirus multiplication cycle, PVX has been important both historically and recently in studies on the synergistic enhancement of virulence that occurs when certain unrelated viruses co-infect a plant, and as a vector for gene expression studies in plants (47). Although individual potexviruses have a limited host range, as a group the potexviruses infect a range of monocotyledonous and dicotyledonous plants from bamboo and lilies to papaya, strawberry, cassava, and potato (1). The virions are flexuous filamentous rods ~14 nm in diameter and 470 to 580 nm in length (see Fig. 3) and appear to be one of the few groups of plant viruses directly

transmitted by the mechanical mode. The capsid is assembled from subunits of a single protein, the viral-encoded CP. The potexvirus genome is an unsegmented positive-sense ssRNA of ~5.8 to 7 kb with a 5'-terminal cap (m^7GpppG) and is polyadenylated at its 3' terminus.

The PVX genomic RNA contains five ORFs (151), which encode (in 5'-to-3' order) the viral RdRp (166K), a so-called triple gene block (TGB) cluster of three proteins required for virus movement (25K, 12K, and 8K), and the viral CP (25 kd) (Fig. 7). Following uncoating in a plant cell, the viral genomic RNA is translated as a monocistronic mRNA to produce the RdRp (encoded by the 5'-proximal ORF), which then copies the viral genomic positive-sense RNA to produce full-length complementary negative-stranded RNA. This is then transcribed by the RdRp to produce additional copies of full-length genomic positive-sense RNA, or if the RdRp uses internal subgenomic promoters, a set of 3'-collinear sgRNAs. Each of the sgRNAs contains sequences identical to the 3' end of the viral genome, and these function as the mRNAs for the viral movement proteins (TGB) and CP (see Fig. 7). A variety of *in vivo* and *in vitro* experimental studies support this mechanism for sgRNA synthesis and this view of potexvirus replication and expression (reviewed in 1 and 214). This strategy in general generates a family of 3'-co-terminal sgRNAs such that each gene to be expressed is located at the 5' end of one of the sgRNAs (i.e., they are each functionally a monocistronic mRNA). In the case of PVX, the largest (2.1 kb) and the smallest (0.9 kb, encoding CP) sgRNAs are monocistronic and the major sgRNAs, and these encode the 25-kd movement protein and CP, respectively. However, the third sgRNA (1.4 kb), which is less abundant, functions as a bicistronic mRNA. It is translated by leaky ribosome scanning to produce the 12K and 8K proteins (349).

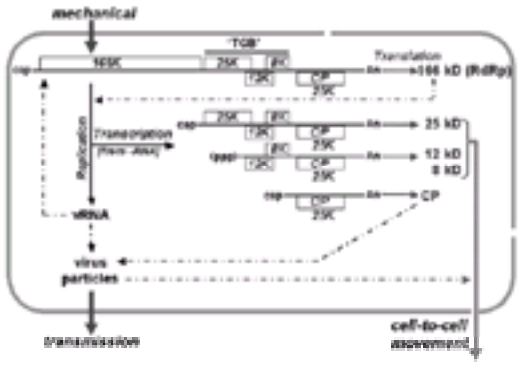

FIG. 7. Multiplication of potato virus X (PVX).

For PVX and other potexviruses, the first and largest ORF was originally predicted to encode the viral replicase (RdRp = 166K protein) based on sequence comparisons that showed it contained the conserved motifs characteristic of the methyltransferase/helicase/polymerase arrangement of the alphavirus supergroup (see Chapter 13). Mutational studies show that the 166K protein is the only viral protein that is absolutely required for PVX RNA synthesis. In particular, mutation of the GKS nucleotide binding motif characteristic of helicases or the conserved GDD motif found in viral RdRps eliminates virus replication and infectivity in plants (61,210). Viral genome length positive- and negative-sense ssRNAs and the three sgRNAs, as well as the corresponding dsRNA forms, have been identified in PVX-infected protoplasts or plants (80,236,271,349). Consistent with its function as an mRNA, the viral genomic RNA from PVX and other potexviruses is infectious and is translated *in vitro* into the RdRp encoded by the first ORF (23,136). The largest (2.1 kb) and smallest (0.9 kb) sgRNAs, as well as the viral genomic RNA, are capped and polyadenylated, and infectivity studies, as well as *in vitro* translation studies, show that the 5'-cap structure is necessary for efficient infection (1,136,236). Whether the low abundance PVX 1.4-kb sgRNA that encodes the 12K and 8K proteins is capped has not been directly determined. In general, sgRNAs commonly have the same 5' and 3' modifications as do the genomic RNA, but this is not always the case.

The PVX 1.4-kb sgRNA functions as a bicistronic mRNA, with the 12K and 8K proteins being translated by a leaky ribosome scanning mechanism. This was shown in *in vivo* studies using PVX engineered to express either GUS or GFP as a visual marker for virus movement, and transgenic plants that expressed different combinations of the TGB-encoded proteins (349). Because of the PVX expression strategy, the gene encoding GUS or GFP could be cloned just upstream of the *CP* gene so that it would be expressed from a duplicated copy of the CP subgenomic promoter. Thus, during infection the marker protein would be translated from an sgRNA separate from the other virus proteins (Fig. 8). Because PVX has a helical capsid, such engineered genomes can also be encapsidated into infectious virus particles.

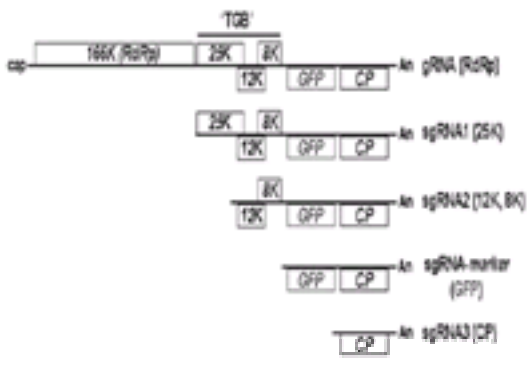

FIG. 8. Strategy to express a foreign gene using potato virus X (PVX).

Mutant PVX-GUS virus or transcripts that could not express either the 25K (D25K), the 12K (D12K) or the 8K protein (D8K, engineered by inserting a premature stop codon so that the overlapping *12K* ORF would not be affected) were not infectious when inoculated onto wild-type plants. Histochemical staining of inoculated leaves for GUS activity showed that each of these mutants is defective in cell-to-cell movement: GUS activity is restricted to the single initially infected cells. The cell-to-cell movement defect of each mutant could be rescued in *trans* when these were inoculated onto certain transgenic plants. In all cases, save one, each mutant was infectious on transgenic plants that expressed the corresponding ORF as a monocistronic mRNA or from a bicistronic or tricistronic mRNA in which this ORF was the 5'-most ORF in the transgene. Thus, for example, the D12K mutant was infectious on transgenic plants expressing either the *12K* ORF alone or the bicistronic *12K-8K* transgene but was not rescued on transgenic plants that expressed the tricistronic *25K-12K-8K* transgene in which the *12K* ORF was internal. The one exception was the D8K mutant: this was rescued on transgenic plants that expressed either the *8K* ORF alone or the bicistronic *12K-8K* transgene, thus showing that it is translated from a bicistronic mRNA (see Fig. 7). Inspection of the sequences surrounding the *12K* ORF initiation codon showed that it was in a suboptimal context for translation initiation, consistent with its being translated by leaky ribosome scanning. This was shown by constructing a set of PVX-GFP mutants in which the *12K* ORF was internally deleted (to remove any IRES), or its initiation codon was eliminated, or mutated to a stop codon or optimized initiation sequence. Because most of these mutations would eliminate translation of the 12K protein, each mutant was tested for infectivity on transgenic tobacco plants that expressed the *12K* ORF. The only mutant that could not be rescued on these transgenic plants was that in which the 12K initiation codon had been mutated to an optimized context. This mutant could be rescued only on transgenic plants that expressed the bicistronic *12K-8K* transgene, showing that the 8K protein is translated by leaky ribosome scanning (349). Thus, it appears that the amounts of the 12K and 8K proteins are regulated, relative to the 25K protein and other viral proteins, in at least two different ways. First, the bicistronic sgRNA encoding the 12K and 8K proteins is present at much lower levels in infected cells than are the mRNAs for the 25K protein, CP, and RdRp. Second, the relative amounts of the 8K and 12K proteins are regulated by leaky ribosome scanning. An interesting aspect of these PVX mutant studies is that although the appropriate transgenic lines could rescue PVX mutants for local cell-to-cell movement, in no case was there complementation for long distance systemic infection.

PVX sgRNAs, genomic RNA, and full-length complementary negative-sense RNA can be synthesized *in vitro* using membrane-containing extracts from infected plants (86). This suggests that PVX replicates in association with cytoplasmic membranes, like most if not all positive-sense plant and animal RNA viruses, including TEV and TMV (35). Consistent with this, virus replication appears to occur associated with virus-induced cytoplasmic laminate inclusions (“viroplasms”) in plant cells (1,62). PVX genomic RNA contains an 84-nt 5'-UTR and a 72-nt 3'-UTR. The 3'-UTR contains cis-acting sequence elements important for initiation of RNA negative-strand synthesis. These include a hexanucleotide sequence (5'-ACUUAA-3') that is conserved among potexviruses and a downstream U-rich motif (5'-UAUUUUCU-3') that has been identified in PVX and reported to bind host proteins from tobacco (322,372). The PVX 5'-UTR includes an AC-rich region (nucleotides 1 to 41) and contains cis-acting elements required for efficient translation (268,387) and presumably virus assembly, this last inferred from studies of papaya mosaic virus assembly (319). By analyzing positive- and negative-strand RNA accumulation in tobacco protoplasts that had been transfected with PVX transcripts, mutational studies have shown that multiple sequence and structural elements in the 5'-UTR affect the accumulation of both genomic RNA and sgRNA, without significantly affecting levels of negative-strand RNA (173,227). In particular, thermodynamic predictions and the analysis of solution structure by chemical modification and RNase digestion suggest that nucleotides 1 to 203 contains two well-defined stem-loop structures (SL1 and SL2), both of which terminate in stable GAAA tetraloops, a motif shown in other studies to enhance RNA stability (Fig. 9). Site-directed mutations introduced into SL1 show that both its sequence and structure are required for positive-strand RNA accumulation, with the internal loop C (closest to the terminal tetraloop) and its two flanking stems being particularly critical. Both the formation of and specific nucleotides within loop C were essential for positive-strand RNA accumulation, as was base-pairing within and the length of the flanking stems. Increasing the length or stability of these two stems drastically reduced positive-strand RNA accumulation (both genomic and sgRNA), suggesting that they may function to position other elements to interact with viral and/or host proteins. The sequence of the tetraloop was also important beyond just stabilizing structure (227).

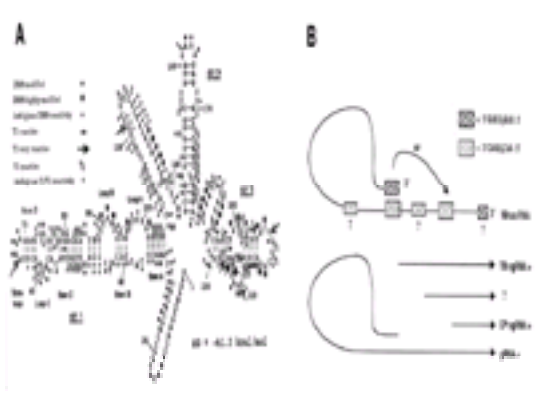

FIG. 9. A: Structure of the 5' end of potato virus X (PVX) genomic RNA. Shown are three predicted stem-loop structures (SL1, SL2, SL3) as determined by a variety of *in vitro* chemical methods (indicated by *symbols*). Labeled in SL1 are the tetraloop and specific stems and loops discussed in the text. **B:** Model for PVX positive-strand (+) RNA synthesis from the viral negative-strand (–) RNA. Shown are the PVX -RNA and the +RNA products (full-length and subgenomic RNAs (sgRNAs). The *black hatched box* corresponds to the element located 4 nucleotides from the 3' end of the –RNA (5'-GUUUAGUU-3'). The *gray hatched boxes* mark the locations of the octanucleotide elements (3'-CAAUUCAA-5') upstream of the triple gene block (TGB) and coat protein (CP) open reading frames (ORFs). The putative octanucleotide element near the 12K ORF and corresponding sgRNA for the 12K and 8K proteins are also shown (indicated by ?). An additional putative octanucleotide element within the 166K ORF is also marked with a “?” below it. (A from ref. 226, with permission; B from ref. 175, with permission.)

The relevance of these findings to virus genomic and sgRNA replication was shown by inoculating PVX mutants with specific alterations within SL1 in the 5'-UTR onto plants and analyzing revertants that accumulated following serial passages (226). Mutational studies using the protoplast replication assay also showed that conserved octanucleotide sequence elements located upstream of the two major PVX sgRNAs (2.1 kb and 0.9 kb) and the location of each element relative to the sgRNA start site were essential for sgRNA accumulation (174). Notably, these octanucleotide elements contain the conserved hexanucleotide element that is in the 3'-UTR of potexvirus genomic RNA, and they also exhibit complementarity to sequences in an apparently unstructured region of the 5'-UTR. The importance of this complementarity and of the sequence of the conserved octanucleotide elements was shown by inoculating protoplasts or plants with PVX transcripts that contained mutations within these elements, as well as compensatory mutations. Complementarity between the 5' terminus (which would be the 3' terminus of the negative-strand RNA) and the conserved octanucleotide elements is important for accumulation of both genomic RNA and sgRNA, and long distance interaction is required for all positive-strand RNA accumulation. In addition, the conserved octanucleotide sequences themselves are important for sgRNA accumulation.

Based on these studies, a model for PVX positive-strand RNA accumulation has been proposed in which the initiation events for synthesis of genomic RNA are a prerequisite for synthesis of all positive-strand RNA species (see Fig. 9). In this model, initiation of positive-strand RNA synthesis requires an interaction on the full-length negative-strand RNA template between the 3'-terminal element (defined by the element in the 5'-UTR of the genomic RNA) and a complementary element on the negative-strand RNA. The two octanucleotide elements upstream of the *TGB* and *CP* genes potentially act as partners in this process. Following initiation, sgRNA synthesis proceeds, possibly enhanced by additional interactions between the 3'-terminal element and the octanucleotide elements. Alternatively, the process can be modeled on the genomic positive-strand RNA: similar interactions would occur to generate truncated species during negative-strand RNA synthesis, with these then functioning as templates for sgRNA synthesis, as proposed for coronaviruses (see Chapter 35) and for the plant virus red clover necrotic mosaic virus (175). Another hypothesized role for the conserved elements is that they signal the replication machinery to pause or terminate RNA synthesis. In this model, the conserved element (GU-rich) at the 3' terminus of the replicating negative-strand RNA would act to terminate negative-strand RNA synthesis and allow the replication complexes to initiate positive-strand RNA synthesis. Subsequently, once the GU-rich conserved octanucleotide sequences upstream of the *TGB* and *CP* genes were synthesized as the positive-strand RNA was made, these would cause pausing or termination and thus reinitiation to synthesize the sgRNAs.

Viral CP is required for cell-to-cell movement of PVX, and several lines of evidence suggest that PVX moves from cell to cell in the form of encapsidated virus particles. When plants are inoculated with a PVX mutant in which the *CP* gene is replaced with the gene encoding GFP (PVX-GFPDCP) so that infected cells can be visualized by confocal microscopy, the virus is not infectious and is found to be limited to single inoculated cells (253). Mutational studies also show a correlation between the ability of altered CP to assemble virus particles and the ability of such mutants to spread on inoculated leaves (46). CP is detected in the central cavity of plasmodesmata when thin sections of leaves from PVX-infected tobacco plants are immunogold labeled to detect viral CP and examined by electron microscopy. In contrast, in transgenic tobacco plants that express the PVX CP, immunogold staining shows that CP is found throughout the cytoplasm and not localized to plasmodesmata. These transgenic plants make functional CP since the defective PVX-GFPDCP mutant that is missing the *CP* gene is rescued when inoculated onto the CP-expressing plants. Furthermore, in these infected plants CP is again found localized to plasmodesmata. Extending these studies, an affinity-purified antivirion antisera that can distinguish between CP subunits and assembled virions, labels plasmodesmata in PVX-infected plants, suggesting that PVX virions move from cell to cell (300).

Tobacco Mosaic Virus: Subgenomic RNA and Termination Suppression

The genus *Tobamovirus* comprises 15 members, of which TMV is the type member. TMV and the closely related tomato strain of TMV (now called tomato mosaic virus [ToMV]) are the best characterized on the molecular level. TMV, as already discussed, has been important historically in the investigation of viruses and the field of molecular biology. Beyond what has already been cited, its prominence in the study of plant viruses includes development of the local lesion assay, the first quantitative biological assay for plant viruses in which necrotic lesions on a leaf can be counted much like plaques; the use of viral replicase to engineer virus-resistant plants; and the nature of a dominant host gene that confers resistance to virus infection (Fig. 10). The economically most important tobamoviruses are TMV, which infects tobacco and other mostly solanaceous plants, ToMV in tomato, pepper green mottle virus, and odontoglossum ringspot virus in orchids. The virions are rigid helical rods approximately 18 nm in diameter and 300 nm in length (see Fig. 3) and, like potexviruses, are directly transmitted by the mechanical mode. The capsid is assembled from subunits of a single protein, the viral-encoded CP. TMV is extraordinarily stable: it not only persists in dead plant matter in the soil and on contaminated seeds, but has also been reported to exist for years in cigars and cigarettes made from infected tobacco leaves (5). The tobamovirus genome is an unsegmented positive-sense ssRNA of ~6.4 to 6.6 kb with a 5'-terminal cap (m^7GpppG) followed by an AU-rich 5'-UTR of about 70 nt. The 3'-UTR consists of sequences that can fold into a number of pseudoknots followed by a transfer RNA (tRNA)-like structure at the terminus, which in TMV and most tobamoviruses, can accept histidine *in vitro*. In TMV, the 3'-UTR contains five pseudoknots, two of which are in the tRNA-like terminus (204,313). Positive-sense RNA plant viruses in a number of genera have a 3' terminus that, like that of the TMV genome, can fold into a tRNA-like structure that encompasses pseudoknots: Watson-Crick base pairing between a loop and a single strand region in the same RNA molecule. This distinguishes them from tRNAs, which do not contain pseudoknots. The significance of pseudoknots is that they introduce structure into RNA molecules, which can potentially provide specificity in terms of interactions with proteins or catalytic reactions. The 3' tRNA-like structures in those positive-sense RNA plant viruses in which they are found have been shown to be important for negative-strand RNA synthesis. They can be aminoacylated *in vitro* and *in vivo*, but only three specificities have been reported for different plant viral RNAs: histidine, valine, or tyrosine.

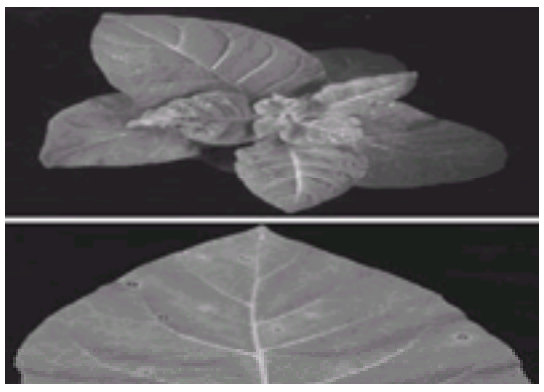

FIG. 10. Tobacco mosaic virus (TMV) infection of plants with or without the dominant *N* gene. **Top:** Systemic mosaic symptoms of TMV infection on *nn* tobacco plants. **Bottom:** Localized necrotic lesions typical of the hypersensitive response (HR) on a leaf from a TMV-infected tobacco plant carrying the *N* gene. (Photographs courtesy of Dr. Milton Zaitlin, Cornell University.)

The TMV genomic RNA contains four ORFs (119), which encode (5' to 3'): a methyltransferase/helicase and RdRp (126K and 183K, respectively), the MP (30K, referred to as the 30-kd protein), and the viral CP (17.5K) (Fig. 11). The viral genomic RNA is infectious (63,118), consistent with its initial role as an mRNA for translation of the viral RdRp (183K + 126K proteins). Following entry into the cell, the removal of a few CP subunits from the virion end that contains the 5' terminus of the genome appears to initiate uncoating. *In vitro*, this can be accomplished by incubating virions at pH 8.0 or for brief periods in low levels of sodium dodecylsulfate (SDS) (238,375). Because some cations can slow or prevent this process, it has been suggested that removal of Ca^{2+} when virions encounter the low Ca^{2+} concentrations inside the cell may induce a conformational change and removal of these few CP subunits. After this, disassembly of about three-fourths of the genome rapidly proceeds cotranslationally as ribosomes translate the 126K and 183K proteins. This was first shown to occur *in vitro* by incubating pH 8.0 treated TMV virions in rabbit reticulocyte cell-free protein synthesizing extracts. It was subsequently shown *in vivo*, both by examining extracts from tobacco epidermal cells that had been inoculated with radioactively labeled virions, and in time course studies in which reverse transcription and PCR were used to analyze the parts of the viral genome that remained encapsidated at different times following inoculation of tobacco protoplasts (314,375,380). Following this 5'-to-3' disassembly, the remainder of the genome is coreplicationally disassembled in the 3'-to-5' direction as replication of complementary negative-sense RNA is initiated. This was concluded from protoplast studies again, in which it was shown that particles from which large regions of the *126K* and *183K* ORFs have been deleted cannot undergo 3'-to-5' disassembly. However, these will fully disassemble if the protoplasts are co-inoculated with TMV genomic RNA that can provide the 126K and 183K proteins in trans. Furthermore, virions in which the genomic RNA is mutated in sequences in or near the conserved methyltransferase and helicase motifs within the 126K protein are also defective in final 3'-to-5' disassembly (379).

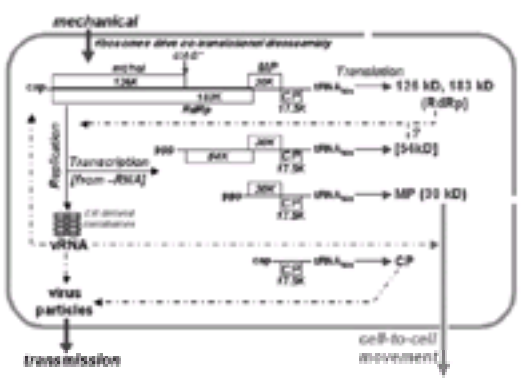

FIG. 11. Multiplication of tobacco mosaic virus (TMV).

As described previously, following initial 5'-to-3' disassembly, the 126K and 183K proteins are translated from the genomic RNA. The 183K protein is produced by readthrough translation approximately 5% to 10% of the time of the UAG codon that terminates the 126K protein. This was first shown *in vitro* using rabbit reticulocyte extracts primed with TMV genomic RNA (260), and it was subsequently reported that tobacco plants contain two suppressor $tRNA^{tyr}$ having a 5'-GYA-3' anticodon that can accomplish this (21). Readthrough (more properly termination suppression) is context dependent: in TMV the two codons just downstream of the suppressed UAG are critical for efficient readthrough *in vitro* and *in vivo* (320,344). As a result of this readthrough translation, the two proteins are read in the same frame and the amino acid sequence of the 126K protein is contained within the N-terminus of the 183K protein. The efficiency of readthrough regulates the relative amounts of the 183K and 126K proteins made. The sequence of the TMV genomic RNA first showed that the 126K (and thus the N-terminal region of the 183K) protein contains conserved motifs typical of methyltransferases and helicases, and the 183K readthrough domain contains in addition the GDD motif typical of a viral RdRp, with the arrangement of these motifs being characteristic of that found in the alphavirus superfamily (see Chapter 13). The 126K protein has also been shown to covalently bind [a-^{32}P]GTP (93). This, combined with the studies described previously and additional mutational studies in which deletion of the *MP* and *CP* ORFs was shown not to inhibit replication (225), led to the suggestion that the 183K protein, perhaps together with the 126K protein, is required for viral replication and that these two proteins make up the subunits of the replicase. Consistent with this, the 126K and 183K proteins are found in membrane-associated preparations of viral replicase and copurify with viral RdRp activity. Antibodies against different regions of the 126K protein also inhibit RdRp activity *in vitro* (256,257). Using a

complementing system in which the 183K and 126K proteins could be expressed from separate RNAs, it has recently been shown that the 183K protein is apparently the RdRp and can act in *trans* because mutants that express only this readthrough form can replicate all forms of viral positive- and negative-sense RNA, and can synthesize the viral proteins, move from cell to cell, and replicate defective deleted forms of the genomic RNA that themselves do not encode the 126K or 183K proteins (205). The 126K protein seems to increase the efficiency of replication approximately 10-fold, apparently acting in cis. Whereas expression of the 126K protein from a defective RNA does not increase replication of the helper virus expressing the 183K protein, the 126K-expressing defective RNA itself is efficiently replicated in the presence of this helper virus. This 126K-expressing defective RNA, however, is not efficiently replicated by wild-type TMV that expresses both the 126K and 183K proteins. This suggests that efficient TMV replication requires the 183K protein to form a heterodimer with the 126K protein that itself is already bound to the template RNA (205).

Following initial translation of the 126K and 183K proteins, these act to replicate full-length complementary negative-strand RNA. This then serves as the template for the synthesis of additional copies of the full-length genomic RNA or, if the RdRp (183K + 126K) recognizes internal subgenomic promoters, three subgenomic RNAs, each of which is functionally monocistronic (204,313) (see Fig. 11). Unlike the potexviruses, there are not any conserved sequences that aid in identifying the viral subgenomic promoters. The smallest sgRNA is the most abundant and is translated into the viral CP. The middle-sized sgRNA, which accumulates to much lower levels than the CP sgRNA, is translated into the viral MP. Mutational studies, and complementation studies using mutant viruses and transgenic plants that express the MP, show that MP is the only viral protein essential for cell-to-cell movement (71,225). The CP, although not required for cell-to-cell movement, is required for systemic infection of the plant through the phloem (64). As is the case for the potexviruses, the sgRNAs serve to regulate expression of the MP and CP both temporally and quantitatively. Whereas CP is produced late during infection and in extremely large amounts, MP is produced early, accumulates to low levels, and decreases at late times following infection (16,65). In addition to differences in the accumulated levels of the two sgRNAs, the sgRNA for the MP is not capped and has a long 5'-UTR. In contrast, the sgRNA for the CP is capped and has a short AU-rich 5'-UTR, which together appear to make it an efficient mRNA (204). The longest sgRNA found in TMV-infected cells accumulates to low levels and is predicted to encode a 54-kd protein with the same sequence as the readthrough domain of the 183K protein. Although such a protein is translated from this sgRNA *in vitro* , this 54-kd protein has never been detected in infected plants or in protoplasts (37,329). The predicted protein is also not detected in transgenic plants that are engineered to express this sgRNA, despite the fact that these plants are resistant to TMV infection (121). The studies that have been done suggest that this sgRNA for the 54-kd protein is translated: it is associated with polyribosomes in infected cells, and analysis of mutant forms in infected protoplasts indicates that its translation, not simply the presence of the sgRNA, is required to inhibit virus replication (37,329). Thus, although it stands as the first example of replicase-mediated resistance as an approach to engineer virus-resistant plants, the 54-kd protein remains enigmatic. Comparing TMV to another alphavirus, namely Sindbis (see Chapter 30), in which the replicase subunits are generated by a combination of readthrough and proteolytic processing by the viral-encoded proteinase nsp2, and considering that the predicted 54-kd protein would be the equivalent of nsp4 in Sindbis, it is tempting to speculate that the 54-kd protein is highly labile and may play a regulatory role in suppressing the synthesis of full-length negative-strand RNA during TMV infection while allowing the synthesis of all forms of positive-sense RNA (sgRNA and genomic RNA) to continue, analogous to what occurs during Sindbis replication. Just like Sindbis, TMV negative-strand RNA replication ceases early in infection, as the replication of genomic RNA and sgRNAs continues, so that late in TMV infection there is an asymmetric production of the viral positive-strand RNAs. Studies of TMV replication using recently described *in vitro* template-dependent membrane-associated RNA polymerase preparations from infected tomato plants (256) should help to solve this mystery of the 54K protein and better define the functions of the 183K protein alone, or as a heterodimer with the 126K protein, in regulating the synthesis of the different form of viral RNA.

Like other cytoplasmic positive-sense RNA viruses, TMV replication occurs in association with cytoplasmic membranes. This was first suggested by ultrastructural studies of so-called X bodies or viroplasms as sites of virus replication and protein synthesis (99), which were described as being composed of ER, ribosomes, virus rods, and bundles of tubules. Purified preparations capable of directing TMV replication in a template-dependent manner have now been shown to be membrane-bound complexes (256). The effects of TMV infection on the organization of the ER have been examined by infecting transgenic tobacco plants that expressed an ER targeted GFP fused to the retention signal HDEL so that GFP accumulated in the ER and ER structure could be examined by confocal microscopy (284). Early in infection, the ER tubular network is converted into large cytoplasmic aggregates. Remarkably, late in infection these aggregates disappear and the normal ER network is reformed (284). That these ER-derived membranes are sites of virus replication has been shown by indirect immune fluorescence staining with antibodies against the TMV RdRp and *in situ* hybridization for viral RNA. These approaches show that the replicase and viral RNA are found associated with ER membrane and the ER-derived aggregates (219,284). Based on localization of a TMV GFP:MP fusion protein in infected plant cells and infected protoplasts, it appears that the MP plays a central role in establishing these ER-associated replication sites and in the transient reorganization of the ER membrane network (see Virus Movement) (134,284). Two different approaches have also implicated host proteins in TMV replication. The analysis of TMV recombinant viruses and mutants that could induce or overcome the so-called gene-for-gene resistance response (see Plant Responses to Virus Infection) in tobacco plants that contain the dominant *N* gene have identified the helicase domain in the 126K/183K RdRp as being responsible for induction of the hypersensitive response that characterizes this type of host defense response (98,259). This suggests that the TMV RdRp interacts with the *N* gene product or other host factor in the *N* gene–mediated signal transduction pathway. The analysis of proteins that copurify with TMV RdRp activity from infected tomato plants has implicated a protein related to yeast GCD10, the RNA-binding subunit of yeast eIF-3, in virus replication. An antibody-linked polymerase assay was used to show that active TMV RdRp complexes bind to antibodies against the yeast GCD10 protein. Furthermore, these anti-GCD10 antibodies inhibited *in vitro* synthesis of viral ssRNA and dsRNA by the purified RdRp, and this could be reversed by prior addition of GCD10 itself (257).

Cis-acting sequences in the 5'-UTR and 3'-UTR of the TMV genome have been implicated in efficient viral translation and replication. The study of virus mutants and recombinant viruses has shown that within the 205 nt 3'-UTR, the $tRNA_{his}$ structure and the 3'-most pseudoknot just upstream of this structure are both involved in negative-strand RNA replication (63,337). Sequence elements in both the 68 nt 5'-UTR and the 3'-UTR, together with the 5' cap, are required for efficient translation of the viral genome. In this regard, the 3'-UTR appears to substitute for the lack of a poly(A) tail in synergistically interacting with the cap to facilitate translation. The 5'-UTR (also called the *leader sequence*) appears to

lack any stable secondary structure and acts as an efficient translational enhancer *in vitro* and *in vivo* when fused to a reporter gene (87,114). The 5'-UTR of many TMV strains contains two conserved regions—three copies of an 8 nt direct repeat element and a (CAA)n repeat region—and mutational studies suggest that these are functionally redundant in their effects on translation. By fusing different combinations of these two elements as a leader to a GUS reporter gene and expressing these mRNA constructs in carrot protoplasts, it has been shown that the core regulatory element consists of one copy of the 8 nt direct repeat and a 25 nt (CAA)n region, with the (CAA)n region being the more critical one. Furthermore, by combining such constructs with sequences from the TMV 3'-UTR, a 72 nt region that contains the three pseudoknots located just upstream of the $tRNA_{his}$ was also shown to be required for efficient translation (115,198). This synergism in translation involves interactions with both the 5' cap and the translational enhancer region within the 5'-UTR, with sequences within as well as the structure of the pseudoknots being important (198). These studies suggest that the 5' and 3' ends of the viral genome interact with each other to regulate translation, and perhaps replication. Consistent with this, a 102-kd protein that binds to both the (CAA)n region and the 72 nt 3'-UTR pseudoknot region has been identified in wheat germ extracts (339). The precise nature of these interactions, and whether the 3'-terminal $tRNA_{his}$ may also interact with sequences in or complexes formed at the 5' end of the genome to potentially regulate replication and translation, has not been determined. Further biochemical studies are needed to address these questions.

With the report in 1955 that TMV virus particles could be assembled *in vitro* from the component viral RNA and CP (105), this assembly process has been extensively studied *in vitro*. The *in vivo* studies that have been done (378) are compatible with the model that has been developed based on *in vitro* analyses (36,199). Encapsidation initiates at a sequence-specific stem-loop structure within an origin of assembly that is located within the *MP* ORF for most tobamoviruses (Fig. 12). Fusion of this assembly origin to nonviral RNAs will direct their assembly into virus-like particles. Loop 1 of the assembly origin interacts with and is threaded through the center of a two-layered disk composed of CP, with both the 3'-to-5'ends of the viral RNA trailing from one side of the disk. The association of the RNA with a central groove between the two layers of the disk causes a conformational change in the disk to a so-called lockwasher configuration (see Fig. 12). Elongation rapidly proceeds in the 3'-to-5' direction as additional disks are added and lengths of the genome bearing the 5' end are looped through the central cavity of the new disk and inserted into the central groove, inducing a change to the lockwasher configuration with each new addition as the helix is assembled. Encapsidation of the exposed 3' end of the genome appears to occur more slowly by the addition of smaller aggregates (the so-called A form) of CP subunits, although there is some disagreement as to how this occurs. A consequence of the assembly origin being located within the *MP* ORF (or the *CP* ORF for two tobamoviruses) is that the corresponding sgRNA is also encapsidated, the amount found in virus preparations being determined by the relative level of expression of the sgRNA.

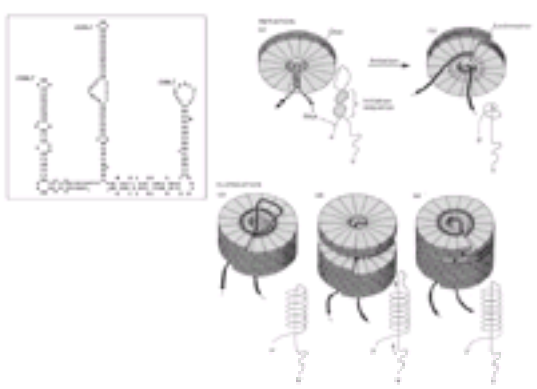

FIG. 12. Assembly of tobacco mosaic virus (TMV). **Inset:** Origin of assembly of TMV. (From Darnell JE, Lodish H, and Baltimore D. *Molecular cell biology,* 1st ed. New York: Scientific American, 1986, with permission; **inset** adapted from ref. 220, with permission.)

Turnip Yellow Mosaic Virus (TYMV): Subgenomic RNA, Polyprotein, and Independent Initiation

There are ~20 viruses in the genus *Tymovirus,* of which *t*urnip *y*ellow *mo*saic virus (TYMV) is the type member and best characterized on the molecular level. Tymoviruses are naturally found in uncultivated dicotyledonous plants and are transmitted by beetles. Each virus has a narrow host range, and none has been reported to cause economically important diseases of crop plants (117). TYMV has been important historically as one of the earliest examples of the infectious nature of viral RNA and as a model for investigating the structure of isometric virus particles (215,313). TYMV virions are T=3 icosahedral particles that are 29 nm in diameter and composed of 180 copies of a single protein, the 20-kd CP. Each CP subunit is folded into an eight-stranded antiparallel (jellyroll) b-barrel, and these are arranged in pentameric clusters at the vertices of the virus particles. The genome is an unsegmented positive-sense ssRNA of ~6.3 kb with a 5'-terminal cap (m^7GpppGp) and a 3' terminus that can form a tRNA-like structure (Fig. 13). TYMV was the first virus for which it was shown that this type of tRNA-like 3'-terminal end could accept an amino acid, in this case valine (263), and it has recently served as a model for unraveling the role of such structures in directing the viral RdRp to recognize the viral 3' end and initiate RNA negative-strand synthesis.

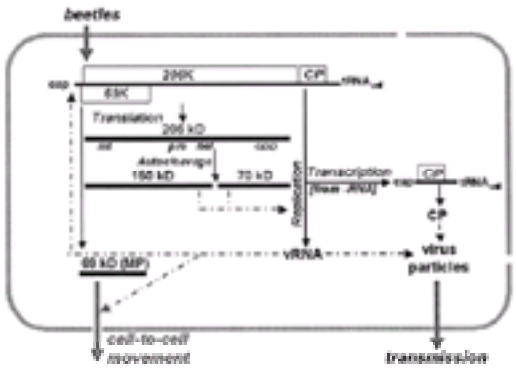

FIG. 13. Multiplication of turnip yellow mosaic virus (TYMV).

The TYMV genome contains three ORFs, which encode (5' to 3') the MP (*69K*), the RdRp (*206K*), and the viral CP (*20K*) (88) (see Fig. 13). It is a very compact coding arrangement. The 5'-UTR is 87 nt, with the *69K* ORF initiating at nucleotide 88. This ORF extensively overlaps the *206K* ORF, which initiates only 7 nt downstream in a different reading frame at nucleotide 95. There is only a short intergenic region (~15 nt, depending on the isolate) between the end of the *206K* ORF and the start of the CP (*20K*) ORF, which is followed by a 107 nt 3'-UTR. The 206-kd protein contains (starting from its N terminus) a methyltransferase motif, a helicase nucleotide binding site motif (GXGKT), a papain-like protease domain, and the GDD motif characteristic of a viral RdRp. Sequence similarities and the arrangement of the methyltransferase, helicase, and GDD motifs place TYMV in the alphavirus family. It has been suggested that upon entering a cell, deprotonation of histidine residues in the CP may aid in virion disassembly (117).

The TYMV multiplication cycle has been deduced based on *in vitro* translation of both virion RNA and infectious transcripts of cloned full-length genomic cDNA, as well as identification of viral RNA in infected plants. Consistent with the virion genomic RNA being infectious, the genome is first translated into the 69-kd and the 206-kd proteins. The 206-kd protein autocatalytically processes itself into a 150-kd protein (containing the methyltransferase, papain-like protease, and helicase domains) and a 70-kd protein (containing the GDD motif) (see Fig. 13). The 150-kd and 70-kd proteins together apparently constitute the RdRp, which uses the genomic positive-strand RNA as the template to replicate full-length complementary negative-strand RNA. This then functions as the template for the replication of viral positive-strand RNAs, both full-length genomic RNA or, if the internal subgenomic promoter is recognized, an sgRNA that is translated into CP. The CP sgRNA is encapsidated into virus particles; hence, its translation into CP was demonstrated *in vitro* using virion RNA in cell-free protein synthesizing lysates from rabbit reticulocytes or wheat germ. The CP sgRNA has also been detected associated with polyribosomes in infected plants (220). Viral RNA replication takes place in the cytoplasm, associated with membranes. However, unlike TEV, PVX, or TMV replication, these membranes appear to be derived from the chloroplast outer membrane. TYMV infection causes clumping of chloroplasts and invagination of the chloroplast outer membrane. Both viral RNA and RdRp localize to these chloroplast-associated peripheral vesicles in infected cells (220).

Most of the details of TYMV multiplication have been deduced using infectious transcripts of the cloned TYMV genomic cDNA, into which mutations could be introduced and studied for their effects on *in vitro* translation, replication in Chinese cabbage or turnip protoplasts, and infectivity in these same hosts. The full-length TYMV genomic RNA is translated *in vitro* into the 69-kd protein, which migrates at 75 kd apparently because it is highly basic (pI = 12.1), and the 206-kd protein, which is incompletely processed *in vitro* to the 150-kd and 70-kd proteins. In contrast to what one would expect for leaky ribosome scanning, mutations of the initiation codon for the 69-kd protein (nucleotides 88 to 90) have no effect on expression of the 206-kd protein, but mutations of the initiation codon for the latter (nucleotides 95 to 97) significantly increase expression of the 69-kd protein (88). It has been suggested that similar to influenza virus B segment 6, in which the initiation codons for the overlapping *NB* and *NA* ORFs are only 4 nt apart (see Chapter 46), translation of the 69-kd and the 206-kd proteins is initiated by random ribosome movement in which the 40S subunit moves both 5'®3' and 3'®5' until the AUG initiation codon is encountered. The identification of the *69K* ORF as encoding the viral MP is based on mutations that eliminated the initiation codon at nucleotide 88 or caused premature termination of its translation: such mutants replicate normally in protoplasts but fail to form local lesions on inoculated leaves or systemically infect plants, thus suggesting that they are defective in cell-to-cell movement. Consistent with its proposed role as an MP, antisera specific for the 69-kd protein has detected the protein associated with an insoluble cell wall fraction from TYMV systemically infected leaves, and it appears to be maximally expressed in young, expanding systemically infected leaves (29). The CP is not needed for local cell-to-cell movement. A TYMV mutant in which two-thirds of the *CP* ORF is deleted can replicate normally in protoplasts and produce chlorotic local lesions on inoculated leaves (88). However, this mutant does not systemically infect the host, showing that in addition to beetle transmisson, the CP is needed for systemic infection via the phloem.

Using antisera specific for the N- and C-terminal regions of the 206-kd protein, it was shown *in vitro* that the 206-kd protein is processed into a 150-kd protein (recognized by the N-terminal–specific antisera) and an apparently unstable 70-kd protein (recognized by the C-terminal–specific antisera) (88). This resembles the processing of Sindbis virus RdRp by autocatalytic proteolysis to nsp123 and nsp4, with the TYMV 70-kd protein corresponding to Sindbis nsp4 (see Chapter 30). Whether there is additional processing *in vivo* of the 150-kd protein, analogous to the processing of nsp123 during Sindbis infection, is not clear as there is disagreement about a viral 115-kd protein being a subunit of the RdRp. Further studies are needed to determine whether the 150-kd protein is further processed and what role, if any, processing of the 206-kd protein and its products plays in regulating the levels of newly synthesized viral positive- and negative-sense RNA. Mutational studies have mapped the protease domain (amino acids 670 to 885) and the cleavage site within the 206-kd protein. Consistent with its proposed function as a papain-like proteinase, mutation of Cys^{783} and His^{869} within the protease domain of the 206-kd protein prevent its autocatalytic cleavage to the 150-kd and 70-kd proteins (88). Furthermore, TYMV missense mutants in which the initiation codon for the *206K* ORF is eliminated, or the helicase or GDD motifs are mutated, are noninfectious and do not replicate in protoplasts. This is consistent with both

proteins being required for replication, with the 150-kd protein having helicase activity and the 70-kd protein being an RdRp. Complementation studies using the TYMV helicase and GDD mutants together, or each mutant complemented with a helper TYMV in which the CP was deleted, further suggest that the 150-kd and 70-kd proteins may function as a heterodimeric complex and act in a *cis*-preferential manner (371). The complementing helicase and GDD mutants can support the replication of each other in *trans*, but they do so poorly. When each mutant is complemented with the helper virus, they replicate to 20% or less of the level of the helper RNA. However, if a TYMV deletion mutant that cannot make the 70-kd protein is substituted for the GDD missense mutant that produces a defective 70-kd protein, the deletion mutant does accumulate to high levels, comparable to the helper virus. This deletion mutant could also complement the defective helicase missense (150-kd) mutant; however, again the 70-kd protein deletion mutant replicated to approximately 10-fold higher levels than did the helicase mutant. This suggests that the 70-kd protein can act in *trans* but that the 150-kd protein acts in a *cis*-preferential manner, leading to a model similar to that proposed for the TMV 183-kd and 126-kd proteins: the 150-kd protein binds to the negative strand promoter in *cis*, and the 70-kd protein, also showing some *cis* preference, forms a stable heterodimeric complex with the 150-kd protein, thus favoring replication of the RNA encoding the active complex.

It appears that TYMV virion RNA is rapidly packaged following replication so that it is not accessible to the host cell CCA-tRNA nucleotidyltransferase. Thus, the tRNA-like structure at the 3' end of the virion RNA terminates in 5'-CC-3' but is efficiently adenylated to 5'-CCA-3' *in vitro* by CCA-tRNA nucleotidyltransferase. In this form, it is an active *in vitro* substrate for aminoacylation with valine by valyl-tRNA synthetase from yeast or wheat germ (88). Valylated TYMV RNA has also been detected in infected plant cells. Although this tRNA-like structure has only limited sequence similarity to higher plant $tRNA^{val}$, it does have a valine -CAC- anticodon and an -ACAC- present in the anticodon loop of all eukaryotic $tRNA^{va}$, and it structurally resembles tRNAs on the secondary and tertiary levels. As discussed for TMV, the TYMV tRNA-like structure is distinct from cellular tRNAs in having a pseudoknot, which is involved in building the amino acid acceptor stem. The role of the TYMV $tRNA_{val}$-like structure in virus replication has been extensively investigated, using either the viral genomic RNA or an *in vitro* transcript comprising a 3'-terminal fragment of the genomic RNA. *In vitro*, the valylated TYMV tRNA-like structure tightly binds elongation factor eEF1a from wheat germ or EF-Tu from *E. coli.* Initial mutational studies showed a direct correlation between valylation and TYMV RNA replication in protoplasts or viral infectivity in plants. In addition, mutation of the TYMV aminoacylation specificity from valine to methionine, a novel specificity for viral tRNA-like structures, produced infectious virus, and there was now a direct correlation between the ability of mutated forms of this altered TYMV genome to accept methionine and replicate (88,90). Thus, the valine specificity does not appear to be crucial here, and the results suggested that aminoacylation might be required for efficient replication of TYMV RNA.

However, tymovirus genomic RNAs exhibit a wide range of tRNA mimicry, from highly developed, as in the case of TYMV, to minimal, and it was possible to construct infectious variants of TYMV that were not aminoacylated (89,122). The starting point for these variants was a chimeric TYMV genomic RNA in which the 3'-$tRNA_{val}$–like structure had been replaced with 3'-sequences from TMV. Although it could accept histidine *in vitro*, this chimeric TYMV-TMV genome was not infectious, but it did replicate to ~3% the level of wild-type TYMV in protoplasts. Adding back TYMV sequences from the anticodon loop and amino acid acceptor stem to the 3' region of this chimeric genome increased its replication a few fold. Two of these chimeric genomes could be serially passaged in plants, eventually giving rise to two highly infectious TYMV-TMV variant viruses which had accumulated some minor additional changes in their 3'-end sequences. Unexpectedly, these two infectious TYMV-TMV variants, both of which now contained the valine-specific anticodon loop, could be adenylated to produce -CCA- 3' ends *in vitro*, but they could not be aminoacylated. Thus, aminoacylation is not obligatory for virus replication. This suggests that a number of structural features of the viral 3' end can contribute to genome amplification and infectivity, and that these have the ability to compensate for lack of aminoacylation (122). Of course, some of the TYMV 3'-terminal sequences added back to these chimeras could have included critical promoter elements needed for negative strand synthesis that would be recognized by replicator complexes and overlap the determinants for valylation. However, the ability of the TYMV RdRp to efficiently transcribe a range of unmodified tRNAs and tRNA-like structures, some quite short, in addition to the heterogeneity in the 3'-terminal sequences of the TYMV-TMV chimeras themselves, brought into question the very existence of such specific promoter elements, either in terms of sequence or structure, to direct negative strand synthesis. Using a TYMV RdRp preparation from infected plants to transcribe different RNA templates *in vitro*, it was determined that a 27 nt fragment encompassing the 3' terminus and pseudoknotted acceptor stem, or a 21 nt fragment encompassing this 3' end and adjacent hairpin, were efficiently transcribed, each correctly initiating at the penultimate C in the unpaired terminal 5'-CCA-3' sequence (68,318). By testing additional truncated, mutated, and duplicated templates, as well as unstructured C-rich templates or a 12 nt (CCA)n template, the minimal template requirement for initiation of negative-sense RNA synthesis by the TYMV RdRp has been defined. The surprising answer is that the TYMV RdRp can recognize any sterically accessible 5'-CC(A/G)-3' triplet; indeed, it will accurately initiate at multiple internal sites on unstructured C-rich or (CCA)n templates. However, the introduction of nonspecific secondary structure into such templates can confer specificity in terms of the 5'-CC(A/G)-3' triplets at which the RdRp will initiate transcription (68,318). Thus, there are no specific promoter elements within the acceptor stem and upstream regions of the TYMV tRNA-like structure: the specific target for initiation by the TYMV RdRp appears to be 5'-CC(A/G)-3'. The function of the tRNA-like structure would appear to be to prevent internal initiation of negative-strand RNA synthesis and place the 3'-terminal correct initiation site (-ACCA-) in a very accessible location. In addition, tRNA mimicry becomes important here for viral negative-strand RNA synthesis. The TYMV genome terminates in 5'-CC-3'. However, the 3'-terminal A is essential for initiation of negative-strand RNA synthesis, and this is added by the host CCA-tRNA nucleotidyltransferase, which recognizes the viral 3' tRNA-like structure and adenylates it. Thus, tRNA mimicry creates the proper 5'-CCA-3' terminus for the viral RdRp to initiate negative strand synthesis. Recent studies show that the RdRp of turnip crinkle virus (a carmovirus in the family *Tombusviridae*) and phage Qb replicase can also, to varying degrees, initiate transcription *in vitro* at CCA sequences without unique promoter elements. Thus, initiation at CCA sites with specificity being conferred by preference for 3'initiation sites and RNA structure may be common among the RdRps encoded by positive-sense RNA viruses (384).

Luteoviruses: Subgenomic RNA, Frameshift, Leaky Ribosome Scanning, Termination Suppression, and Polyprotein

The viruses that were formerly grouped as luteoviruses (“luteo” is Latin for “yellow”, referring to a characteristic symptom

produced by these viruses) have recently been reclassified within two genera in the new family of *Luteoviridae:* *Luteovirus* (formerly subgroup I) and *Polerovirus* (formerly subgroup II) (347). *Enamovirus* is a third genus in this family and consists solely of pea enation mosaic virus type 1 (PEMV1). PEMV1 exists in an interdependent relationship with a second virus, PEMV2. The genome organization of PEMV1 resembles that of the poleroviruses; however, PEMV2 is classified as an umbravirus. Only the luteoviruses and poleroviruses will be discussed here. Viruses within these two genera are grouped as *Luteoviridae* because of their biological properties, and they are clearly similar in the genes encoded in the 3' halves of the viral genomes. However, the genetic organization of the 5' halves of the luteovirus and polerovirus genomes is quite distinct. The luteovirus-encoded RdRp is similar to the RdRp encoded by tombusviruses and umbraviruses, among others; but the polerovirus-encoded RdRp resembles that of the sobemoviruses. The divergent nature of the 5' halves of the luteovirus and polerovirus genomes has led to the suggestion that these two genera were generated by horizontal gene transfer (229).

Of the ~20 viruses in these two genera, barley yellow dwarf virus (BYDV) (luteovirus, although some isolates may be poleroviruses), and the poleroviruses potato leaf roll virus (PLRV), beet western yellows virus (BWYV), and cereal yellow dwarf virus (CYDV) occur worldwide and cause significant losses in crops of economic importance. Although PLRV infects only potatoes, it can cause devastating disease and high losses. BYDV and CYDV affect a wide range of grains, including barley, oats, wheat, and rye, causing significant losses in these crops annually. The viruses are transmitted in nature by aphids. With the exception of BWYV, most luteoviruses and poleroviruses have very narrow host ranges. This, combined with their phloem restriction, have made them difficult to study. Although complete cDNA clones have been generated for a few of the viral genomes (202,275,385), the phloem limitation of virus infection means that, in contrast to viruses that infect mesophyll cells, neither the cDNAs nor the virions can be mechanically transmitted to plants for experimental studies. Agroinfection has been successfully used to infect plants with the cDNA clone for BWYV (202), but this approach does not efficiently work for many monocotyledonous plants, such as those infected by BYDV. PLRV gene functions have been, in part, studied by expressing the viral genome or individual ORFs in transgenic plants (275). The virions are T=3 icosahedral particles that are 24 to 30 nm in diameter and composed of 180 copies of the 22-kd CP, some fraction of which has a C-terminal extension of ~50 kd (CP-AT) (229). BYDV-PAV (luteoviruses), and PLRV and BWYV (poleroviruses), are the best characterized *Luteoviridae* at the molecular level. Each virus has a genome of unsegmented positive-sense ssRNA of ~6 kb. The PLRV genomic RNA has a genome-linked viral-encoded protein (VPg) of 7 kd covalently attached to its 5' terminus. In contrast, the BYDV-PAV genome does not have this or any other known modification at its 5' terminus (12). The luteovirus and polerovirus genomes do not contain either a poly(A) tail or a tRNA-like structure at their 3' end. A combination of approaches has been used to investigate the multiplication of these viruses. These include transfection of protoplasts with virion genomic RNA and transcripts of cloned cDNA, expression of cloned ORFs in *E. coli* (which also provides viral proteins for generating specific antisera), hybridization studies with sequence-specific probes and immunoblot studies with specific antisera to detect viral RNAs and proteins in infected plants and protoplasts, and *in vitro* translation of genomic and sgRNAs. Given that infected protoplasts can produce virions, aphids can be fed on protoplast extracts through a membrane to acquire virions with mutated genomes and transmit these to plants. This has allowed for mutational and complementation studies to study the functions of some of the viral proteins in aphid transmission and in systemic infection of plant hosts.

BYDV-PAV genomic RNA encodes six ORFs, numbered 1 through 6 (5' to 3') (Fig. 14). ORF 2 (*60K*) is predicted to encode a protein containing the GDD motif characteristic of a viral RdRp. It is translated from the genomic RNA both *in vivo* and *in vitro* only as a C-terminal fusion to the protein (39 kd) encoded by ORF 1 by a ¯1 ribosomal frameshift (72,233). These are the only proteins translated directly from the genome. Consistent with the presence of the GDD motif within the C-terminus of this fused protein, deletion studies show that both ORFs 1 and 2 are essential for viral replication in plant protoplasts (233). Because the ribosomal frameshift appears to occur £8% of the time in BYDV-PAV, the majority of the time, ORF 1 is translated into a 39-kd protein, the function of which alone is unknown. Although the 39-kd protein has been proposed to be a helicase, it does not appear to have homology to any known helicases (233). By analogy to other positive-sense viruses, it is assumed that following translation of the genomic RNA, the RdRp (99 kd), perhaps together with the 39-kd protein, uses the genomic positive-strand RNA as a template to synthesize full-length complementary negative-strand RNA, which then serves as template for the replication of additional genomic positive-sense RNA and three 3' coterminal sgRNAs (see Fig. 14), all of which have been detected in infected plants (169). The largest of these (sgRNA1) functions as a tricistronic mRNA. It is translated into the CP (22 kd), a small amount of CP with a C-terminal 50-kd extension (CP-AT) generated by occasional ribosomal readthrough of the CP stop codon (50,102), and a 17-kd protein which appears to be the MP. ORF 4, which encodes the 17-kd protein, is completely contained within ORF 3 encoding the CP. The initiation codon of ORF 4 is in a better context than that of ORF 3, and mutational studies show that ORF 4 is translated into the 17-kd protein from sgRNA1 by leaky ribosome scanning (76). Mutational studies also show that the 17-kd protein is not required for viral replication or encapsidation in protoplasts, but is required for systemic infection of plants, thus suggesting that it may be a viral MP (48). The protein encoded by ORF 5 is translated only as a C-terminal extension fused to the CP by readthrough of the CP stop codon; thus, it is called *RTD,* for *readthrough domain.* Mutational and complementation studies show that it is required for aphid transmission (48), and it is referred to here as *AT* for the sake of clarity. Subgenomic RNA2 contains only ORF 6, which potentially encodes a small protein that is highly variable in length (4.3 to 7.1 kd) and sequence among different BYDV-PAV–like isolates. The protein encoded by ORF 6 has only been detected *in vitro* (169). Subgenomic RNA3 does not contain any ORFs. Nevertheless, both sgRNA2 and sgRNA3 accumulate to high levels in infected plant cells. It has been suggested that sgRNA2 and sgRNA3 may be regulatory RNAs (229,230).

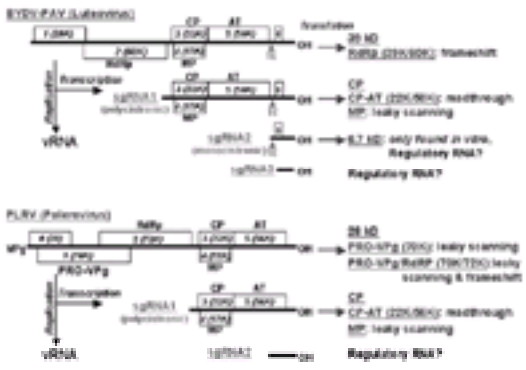

FIG. 14. Replication and transcription of barley yellow dwarf virus (BYDV-PAV strain) and potato leaf roll virus (PLRV). *TE* indicates the location of the translational enhancer.

Although *Luteoviridae* do not replicate in their aphid vectors, they do follow a circulative pathway that requires virions to be transported across three barriers following acquisition: the hindgut epithelium, across which virions enter the hemocoel, and the basal lamina and plasma membrane of the accessory salivary glands, to which they are actively transported from the hemolymph. Virions are then introduced into the phloem of a plant through the salivary duct as the aphids feed. Electron microscopic studies suggest that virion transport across the hindgut epithelium and accessory salivary gland plasma membrane may occur by receptor-mediated endocytosis (229). Mutational studies with BYDV-PAV suggest that the AT extension in the CP-AT subunits is required for transport of virions from the hemolymph into the salivary glands (48). This transport is an interesting example of the virus taking advantage of a symbiotic relationship. The aphid hemocoel contains a high level of proteins called *symbionins* that are produced by intracellular endosymbiotic bacteria (*Buchnera* species) and are homologs of the *E. coli* chaperonin groEL. Symbionins have been shown to bind the AT readthrough domain in BYDV-PAV, PLRV, and BWYV *in vitro*, and aphid transmission studies with viral mutants suggest that binding of symbionins to the virus particle may protect it from degradation in the aphid (101,143,345). The few CP-AT subunits incorporated into virions are found as a ~58-kd cleavage product that contains CP fused to the N-terminal half of AT, although full-length 72-kd CP-AT can be found in infected plant cells (48,50,233,365). Analysis of these BYDV virions and mutational studies of BWYV AT (33) show that the N-terminal half of AT, fused to CP, is required for aphid transmission. However, synthesis of the full-length 72-kd CP-AT fusion does appear to affect virus accumulation in infected plants (33,48,388).

PLRV also encodes 6 ORFs. The 5' half of the genome that encodes ORFs 0, 1, and 2 is organized quite differently than the corresponding region of BYDV-PAV (see Fig. 14). A viral-encoded VPg is covalently bound to the 5' end of the genome RNA. ORF 0 (*28K*) and ORF 1 (*70K*) may be translated by leaky ribosome scanning, but this has not been shown experimentally. The function of the ORF 0 encoded product is unknown. Mutational studies with BWYV suggest that ORF 0 is not needed, either for systemic infection or aphid transmission (388). Only ORF 1 and ORF 2 are essential for virus replication in protoplasts. The 70-kd protein encoded by ORF 1 has the catalytic triad characteristic of chymotrypsin-like proteases (PRO) in its N-terminal region and a helicase domain, between which is the VPg sequence. Consistent with VPg (7 kd) being produced by proteolytic processing, it has been identified in PLRV-infected plants at the N-terminus of a 25-kd apparent precursor protein that can bind RNA (274,276). ORF 3 (*72K*) encodes the putative RdRp since it is predicted to contain the GDD motif. It is only translated as a C-terminal fusion with PRO-VPg by infrequent ¯1 ribosomal frameshifting, reminiscent of the situation for ORF 1 and 2 in BYDV-PAV (187). Thus, in contrast to viruses like TEV and poliovirus, it would appear that PLRV VPg is produced in great excess over the RdRp.

In contrast to this divergence in the 5' end of the genome, ORF 3 (*22K*), ORF 4 (*17K*), and ORF 5 (*56K*) correspond to the same ORFs in BYDV-PAV and are also expressed from a subgenomic RNA (sgRNA1) to encode CP, a proposed MP, and AT, respectively (see Fig. 14), with AT only translated as the fused CP-AT as the result of occasional readthrough of the CP stop codon (143,223,228,334,336). There is also a second subgenomic RNA (sgRNA2), which in this case is not predicted to encode any ORFs. The PLRV 17K protein (ORF 4) is proposed to be an MP based on its having properties similar to those of other well-characterized MPs such as the TMV 30-kd protein. In particular, the PLRV 17-kd protein can nonspecifically bind single-stranded nucleic acid *in vitro*, is phosphorylated, and has been reported to localize to plasmodesmata in infected plants or when expressed in transgenic plants (309,335,336). This corresponds to the suggestion that BYDV-PAV ORF 4 encodes an MP. However, mutational studies of BWYV using agroinfection to introduce the mutated cDNAs into tobacco led to a very different conclusion: that ORF 4 was dispensable for virus systemic infection and aphid transmission, but that the C-terminal half of AT was required for systemic infection and a potential MP (33,388). Thus, the picture is confusing in terms of movement. Given the technical limitations involved in investigating luteovirus infection in plants, studies of BYDV-PAV, PLRV, and BWYV have not directly studied virus movement, nor do they distinguish between local cell-to-cell movement and systemic infection. In addition, the potential functions of the CP in local or long-distance systemic movement have not been addressed, although for BWYV it was concluded that the CP is needed for systemic infection (388). A better understanding of the phloem cell types between which these viruses move and the functions of CP in local and long-distance movement, coupled with direct investigation of luteovirus and polerovirus movement, should clarify this situation.

Luteoviruses and poleroviruses are notable for the sheer number of strategies they employ to regulate and maximize their gene expression: (a) sgRNAs, some of which appear to be regulatory molecules rather than mRNAs; (b) leaky scanning to produce CP and MP (ORF 4), and likely translate ORFs 0 and 1; (c) polyprotein synthesis and autocatalytic processing (poleroviruses) of PRO-VPg, and likely PRO-VPg-RdRp, to produce VPg, probably in different functional forms analogous to TEV and poliovirus; (d) ¯1 ribosomal frameshifting to produce RdRp; and (e) readthrough to produce CP-AT, the capsid subunit essential for aphid transmission. Beyond the number of strategies, there are some novel luteovirus twists here that have been reported in studies of BYDV-PAV. Frameshifting to produce RdRp occurs at a shifty heptanucleotide sequence (5'-GGGUUUU-3' in BYDV-PAV, 5'-GGGAAAC-3' in PLRV) and involves a downstream pseudoknot or hairpin structure (230), as reported for other viruses. However, a higher rate of frameshift was found when

the intact BYDV genome was translated *in vitro* in wheat germ extracts than when a reporter gene, in which the BYDV frameshift site was inserted so that the coding sequence was mostly in the −1 frame, was used (72). Mutational studies identified sequences 4 kb downstream in the 3'-UTR of the BYDV-PAV genome that appear to be required for efficient frameshifting (367). Readthrough to produce CP-AT in BYDV-PAV requires at least five copies of a series of tandem repeats of the sequence 5'-CCN NNN-3', beginning 12 to 21 nt downstream of the CP stop codon, with no apparent secondary structure in this region. Deletion studies further identify an additional element ~700 nt downstream within ORF 5 that is also needed for readthrough (32). Even given all of this, perhaps one of the most puzzling aspects of BYDV translation is its cap-independent nature, and the solution here may be the most novel of all.

A 109 nt sequence element located in the 3'-UTR of BYDV-PAV between ORFs 5 and 6 has been identified as a translational enhancer, and thus named 3'TE (see Fig. 14). It appears to mimic a 5' cap in interacting with eIF4F, either directly or indirectly, to facilitate efficient translation of uncapped mRNAs (366). This conclusion is based on *in vitro* and *in vivo* studies using a GUS reporter gene that contained different 5'-UTR sequences (BYDV, TMV, or plasmid) that were or were not capped, in combination with different 3'-UTR sequences [BYDV or plasmid with poly(A) tail]. Without a 5' cap, the GUS reporter gene is very inefficiently translated *in vitro*, whether or not a poly(A) tail is present. However, if the GUS reporter is flanked by the 5'-UTR from BYDV upstream and the 3'TE inserted in its 3'-UTR, it is efficiently translated *in vitro* without a cap, with the level of translation being comparable to that of GUS with a 5'-cap but lacking the 3'TE. The relative enhancing effect of the 3'TE is the same *in vitro* and *in vivo* in oat protoplasts, although additional BYDV 3'-UTR sequences are needed *in vivo* to substitute for a poly(A) tail, whether the 3'TE or a 5' cap is present. The 3'TE within the 3'-UTR enhances translation of uncapped mRNA when the BYDV 5'-UTR is present upstream of the GUS reporter, but has the same effect without the BYDV 5'-UTR sequences if the 3'TE itself is placed in the 5'-UTR region upstream of the GUS coding sequence. Thus, the 3'TE can functionally substitute for a 5' cap in this position and, in either position, it was found to decrease the amount of eIF4F needed for maximum translation *in vitro*. Furthermore, in competition studies, excess 3'-TE RNA inhibits *in vitro* translation of capped GUS mRNA in *trans*, and this effect is reversed by addition of excess eIF4F. Thus, the 3'TE appears to act to recruit translation factors and ribosomes by interacting with eIF4F, either directly or indirectly. The BYDV 5'-UTR is proposed to function for long distance 3'–5' interactions, probably by also interacting with eIF4F or other host factors rather than through direct base pairing, to position the recruited translation machinery at the 5' end of the viral genome (366). The significance of this translational enhancer being located between ORFs 5 and 6 (see Fig. 14) is that it would act to enhance translation of the genome and sgRNA1 to produce BYDV proteins. At the same time, its presence at the 5'-end of sgRNA2, which accumulates to high levels later in infection, could inhibit translation of genomic RNA by effectively competing for eIF4F and translation factors to favor replication and encapsidation. Of course, it could eventually act to inhibit translation of sgRNA1 as well.

Brome Mosaic Virus: Multipartite, Subgenomic RNA

The *Bromoviridae* comprise five genera: *Bromovirus, Cucumovirus, Alfamovirus, Ilarvirus,* and *Oleavirus* (347). All of these viruses have positive-sense tripartite genomes that consist of three separate segments of positive-sense ssRNA. The three genomic segments are separately encapsidated in distinct particles. This separation of gene function on physically distinct RNAs was historically a major advantage before the development of recombinant DNA approaches. Genetic reassortment of the genomic segments between different strains or mutants of the same virus, or different related viruses within these genera, made mapping gene functions relatively straightforward. In addition, studies of viral replication were facilitated by the components of the RdRp being encoded on two different segments distinct from the third genomic RNA that encodes the MP and CP. Thus, the RdRp activities could be mutated separately from promoters for positive-strand RNA and negative-strand RNA synthesis on the third genomic RNA, in effect using this third RNA as a reporter to identify essential replication functions in the RdRp and to investigate the mechanisms of genomic RNA, complementary RNA, and sgRNA synthesis. BMV, the type member of the bromoviruses, together with cowpea chlorotic mottle virus (CCMV) (bromovirus), cucumber mosaic virus (CMV) (cucumovirus), and alfalfa mosaic virus (alfamovirus) are among the best characterized viruses in the *Bromoviridae*. BMV illustrates many of the principles governing gene expression of multipartite plant viral genomes, and is the focus here. Although BMV combines expression of a sgRNA with the multipartite strategy, different multipartite positive-sense ssRNA plant viruses combine a number of the strategies that have been discussed, with their segmented genome approach, such as polyprotein synthesis and processing by a viral-encoded proteinase (comoviruses); readthrough and sgRNA (tobraviruses); or sgRNA, readthrough, and leaky scanning (hordeiviruses) (123). Multipartite viruses that use the polyprotein approach can have a viral VPg linked to the 5' ends of the genomic RNAs and 3' poly(A) tails, as do the comoviruses. The others, in general, have 5' caps combined with a poly(A) tail, a tRNA-like structure, or no known modification at the 3' ends of their genome segments.

BMV, although not of major economic importance, is historically important as the first RNA virus for which infectious genomic transcripts were generated *in vitro* from cDNA clones (8) and a model for investigating how positive-sense RNA plant viruses replicate their genomes and transcribe sgRNA (6,231). More recently, the demonstration that BMV can replicate in yeast has led to a novel approach to study virus replication *in vivo* and use yeast genetics to identify host factors involved in BMV replication (159). There appear to be no efficient invertebrate vectors for bromoviruses, although beetles and nematodes have been experimentally shown to transmit them. The viruses can be mechanically transmitted, in both the laboratory and field. The virions have T=3 quasi-icosahedral symmetry and are about ~28 nm in diameter. These are composed of 180 copies of the viral 20-kd CP, with each subunit having a b-barrel structure that is uncharacteristically perpendicular to the capsid surface so that the pentameric and hexameric subunit clusters have a bulging knoblike appearance (7,186). The N-termini of the CP subunits are internal and appear to interact with the encapsidated viral genomic RNA. The BMV genome consists of three distinct segments of positive-sense ssRNA that are 3.2 kb (RNA1), 2.9 kb (RNA2), and 2.1 kb (RNA3) in size, each with a 5' cap (m^7GpppGp) and a 3' tRNA-like structure that contains a pseudoknot and can accept tyrosine *in vitro* (Fig. 15). Density gradient centrifugation shows that these, together with the subgenomic RNA encoding the viral CP (RNA 4), are separately encapsidated into three different particles: (a) 3.2-kb genomic RNA (gRNA) in the highest density particles; (b) 2.9-kb gRNA in the intermediate density particles; and (c) 2.1-kb gRNA and 0.9-kb sgRNA in the lowest density particles (7). The CP sgRNA, like the genomic RNAs, has a 5' cap and a 3' $tRNA_{tyr}$-like structure (see Fig. 15).

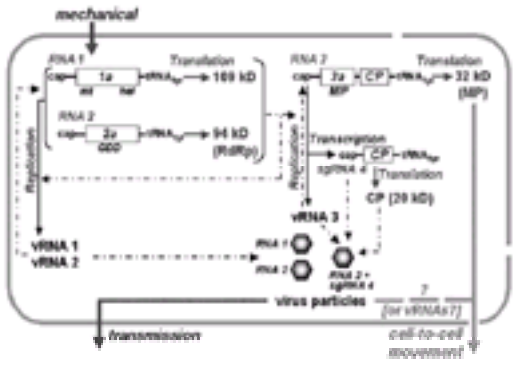

FIG. 15. Multiplication of brome mosaic virus (BMV).

How the virions are uncoated is not well understood. What is clear is that the three genomic RNAs and subgenomic RNA4 (hereafter [sg]RNA4) are each monocistronic and translated into the protein encoded by the single or the 5'-proximal gene. RNA1 and RNA2 are the only genome segments required for virus replication, as shown by direct transfection of plant protoplasts. These are translated, respectively, into proteins 1a (109 kd) and 2a (94 kd) (see Fig. 15), which coordinately act to replicate all three genomic RNAs by way of negative strand intermediates, as well as recognize an internal promoter on RNA3 to transcribe it into the 0.9-kb [sg]RNA4 that encodes the CP. RNA3 itself is translated into the viral MP (32 kd). Consistent with BMV having a positive-sense ssRNA genome and the previously described picture, the three genomic RNAs together are infectious, and each of these, as well as [sg]RNA4, is translated into the corresponding protein *in vitro* (6). This view of BMV multiplication and gene expression is supported by a variety of experimental studies that were facilitated by the generally high efficiency with which RNA can be transfected into protoplasts and the ability to prepare highly active template-dependent replicase-containing extracts from BMV-infected plants (232), in addition to the segmented nature of the BMV genome. Protein 1a contains conserved motifs characteristic of RNA methyltransferases (N-terminal domain) and helicases (C-terminal domain), and the central region of protein 2a contains the GDD motif characteristic of a viral RdRp. The arrangement and sequences of these resemble those in Sindbis and other alphaviruses, placing BMV in the alphavirus superfamily. Mutations in any of these conserved domains of 1a or 2a block or alter virus RNA replication and sgRNA transcription (6). Consistent with the N-terminus of 1a (methyltransferase) having a role in capping viral genomic and subgenomic RNA, 1a expressed in *E. coli* or yeast has been shown to methylate GTP at the 7 position of guanine in a reaction requiring *S*-adenosylmethionine and to form an adduct with m(7)GMP (10,178). Evidence further suggests that proteins 1a and 2a interact. Pseudorecombinant studies in which RNA1 and RNA2 from BMV and the bromovirus CCMV were exchanged first suggested that 1a and 2a had to be "compatible": such pseudorecombinants do not replicate in protoplasts, not even supporting the replication of BMV RNA3, which can be replicated by either homologous *1a/2a* gene combination (75). In addition, antisera against BMV 1a coprecipitates 1a and 2a from BMV RdRp-containing extracts (280). The C-terminal helicase region of 1a has been shown to interact with the N-terminal region of 2a by Far Western blotting and yeast two-hybrid assays (9,248), and recombinant studies suggest that the core RdRp region of 2a interacts with 1a as well (321). That the 32-kd protein encoded by the *3a* gene is the MP is suggested by several lines of evidence. RNA3 is not needed for viral replication in protoplasts but is essential for virus infectivity in plants. In addition, genetic studies show that deletions in the *3a* gene confine virus infection to individual cells; such mutations prevent the appearance of local necrotic lesions on the inoculated leaves of an appropriate plant host (234). The 32-kd protein also has properties reported for other viral MPs, such as the TMV 30-kd protein: it cooperatively binds single- stranded nucleic acids *in vitro* in a sequence-nonspecific manner, and it has been immunolocalized to plasmodesmata in BMV-infected plants (109,161).

Mutational studies also show that the CP is needed for systemic infection via the phloem, but whether it is required as well for local cell-to-cell movement has not been resolved. Mutations that disrupt the CP of BMV or CCMV have been reported to slow down, but not eliminate, virus spread within the inoculated leaf, based again on the rate of appearance and size of local lesions (7,103). However, mutation of the BMV CP appears to block cell-to-cell spread in some hosts, and studies with chimeric viruses in which the MP and/or CP was exchanged between BMV and CMV suggest a "compatibility" for MP–CP combinations in cell-to-cell movement, although in the latter studies an antagonistic effect of the CMV CP on the BMV MP could not be excluded (239). The important question is whether mutations in the CP affect BMV cell-to-cell movement directly or whether these inhibit local spread within the inoculated leaf through the minor veins. Studies with PVX have shown that infection of an inoculated leaf involves not only virus moving directly from cell to cell, but also virus entering the phloem and exiting locally (292). The question of the mode of cell-to-cell spread is particularly intriguing for BMV given its tripartite genome. Whether moving as encapsidated virus particles or viral RNAs directly complexed with MP, do the genomic RNAs move independently into adjacent uninfected cells until all three (and perhaps [sg]RNA4 as well) accumulate in the same cell, or is there a mechanism to coordinate movement of the three genomic RNAs as they move from cell to cell?

BMV replication occurs in the cytoplasm in association with ER-derived membranes, as reported for other positive-sense RNA viruses. Viral RdRp activity isolated from BMV-infected plants is membrane associated. In addition, immune staining with specific antisera against 1a, 2a, or ER marker proteins, or to detect 5-bromouridine incorporation into replicating viral RNA, show that 1a, 2a, and nascent viral RNA colocalize to cytoplasmic vesicles that also contain ER marker proteins (286). The BMV multiplication cycle is temporally regulated at the level of positive-sense RNA and negative-sense RNA synthesis, and the transcription of [sg]RNA4 to produce the CP, as has also been shown for PVX, TMV, and TYMV. The accumulation of positive-and negative-sense RNA is independently regulated such that late in infection, there is an ~100-fold excess of the genomic RNAs and [sg]RNA. Because [sg]RNA4 transcription is dependent on prior replication of complementary negative-strand RNA, it does not accumulate to high levels until later in infection, at which time efficient translation of [sg]RNA4 into CP appears to compete with that of the nonstructural proteins (1a, 2a, and particularly MP), inhibiting these while large amounts of CP are synthesized for encapsidation of virions (7). The cis-acting sequence elements involved in transcription of BMV [sg]RNA4 and replication of BMV negative-strand RNA and genomic positive-sense RNA have been well characterized in both *in vivo* studies that analyzed the effects of

specific mutations on the accumulation of different RNA species in protoplasts and *in vitro* studies with BMV template-dependent RdRp preparations from infected plants in which specific templates could be tested and initiation sites more precisely mapped. The 250 nt intercistronic region between the *MP* and *CP* genes on RNA3 in particular contains important sequence elements for the regulation of replication as well as transcription. Transcription of [sg]RNA4 initiates internally on negative strand copies of RNA3 within a 100 nt sequence in this intercistronic region located upstream of the *CP* gene (231) (Fig. 16). This subgenomic promoter consists of a core promoter of 20 nt located immediately upstream of the *CP* gene that directs specific basal transcription of [sg]RNA4, and additional upstream activating sequences that consist of an oligo(A) tract and partial repeats of core promoter sequences that act to increase levels of [sg]RNA4 transcription (108,216).

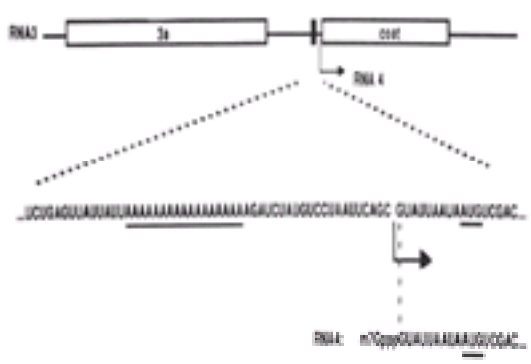

FIG. 16. Internal promoter for brome mosaic virus (BMV) subgenomic RNA4 ([sg]RNA4) encoding the capsid protein (coat or CP). The sequence of the intercistronic region is shown, below which is the 5'-terminal sequence of [sg]RNA4. AUG of the CP is underlined. (From ref. 220, with permission.)

Replication of BMV RNAs involves cis-acting sequences within the 5'-UTR and 3'-UTR of RNA1, RNA2, and RNA3, as well as internal sequences within the *2a* gene of RNA2 and a 150 nt sequence within the intercistronic region of RNA3. This 150 nt sequence is located upstream of the oligo(A) tract and most of the subgenomic promoter, overlapping sequences at the 5' end of the activating region. The promoter sequences for negative strand RNA synthesis have been mapped to the 3'-terminal 200 nt of the genomic RNAs that include the $tRNA_{tyr}$-like structure (6). Unlike TYMV, encapsidated BMV genomic RNAs terminate in 5'-CCA-3', but *in vitro* transcribed genomic RNAs that lack the 3'-terminal A residue can be adenylated by cellular CCA-tRNA nucleotidyltransferase *in vitro*. Like TYMV, BMV negative-strand RNA synthesis starts at the penultimate C within this terminal 5'-CCA-3' sequence, and thus it is assumed that adenylation of the 3' end of BMV positive strand RNAs by host CCA-tRNA nucleotidyltransferase must normally occur *in vivo*. The role of tRNA mimicry in BMV replication has not been as extensively studied biochemically as it has for TYMV. Interestingly, a recent study of the template requirements for initiation by the RdRp of TYMV and BMV reported that BMV RdRp can initiate synthesis internally at 5'-ACCA-3' sequences, but does so inefficiently. However, it could efficiently initiate at internal 5'-AUGC-3' sequences (69). The *cis*-acting sequences within the 5'-UTR regions of the BMV genomic RNAs are presumed to be involved in initiation of positive-strand RNA synthesis. These, and the 150 nt internal intercistronic sequence required for efficient accumulation of BMV RNA3, all contain a sequence similar to the motif 5'-GGUUCAAyyCC-3' (y = U or C), which is one of two consensus elements (Box B) found in cell RNA pol III promoters and also corresponds to the invariant residues of tRNA TYC loops (7). Mutations in this sequence within the 5'-UTR of RNA2 or the intercistronic region of RNA3 each reduce the accumulation of the corresponding RNA *in vivo*, and several proteins from barley extracts have been reported to bind to the Box B–like element within the 5'-UTR of RNA2 or the complement of this element within the 3'-UTR of the negative strand of RNA2 (92,265).

The involvement of Box B–like elements in the replication and/or accumulation of BMV RNA, the binding of host proteins to these elements, and the presence of cellular proteins in partially purified preparations of BMV RdRp (280,281) have been cited as circumstantial evidence for the involvement of host proteins in BMV replication. More direct evidence for this, as well as more detailed analysis of viral replication, has been obtained through studies of BMV replication in yeast (154,155,159). In this system, BMV proteins 1a and 2a are each expressed from separate yeast 2-μ plasmids having an *HIS3* (for 1a) or *LEU2* (for 2a) selectable marker so that the transformed yeast strain (*his3*$^-$ *leu2*$^-$ *trp1*$^-$ *ura3*$^-$) can be selected for growth in the absence of histidine and leucine. These are constructed such that the mRNAs encoding 1a or 2a are transcribed from the yeast *ADH* promoter; however, most of the 5'-UTR and 3'-UTR from RNA1 and RNA2 are missing, so these RNAs cannot be replicated. Replication is assayed by introducing RNA3, either by transfecting yeast coexpressing 1a and 2a with *in vitro* transcripts of RNA3, or by *in vivo* transcription of a RNA3 cDNA from a yeast *CEN4* plasmid (*TRP1* selectable marker) or chromosomal insertion (Fig. 17). In these latter two cases, RNA3 cDNA is flanked by the *GAL1* promoter and the self-cleaving ribozyme from hepatitis d virus. Growth in galactose induces transcription of RNA3, and the ribozyme cleaves the transcript at its natural 3' end. In the presence of BMV 1a and 2a, this RNA3 transcript, which is complete with its natural 5'-UTR and 3'-UTR, is correctly replicated in yeast via its complementary strand, and [sg]RNA4 is transcribed. For purposes of selection or screening, the *CP* gene on RNA3 can be replaced with the yeast *URA3* gene or the bacterial GUS or choramphenicol acetyltransferase (CAT) coding sequence. These will be translated from [sg]RNA4, thus allowing for selection of yeast replicating RNA3 (in the case of transfection of *in vitro* transcripts) based on uracil-independent growth of the appropriate yeast strain, or screening of RNA3 replication based on GUS or CAT assays. Selection against expression of the *URA3* gene (growth in 5-fluoroorotic acid) can also be used to isolate mutants defective in BMV 1a- and 2a-dependent replication of RNA3 (154). The *MP* coding sequence has also been replaced by *CAT* to assay for translation of RNA3 relative to its replication, the latter determined by Southern blotting with appropriate probes (160).

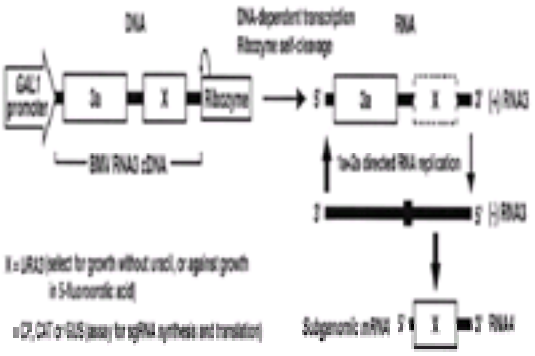

FIG. 17. A yeast system to study brome mosaic virus (BMV) RNA replication. (From ref. 154, with permission.)

The intriguing finding is that RNA3 is faithfully replicated and transcribed in the presence of 1a and 2a in yeast. This suggests that whatever host factors may be involved in BMV replication, yeast must contain equivalent factors that can substitute for those present in plants (159). Beyond this finding, the power of the yeast system is the ability to investigate the independent as well as the coordinate effects of 1a or 2a on replication and transcription of RNA3 and to select for host mutants that block different stages of RNA3 replication and transcription. Using this system, it was found that BMV 1a alone acts to stabilize RNA3 positive-sense transcripts expressed from the *GAL1* promoter, increasing their half-life from 5-to-10 minutes to greater than 3 hours. Using a *CAT* reporter gene in place of the *MP* coding sequence, this 1a stabilization appeared to block translation of RNA3, which led to the suggestion that 1a interacts with RNA3 to recruit it (and by inference RNA2 and RNA1) away from translation and into RNA replication (160). What sequences does 1a interact with in RNA3?: The intercistronic 150-nt "replication signal" that includes the consensus Box B–like element. Mutational analysis of RNA3 in this 1a-dependent yeast system shows that this 150-nt "enhancer of RNA3 replication" is required for this 1a stabilization of RNA3, and beyond this is sufficient to confer 1a-dependent stabilization when fused to the 5' end of b-globin RNA (328). Using 5-fluoroorotic acid to select against replication of a chromosomal insertion of RNA3 that expresses the *URA3* gene in place of the *CP* gene, recessive mutations in a number of yeast genes have now been identified that inhibit this BMV 1a- and 2a-dependent replication and transcription of RNA3. Characterization of these and other yeast genes that affect BMV replication and transcription in yeast is a powerful approach for deciphering the involvement of host proteins in RNA virus replication. One yeast protein, Lsm1p, a cytoplasmic protein related to core RNA splicing factors, has been shown to be involved in the 1a stabilization of RNA3 through interactions with the 150-nt element that contains the Box B–like consensus sequence (74). An additional interesting question is why does BMV replicate in yeast at all. This is apparently not true for all positive-sense RNA viruses: to date, only BMV and a few nodaviruses have been reported to replicate in yeast.

Enveloped Viruses

Given the plant cell wall and the movement of plant viruses from cell to cell without going through an extracellular phase, the existence of enveloped plant viruses raises a number of interesting questions in terms of viral adaptation. At what site(s)within the plant cell will these viruses bud to acquire their envelope? Surely the plant cell wall poses problems for budding at the plasma membrane, the site of maturation for most, although not all, enveloped animal viruses. Why would a plant virus have an envelope? Does the envelope and its associated glycoproteins have a role in infecting the plant host, or do they serve a separate function? What is the relationship between the form of the virus that moves from cell to cell to infect the plant and the virion? As already alluded to for tospoviruses such as TSWV (see Plant-to-Plant Transmission), and described in more detail later, the enveloped virion with its glycoproteins may represent an adaptation to a dual lifestyle: that of an "animal-infecting virus" as well as a plant virus. The genomic organization of the tospoviruses, and plant-infecting rhabdoviruses that have been characterized, suggests that they are "animal viruses" that encode one extra, unique protein—a movement protein needed for the virus to invade and infect plants. An important issue then becomes how virus maturation may be regulated in infected plant cells. Being negative-sense (nucleorhabdoviruses and cytorhabdoviruses) or ambisense (tospoviruses), transcripts of cDNA clones are not infectious. Thus, the interactions of these viruses with their hosts have been difficult to study, and a number of the details of their replication are sketchy or inferred by analogy to other, better characterized animal viruses within the same family. These particular plant viruses are included here, not to focus on the details of their replication, but to illustrate possible adaptations of enveloped viruses when infecting a plant.

Tomato Spotted Wilt Virus

Topsoviruses, a genus in the *Bunyaviridae*, have emerged as serious pathogens of crops in the past 20 years. In nature, the viruses are transmitted by thrips, but they can be mechanically transmitted in the laboratory. TSWV, the type member and best characterized of the tospoviruses, is in the current "top ten" of plant viruses in terms of economic losses worldwide (272). The recent emergence of TSWV, as well as a number of other tospoviruses, has been attributed to the increased worldwide prevalence of one of its major vectors, the western flower thrips (*Frankliniella occidentalis*), and the increased movement of ornamental plants as the result of increased world trade. TSWV infects >900 plant species of monocotyledonous or dicotyledonous plants, but other topsoviruses generally have more narrow host ranges (237). TSWV is a typical *Bunyaviridae* in terms of virion structure and overall genomic organization. Virions are spherical enveloped particles ~80-to-120 nm in diameter, with surface projections (spikes) composed of two viral-encoded glycoproteins, G1 and G2. The three genomic segments of the viral tripartite genome are associated with the nucleoprotein N and a few copies of the viral RdRp (L protein) to form three separate nucleocapsids within the enveloped particles (see Chapter 48). There is no matrix protein.

TSWV has three genomic ssRNA segments designated *L* (large), *M* (middle), and *S* (small) (Fig. 18) that are organized and expressed overall as are the genomic segments of the animal-infecting *Bunyaviridae* (see Chapter 48). The L

segment encodes a single protein, L (330 kd), shown to be the viral RdRp in several animal-infecting *Bunyaviridae.* The TSWV M segment encodes the viral glycoproteins, G1 and G2, on the complementary strand, and a nonstructural protein NSm (33.6 kd), which is translated from an sgRNA that is 5' coterminal with the viral genomic M segment. The S segment encodes the nucleoprotein N (30 kd) on the complementary strand, and a nonstructural protein NSs (54 kd), which like NSm, is translated from an sgRNA that corresponds to the 5' end of the viral genomic S segment. Thus, both the M and S segments of TSWV are expressed by an ambisense strategy (67,180,181) (see Fig. 18). All of the *Bunyaviridae* are principally negative sense viruses in terms of their replication strategy. Thus, TSWV, like other *Bunyviridae* and negative sense RNA viruses, contains the viral-encoded RdRp (L protein) associated with the nucleocapsids in the enveloped virus particles and in infected plant cells (346). L is the putative RdRp of TSWV based on sequence similarity to the RdRp of other *Bunyaviridae* and negative sense RNA viruses (66). Consistent with this, detergent-disrupted TSWV virions have been shown to contain an RdRp activity *in vitro* (4). The L protein is an endonuclease as well as an RdRp. The endonucleolytic activity is required because *Bunyviridae,* like the segmented negative strand influenza viruses and "ambisense" arenaviruses, require capped primers to initiate transcription of mRNAs. These are acquired from host mRNAs in the cytoplasm, not the nucleus, by a "cap snatching" mechanism (see Chapter 48). For TSWV, primer extension analysis has shown that the two mRNAs transcribed from the S segment contain nonviral sequences 12 to 20 nt in length at their 5' ends (184) (see Fig. 18). In addition, when plants are co-infected with TSWV and alfalfa mosaic virus (AMV) (a *Bromoviridae* with a genome organization like BMV), the heterogeneous 5' ends of the TSWV mRNAs can be acquired from the co-infecting AMV RNAs, thus clearly showing that this cap-snatching does occur in the cytoplasm. By analogy to other well-characterized negative strand RNA viruses such as vesicular stomatis virus (VSV), it is generally assumed that the TSWV N protein regulates the switch from mRNA transcription to viral genome replication (see Fig. 18). Consistent with this, both TSWV genomic and full-length complementary RNAs are found associated with N protein in RNP particles in infected plants (181). Using antisera generated against NSs expressed from a baculovirus vector in insect cells, NSs has been found associated with what has been described as fibrous structures or paracrystalline arrays in the cytoplasm of infected TSWV plant cells (182,237). Its function remains unknown. It is also not known how the viral nucleocapsids are released from virions following their introduction into plant cells by thrips. It is generally assumed by analogy with other enveloped viruses that they are taken up in cytoplasmic vesicles, with release occurring by fusion of the viral envelope with the vesicle membrane (Fig. 19).

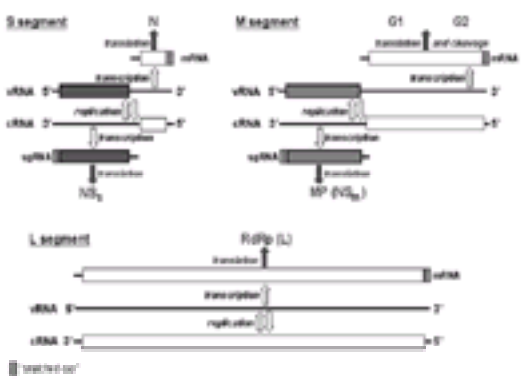

FIG. 18. Tospovirus replication and gene expression. (Adapted from ref. 272, with permission.)

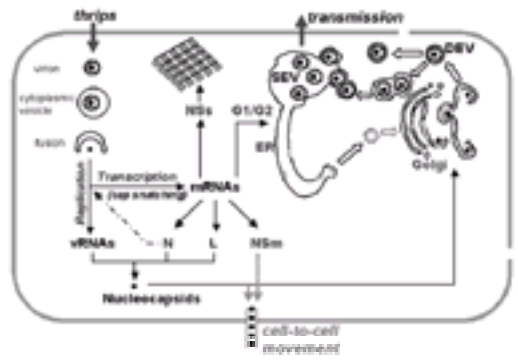

FIG. 19. Multiplication of tomato spotted wilt virus (TSWV). Stages of virion uncoating have been proposed based on analogy to animal bunyaviruses. DEV, double-enveloped virus; SEV, single-enveloped virus. See text for details. (Adapted from refs. 170 and 272, with permission.)

The distinctive feature of the genomic organization of TSWV when compared with that of the animal-infecting *Bunyaviridae* is the presence of an additional virus-sense gene in the M segment, which is expressed from an sgRNA (see Fig. 18). Evidence suggests that this encodes the viral MP. In infected plant cells, viral RNPs are seen associated with unique large tubular structures that extend into adjacent cells from what appear to be highly modified plasmodesmata. NSm immunolocalizes to these unique tubules, and has been shown to be necessary and sufficient to induce such tubules when transiently expressed in plant protoplasts or insect cells. In addition, NSm immunolocalizes to plasmodesmata in transgenic plants that express this protein (183,273,327). Although viral RNPs are associated with or within these tubules, transient expression studies in plant protoplasts show that N protein is not required for the formation of the tubules. Thus, it has been suggested that viral RNPs move from cell to cell in the plant through these MP-containing tubules (see Fig. 19). This picture of TSWV movement in infected plants envisions a pathway quite distinct from and clearly not involving enveloped virions with their associated G1 and G2 glycoproteins. As already discussed, the enveloped virion structure and G1 and G2 glycoproteins are required for thrips recognition and acquisition of TSWV but not for plant infection, as clearly demonstrated by the fact that plant-infectious TSWV lacking the envelope

structure and glycoproteins can be generated by repeated mechanical passage in plants (285) (see Plant-to-Plant Transmission). Only thrips in the larval stage can acquire the virus, which they ingest during feeding on plants. Ultrastructural studies show that virions are transported along the lumen of the thrips digestive tract to the midgut, where they appear to cross the midgut wall by endocytosis to enter the hemocoel. From the hemocoel, they invade the salivary glands. However, unlike the *Luteoviridae,* topsoviruses replicate in their thrips hosts, persistently infecting the insects without being pathogenic. Evidence for this includes the detection of the nonstructural protein NSs in infected thrips and the identification of viral inclusions in endothelial cells, muscle cells, and the salivary glands (237). Using gel overlay and immune labeling assays, two candidate thrips receptor proteins that recognize TSWV glycoproteins have been identified: a midgut protein that can bind both G1 and G2, and a protein found in all tissues except the midgut that recognizes G2 (17,171). The functions of these thrips proteins in virus acquisition and circulation has not been determined.

Where does TSWV virion assembly occur in infected plant cells? For those animal-infecting *Bunyaviridae* where it has been investigated, the viral G1/G2 polyprotein precursor has a signal sequence so that it is cotranslationally transported into the ER lumen, being processed to G1 and G2 by host cell peptidases and glycosylated as it transits from the ER to the Golgi stacks. The heterodimeric G1:G2 complex contains a Golgi-retention signal, so that virion assembly occurs by viral RNPs associating with G1:G2-containing areas of Golgi membranes and budding into the Golgi. These assembled virions are then transported to the cell surface in vesicles, where they are released from the cell as the vesicles fuse with the plasma membrane (see Chapter 48). Until recently, the pathway for TSWV virion morphogenesis in plant cells has not been clear. The TSWV G1/G2 precursor is predicted to contain a signal peptide and has been shown to be processed when expressed in insect cells, where it was also reported to be associated with cellular membranes, including the plasma membrane (3). However, this study done in insect cells does not answer the question concerning where virions mature in infected plant cells. Ultrastructural and immune labeling studies have reported virus particles or virion proteins associated with what morphologically appeared to be ER membrane in infected plants cells or Golgi-like structures in infected thrips cells, leading different authors to state that TSWV acquires its envelope by budding into the ER or the Golgi. However, the identity of these membrane structures was never determined by immune labeling for appropriate ER and Golgi marker proteins. A major advance in this area is the recent development of a plant protoplast system for investigating TSWV infection in which more than >50% of the cells (*Nicotiana rustica* tobacco cells) can be infected with TSWV particles and maintained for several days (172). Using this synchronous infection system for ultrastructural studies and immune staining for compartment-specific marker proteins, the TSWV glycoproteins G1 and G2 were found to accumulate in Golgi membranes. These areas of the Golgi then appear to wrap around viral RNPs in the cytoplasm to form double-enveloped particles (DEV) (see Fig. 19). At later stages of infection, both in the infected protoplasts and in cells in TSWV-infected plants, these cytoplasmic DEV double-enveloped particles can be found fused to each other and fusing to ER membrane to form single-enveloped particles (SEV, the virions) clustered in membrane-bound bodies in the cytoplasm or in the ER (170) (see Fig. 19). Thus, rather than be transported in Golgi-derived vesicles to the plant plasma membrane with its cell wall, TSWV appears to have adapted a strategy that allows mature virions to move back from the Golgi to the ER and accumulate there, as well as in the cytoplasm. It is suggested that when thrips feed, they acquire TSWV virions from these sites of accumulation in the ER (170).

Rhabdoviruses: Sonchus Yellow Net Virus and Lettuce Necrotic Yellows Virus

Plant viruses have historically been categorized as rhabdoviruses based on ultrastructural examination of infected plant cells or virus preparations, which identify enveloped virus particles that are bullet shaped in unfixed preparations or bacilliform when fixed (Fig. 20). Virions are 45 to 100 nm wide and 130 to 250 nm long, and in nature are transmitted by aphids, leafhoppers, or planthoppers, depending on the virus. Like the tospoviruses, these viruses infect and multiply in their insect vectors, thus leading a dual lifestyle as an animal-infecting and plant-infecting virus. Approximately 75 plant viruses are currently listed as possible rhabdoviruses, although it is not clear that all of these represent distinct viruses or are in fact rhabdoviruses. About 15 of these viruses have been sufficiently characterized in terms of virion structure and composition, host range, vector transmission, serology, nucleic acid hybridization, and ultrastructural alterations in infected plant cells to be placed in the genus *Cytorhabdovirus* or *Nucleorhabdovirus* (158). As these names imply, the plant rhabdoviruses are grouped based on the site of virus multiplication, as determined by electron microscropic examination of infected plant cells. Nucleorhabdoviruses form nuclear inclusions and appear to bud from the inner nuclear envelope to accumulate in perinuclear spaces. Cytorhabdoviruses are seen to form at cytoplasmic membranes and accumulate in the cytoplasm. Of these, sonchus yellow net virus (SYNV; a nucleorhabdovirus) and lettuce necrotic yellow virus (LNYV; a cytorhabdovirus) are the best characterized in terms of sequence analysis.

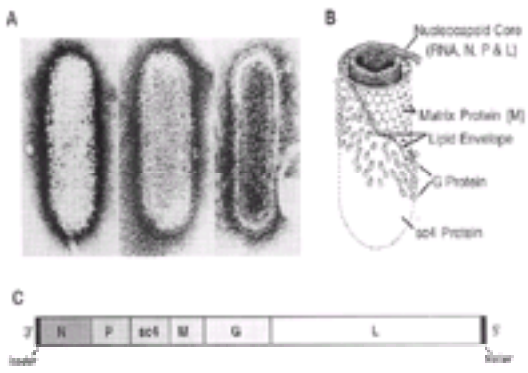

FIG. 20. Structure and genome organization of sonchus yellow net virus (SYNV), a nucleorhabdovirus. (From ref. 158, with permission.)

Electron microscopy of purified virions, combined with detergent disruption, gel analysis of viral proteins, and RNA analyses, show that plant rhabdoviruses, as typified by SYNV and LNYV, resemble VSV in structure and composition (158) (see Fig. 20). Virions are composed of a lipid envelope from which project spikes made of the viral-encoded G

glycoprotein, which is presumed to exist in a trimeric form as in VSV. Within the envelope, the virion core is composed of a helical RNP that consists of the viral genomic unsegmented negative-sense ssRNA (~11 to 14 kb) surrounded by N protein to form the nucleocapsid, in association with a few copies of the viral P and L proteins that make up the RdRp (see Fig. 20). The location of the matrix protein M has not been unambiguously determined, but like VSV, it is assumed to be involved in coiling the nucleocapsid and interacting with the internal domains of G (see Chapter 38). The available evidence suggests that replication of the plant rhabdoviruses resembles that of VSV. Treatment of LYNV virions with nonionic detergent activates a viral RdRp that transcribes RNAs complementary to the viral genome *in vitro* (158). The RdRp activity is associated with loosely coiled nucleocapsids that contain N, L, and P, in addition to the virion ssRNA. Interestingly, similar treatment of SYNV virions does *not* activate RdRp activity, but such an activity can be extracted from the nuclei of plant cells infected with SYNV (358). This SYNV RdRp activity co-sediments with viral nucleocapsid cores and contains the viral N, L and P proteins, based on copurification and immune precipitation studies (359). Antibody inhibition studies show that L is a functional component of the RdRp activity. Kinetic analysis of the products transcribed *in vitro* shows that like VSV, SYNV transcription occurs by a stop-start mechanism in which the individual mRNAs for each gene are sequentially transcribed starting at the 3' end of the viral genome and continuing through to the 5' end, with the RdRp pausing at intergenic regions between each gene to polyadenylate and terminate the upstream gene, and then transcribe the next gene in order (see Chapter 38). Also like VSV, the relative abundance of each mRNA is determined by the gene order in the viral genome, with the 3'-proximal N mRNA being most abundant and the 5'-proximal L mRNA being transcribed in the lowest amount (359). All of the mRNAs are polyadenylated by the viral RdRp activity. Like VSV, a positive-sense short leader RNA is transcribed from the 3' end of the genomic RNA; but unlike VSV, the SYNV leader RNA is also polyadenylated (359). Thus, while the picture is one of virions containing RNP cores that can initiate transcription upon uncoating, as one would expect for a negative-sense RNA virus, the SYNV core-associated RdRp appears to require activation within the host cell. This, along with the polyadenylation of the SYNV leader RNA, appears to reflect adaptations necessary for the nuclear multiplication of this virus.

The complete sequence of the SYNV genome shows an organization that is the same as VSV, with one additional gene *sc4* not found in VSV (reviewed in 358) (see Fig. 20). The 3' leader sequence is followed by the genes encoding N, P, M, G, and L in the same order as they occur in VSV (see Chapter 38). The *sc4* gene is located between the P and M genes (see Fig. 20). The 3' leader and 5'-proximal noncoding region of SYNV are distinct from those in VSV and other animal-infecting rhabdoviruses, but the intergenic gene junctions are highly conserved (158) (Table 4). The sc4 protein is found in virions (see Fig. 20) and appears to be phosphorylated *in vivo*. Although its precise location is unknown, it is solubilized from virions by treatment with nonionic detergents. It has been suggested that sc4 might be the viral MP, although it could also play a role in aphid transmission (158). SYNV induces the formation of viroplasms in the nuclei of infected plant cells. The viral N, L, and P proteins have been immunolocalized to these nuclear viroplasms, which appear to be the sites of viral replication and the source of the RdRp activity that can be extracted from nuclei of infected cells (217,359). N and P also appear to contain NLSs: when N or P are individually expressed from a PVX vector (see Fig. 8), each accumulates in the nucleus, and if expressed as fusions to GUS, the GUS:N and the GUS:P fusion proteins are also targeted to nuclei (217). Ultrastructural studies show SYNV virions budding at the inner nuclear membrane to accumulate in swollen perinuclear spaces between the inner and outer nuclear envelopes. Thus, the rather striking adaptation to replicate in nuclei, as opposed to VSV, which replicates in the cytoplasm, appears to be a strategy to acquire the viral envelope from the inner nuclear envelope rather than the plant cell plasma membrane. The current model for SYNV multiplication (Fig. 21A) proposes that upon entering a cell, the viral nucleocapsid cores are released into the cytoplasm, possibly in association with the ER, and these are transported into the nucleus, where the SYNV RdRp is activated and primary transcription occurs. Viral mRNAs are transported to the cytoplasm, where they are translated, and newly synthesized N, L, and P are transported into the nucleus to continue transcription of viral mRNAs and replicate the viral genome. Presumably, newly synthesized viral M and sc4 proteins also have to be transported to the nucleus: M for virion assembly and sc4 since it is present in virions. Because tunicamycin interrupts SYNV budding at the nuclear envelope and causes nucleocapsids to accumulate at the nuclear periphery, it is proposed that newly synthesized G is transported to the inner nuclear envelope, and virus buds at these sites into the perinuclear space between the inner and outer nuclear membranes (158). This model envisions that viral cores lacking an envelope are exported from the nucleus and move cell to cell, presumably through plasmodesmata, as an alternative to virion assembly (see Fig. 21), as is the case for TSWV.

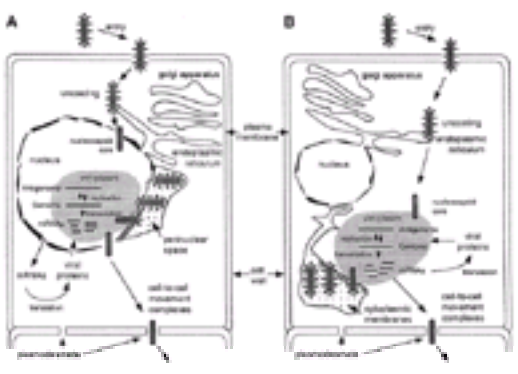

FIG. 21. Multiplication of **(A)** nucleorhabdoviruses and **(B)** cytorhaboviruses. (From ref. 158, with permission.)

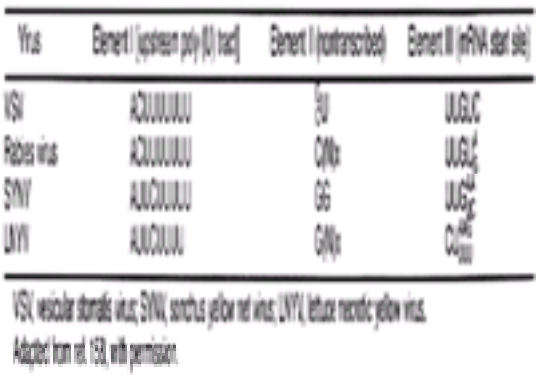

Virus	Element I (upstream poly (A) tract)	Element II (untranscribed)	Element III (mRNA start site)
VSV	ACUUUUUU	3U	UUGUC
Rabies virus	ACUUUUUU	CUUa	UUGU$_C^G$
SYNV	AUUCUUUU	GG	UUG$_C^{GA}$
LNYV	AUUCUUU	GUUa	C$_{UUU}^{AG}$

VSV, vesicular stomatitis virus; SYNV, sonchus yellow net virus; LNYV, lettuce necrotic yellows virus.

TABLE 4. *Sequence elements in the intergenic regions of plant and animal rhabdoviruses*

In the context of the nuclear replication of SYNV, the presence of an inactive form of the RdRp within virions and the polyadenylation of the leader RNA make sense. Packaging of an inactive RdRp provides a mechanism to prevent premature transcription from occurring in the cytoplasm before nucleocapsid cores are transported to the nucleus. Host activation of the RdRp could involve a posttranslational modification, such as phosphorylation of L or P within the RdRp complex, or of the core structure such that it can be transported into the nucleus. Polyadenylation of the leader sequence may prevent this RNA from being degraded within the nucleus. Although there are some biochemical and immune localization studies to support aspects of this model, the proposed pathways for viral assembly and movement are primarily based on ultrastructural studies. Cell biological and additional biochemical studies are needed to investigate the interesting questions raised by this model. Essentially nothing is known about the form in which the virus moves from cell to cell to invade the plant, or the process of movement. Perhaps M is required only for virion assembly at the inner nuclear envelope, and flexible nucleocapsids, in association with sc4 as well as P and L, are the form that exits from the nucleus and moves from cell to cell. What regulates whether genomic RNPs are packaged into virions or transported from cell to cell? Could it be posttranslational modifications of sc4, such as phosphorylation or dephosphorylation? If sc4 is not the viral MP, what is the MP? As is clear from studies of TSWV, appropriate mutational studies and cell-based systems are needed to investigate viral morphogenesis and movement, for both the nucleorhabdoviruses and the cytorhabdoviruses. LYNV has not been completely sequenced, but genome mapping studies suggest that it has a genome organization similar to that of SYNV (158). Based exclusively on ultrastructural studies of LYNV and barley yellow striate mosaic virus, replication of cytorhabdoviruses is proposed to occur in the cytoplasm in association with what appear to be ER membranes, and virions appear to assemble by budding into vesicles that may be derived from the ER (158) (see Fig. 21). These studies suggest that cytorhabdoviruses also use internal membranes—perhaps the ER—for assembly, and it is again proposed that nonenveloped viral RNPs move from cell to cell by an alternate route. The development of appropriate model cell-based systems for investigating both these genera of rhabdoviruses should help to define the principles involved in the adaptation of enveloped viruses to infecting plants.

Viruses with DNA Genomes

Caulimoviruses: Cauliflower Mosaic Virus

The *Caulimoviridae* comprises the plant-infecting pararetroviruses. The viruses in this family, like the *Hepadnaviridae* (see Chapter 86), have circular dsDNA genomes and replicate by a reverse transcription mechanism by way of a positive-sense ssRNA template. The two genera of *Caulimoviridae*—*Caulimovirus* (12 viruses) and *Badnavirus* (13 viruses)—are distinguished based on virion morphology (icosahedral or bacilliform) and genome organization (347). Given its dsDNA genome, CaMV, the type member of the caulimoviruses, was the first plant virus to be cloned and sequenced. Thus, it has been extensively characterized in terms of its molecular biology and host interactions. CaMV, in addition to providing what is still generally the promoter of choice for generating transgenic plants (the 35S promoter), has been a model for investigating the replication and gene expression strategies of the caulimoviruses in particular, and mechanisms of translational control in general. Caulimovirus particles are icosahedral (T=7), 45 to 50 nm in diameter, with the capsid being composed of subunits of a single protein, CP, which in CaMV exists in two processed forms of 37 kd and 44 kd. CaMV particles also contain minor amounts of three additional viral-encoded proteins: a 15-kd nucleic acid–binding protein, and a protease (PR) and reverse transcriptase (RT) that are synthesized as the PRO-RT polyprotein product of a single ORF. Most caulimoviruses are transmitted in nature by aphids in a noncirculative manner, neither circulating in nor infecting the vector. Although each virus has a fairly narrow host range, individual caulimoviruses cause serious yield losses in economically important crops, such as cauliflower, turnips, and blueberries (144,310). CaMV infects crucifers, including *Brassica* species, such as turnip and cauliflower.

The CaMV circular dsDNA genome is 8 kb and contains three discontinuities: two in the viral positive strand (same polarity as viral mRNA transcripts) and one in the complementary viral negative strand (Fig. 22). There is a short 5' overlap at each discontinuity, with ribonucleotides often attached to the 5' ends. These discontinuities are formed by strand displacement synthesis during reverse transcription of the 35S pregenomic positive strand RNA. CaMV encodes seven major ORFs (I to VII). Mutational studies show that ORFs I through VI are essential for viability and infectivity. These encode: the viral MP (I, 45 kd), n aphid transmission factor (ATF, II, 18 kd), a minor capsid component (pIII, 15 kd), a precursor of the capsid protein (pre-CP = GAG, IV, 56 kd), a polyprotein (V, POL, 80 kd) that is processed to an aspartic proteinase (PR) and reverse transcriptase (RT) with an RNase H domain (RH), and a multifunctional translational transactivator (TAV, VI, 62 kd) (144) (see Fig. 22). These functional assignments are supported by a large number of experimental studies. ORF I is essential for cell-to-cell movement and systemic infection of the plant. The encoded MP has been localized to unique large tubules that contain virus-like particles and extend from plasmodesmata in infected cells, and it can induce these tubules when expressed in cultured cells (208,261,340). ATF forms inclusion bodies in infected cells and has been shown to bind to virus particles. CaMV ATF mutants are infectious when mechanically inoculated onto plants, but they cannot be transmitted by aphids. It is not precisely known how ATF acts. However, aphids which are fed ATF can acquire and transmit ATF-defective CaMV, suggesting that ATF may interact

with the cuticular lining of the aphid stylet (307,310). pIII, found associated with virus particles, can bind DNA in a sequence-nonspecific manner and appears to function as a tetramer. It has been suggested that it compacts the viral genomic DNA during virion assembly (60,200). GAG, or pre-CP, as synthesized, contains highly acidic N- and C-terminal regions, which are removed by the viral aspartic proteinase (PR) to form the mature capsid proteins of 44 kd and 37 kd: the 37-kd protein is contained within the 44-kd protein sequence. It is not known whether one or both of these CP forms is the functional capsid protein (144). The polyprotein product of ORF V (POL = PR-RT) if expressed in *E. coli* or translated *in vitro* in reticulocyte extracts, self-cleaves into the N-terminal PR (20 to 22 kd) and C-terminal RT (56 kd). PR contains the consensus motif found in aspartic proteinases, and mutation of this motif destroys proteolytic activity and is lethal for the virus. PR processes both the POL polyprotein to PR and RT and the pre-CP (GAG) (341). The expected RNA:DNA replication intermediates and RT, activity have been identified in the cytoplasm of infected cells, and the RT activity has been characterized (27,262). TAV is a translational activator required for the 35S pregenomic RNA to be translated as a polycistronic mRNA (112,311). It also forms inclusion bodies, distinct from the ATF inclusions, that appear to be the site of virus assembly and reverse transcription. Virus particles, pregenomic RNA, and reverse transcriptase all copurify with these inclusions (262,315).

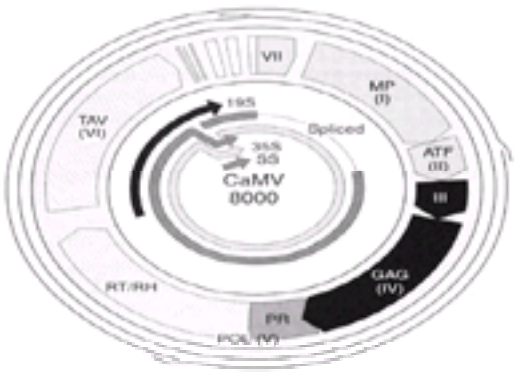

FIG. 22. Genome organization of cauliflower mosaic virus (CaMV). The open circular viral dsDNA with its overhangs (discontinuities) is indicated by the *outer two lines.* The arrangement of the open reading frames (ORFs) is shown on the main circle, with the six short ORFs within the 35S RNA leader indicated by *white boxes.* The 35S, 19S, short stop (SS) and essential spliced transcripts are each indicated by the *inner circular arrows.* (From ref. 144, with permission.)

Although the early events of caulimovirus uncoating are not well understood, it appears that upon infection, virus particles deliver the viral dsDNA to the nuclear pore, where it is released into the nucleus and the discontinuities are sealed by host enzymes to form a supercoiled minichromosome. Host RNA pol II complexes transcribe these minichromosomes. Transcription is unidirectional, using two viral promoters to produce two major capped and polyadenylated transcripts that are named for their sedimentation characteristics: the 35S RNA (also termed the *35S pregenomic RNA*), which is transcribed from the 35S promoter, and the 19S RNA, transcribed from the 19S promoter (Fig. 22 and Fig. 23). The relative amounts of these transcripts are determined by the promoter strength. The 35S promoter is very strong owing to the presence of several enhancer elements, which in combination make it a constitutive promoter in most plant cell types. The 19S promoter is relatively weak *in vitro*, but *in vivo* could be influenced by the enhancer elements within the 35S promoter region (54,91,129,249,250). The 19S RNA is monocistronic and is translated into TAV. The 35S RNA is translated into the remaining five essential proteins (MP, ATV, pIII, pre-CP [GAG], POL [PR-RT]) by two unusual mechanisms in eukaryotic cells: ribosome shunting (84,113) and reinitiation, the latter of which makes it functionally a polycistronic mRNA (112,311) (see Fig. 23). The 35S RNA has 180-nt terminal repeats and, similar to hepadnaviruses and retroviruses, functions both as the major viral mRNA and the template for reverse transcription to synthesize the viral dsDNA. The polyadenylation signal for both the 19S RNA and the 35S RNA is located 180 base pairs downstream of the transcription start site for the 35S RNA. The 180-nt terminal repeats at the ends of the 35S RNA are created by RNA pol II ignoring this polyadenylation signal on its first passage to transcribe around the circular genome and terminate on the second encounter with this signal. The polymerase will occasionally recognize the polyadenylation signal on its first encounter, thus producing a 180 nt “short stop” RNA, the function of which is not known (144) (see Fig. 22). Alternatively spliced transcripts of the 35S RNA have also been detected using reporter gene constructs in transiently transfected protoplasts and in CaMV-infected cells. All of these use an acceptor site within ORF II, but differ in using a donor site near the end of the RNA leader region or at sites within ORF I (Fig. 22). The function of these spliced transcripts is not known, but mutation of the common splice acceptor site suggests that splicing is essential for viral infectivity (176).

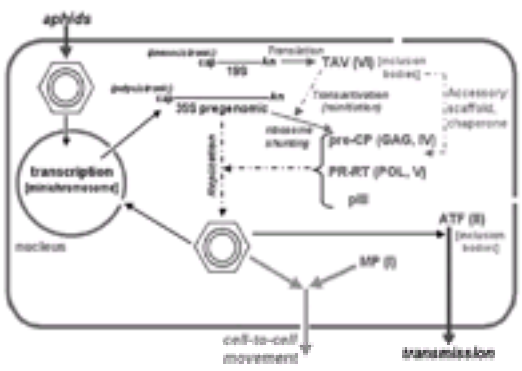

FIG. 23. Multiplication of cauliflower mosaic virus (CaMV).

Whereas the 19S RNA can be translated *in vitro*, the 35S RNA, and most of its spliced variants, cannot because of its polycistronic nature and a long highly structured 600-nt leader. This leader prevented *in vitro* translation of the 35S RNA until the recent development of a cell-free wheat germ system in which ribosome shunting could occur (138,308). Thus, most of the studies on the translation of the 35S RNA have been done by expressing appropriate dicistronic and polycistronic reporter gene constructs transiently in plant protoplasts or in transgenic plants. The earliest indication that the 35S RNA was polycistronic was the polar effects that certain mutations in ORF VII or *ATF* had on the expression of viral proteins encoded by the downstream ORFs (145 and citations therein). Most of the ORFs downstream of ORF VII are poorly expressed in protoplasts or transgenic plants unless TAV is present. In particular, transient expression studies with CAT or GUS reporter genes inserted in dicistronic constructs derived from the CaMV 35S RNA or at different sites along the 35S RNA transcript from figwort mosaic virus (also a caulimovirus) showed that these could be expressed, but only if TAV was provided in *cis* or in *trans* (112,311). Activation by TAV is specific for downstream ORFs and does not require virus-specific sequence elements, nor does TAV induce internal ribosome binding or ribosome shunting. Rather, TAV acts on ribosomes migrating through and apparently translating regions upstream of the reporter gene, thus suggesting that it acts by allowing ribosomes to reinitiate translation at a downstream ORF.

The 600-nt leader of the CaMV 35S RNA contains seven to nine short ORFs (sORFs) depending on the strain, and both chemical and enzymatic probing show this region to be highly structured (138) (Fig. 22 and Fig. 24). Normally in eukaryotic translation, the presence of such features will inhibit ribosome scanning unless there is an IRES (see Chapter 23) or the ribosomes can bypass or “shunt” around the sORFs and structured region. Expression studies with appropriate reporter gene constructs in protoplasts and transgenic plants first suggested that ribosome shunting is the mechanism by which translation is initiated on the first ORF (VII) in the CaMV 35S RNA (see Fig. 24). Of the six sORFs shown within the 35S RNA leader in Figure 24, A to D are only 2 to 8 codons each, but E and F are 26 and 33 codons, respectively. Transient expression studies first showed that some regions of the 35S leader are more inhibitory to translation than other regions or the intact 600-nt leader. In particular, the very short sORFs A to D do not inhibit translation of a downstream reporter gene, but E and F are strongly inhibitory to translation of ORF VII or a downstream reporter gene. Insertion of a stable stem-loop structure near the cap or within a duplication of the first 60 nt of the leader inhibits translation, but insertion of the stem-loop or the GUS coding sequence in the middle of the leader does not. That this is not a linear process was shown by expressing the capped 5' half of the leader and the 3' half fused to a CAT reporter gene as two distinct molecules in protoplasts: CAT was expressed only when both transcripts were expressed in the same cell. These studies suggested that ribosomes initiate translation on the 35S RNA by cap-dependent scanning, but can bypass or shunt around the central region of the leader. By inserting AUGs at different positions within the leader, the shunt donor site was located in the first 100 nt of the leader, past the termination codon of sORF A, and the shunt acceptor site was mapped to within sORF F (111,113). The development of an *in vitro* wheat germ translation system in which ribosome shunting can occur has led to a more detailed examination of the shunting mechanism (308). In particular, insertion of the leader between the coding sequences for GUS upstream and CAT downstream prevents expression of CAT activity, clearly showing that an IRES is not present within the leader sequence. By constructing an in-frame fusion of sORF F with the CAT coding sequence, the relative rates of scanning through the leader (translation of the longer F:CAT fusion protein) and shunting (translation of the shorter CAT protein) could be determined, and mutational studies showed that the structure of stem 1 (see *st1,* Fig. 24) is important for shunting to occur. Mutations that abolish stem 1 drastically reduce CAT expression, and compensatory mutations that restore stem 1 structure restore CAT expression. In fact, stem 1 and flanking sequences alone will allow shunting, and sORF A preceding stem 1 enhances shunting (84).

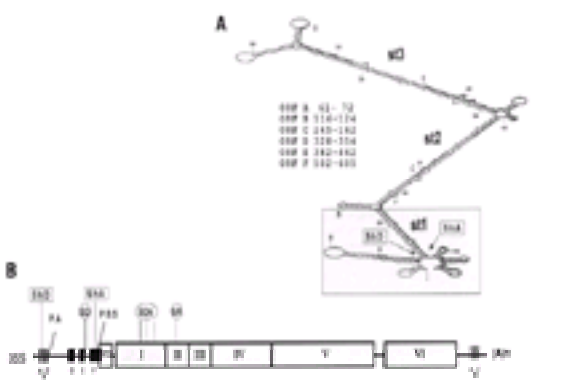

FIG. 24. A: Extensive secondary structure of the CaMV 35S RNA leader. Shunt donor (*ShD*) and Shunt acceptor (*ShA*) sites and stems (*st*) are indicated. **B:** CaMV 35S RNA. *Black boxes* represent small open reading frames. (From ref. 84, with permission.)

The importance of sORF A was further shown by constructing viruses with mutations that eliminated the various sORFs or structures within the leader. Viable mutants were obtained that were very delayed in the time of appearance of symptoms. Serial mechanical passage of these in turnip plants produced phenotypic revertants that resembled wild-type CaMV in their disease production. Analysis of these showed that sORF A and secondary structure within the central region of the leader are important for viral infectivity and thus presumably ribosome shunting (266). Further investigation of ribosome shunting by *in vitro* translation in reticulocyte as well as wheat germ extracts and expression of reporter constructs in plant protoplasts showed that proper translation and termination of a short upstream ORF is required for shunting to occur and that TAV increases shunting efficiency (137,267,295). Thus, the shunt-mediated translation appears to require reinitiation, which can be facilitated in the presence of TAV. As to the mechanism of ribosome shunting, a model has been proposed in which scanning 40S subunits and 80S ribosomes translating through sORF A stall when they encounter the stable hairpin structure. Proper termination of translation of sORF A by the 80S ribosomes promotes reinitiation, such that on release of the encoded peptide and dissociation of the 60S subunit, the reinitiation-competent 40S subunit skips over the stem and resumes scanning downstream (137). Why have this

elongated 480-nt hairpin in the middle of the leader in the first place, necessitating ribosome shunting at all? Yeast three-hybrid studies show that CP specifically interacts with a purine-rich sequence at the top of this elongated hairpin (128). Thus, ribosome shunting ensures, in the context of this structure, that translation of the 35S RNA and its encapsidation as a template for reverse transcription of the viral dsDNA can both occur.

CaMV replicates by reverse transcription of the 35S RNA. Unlike retroviruses, and more similar to hepadnaviruses, the CaMV dsDNA is packaged into virions, and it does not integrate into host chromosome during normal multiplication. Rather, it exists as autonomously replicating circular minichromosomes in the nuclei of infected cells. However, the mechanism of reverse transcription is more similar in several respects to that of the retroviruses (see Chapter 57) than the hepadnaviruses. Reverse transcription occurs in the cytoplasm. Yeast three-hybrid studies show that the zinc finger motif (C-X_2-C-X_4-H-X_4-C) and an adjacent basic domain in the central region of CP are essential for strong and specific interaction with the purine-rich sequence in 35S RNA leader. This is consistent with a model in which the 35S RNA is first encapsidated and then transcribed within the virus particle (128). Studies suggest that the acidic C- and N-terminal regions of pre-CP, which are cleaved by the viral PR, may regulate packaging of the 35S (pregenomic) RNA and nuclear targeting of the virus particles. Presence of the CP C-terminal acidic domain prevents interaction of the CP with the 35S RNA leader, suggesting that it may ensure that 35S RNA is available as mRNA until late in infection when sufficient virion proteins, including PR (ORF V), which cleaves this domain, are present (128). Cleavage of this C-terminal domain would allow CP binding to and encapsidation of 35S RNA, presumably together with bound RT. Like retroviruses, reverse transcription is initiated from a tRNA primer ($tRNA_{met}$), which binds to a primer binding site on the 35S RNA at a position ~600 nt downstream of the 35S promoter, which is ~400 nt downstream of the end of the first terminal repeat at the 5' end of the 35S RNA. Synthesis of the complementary DNA negative strand proceeds to the end of the 35S RNA, where the template switch occurs as the 3' end of this newly synthesized negative strand DNA melts from the 5' end of the 35S RNA template and anneals to the terminal repeat at the 3' end of the same or another 35S RNA. Synthesis of the DNA negative strand continues along the 35S RNA, passing the primer binding site and the 5' end of the of the molecule (overshooting) to create the 8-nt discontinuity or terminal repeat at the ends of the negative strand DNA. As this proceeds, regions of the RNA template that have been reverse transcribed are digested by RNase H, except for oligo(G) stretches—two for the genome shown in Figure 22—which are resistant and serve as primers for DNA positive strand synthesis. Again, the polymerase will overshoot, creating the two discontinuities or short terminal redundancies in the viral positive strand DNA (27,262) (see Fig. 22). Encapsidation of the 35S RNA and reverse transcription within the virus particles appear to occur within the TAV inclusion bodies, and it has been suggested that the TAV matrix may provide accessory scaffolding or chaperone functions important in virus assembly. At this point, the virus particles with their dsDNA can either target back to the nucleus, contributing to the transcription pool, or move from cell to cell, apparently through the plasmodesmal-associated tubules that contain the viral MP (see Fig. 23). The fully processed virus CP contains an N-terminal NLS, which is exposed on the surface of virus particles but is masked if the N-terminal acidic domain of pre-CP is present. Thus, the presence of the N-terminal acidic domain keeps pre-CP in the cytoplasm, where it can be targeted to inclusion bodies for virus assembly. Once particles are assembled, cleavage of this domain by the viral PR exposes the CP NLS, and the virus particle can be transported to the nucleus (201). The CP is also phosphorylated by a host casein kinase II, which apparently stabilizes it (201), and it has been reported to be methylated and glycosylated. Not addressed by this model is the question of whether the presence of the N-terminal acidic domain of pre-CP or other CP modifications may play a role in the virus particles being directed to move from cell to cell or bind ATF for aphid acquisition.

Geminiviruses

The *Geminiviridae* are named for their unusual capsid structure. Virions in this family have paired incomplete (T=1) icosahedral capsids (gemini = twin moons), ~18 × 30 nm, composed of subunits of a single CP (29 kd) (Fig. 25). The viral genomes are covalently closed circular ssDNA (~2.5 to 3.0 kb), with a single ssDNA molecule encapsidated in each geminate particle (193). *Geminiviridae* comprise three genera based on genome organization, vector specificity, and host range properties (Fig. 26). Mastreviruses (type member, maize streak virus [MSV]) have a single genomic component of ssDNA, are transmitted by different leafhopper species and, with two exceptions (bean yellow dwarf virus [BYDV] and tomato yellow dwarf virus [TYDV]), infect monocotyledonous plants. Begomoviruses (type member, bean golden mosaic virus) are transmitted by whiteflies (*Bemicia tabaci,* A and B biotypes), infect dicotyledonous plants and, with a few exceptions (e.g., some isolates of tomato yellow leaf curl virus [TYLCV]), have two distinct genomic components (A and B) that are both required for infectivity and separately encapsidated. TYLCV has a single genomic component that is similar in its overall organization and sequence of the CP to the A component of the begomoviruses. Curtoviruses (type member, beet *curly top* virus [BCTV]), like mastreviruses, are transmitted by leafhopper species (except for tomato pseudo-curly top virus, which is transmitted by planthoppers) and have a single genomic component, the organization of which looks like a hybrid of the mastrevirus virion-sense (V) ORFs and the begomovirus complementary-sense (C) ORFs (see Fig. 26). Like the begomoviruses, curtoviruses infect dicotyledonous plants (34). With the notable exception of BCTV, individual *Geminiviridae* have narrow host ranges. Nevertheless, they have emerged in recent years as one of the most serious groups of plant viral pathogens worldwide because of the widespread expansion of the B biotype of *B. tabaci* and the ability of viruses in mixed infection to give rise to new strains and isolates through recombination (141,150).

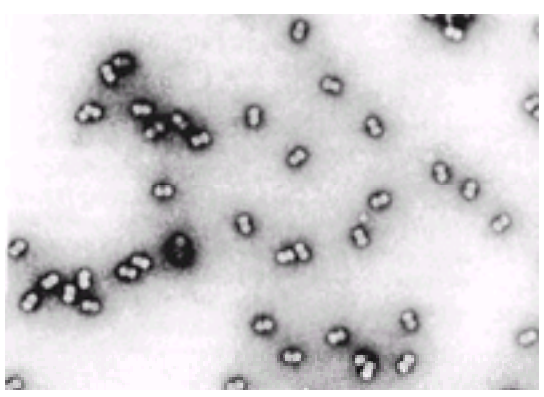

FIG. 25. Electron micrograph of virions of bean golden mosaic virus, a begomovirus. (From ref. 5, with permission.)

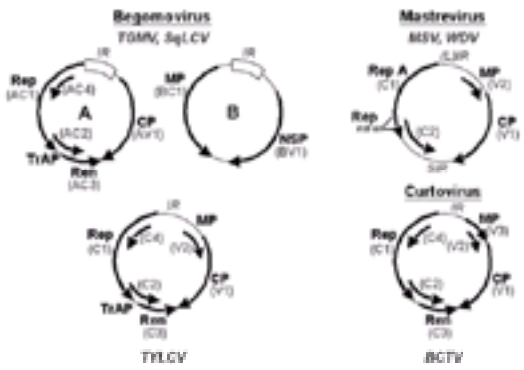

FIG. 26. Genome organization of different genera in the *Geminiviridae*.

Viral genes are transcribed bidirectionally from an intergenic region (IR), named the *long intergenic region* (LIR) in mastreviruses (see Fig. 26). Genome sequences for several begomoviruses first showed that this 200-nt IR was identical in the A and B components, and thus it has been called the *common region* in these bipartite viruses (193). The encapsidated ssDNA is the virion-sense positive strand. Viral ORFs were traditionally named based on their being encoded on the virion-sense (V) strand or the complementary-sense (C) strand, which for some viruses were referred to as the *rightward* (R) or *leftward* (L) transcribed ORFs (see *arrows* in Fig. 26). For example, AC1 and AL1 referred to the same ORF. Adding to this confusion, ORFs with the same name did not always encode the same function. Thus, CP was encoded by the AV1 or AR1 ORF in begomoviruses, but by ORF V2 in MSV. The nomenclature in Figure 26 represents an emerging consensus for naming the viral ORFs. For clarity, individual gene functions, when known, will be referred to. These are summarized in Table 5 for the different virus groups, based on mutational and infectivity studies, transient expression assays in protoplasts, and cell-based assays in infected and transgenic plants.

Function	Begomovirus[a] TGMV, SqLCV, ACMV	TYLCV	Curtovirus[a]	Mastrevirus[a]
Replication	Rep (AL1, AC1) Ren (AL3, AC3)	Rep (C1) Ren (C3)	Rep (C1) Ren (C3)	Rep (C1)[b] Rep A (C1)
Transcription				
Represses Rep	Rep (AL1, AC1), (AL4, AC4)			
Activates late (V) genes	TrAP (AL2, AC2)	TrAP (C2)		Rep A (C1)
Encapsidation and Insect Transmission	CP (AR1, AV1)	CP (V1)	CP (V1)	CP (V1)
Movement	MP (BL1, BC1) NSP (BR1,BV1)	MP (V2) CP (V1)	MP (V2) CP (V1)	MP (V2) CP (V1)
Host activation[c]	Rep (AL1, AC1)		C4	Rep A
Symptoms	MP (BL1, BC1)	C4	C4	MP (V2)
Suppress host defenses	TrAP (AL2, AC2)		C2	
Regulate viral ssDNA accumulation	CP (AR1, AV1)	CP (V1) MP (V2)	V2	CP (V1)

TGMV, tomato golden mosaic virus; SqLCV, squash leaf curl virus; ACMV, African cassava mosaic virus; TYLCV, tomato yellow leaf curl virus; WDV, wheat dwarf virus; MSV, maize streak virus; BCTV, beet curly top virus; PCNA, proliferating cell nuclear antigen.

[a]Functions have been determined based on mutational, infectivity, biochemical and cell biological studies with these, as well as several other, bipartite geminiviruses. For every function has been shown for each virus: TGMV, MSV, and ACMV have been models for replication. TGMV, MSV, and MSV have been models for transcription. SqLCV has been a model for virus movement. BCTV has been a model curtovirus. See recent reviews for additional details and references [24, 102, 132, and 194].

[b]Activation of PCNA transcription, induction of cell division, and/or trans-Rb based on studies with TGMV, BCTV, and [65].

TABLE 5. *Geminivirus gene function*

The bipartite begomoviruses, such as TGMV, ACMV, and squash leaf curl virus (SqLCV), encode proteins needed for replication (Rep, Ren), transcriptional regulation (TrAP), and encapsidation (CP) on their A component, and two essential movement proteins (MP and NSP) on the B component (see Fig. 26 and Table 5). In some begomoviruses, there is an additional ORF, *AC4,* which for TGMV has been reported to repress transcription of *AL1* weakly in transient expression assays in plant protoplasts. However, mutational studies of TGMV show that *AC4* is dispensable for virus infection (94,127,269). Mutational and transient expression studies show that Rep (replication initiation) is essential for virus replication. Ren (replication enhancer) is not essential for replication, but it interacts with Rep to increase the efficiency of viral replication (97,312,333). Using appropriate GUS reporter gene constructs in transiently expressing plant protoplasts, TGMV TrAP (transcriptional activator protein) has been shown to activate transcription of the V genes encoding CP and NSP on the A and B component, respectively. TrAP binds ssDNA in a sequence-nonspecific manner, and only weakly binds dsDNA (133,246,330). The biochemical properties of TGMV TrAP expressed from a baculovirus vector in insect cells have been studied. TrAP is a phosphoprotein that binds and requires zinc for optimal interactions with ssDNA. The highly acidic C-terminal domain of TrAP acts as a transcriptional activator. When fused to the DNA binding domain of the yeast transcriptional activator GAL4, it specifically activates expression of a *CAT* reporter gene driven by a minimal adenovirus E1B promoter with GAL4 binding sites in mouse cells, or of an *E. coli lacZ* gene expressed from the GAL1 promoter in yeast (133). Thus, it has been suggested that TrAP, like adenovirus E1A (289R) or herpes simplex virus VP16, may act as a transcriptional coactivator, interacting with cellular transcription factors bound to sequence-specific promoter elements to cooperatively recruit the basal transcription machinery. Transcriptional regulation by TrAP is complicated. Analysis of the expression of GUS reporter gene constructs in transgenic plants shows that TrAP activates transcription of the CP promoter in mesophyll cells but derepresses the expression of this promoter in phloem cells (331). CP is required for encapsidation, and studies in which the CP of the curtovirus BCTV was substituted for that of the begomovirus ACMV showed that CP is required for insect acquisition and transmission (31) (see Plant-to-Plant Transmission). The B component encodes two movement proteins because, like most animal DNA viruses, geminiviruses replicate in the nucleus. Thus, NSP and MP are required to cooperate in moving the viral genome across the nuclear

envelope, through the cytoplasm, and across the cell wall. Studies with SqLCV show that NSP is a *n*uclear shuttle *p*rotein that binds viral ssDNA and transports it between the nucleus and cytoplasm. Like many other rapidly shuttling nuclear proteins, including HIV Rev and adenovirus E1B-55 kd and E4-34 kd, SqLCV NSP contains nuclear localization signals and a leucine-rich nuclear export signal (NES). MP traps NSP-genome complexes in the cytoplasm and, analogous to the MPs encoded by the RNA viruses discussed in this chapter, acts to move these across the cell wall through what appear to be modified plasmodesmata (194). The bipartite begomovirus CP is not required for systemic infection of natural hosts. Mutational and functional studies for TYLCV, including the finding that TYLCV can complement a TGMV TrAP mutant in tobacco protoplasts, suggest that each of the ORFs on its single genomic component encodes functions analogous to the bipartite virus A component (133,164,246,247,370), except for the extra *V2* (MP) ORF and perhaps *C4* (see Fig. 26). Mutational studies suggest that *V2* may encode the MP, and in contrast to the bipartite begomoviruses, CP is also needed for viral movement. *C4* affects TYLCV infection, depending on the host, showing that it is does not encode an essential movement protein. It appears to play a role in the development of symptoms (163,370).

Mastreviruses, such as MSV and wheat dwarf virus (WDV), while having a distinct genome organization from the begomoviruses, encode proteins that carry out analogous functions in viral replication (Rep), transcriptional activation (Rep A and/or Rep), movement (MP), and encapsidation and insect transmission (CP) (see Fig. 26 and Table 5). One major distinction from the begomoviruses is the processing of viral transcripts. All geminiviral genomes are bidirectionally transcribed to produce mRNAs that are polyadenylated and are likely to be capped; and all of the viral promoters are in the IR (LIR), except those for *TrAP* and *Ren,* and perhaps *AC4,* in begomoviruses. For the TGMV A and B components, a single unspliced V-sense transcript is translated into CP or NSP. The pattern of C-sense transcripts is complicated, but only TrAP and Ren appear to be translated from a bicistronic mRNA, and none of the transcripts is spliced (34,132). In contrast, splicing is essential in MSV and WDV. Rep, which is essential for viral replication, is translated from a spliced transcript that fuses ORFs C1 and C2 (306,377) (see Fig. 26). The corresponding unspliced transcript is translated into Rep A (C1), which shares ~200 N-terminal residues with Rep and alone, or together with Rep, activates expression of the V-encoded genes (45,53,142). This is analogous to the role of TrAP in activating *CP* and *NSP* transcription, although the mechanisms may not be identical. For WDV, only a single V-sense transcript has been detected that would be translated into MP and CP, but how CP is translated is not known. In MSV, there are two V-sense transcripts that initiate either 1 or 142 nt upstream of the MP coding sequence. Both of these are spliced within the MP coding sequence. It appears that MSV CP is translated from an abundant spliced form of the former (shorter) transcript, and MP is translated from a low abundance unspliced form of the latter with a 142 nt leader sequence (377). Mutational studies show that both MSV MP and CP are needed for systemic infection (28,195), and transient expression studies in plant protoplasts or plants biolistically bombarded with a GFP:MP fusion suggest that MSV MP has an analogous function to MP in the bipartite begomoviruses, but CP carries out the nuclear shuttling role of NSP (185,209). MSV MP is predicted to have a transmembrane domain, making it quite distinct from the bipartite virus MP. The curtovirus BCTV, like the mastreviruses, produces several V-sense transcripts, consistent with its complex genome organization (see Fig. 26). Based on mutational and transient expression studies, BCTV Rep (C1), Ren (C3), and CP (V1) are analogous to these same proteins in begomoviruses or mastreviruses (148,149,324). Like the mastreviruses, BCTV MP (V3) and CP (V1) are both required for systemic infection and thus may perform analogous roles to the SqLCV MP and NSP, or the MSV MP and CP, respectively. BCTV C2 is not analogous to TrAP in that it is not a transcriptional activator. However, both BCTV C2 and TrAP may play a similar role in counteracting host defenses against infection (149,356) (see Plant Responses to Virus Infection). C4 appears to induce cell division in BCTV-infected vascular cells and could function in inducing cells into S phase, as does Rep (189). V2 is unique to the curtoviruses and has been reported to be involved in regulating viral ssDNA accumulation (324).

Following introduction by the vector, how the viral genome is uncoated and delivered to the nucleus is not known. The identification of viral circular dsDNA as well as genomic ssDNA in infected plants was the first indication that the viral genome replicates through a dsDNA intermediate, as one might expect (Fig. 27). Since virion ssDNA is infectious, it appears that the dsDNA replicative form is synthesized from the incoming viral ssDNA genome (the positive strand) by host DNA replication enzymes, with cellular DNA polymerase a-primase complex also synthesizing the primer for synthesis of the complementary DNA strand. In the mastreviruses, such a primer—a ~75-to-80 nt oligodeoxyribonucleotide that contains several ribonucleotides at its 5' end—is found bound to the viral genome within the *small intergenic region* (SIR) in virions (see Fig. 26). This serves as a primer for synthesis of the viral complementary DNA strand *in vitro* (34,193). Such a primer is not present in virion ssDNA of begomoviruses or curtoviruses, suggesting that it would have to be synthesized by host enzymes upon infection. Studies of ACMV replication intermediates suggest that such an RNA primer may be synthesized within the IR (302). As shown in Figure 27 for the begomoviruses, geminivirus multiplication involves the same nucleocytoplasmic trafficking of viral mRNAs and proteins, and the same temporal regulation of viral gene expression, as the multiplication of nuclear-replicating animal DNA viruses. It is assumed that host RNA pol II complexes transcribe the viral dsDNA template into viral mRNAs. These are then transported to the cytoplasm, where they are translated. The C-sense genes (*Rep, TrAP, Ren, MP,* and *C4,* if present) are transcribed first. With the exception of the plant virus–specific MP, these correspond to the early genes found in DNA animal viruses and phage, encoding nonstructural proteins for regulating viral gene expression and initiating viral DNA replication. Trap, Rep and Ren are transported to the nucleus, where Rep and Ren initiate synthesis of viral genomic ssDNA by rolling circle replication, apparently in much the same way as the ssDNA phage fX174 (see Chapter 22) (301,326). Probably early in infection, the newly synthesized viral ssDNA positive strands are copied to make additional dsDNA templates for transcription. TrAP (Rep A, Rep, or both, in mastreviruses) will activate transcription of the *CP* and *NSP* (late) genes, and as Rep accumulates, it will repress its own transcription (147,332). CP and NSP are synthesized in the cytoplasm and transported to the nucleus. Studies with SqLCV suggest that initially, CP sequesters genomic ssDNA away from the viral dsDNA replication pool without encapsidating it, to make it available for NSP binding (278). NSP–genome complexes are exported to the cytoplasm, where MP will trap them and move them across the cell wall. As CP accumulates, virus particles will be assembled in the nucleus (34,193). In mastreviruses, and perhaps curtoviruses, CP appears to serve a dual role of exporting newly replicated viral ssDNA genomes to the cytoplasm for movement by MP and encapsidating these into virions within the nucleus for insect transmission (185,209).

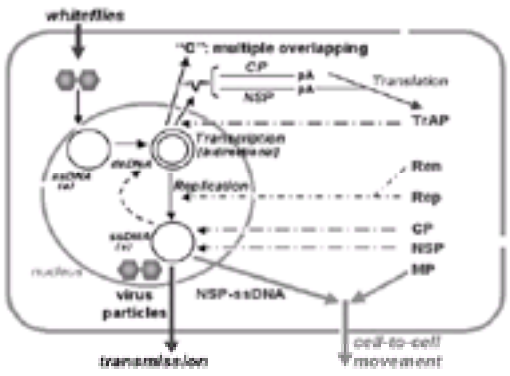

FIG. 27. Multiplication of begomoviruses.

The sequence identity of the IRs (common regions) in the A and B components of the bipartite begomoviruses such as TGMV and ACMV first suggested that the viral replication origin was located within this region. This was further reinforced by the fact that the IR (or LIR) in all geminiviruses contains a potential stem-loop structure with a conserved nonanucleotide sequence in the loop, 5'-TAATATTAC-3', which resembles the origin for positive strand synthesis in fX174 and bacterial plasmids that replicate by a rolling circle mechanism. Two approaches first showed that geminiviruses replicate by this mode. Two-dimensional gel electrophoresis of extracts from ACMV-infected plants identified the expected DNA intermediates for rolling circle replication (301). In separate studies, plants were inoculated with plasmids that contained heterodimers of WDV or ACMV, or the genomes of two strains of BCTV cloned as tandem direct repeats in the two possible combinations. In the BCTV studies, two predominant types of progeny genomes were recovered, depending on the order in which the two BCTV strains were cloned, and the sequences of these progeny were consistent with rolling circle replication initiating within the conserved stem-loop structure in the IR (326). The same conclusion was drawn in the WDV and ACMV studies (139,323), and the latter mapped the initiation site for viral positive strand ssDNA synthesis to the conserved nonanucleotide sequence TAATATT¯AC. *In vitro* biochemical studies show that Rep from WDV, TYLCV, and TGMV is an endonuclease that nicks virion sense ssDNA at this same position (140,191,255). Further biochemical characterization of WDV and TYLCV Rep using appropriately end-labeled ssDNA substrates show that Rep is also a ligase, capable of catalyzing a strand transfer reaction following cleavage at the viral replication origin *in vitro*. The reaction intermediate is Rep covalently linked to the 5'-end of the cleaved DNA through a phosphodiester bond to tyrosine-103, which identifies this residue as the one mediating DNA cleavage (140,190,191). Thus, analogous to fX174 rolling circle replication, these studies suggest that Rep nicks the viral origin in the positive strand of the dsDNA to initiate replication and remains bound to the 5' end of the nicked strand as a new virion-sense ssDNA is copied from the complementary strand, presumably by host DNA replication complexes. Rep is also the terminase, with its endonuclease and ligase activities resolving the nascent virion ssDNA into genome-length units and reinitiating synthesis of a new ssDNA positive strand after each round of rolling circle replication. Although TYLCV and TGMV Rep have ATPase activity *in vitro*, this activity is not DNA dependent, and Rep has only weak homology to consensus helicase motifs.

The conserved potential stem-loop structure containing the invariant nonanucleotide sequence is essential for replication (197,255) and the only element common to the positive strand origins of geminiviruses. However, geminivirus replication origins are, in general, virus specific, a consequence at least in part of Rep being a sequence-specific dsDNA binding protein. The TGMV Rep binding site is a 13-bp element that contains two pentanucleotide repeats (*underlined*): 5'-GGTAGTAATAGGTAG-3'. It is located upstream of the conserved potential stem-loop, between the TATA box and transcriptional start site for Rep mRNA, and Rep binding to this motif also represses Rep transcription (reviewed in 132). Related but not identical elements located in a similar position are also found in the IR of curtoviruses and other begomoviruses, and the Rep binding site is necessary, but not sufficient, for virus-specific origin recognition in these viruses (51,104). The Rep binding site and a palindromic AG motif, located between the binding site and conserved potential stem-loop, are also essential for origin function in TGMV, (132). Mutations in the TATA box of the Rep promoter, a G box motif, and a CA motif decrease the efficiency of TGMV replication, but whether the contribution of these sequences involves binding of transcription factors or other host factors has not been determined (254). TGMV appears to bind DNA as a dimer but exists in solution as an octamer.

The modular structure of the geminivirus positive strand replication origin is also evident in studies of WDV, although there are multiple rather than a single Rep-binding site (consensus: GTGTGAN$_{22\text{-}23}$GTG(G)TC) (130). A detailed study of WDV Rep binding to its own LIR using gel-shift assays, electron microscopy, and DNase footprinting identifies three distinct Rep-DNA complexes: two high-affinity complexes located in the regions of the two divergent TATA boxes for C-sense and V-sense transcription (see Fig. 26), and a low-affinity complex that assembles in the region containing the conserved stem-loop under conditions supporting site-specific cleavage of the invariant sequence TAATATT¯AC (45). The WDV stem-loop would form a dsDNA region containing the sequence GTGG(T)GG, and it is proposed that this half binding site directs formation of the low-affinity complex, which would be capable of producing the sequence-specific cleavage within the loop. It is also proposed that the high-affinity complexes in the regions of the V-sense and C-sense TATA boxes may function, respectively, in up-regulation of V-sense transcription and repression of C-sense transcription, although the latter has not been shown to be a property of mastrevirus Rep. The latter high-affinity complex is essential for origin activity, suggesting that a Rep oligomeric complex formed at this site could also contact the low-affinity site, thus bending the DNA and positioning the Rep complex to initiate replication by site-specific nicking of the positive strand (45). A similar bent structure has been proposed for TGMV Rep, mediated by Rep–Ren interactions (132). The DNA binding domain is present in both WDV Rep and Rep A. Thus, an interesting possibility is that Rep A–Rep hetero-oligomers, as well as homo-oligomers of each protein, have the potential to finely regulate different aspects of viral replication and transcription. The involvement of cellular proteins in any or all of these interactions is one area yet to be explored. The situation described for WDV Rep interacting with the LIR resembles in a number of respects that of SV40 large T interacting with the viral origin region (see Chapter 63).

A problem that geminiviruses have in common with the majority of animal DNA viruses is that fully differentiated plant cells lack detectable levels of the DNA replication enzymes that the virus will need for its own replication. DNA replication and cell division in mature plants is restricted to meristems at the growing points of the plant, developing leaves and roots, and the cambium that gives rise to the vascular system. Infection by a number of geminiviruses, such as SqLCV, BCTV, and Abutilon mosaic virus (AbMV), is restricted to the phloem. Studies with SqLCV suggest that, in this situation, the virus replicates in actively dividing procambial cells (developing phloem cells) that will differentiate into phloem (369). Other geminiviruses, such as TGMV and MSV, can infect a variety of differentiated plant cells, and studies suggest that these viruses, similar to DNA animal viruses, may induce cells to synthesize S-phase replication enzymes by a number of possible mechanisms, but without necessarily inducing cell proliferation. Studies of TGMV-infected tobacco plants and of transgenic plants that express TGMV Rep showed that Rep induces synthesis of proliferating cell nuclear antigen (PCNA), the processivity factor for DNA polymerase d (240), although the cells are not induced to divide. Whether this is a direct or indirect effect of Rep on PCNA transcription is not known. A common strategy of DNA animal viruses such as SV40, adenoviruses, and some human papillomaviruses, is to induce cells into S phase by encoding an immediate early or early protein with the consensus LXCXE motif that will bind to the pocket of the tumor suppressor Rb (and the related p107 and p130) to sequester Rb or target it for degradation (see Chapter 63 and Chapter 67). Plant proteins related to RB have been identified (termed *RBR*, for Rb-related protein). The Rep and Rep A of mastreviruses contain an LXCXE motif, and WDV Rep A (but not Rep) interacts with a plant RBR by means of this motif in yeast two-hybrid assays. The functional significance of this interaction is suggested by studies in wheat protoplasts. Mutation of the LXCXE motif in RepA/Rep complexes reduces the ability of WDV to replicate in these cells. Furthermore, wild-type WDV replication is reduced when these protoplasts are cotransfected with a plasmid that will produce high levels of either the maize RBR ZmRb1 or the human pocket protein p130 (381,382). TGMV Rep has also been reported to interact with a maize RBR in yeast two-hybrid studies, or using a GST pull-down assay to identify complexes when Rep is coexpressed with a GST:RBR fusion protein in insect cells (2). However, this TGMV Rep–RBR interaction appears to be about 10-fold weaker than that of SV40 large T with RBR (179). Begomovirus Rep proteins do not contain the pocket binding motif LXCXE. Deletion studies map the interaction domain in TGMV Rep to 80 residues that overlap the DNA cleavage/ligation, DNA binding, and oligomerization domains of Rep. These 80 residues have no homology to any known plant RBR binding proteins or any other proteins, except for begomovirus Rep proteins, suggesting that whatever the sequences involved in this RBR interaction, it is a novel or previously unrecognized motif (179). Additional studies should establish whether these Rep proteins directly interact with RBRs *in vitro*. To date, there is no evidence for direct interaction of WDV Rep or TGMV Rep with RBRs in plant cells, nor have the plant RBRs been shown to function in cell cycle control in plants as do Rb and other pocket domain proteins in mammalian cells. The geminiviruses are good models for investigating these aspects of cell cycle control, as well as regulation of DNA replication in plant cells.

VIRUS MOVEMENT

For virus infection to disseminate throughout the plant, the virus first moves from cell to cell within the inoculated leaf and enters the vascular system. For the majority of plant viruses, with the exception of phloem-restricted viruses like the luteoviruses and certain geminiviruses, this involves moving from infected mesophyll cells to bundle sheath cells, and from these into phloem parenchyma and/or companion cells, from which the virus will enter the sieve elements. From the sieve elements, the virus can infect additional sites within the inoculated leaf, as well as follow photoassimilate flow to move to distant leaves and systemically infect the plant (242) (see Fig. 5). Phloem-restricted viruses appear to move locally between companion cells, phloem parenchyma, and bundle sheath cells, and from leaf to leaf through the sieve elements. Some viruses also move from leaf to leaf through xylem. The study of plant virus-encoded MPs has revealed how viruses can alter plasmodesmata to move from cell to cell and enter phloem tissue. We understand less about how viruses enter into and exit from sieve elements or the xylem to systemically invade the plant.

Movement proteins do more than simply move the viral genome across the barrier of the plant cell wall. They coordinate replication of the viral genome with its directed movement within, as well as between, plant cells. In doing this, MPs use the cellular machinery for trafficking macromolecules. The final act of crossing the cell wall is preceded by a series of regulated events in which MPs interact not only with replicating viral genomes but also with the endomembrane system, the cytoskeletal network, and in the case of geminiviruses, the nuclear import and export machinery. Thus, the study of MP function in the past decade has been to a large extent an investigation of intracellular and intercellular transport in plants. Genetic studies have established that MPs are critical determinants of plant virus host range and pathogenic properties. Thus, as knowledge has been gained about MP function, this has also suggested new approaches for engineering virus-resistant plants.

Approaches to Investigating Virus Movement

A variety of approaches, each designed to address different questions, have been used to investigate MP function (reviewed in 43 and 194). Genetic studies identified the viral gene(s) encoding the MP(s) and defined the role of the MP(s) in infectivity, host range, and pathogenesis. MP null mutants were noninfectious in all host plants, but could replicate and assemble virions in protoplasts. Partially defective MP missense mutants, such as alanine-scanning mutants, could be altered in their host range phenotype, still infecting some host plants but not others, and produce attenuated symptoms. This role in pathogenesis was underscored by the finding that transgenic plants that expressed one of a number of viral MPs phenotypically resembled virus-infected plants. By inserting a *GUS* or *GFP* reporter gene into the viral genome, the precise stage at which virus infection was blocked could be determined. This approach identified the path followed by the virus in infecting a leaf and moving long distance from leaf to leaf, and the role of other proteins, such as CP, in affecting virus movement locally or systemically could also be examined (see Fig. 5). Immunogold labeling of systemically infected leaves or protoplasts, usually using antisera raised against MPs overexpressed from plasmids in *E. coli,* and subcellular fractionation of infected plant tissue provided information about MP function based on where the MP was found. In virus-infected or transgenic plants that expressed the MP, some MPs encoded by viruses like TMV or red clover necrotic mosaic virus (RCNMV; a dianthovirus) were localized to plasmodesmata that were not morphologically altered, and there was no evidence of virus particles being present. The MPs encoded by other viruses like CaMV and TSWV were localized to tubules that extended from what appeared to be altered plasmodesmata, and virus-like particles were associated with or within these tubules, consistent with a

requirement for CP in cell-to-cell movement. For PVX, virus particles were associated with “swollen” plasmodesmata, but no tubules were present. Consistent with this association with plasmodesmata, most viral MPs (with the exception of SqLCV NSP) cofractionated with cell wall and plasma membrane fractions from infected or transgenic plants. The TMV 30-kd MP and SqLCV MP also cofractionated with ER membrane. Indirect immune fluorescence staining of plant protoplasts infected with the virus or expressing the viral MP and confocal microscopy further showed association of the TMV MP with microtubules, actin filaments, and ER membrane, and the SqLCV MP and NSP with ER membrane and nuclei, respectively. *In vitro* binding assays showed that a common property of most viral MPs was the ability to bind nucleic acids cooperatively and in a sequence-nonspecific manner, consistent with their role in moving the viral genome. Thus, as first shown for the TMV and RCNMV MPs, the MPs encoded by many positive-sense RNA viruses bound ssRNA and ssDNA *in vitro*. The begomovirus SqLCV NSP was shown to be an ssDNA binding protein. For viruses, such as TSWV, in which CP is also required for local cell-to-cell movement, the MP (NSm) has been shown to interact with the nucleocapsid protein (N).

The dynamics of MP function and the effects of MPs on plasmodesmata have been investigated using two basic approaches in plants and model studies in plant protoplasts. Dye-coupling studies in which fluorescently tagged dextrans of different sizes were microinjected into tobacco mesophyll cells of transgenic plants that expressed an MP, or co-injected with an *E. coli*– expressed MP into mesophyll cells in leaves of wild-type plants, were designed to test a particular property of MPs, namely their ability to affect the gating properties of plasmodesmata in the absence of virus infection (Fig. 28). By microinjecting fluorescently labeled MP, or unlabeled MP together with RNA or DNA fluorescently labeled with TOTO-1 iodide, the movement of the MP itself or its ability to move nucleic acids in *trans* could also be tested. As first shown for TMV and RCNMV, the ability to increase the size exclusion limits of plasmodesmata was a common feature of MPs encoded by a number of plant viruses, and the MPs could themselves move from cell to cell and facilitate movement of nucleic acids as well (110,361,376). Concerns about possible artifacts as the result of the high pressure microinjection techniques used in these studies, as well as the effects of posttranslational modifications (most, if not all, MPs are phosphorylated), led to the examination of GFP:MP fusion proteins expressed within mesophyll cells from plasmids that were introduced by biolistic bombardment, or expressed from a PVX vector (Fig. 29**A**), with generally the same results (156). A complication in all of these studies was the growing recognition that the gating properties of plasmodesmata were developmentally regulated and that large proteins could move between mesophyll cells at certain developmental stages (156,252). This, and mutational and subcellular fractionation studies that showed that MP expression and function were regulated during infection, led to investigations of mesophyll cells in plants, and plant protoplasts, infected with a virus that expressed either free GFP or a GFP:MP fusion protein (reviewed in 194). Using confocal microscopy, in combination with immunostaining for appropriate marker proteins, the TMV MP was shown to form specific associations with microtubules and microfilaments, as well as the ER, both in infected protoplasts and plants (134,218,224,284). Time course studies could be done in single protoplasts embedded in agarose, or in expanding local lesions on leaves inoculated with the GFP-expressing TMV, because the visibly expanding necrotic lesion and GFP allowed the precise identification of the infected cells visually and by confocal microscopy (134,218) (Fig. 30). These studies showed that MP function was regulated. MP did not move beyond the leading edge of the infection front, nor were the gating properties of plasmodesmata altered in cells beyond the expanding lesion, in contrast to the results of microinjection and bombardment studies. In addition, the size exclusion limits of plasmodesmata early in infection (leading edge of the lesion) were increased so that 10-kd dextrans would move from cell to cell, but these had returned to normal late in infection (center of lesion). The associations of the MP with the cytoskeleton and endomembrane system were also found to be temporally regulated, as the MP associated with replicated viral RNA at ER-membrane derived sites and moved the genomes along microtubules and actin filaments to plasmodesmata (134,251,284). Other aspects of the dynamics of movement and subcellular associations could also be studied in protoplasts expressing viral MPs. The MP encoded by TSWV, CaMV, and other viruses was shown to induce the formation of tubules in transfected protoplasts (reviewed in 194), and the nuclear shuttling of SqLCV NSP and its interactions with MP to redirect NSP to the periphery of the cell were also shown (298,368).

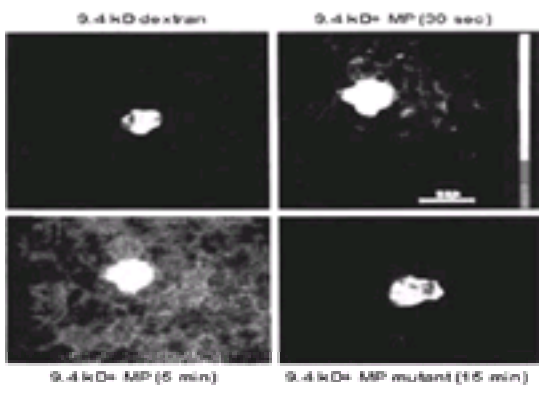

FIG. 28. Dye-coupling studies of red clover necrotic mosaic virus (RCNMV) movement protein (MP) co-injected with 9.4-kd fluorescently tagged dextran into tobacco mesophyll cells. The dextran, when injected alone or with a nonfunctional MP mutant protein, remains in the microinjected cell. When co-injected with wild-type MP, it rapidly moves to surrounding mesophyll cells, indicating that the plasmodesmal gating properties have be altered to allow the passage of larger molecules. (From ref. 110, with permission.)

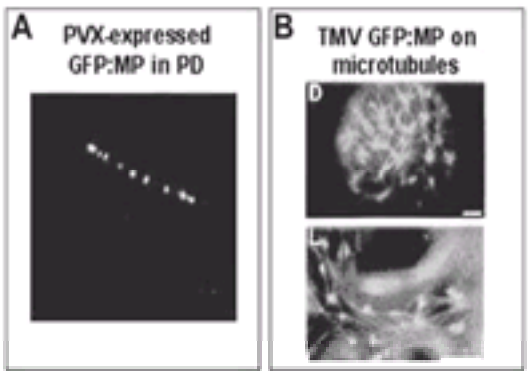

FIG. 29. Studies in living cells of green fluorescent protein (GFP)–movement protein (MP) fusion proteins expressed from an infectious potato virus X vector **(A)** or in tobacco mosaic virus (TMV)-infected protoplasts or plants **(B)**. FIG. 30. Time course of tobacco mosaic virus (TMV) green fluorescent protein (GFP)–movement protein (MP) effects on plasmodesmal gating and associations with the cytoskeleton (microtubules and actin filaments) and endoplasmic reticulum (aggregates) in different cells within an expanding lesion. Because virus is moving outward from the center, cells at the leading edge are at early stages in infection, whereas those at the center are at late stages in infection. (Cartoon based on ref. 134, with permission; figure from Oparka KJ, Boevink P, Santa Cruz S. *Tr Plant Sci* 1996;1:412–418, with permission.)

These studies demonstrate that whereas different viruses may solve the problem of moving the viral genome across the cell wall in a number of different ways, there appears to be a finite number of solutions, and these are not unrelated. MPs, and CPs where these are also required, identify replicated progeny genomes and target these away from the replication pool and along a path toward the cell wall that is distinct from insect transmission. MPs alter plasmodesmata to facilitate movement of the viral genome from cell to cell, sometimes morphologically altering them or affecting their formation as well as function. For a few MPs where it has been investigated, specific associations with ER have been reported. This may not be coincidental since the desmotubule at the center of a plasmodesmata is originally derived from the ER. Similarly, given that actin filaments have been shown to be involved in regulating plasmodesmal function, specific associations of MPs with the cytoskeletal network where these have been documented are probably not coincidental either. Although the same studies have not been done for all plants viruses, there are four well-developed models for the function of MPs encoded by different virus groups. As additional studies are done, these models will be refined, and a few more may be added.

Cell-to-Cell Movement

Studies of the TMV 30-kd protein established the paradigm for MP function, first showing that contrary to a then commonly held view, plasmodesmata were not just boring holes in the plant cell wall, but rather could be modified by a viral MP. This presented a more dynamic view of plasmodesmata than had been previously held (78). TMV represents the simplest case of a virus that needs only one MP and does not require CP for cell-to-cell movement (Fig. 31A). It does require CP for systemic movement through the phloem. The TMV MP has been more extensively characterized than other viral MPs in terms of its effects on the size exclusion limits of plasmodesmata and the details of its regulation and cellular interactions during virus infection (194). In addition to binding viral RNA, the MP interacts with the ER, microtubules, and actin filaments at different stages during the progression of TMV infection. Immune colocalization studies have also localized the TMV MP to sites of viral replication (134,218). The model that has been proposed is that the TMV 30-kd MP binds to replicating viral genomic RNA at ER-anchored replication sites (so-called X bodies) and, at early stages, tracks these along microtubules to establish additional replication sites within the cell. It is suggested that this is the period during which the ER network is disrupted and forms aggregates. From replication sites established in the cortical region of the cell (the periphery), the MP bound to the viral genome is proposed to target it along actin microfilaments to plasmodesmata, where the MP acts to increase the size exclusion limits and move the viral genome into adjacent uninfected cells. The plasmodesmata do not appear to be altered morphologically, and studies suggest that the MP may act like a chaperone to extend the viral genome into a configuration that is compatible with passing through plasmodesmata. Mutational and expression studies show that TMV MP function is regulated in terms of both its synthesis and posttranslational modification. The TMV MP accumulates to high levels early in infection, after which it declines. This appears to be a common property of viral MPs: it has also been documented for other plant viral MPs, including SqLCV NSP and TSWV NSm (183,235,369). Mutational studies suggest that TMV MP function may be regulated by changes in its phosphorylation state (52,360). Temporal regulation of its activity is also evident from studies in expanding TMV lesions. Although the MP localizes to plasmodesmata at both early (leading edge) and late (lesion center) stages of

infection, it acts to increase the size exclusion limits of infected cells in the early stage cells at the leading edge, and not at the center (251) (see Fig. 30). Recent studies suggest that the TMV MP interacts with a cell wall–associated pectin methylesterase, and mutational studies indicate that this interaction is important for TMV MP function (49).

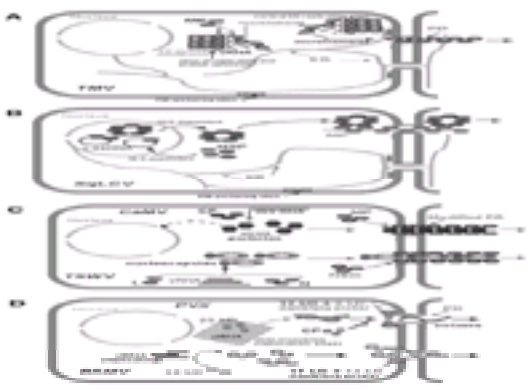

FIG. 31. Models for virus cell-to-cell movement. (**A**) TMV, (**B**) SqLCV, (**C**) CaMV and TSWV, where the MP forms tubules for the movement of encapsidated genomes, and (**D**) examples of triple gene block proteins for a virus that requires (PVX) or does not require (BSMV) CP for local movement. (Modified from ref. 194, with permission.)

The bipartite begomoviruses, such as SqLCV, encode two nonstructural movement proteins (NSP and MP) that are required for cell-to-cell movement and, like TMV, do not require CP for local movement. In contrast to TMV and many other plant viruses, these viruses also do not require CP to systemically infect their natural hosts, and it has been suggested that NSP–ssDNA genome complexes may be the form that moves long distance through the phloem, as well as from cell to cell (153,298). As already discussed, NSP and MP are both required to cooperate in moving the viral ssDNA genome from its site of replication in the nucleus, to and through the cytoplasm, and across the cell wall (see Fig. 31B). SqLCV is phloem limited, which is clearly shown by infecting plants with SqLCV engineered to express free GFP (196). Consistent with this, SqLCV NSP and MP are found only in phloem cells in systemically infected leaves, and it appears that SqLCV infects and replicates in procambial cells. In these immature phloem cells, immunogold labeling shows that MP is associated with unique tubules that extend from and cross the cell walls (369). There are no virus-like particles associated with these tubules, consistent with CP not being needed for movement. These tubules, which are not found in normal uninfected cells, are also labeled with antisera against the ER lumenal binding protein BiP, suggesting that they are derived from the ER. Consistent with this, SqLCV MP cofractionates with ER membrane from infected plants. The cooperative interaction of NSP and MP has been studied using transient expression assays in tobacco protoplasts, where it was also shown that this interaction is regulated (297,298). When each protein is expressed alone, NSP localizes to the nucleus, and MP is found in the cortical cytoplasm at the cell periphery, apparently the consequence of its targeting to the cortical ER (194). However, when NSP is coexpressed with MP in the same cells, NSP is relocalized from the nucleus to the cortical cytoplasm, where it now colocalizes with MP. This interaction is regulated. At late times after cotransfection of these cells, NSP no longer interacts with MP, but rather is found in the perinuclear region of these cells, although MP remains in the cortical cytoplasm (296,298). The model that has been proposed is that NSP, as a nuclear shuttle protein, binds newly replicated viral ssDNA genomes in the nucleus and moves these between the nucleus and cytoplasm. MP, associated with ER-derived tubules, traps these complexes in the cytoplasm and directs them to and across the cell wall. In adjacent uninfected cells, the NSP–genome complex is released, which then targets the viral ssDNA genome to the perinuclear region and delivers it across nuclear pores to initiate a new round of replication (194). The apparent ER origin of the MP-associated tubules and the fact that SqLCV is replicating in actively dividing procambial cells have led to the suggestion that the tubules may be the analog of the desmotubule core of plasmodesmata. Thus, MP is proposed to associate with regions of ER that are destined to form desmotubule, perhaps altering plasmodesmata as they are being formed in the walls of these cells (369). The regulated interaction of NSP with MP, as observed in protoplasts, further suggests that NSP is posttranslationally modified as a consequence of interacting with MP, and it has been proposed that this may involve alterations in the phosphorylation of NSP.

Unlike TMV and SqLCV, TSWV, CaMV, as well as comoviruses and nepoviruses, require CP in addition to a dedicated MP for cell-to-cell movement. All of these viruses, like TMV, infect fully differentiated mesophyll cells. The MP encoded by each of these viruses has been immunolocalized in infected plants to large tubular structures that extend from what appear to be modified plasmodesmata that lack a central desmotubule (see Fig. 31C). These tubules characteristically extend from the walls of infected cells into neighboring cells and have virus-like particles associated with or within them (reviewed in 43 and 194). The role, if any, of cellular components in the formation of these tubular structures remains unknown. Studies that have been done do not show an association with ER, microtubules, or microfilaments. The tubular structures have been reported to form in plant protoplasts or insect cells that transiently express the MP of TSWV (NSm), CaMV (I), or cowpea mosaic virus. These studies show that the MP in each case is necessary and sufficient to induce the formation of these tubules, and neither CP, plasmodesmata, nor any unique plant cell factors are apparently required for this process. CP is required for the formation of the virus-like particles within the tubules (167). The TSWV NSm has recently been shown to interact with the viral nucleocapsid (N) protein (321a). The model that has been proposed, as shown for CaMV and TSWV (see Fig. 31C), is that an encapsidated form of the viral genome—a subviral or viral particle—moves from cell to cell guided through the MP-containing tubular structures and altered plasmodesmata. For CaMV, icosahedral virus particles assembled in the cytoplasm and containing newly reverse transcribed viral genomic dsDNA appear to be the form that is transported from cell to cell. For TSWV, this would be assembled nucleocapsids, which are flexuous rods, containing L protein (the RdRp) as well as the viral genomic components. Presumably, specific interactions of the CaMV CP or TSWV N protein with the MP within the tubules is required to target the encapsidated genomes to the tubules and move these through into the next cell. It has been suggested that tubular structures are needed to accommodate the large diameter of the CaMV icosahedral particles or the TSWV RNPs with their L protein (300). An unresolved issue for both CaMV and TSWV is what regulates the choice between movement of the genome from cell to cell as opposed to an alternate path: the assembled virion targeting the viral genome to the nucleus or

associating with ATF, in the case of CaMV; or nucleocapsid complexes associating with Golgi stacks to assemble enveloped virions, in the case of TSWV. It might be that posttranslational modifications regulate which path is taken. Studies of TEV suggest that it, too, may use a similar mode to move its genome from cell to cell, with the CI cone structures that align with plasmodesmata performing a function similar to that of the large MP-containing tubular structures in CaMV and TSWV (42,293). CP is also required for cell-to-cell movement of TEV. Although it has not been determined whether the TEV genome is transported from cell to cell as virus particles or as a distinct RNA-CP complex, the finding that cell-to-cell movement requires an assembly-competent CP is consistent with virus particles being transported between cells (81,82).

Requiring CP for cell-to-cell movement does not necessarily require the formation of tubular structures. PVX requires CP, as well as the TGB-encoded proteins, for cell-to-cell movement but moves in the absence of any tubular structures. A number of distinct plant viruses encode an analogous set of essential TGB movement proteins, and it is intriguing that some of these, such as barley stripe mosaic virus (BSMV; a hordeivirus) do not require CP for cell-to-cell movement (192). In fact, like SqLCV, BSMV does not require CP for systemic infection of natural hosts. In the case of PVX, a viral mutant in which *GFP* replaced the *CP* gene was found to be confined to single inoculated cells, thus establishing the requirement for CP in cell-to-cell movement. Immune localization studies of infected plant cells and confocal imaging of plants inoculated with PVX that expressed a GFP:CP fusion show that CP localizes to plasmodesmata. Using a virion-specific antiserum, immune electron microscopy further identifies virions within the plasmodesmata of all PVX-infected cell types, leading to the conclusion that PVX virus particles move from cell to cell. However, dye-coupling studies using transgenic plants that express PVX CP show that CP does not affect the gating properties of plasmodesmata (253,299,300). The PVX TGB-encoded 25-kd protein (25K) does affect plasmodesmal gating properties. This was first shown in dye-coupling studies in which PVX viruses that expressed a GUS reporter gene were microinjected into tobacco trichome cells these viruses remained confined to single cells when the 25K protein was not expressed, and only the smallest sized dextrans (4.4 kd as opposed to 10 kd) could now move out of the infected cells (14). However, in infected plant cells, the 25K protein localizes to viral inclusion bodies in the cytoplasm, whereas the TGB-encoded 8-kd (8K) protein localizes to the cell wall. It has been suggested that both the TGB 8-kd and 12-kd proteins may function as membrane anchors since they contain potential transmembrane domains and associate with membranes. In recent studies, plasmids that expressed the PVX 25K protein fused to GFP (GFP:25K) were introduced by biolistic bombardment into transgenic plants that expressed CP, or the TGB 8-kd or 12-kd proteins. The GFP:25K fusion moved from cell to cell in wild-type tobacco plants and tobacco plants that expressed either the 8K or 12K proteins, but it did not move in transgenic plants that expressed either CP or both the 8K and 12K proteins (383).

One model that is consistent with the data is shown in Figure 31D, although other models are possible. This model is based, in part, on the 25K protein binding RNA *in vitro* and having properties similar to the largest TGB protein encoded by BSMV (58 kd) and other viruses. In this model, the 8K and 12K proteins act as membrane anchors. Replicated viral genomic RNA associated with the 25K protein is targeted to the plasma membrane and plasmodesmata through interactions of the 25K protein with the 8K/12K anchors. This interaction somehow facilitates exchange of the CP for the 25K protein bound to the viral genome, while the 25K protein acts to increase the size exclusion limits of the plasmodesmata and the assembled virions move into neighboring cells. The 25K protein is retained in the infected cell through binding to the 8K/12K membrane-anchored complexes and/or because viral CP occludes plasmodesmal sites to prevent its moving through. It has been suggested that early in infection, before CP and the 8K and 12K proteins accumulate, the 25K protein could itself move from cell to cell, creating a “preconditioned” state conducive to virus movement (383). It is also formally possible that the 35K protein and CP both associate with replicated viral genomic RNA as RNPs and, together with the 8K and 12K proteins, participate in assembly of virion complexes once the RNPs are targeted to the membrane sites, or that at sites of replication, CP and viral RNA assembled into virions associate with 25K, and these complexes are then targeted to the cell membrane and wall through interactions of 25K with the 8K/12K complexes. The BSMV TGB-encoded proteins that are analogous to those in PVX are 58 kd (bb), 17 kd (bc) and 14 kd (bd). In BSMV, the 58-kd protein is essential for cell-to-cell movement, and its ability to bind RNA appears to be required for this function (85). RNPs containing BSMV genomic RNA complexed with the 58-kd protein can be isolated from infected plant cells. The 17-kd and 14-kd proteins have potential transmembrane domains and appear to be similar to the PVX 12-kd and 8-kd proteins. A model consistent with the studies of BSMV (85,192) that also draws on parallels to PVX (see Fig. 31D) is that the 17-kd and 14-kd proteins act as membrane anchors. The 58-kd protein forms RNP complexes with replicated viral genomic RNA, which are targeted to the plasma membrane and plasmodesmata through interactions with the 17-kd/14-kd anchors. The 58-kd protein, like the TMV MP, then acts to increase the size exclusion limits of the plasmodesmata, and the 58-kd protein genome complexes move into adjacent cells. Other models are also possible, and as for PVX and other viruses encoding TGB proteins, biochemical and cellular studies of the TGB proteins are required to fully understand how these proteins function and interact to facilitate movement.

Long-Distance Movement

Little is understood about how viruses enter, move through, and exit from the phloem, owing largely to technical difficulties associated with investigating phloem cells without damaging them. Most of what is known is based on immunocytochemical and ultrastructural studies, and the analysis of virus mutants or host range variants (242). A complicating factor in determining the role of MPs in viruses entering the phloem and moving systemically is their requirement in cell-to-cell movement, which is a prerequisite for systemic infection. This is also an issue for those viruses in which CP is also needed for cell-to-cell movement. In addition, in analyzing viral mutants it is difficult to discern whether effects on phloem entry or systemic infection directly involve a stage in vascular transport or are the general consequence of a decrease in virus accumulation and efficiency of infection. This becomes an issue if a threshold level of virus accumulation must be reached for systemic spread to successfully occur, or if a lower efficiency in spread allows time for the host to mount a defense response. Some plant viruses are transported through the xylem. We know even less about this process than about phloem transport of viruses, and it will not be discussed here. Whether phloem-restricted viruses follow the same routes that evidence suggests are used by viruses not so restricted has also not been studied in detail.

It has generally been accepted that viruses that infect mesophyll cells and move through the phloem do so along with the flow of nutrients (photoassimilates), exiting from mature leaves by the same path and at the same sites that

photoassimilates are exported (the minor veins), and entering developing leaves by the same path and at the same sites (major or “lower order” veins) as photoassimilates are imported. This was suggested by classic studies that showed that plant viruses rapidly move toward the growing regions or young leaves in infected plants, and by more recent studies of CaMV infection in which virus accumulation in systemically infected leaves was found to be similar to that of photoassimilate import (203). This has now been directly shown for PVX infection in tobacco, by comparing spread of PVX expressing GFP with that of carboxyfluorescein (CF), a membrane-impermeant fluorescent solute that is transported through phloem in a manner similar to photoassimilate (292). Although virus transport was slower than that of CF, PVX exited from the same lower order veins (class III) into importing regions of developing leaves as did CF, and following infection of mesophyll cells, moved into the minor veins when these matured. The virus, as well as CF, was unable to enter regions of a leaf that were already actively exporting photoassimlate at the time of virus entry into the leaf.

Studies of the progression of infection for a number of plant virus variants and mutants have identified barriers or “control points” for virus movement from bundle sheath cells into phloem parenchyma cells, or from these into companion cells and then into the sieve elements. Plasmodesmal function between these cell types is also regulated (77); thus, not surprisingly, it appears that both viral and host cell factors control virus entry into the phloem. The majority of plant viruses require CP for long distance movement, whether they require CP for cell-to-cell movement or not. Analysis of CP mutants for a number of these viruses, including TMV, TEV, and RCNMV, suggests that CP is essential for entry into and/or spread through the sieve elements of the phloem, probably in the form of virions (242). In the case of TMV and RCNMV, the ability to assemble virions correlated with efficient systemic infection. Immunocytochemical analysis of infection by TMV CP mutants suggested that CP and encapsidation were not required for movement into minor veins but did appear to increase the efficiency of movement from companion cells into sieve elements (79,343). For PVX, a mutant that lacked CP but expressed GFP was inoculated onto transgenic plants that expressed viral CP, and its movement into grafted leaves that did not express CP was examined (300). The PVX mutant systemically infected the CP transgenic rootstock and moved into the grafted nontransgenic leaves, where it remained confined to cells close to major veins because of the lack of CP in the nontransgenic tissue. These studies showed that PVX CP, presumably assembled into virions, is transported through the phloem.

A detailed study using quantitative immune electron microscopy and an MP:GFP fusion to examine cucumber mosaic virus (CMV, a cucumovirus) progression into the minor veins of tobacco raised the interesting possibility that virions may be assembled in sieve elements (26). CMV needs MP (the 3a protein) and CP for cell-to-cell movement. The CMV MP was found associated with plasmodesmata whether it was expressed from infectious CMV or from PVX as an MP:GFP fusion. In minor veins, the MP was clearly present in plasmodesmata connecting companion cells and sieve elements, and in fibrillar formations within the sieve elements. However, in CMV-infected plants, virions were not detected in plasmodesmata, including those between the companion cells and sieve elements, but were found as large aggregates associated with the MP in the sieve elements. It was suggested that the viral genomic RNA, CP, and MP move into the sieve elements as an RNP complex and that virions are subsequently assembled within the sieve elements. Despite the evidence supporting the idea that where CP is required for systemic infection, virions may move through sieve elements, it remains an open point as to whether virions, as such, could pass through the plasmodesmata between sieve elements and companion cells to exit from the phloem.

It has been difficult to distinguish potential functions of MP in phloem entry and systemic movement from its role in cell-to-cell movement. A recent study with RCNMV took advantage of the ability to create partially defective MP mutants using alanine-scanning mutagenesis to identify functions of the viral MP in long distance movement that were distinct from its requirement for cell-to-cell movement (364). Immunocytochemical studies of three different host plants infected with different RCNMV MP mutants showed that MP was required for viral entry into the phloem for systemic infection, acting to facilitate viral movement from phloem parenchyma into companion cells independent of its function in cell-to-cell movement within mesophyll, bundle sheath, and phloem parenchyma.

PLANT RESPONSES TO VIRUS INFECTION

Although plants do not have an immune system, they are not completely defenseless in the face of virus infection. Plants can be nonhosts for or tolerant of infection by particular viruses. In the former instance, there is no evidence of virus replication in the plant, whereas in the latter, virus replicates and can move, but the host shows no or mild disease symptoms and continues to grow. Historically, it has been presumed that in these situations the infecting virus cannot interact with host factors that are involved in its replication or movement. While this may be true in a number of virus–host interactions, the recent demonstration of an innate plant defense response to virus infection suggests other possibilities as well. Potentially susceptible species of plants can also be resistant to infection by viral, bacterial, and fungal pathogens if they contain a dominant or recessive resistance gene, and these have been successfully used in breeding. Little is known about the action of recessive resistance genes; however, dominant resistance (*R*) genes have been shown to respond to a corresponding avirulence (*Avr*) gene in the attacking pathogen. This so-called gene-for-gene interaction induces a hypersensitive response that is usually evident by the local production of necrotic lesions (see Fig. 10) and involves a series of responses in the plant that include the local production of reactive oxygen species and induction of an apoptotic response, and systemic signaling to induce pathogenesis-related proteins. This hypersensitive response eliminates local infection and protects the plant against further attack. A number of *R* genes have been cloned in the past few years, and they appear to be involved in signal transduction pathways (reviewed in 56). One of the best characterized *R* gene responses to virus infection is that of the *N* gene in tobacco in conferring resistance to TMV, in which the corresponding *Avr* gene product has been shown to be the viral 126-kd component of the RdRp (258,259). The *N* gene has been cloned by transposon tagging and, in common with a number of other cloned *R* genes, it appears to encode a cytoplasmic protein that contains a nucleotide binding site and a region of leucine-rich repeats. Such repeats are known to be important in protein–protein interactions. Strikingly, the amino-terminal domain of the *N* gene–encoded protein is similar to the cytoplasmic domain of the *Drosophila* Toll protein and the mammalian interleukin-1 receptor, suggesting that it mediates resistance through a Toll–interleukin-1–type pathway (373).

Mixed virus infections in plants are common. If the two infecting viruses are related (e.g., different strains of a particular virus), one outcome can be the phenomenon of cross protection. As typified in studies of TMV, inoculating plants first with a mild tomato strain of TMV will protect plants against subsequent infection by more virulent strains of TMV. This

cross protection response involves the CP of TMV, and it provided the first example of so-called pathogen-derived resistance in which transgenic plants that expressed a viral gene or protein, in this case the TMV CP, were shown to be resistant to virus infection (reviewed in 20 and 70). Subsequently, other viral genes encoding CP, as well as different viral RdRps and MPs, have been used to engineer virus-resistance plants, as have genes encoding known plant antiviral proteins, such as pokeweed antiviral proteins, a class of ribosome-inactivating proteins found in a wide variety of plants (342). The studies of the mechanism of pathogen-derived resistance quickly made it apparent that although, at times, such as with transgenic plants expressing the TMV CP, the resistance is mediated by expression of a viral protein, in most cases it is conferred by RNA (RNA-mediated resistance). The expressed viral transgene induces a homology-dependent degradation of the infecting virus genome that is mechanistically related to posttranscriptional cosuppression of a nonviral transgene and corresponding cellular gene in transgenic plants, and homology-dependent posttranscriptional gene silencing in plants (PTGS) (18). These, and other studies (11,283), suggested that plant viruses could be initiators as well as targets of PTGS, also called *RNA interference* (RNAi), a phenomenon that occurs in plants, animals (e.g., *Caenorhabditis elegans* and *Drosophila*) and fungi. As can happen in science, these studies on RNA-mediated resistance and investigation of the phenomenon of plant virus synergy converged to show that PTGS is a plant defense against virus infection and that, not unexpectedly, plant viruses can encode suppressors of PTGS as a counterstrategy.

In contrast to the antagonistic interaction in cross protection, mixed infection of plants by two usually unrelated viruses can be synergistic, producing more severe disease symptoms than would be caused by either virus alone and enhancing the replication and/or spread of one or both viruses. This synergistic interaction occurs in a number of mixed plant virus infections. Many of these involve a potyvirus and any of a number of unrelated viruses, which suggested that rather than the potyvirus affecting replication of the co-infecting virus directly, it was more likely to do so indirectly by modulating host functions. Recent studies of the interactions of potyviruses PVY, TEV, and TVMV with PVX, using viral mutants and transgenic plants, showed that the P1/HC-Pro region of the potyvirus genome is responsible for this synergism (277,348). This was directly shown in two ways. Infectious PVX engineered to express the P1/HC-Pro or HC-Pro of TEV was found to have enhanced pathogenicity in tobacco plants (Fig. 32). Similarly, transgenic plants that express the P1/HC-Pro region of TEV or TVMV showed enhanced symptoms when infected with wild-type PVX, which normally produces only mild symptoms on wild-type tobacco. Mutational studies showed that the region of HC-Pro that had been implicated in affecting replication, long distance movement, and pathogenicity of TEV was necessary and sufficient to produce the synergistic increase in disease symptoms, and that both P1 and HC-Pro were required for the increased replication of PVX (277). At the same time, in an attempt to develop a transient assay for investigating PTGS, it was discovered that local injection of *A. tumefaciens* expressing a 35S-GFP construct not only would silence GFP expression in a transgenic plant locally in the inoculated leaf, as hoped, but also would induce PTGS of the GFP expression systemically throughout the entire plant. This was evident by the fact that these plants were no longer fluorescent under ultraviolet light (354). These and subsequent studies showed that PTGS in plants can be triggered by a systemically transmitted signal that is presumed to be nucleic acid (354,357). By infecting these GFP-silenced transgenic plants with PVX vectors expressing different forms of HC-Pro, or using transgenic tobacco plants that contain a preexisting silenced *GUS* transgene, it was shown that HC-Pro could suppress the PTGS of GFP or GUS (13,165,357). Small RNAs approximately 23 nt in length that correspond to both sense and antisense strands are associated with PTGS, and it has been proposed that these provide the specificity for targeted RNA degradation through association with an RNAse III–like enzyme (131,386). Additional studies have shown that encoding such a suppressor of PTGS is a strategy employed by a number of diverse plant viruses, including TMV, CMV (2b), TGMV (TrAP), cowpea mosaic virus (comovirus), a number of potexviruses (although not PVX), tobacco rattle virus (tobravirus), and tomato bushy stunt virus (tombusvirus, 19K) (356,357). In some cases, the viral-encoded suppressor has been identified (shown in parentheses). Thus, not every plant virus encodes such an RNAi suppressor, or counteracts this defense response in the same way. For viruses that do not, like PVX, it has been suggested that the virus can partially evade this host defense, although it clearly does not replicate at its maximal potential in those host plants in which this has been studied. The viral proteins identified as suppressing PTGS had each been identified in mutational studies as a “pathogenicity” factor that affected virus replication, movement, and/or pathogenesis, driving home the point that the roles of a number of these proteins, such as HC-Pro and CMV 2b, in systemic infection and phloem-dependent transport could be explained by suppression of the host PTGS defense response, rather than the protein directly facilitating active virus movement through plasmodesmata. This raises the possibility that some viral MPs could facilitate cell-to-cell movement by hindering intercellular communication required for spread of a PTGS defense (38). Recent studies with PVX suggest that the 25-kd protein, one of the TGB-encoded movement proteins, can block systemic spread of the PTGS signal (355), thus being responsible for the proposed PVX evasion of the PTGS response. Current studies are identifying host genes involved in PTGS. As the functions of these host genes are determined, we will begin to understand the signaling pathways by which PTGS is induced and how it can be suppressed or evaded.

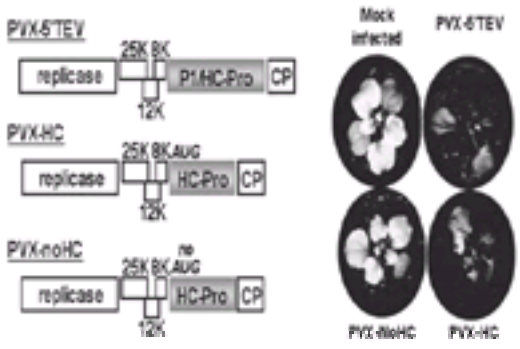

FIG. 32. PVX viruses that express TEV P1/HC-Pro or HC-Pro show enhanced pathogenicity (PVX-5'TEV, PVX-HC). Expression of P1/HC-Pro or HC-Pro protein is required, since PVX expressing HC-Pro without a start codon (PVX-NoHC) does not show enhanced pathogenicity. (From ref. 277, with permission.)

CHAPTER 20 Insect Viruses

Paul D. Friesen and Lois K. Miller

HISTORY OF INSECT VIRUSES

It is likely that insect viruses have existed as long as the insects themselves and have therefore evolved for 350 million years. Insect viruses have long been of interest and concern to humans, as first indicated by scientific reports and literature of the 16th and 17th centuries, which describe insect diseases. In the early 19th century, crystalline polyhedral-shaped bodies called polyhedra were first discovered in association with the “wilting” disease of silkworms. It was subsequently established that the polyhedra were the causal agents of the disease, and by 1920, the silkworm disease was attributed to a filterable virus (reviewed in 14). Finally in 1947, Gernot Bergold (15) made the landmark discovery that the protein matrix of the polyhedra contained rod-shaped virions that are characteristic of the baculoviruses.

Studies in the 1940s and 1950s set the stage for development of insect pathogens as biologic pesticides. Important candidates were the insect viruses, especially the baculoviruses (246). The list of viral candidates was expanded in the 1960s through the discovery of new families of insect viruses, including the iridoviruses, nodaviruses, polydnaviruses, and entomopoxviruses. In the 1960s, significant progress also was made in establishing insect cell lines, and by 1973, a plaque assay for baculoviruses was available (100,131,132). Thus studies of the molecular biology and genetics of virus replication under controlled conditions were possible. Ultimately, the first insect virus (a baculovirus) was registered as a pesticide for use against the cotton bollworm by the United States Environmental Protection Agency in 1975 (reviewed in 192).

The mid-1970s marked the beginning of modern research on the molecular biology of insect viruses. Pioneering studies during this period triggered great interest in diverse applications of invertebrate viruses, including their use as vectors for foreign gene expression and as genetically improved biopesticides. To date, molecular studies on the replication, assembly, and host interactions of insect viruses have contributed enormously to molecular, cellular, and organismal biology.

CURRENT IMPACT OF INSECT VIRUSES

Insect Control

Insects comprise more than 80% of the existing animal species, outnumbering *Homo sapiens* 200 million to 1. Often considered the most successful animals on earth, many insect species are of serious biomedical concern to humans and represent significant pests in agricultural and forestry settings. It is not surprising that throughout history, humans have sought to control the insects. In nature, insect populations are held in balance by diverse factors, including predation, parasitism, and microbial (viral and fungal) infections. Of these regulatory forces, viral diseases can have profound effects.

Viruses can cause widespread epizootics and morbidity in insects, especially within dense populations. In contrast, some viruses have little or no overt effects, but can influence the “health” of a species by stressing the general population. Viral diseases occur in pest insects (gypsy moths, corn earworms, and mosquitoes, among others) as well as beneficial species (honey bees, silkworms, and parasitoids). Diseases of beneficial insects can cause economic and ecologic problems, whereas diseases of pest species can alleviate economic hardship and reduce medical concerns. Natural epizootics by viruses have been frequently observed in agricultural and forest settings, especially when insect populations are high. One of the most dramatic episodes of virus-mediated insect control occurred in North America during infestations of the European spruce sawfly. On accidental introduction of the sawfly baculovirus in the 1930s, sawfly populations declined sharply and remained low because of the continued presence of the virus (4). Such dependence on natural epizootics for insect pest control in agriculture, however, is generally impractical, because crop damage exceeds economically acceptable levels before virus-mediated reduction occurs.

Much effort has been invested at the academic and industrial levels in the development of virus-based biopesticides for the purpose of reducing agricultural dependence on broad-range, environmentally toxic chemical insecticides. Currently in Brazil, more than a million hectares of land are treated annually with a baculovirus to control the soybean looper. In Europe, a different baculovirus is used to control the codling moth, a common pest of fruit crops (192). In the South

Pacific, a nudivirus is used for effective control of the rhinoceros beetle on coconut plantations (297). Several baculoviruses are currently registered as pesticides in the U.S., but their implementation has been pursued primarily by government agencies such as the U.S.D.A. Forest Service. Industrial interest in commercial development of virus insecticides has been sporadic, in part because of restricted markets and limitations in efficacy of these biopesticides. However, as environmental concerns increase and insects acquire resistance to chemical pesticides, it is expected that viral insecticides will have an expanded role in integrated pest-management programs. In particular, the capacity to improve insecticidal efficacy by genetic manipulation of baculoviruses through the insertion of insect-specific toxin or hormone genes holds much promise (118,183,247,266). Field tests of genetically improved baculovirus pesticides have already been conducted in the U.S. and the United Kingdom and have involved participation by multiple companies (reviewed in 20,192).

Foreign Gene Expression Vectors

Baculoviruses are popularly known for their use as highly efficient vectors for foreign gene expression in eukaryotic (insect) cells (reviewed in 144,155,199). This important and widely used application is the direct result of molecular studies on these large DNA viruses and is a striking example of the utility of insect viruses for biotechnology and basic research. Baculovirus expression vectors are distinguished by their capacity to produce unusually high levels of biologically active foreign proteins. Posttranslational modifications and protein folding in infected insect cells parallel those in mammalian cells and thereby provide abundant proteins for applications in vaccine development, therapeutic and diagnostic purposes, and structure/function studies. To date, several thousand genes have been expressed by using baculovirus vectors, which themselves have been recently improved for ease of use and increased protein yields. The biologic activity of these foreign proteins often can be tested directly in the vector-infected insect cells, providing a reliable and efficient system for functional analysis. The unique properties of other insect viruses, including the entomopoxviruses, nodaviruses, densoviruses, and alphaviruses, also are being exploited for use as expression vectors.

Recently the nucleopolyhedroviruses (NPVs) have been evaluated as gene-transfer vectors in mammals and insects (reviewed in 155). Reporter genes placed under control of mammalian promoters and inserted into the virus genome are readily expressed after inoculation of certain mammalian cell lines (26,52,134). Moreover, it has been demonstrated that a recombinant NPV can be used to stably deliver functional genes to the germline of the silkworm *Bombyx mori* (291), suggesting that baculoviruses will provide a useful vector for targeted gene insertion and gene disruption in transgenic insects.

Cell Biology, Host–Virus Interactions, and Evolution

The study of insect viruses has provided unique insights into fundamental biologic processes. Examples include the discovery of the 7-methyl guanosine cap structure of eukaryotic mRNAs by using the insect cypoviruses of *Reoviridae* (89). Studies on translation of cricket paralysis–like viruses have revealed a new mechanism for initiation of protein synthesis (235,282). The polydnaviruses have revealed a novel symbiotic relationship between virus and host that involves virus-mediated immune suppression. Insect viruses also are providing unique opportunities to investigate antivirus defense strategies. Because of their capacity to induce and suppress apoptosis, baculoviruses have provided insight into the role played by programmed cell death as an antivirus defense mechanism and as a contributor to viral pathogenesis. Recombinant baculoviruses also have been used to trap host cell apoptotic regulators (243), providing information on regulation of programmed cell death. Last, apoptotic suppressors of these insect viruses are being used in antiapoptosis therapies involving transgenic organisms (58,133,270).

Insect viruses also have provided unique insight into virus evolution. The close association of insects with plants and higher animals has allowed the natural exchange of viruses, thus contributing to virus evolution. Many insect viruses within the families *Poxviridae, Rhabdoviridae, Reoviridae, Picornaviridae*, and *Parvoviridae* have vertebrate counterparts, spurring speculation that viruses of higher animals evolved from ancient insect viruses. It is therefore likely that understanding the evolution of vertebrate viruses will depend on knowledge of their invertebrate relatives. In addition, some insect viruses have coevolved with viruses of unrelated families. For example, the unusual conservation of specific genes found in baculoviruses, entomopoxviruses, and orthomyxoviruses suggests an evolutionary link between these diverse virus families. Last, certain insect viruses (baculoviruses) readily accommodate host transposons, which are especially abundant and diverse in arthropods. Stable insertion of such host-derived genetic elements accelerates virus evolution and may contribute to the horizontal exchange of genes between invertebrate species.

CLASSIFICATION OF INSECT VIRUSES

Insects are susceptible to highly diverse families of RNA and DNA viruses (Table 1). Many members of these insect virus families have counterparts in vertebrates. Others are unique to arthropods. Nonetheless, insect-specific members of these virus families have novel properties that are conserved between families. A striking example is the use of an occluded form of infectious virus that is required for virus transmission between insect hosts and is conserved among diverse virus families, including the baculoviruses, entomopoxviruses, and cypoviruses.

This chapter focuses on those virus families that are found primarily or exclusively in insects: *Baculoviridae, Nudiviridae, Polydnaviridae, Ascoviridae, Nodaviridae, Tetraviridae,* and the cricket paraly-sis–like viruses. Viruses in which insects are used as temporary hosts during transmission (e.g., arboviruses) are not included, nor are virus families that have well-characterized vertebrate members described in other chapters. These insect viruses and others (entomopoxviruses, iridescent viruses, densoviruses, and cypoviruses) are described by recent reviews (189).

Characteristics	Virus family	Genus	Representative member
dsDNA, enveloped	*Baculoviridae*	Nucleopolyhedrovirus (NPV)	Autographa californica sNPV (AcMNPV)
		Granulovirus (GV)	Cydia pomonella GV (CpGV)
	Nudiviruses[a]	Nonoccluded virus	Hz-1, Oryctes rhinoceros virus
	Polydnaviridae	Ichnovirus	Campoletis sonorensis virus (CsV)
		Bracovirus	Cotesia melanoscela virus (CmV)
	Poxviridae	Entomopoxvirus A	Melanoplus entomopoxvirus
		Entomopoxvirus B	Amsacta moorei entomopoxvirus
		Entomopoxvirus C	Chironomus luridus entomopoxvirus
	Ascoviridae	Ascovirus	Spodoptera frugiperda ascovirus (SfAV)
dsDNA, nonenveloped	*Iridoviridae*	Iridovirus	Chilo iridescent virus
		Chloriridovirus	Mosquito iridescent virus
ssDNA, nonenveloped	*Parvoviridae*	Densovirus	Galleria densovirus
ssRNA, nonenveloped	*Reoviridae*	Cytovirus	Bluetongue virus
		Cypovirus	Cytoplasmic polyhedrosis viruses (CPVs)
		Entomovirus	Colorado tick fever virus
ssRNA, enveloped	*Birnaviridae*	Birna virus	Drosophila X virus
	Togaviridae	Alphavirus	Sindbis virus
	Flaviviridae	Flavivirus	Yellow fever virus
	Rhabdoviridae	Vesiculovirus	Carajas virus
		Lyssavirus	Humpty Dau, Sigma virus
	Bunyaviridae	Bunyavirus	Anopheles A group
		Phlebovirus	Sandfly fever virus
		Nairovirus	Crimean-Congo hemorrhagic fever virus
ssRNA, nonenveloped	*Nodaviridae*	Alphanodavirus	Nodamura virus, Pariti Hooker Virus
	Tetraviridae	Betatetravirus	Nudaurelia capensis β virus
		Omegatetravirus	Nudaurelia capensis ω virus
	Cricket paralysis-like[a]	Cricket paralysis-like	Cricket paralysis virus
			Drosophila C virus

[a]These viruses are currently listed as unclassified by the ICTV.

TABLE 1. *Families of viruses infecting invertebrates*

DESCRIPTION OF INSECT VIRUS FAMILIES

Baculoviridae

Classification of Baculoviruses

Members of the family *Baculoviridae* are taxonomically characterized by their large, circular genome of double-stranded DNA, which is packaged into an enveloped, rod-shaped virion. The family name is derived from the Latin term *baculum,* meaning rod or stick, to describe the virion. Baculoviruses also are distinguished by their two morphologically distinct forms of infectious particles: occluded virus (OV), comprising enveloped virions embedded within a crystalline matrix of protein, and budded virus (BV), comprising a single virion enveloped by a plasma membrane. Baculoviruses are divided into two genera: the nucleopolyhedroviruses (NPVs) and granuloviruses (GVs), previously known as nuclear polyhedrosis viruses and granulosis viruses, respectively. For GVs, a single virion is embedded within each ovicylindrical OV particle, which collectively have a “granular” appearance in the light microscope. In contrast, NPVs have numerous (>20) virions per polyhedral OV particle (polyhedra) which are several microns in diameter and thus easily visualized by light microscopy. OV is produced in the nucleus of NPV-infected cells, whereas OV generally forms after loss of the nuclear membrane in GV-infected cells.

Baculovirus diseases have been reported in more than 500 different insect species. Individual viruses are most often named according to the species of host insect from which they were isolated. For example, *Autographa californica* nucleopolyhedrovirus (Ac*M*NPV) was isolated from the alfalfa looper *Autographa californica,* and *Cydia pomonella* granulovirus (CpGV) was isolated from the codling moth *Cydia pomonella*. In general, baculoviruses have distinct and relatively narrow host ranges that are limited to invertebrate species within a single genus or family. However, certain baculoviruses, including Ac*M*NPV, have broader host ranges, infecting more than 30 different lepidopteran (moth and butterfly) species.

Baculovirus Structure: OV and BV

Baculoviruses sequentially produce BV and OV in their unique, biphasic multiplication cycle. These infectious forms (Fig. 1) contain one or more virions comprising a rod-shaped nucleocapsid that is 250 to 300 nm long and 30 to 60 nm in diameter (recently reviewed in 88). The nucleocapsid is composed of a nucleoprotein core surrounded by a bacilliform proteinaceous sheath, referred to as the capsid. The capsid contains ring-like subunits stacked every 4.5 mm in the longitudinal axis (12). A distinctive morphology at the apical end of the capsid suggests a specialized function, for either DNA packaging, virion budding, nuclear entry, or uncoating (77,269). An essential 78-kd phosphoprotein is associated with this end structure (269). The capsid contains one major 35- to 40-kd capsid protein and additional minor proteins (213,258,264,269). The nucleoprotein core consists of a single molecule of circular, double-stranded DNA associated with protein. The major core protein is a 6.9-kd protamine-like protein, rich in arginine (150,268,285).

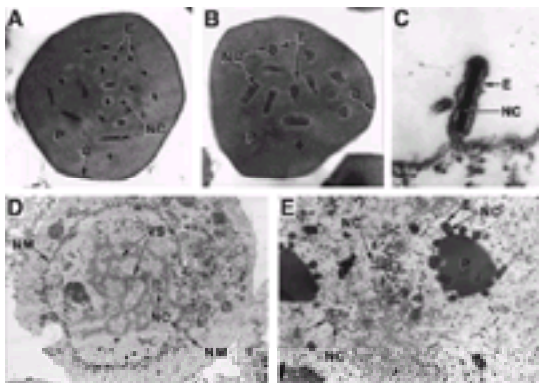

FIG. 1. OV and BV structure of the nucleopolyhedroviruses. **A:** Cross section of the OV particle (2-mm diameter) of a single capsid NPV (*S*NPV). Individual nucleocapsids (*NC*) within a unit membrane envelope (*E*) are embedded within a matrix of polyhedrin protein (*P*). The OV external surface is covered by the thin carbohydrate-rich calyx (*C*). **B:** Cross section of the OV particle (3-mm diameter) of a multicapsid NPV (*M*NPV). Envelopes (*E*) containing two or more nucleocapsids (*NC*) are embedded within the polyhedrin matrix (*P*). **C:** A nucleocapsid budding from the plasma membrane of an NPV-infected cell. The budded virus form *(BV)* of *M*NPVs and *S*NPVs contain a single nucleocapsid (*NC*) of the same dimensions (30 × 250 nm) as OV-derived nucleocapsids (**A, B**). **D:** Thin section of an *M*NPV-infected cell during the late phase of replication. The nucleus, surrounded by the nuclear membrane *(NM)*, contains the virogenic stroma (*VS*) with associated nucleocapsids (*NC*). **E:** Nucleus of an *M*NPV-infected cell at the beginning of the very late,

occlusion phase. Newly assembled nucleocapsids *(NC)* associate with intranuclear membrane envelopes (*E*), then become enveloped, and are embedded within a polyhedrin matrix (*P*). Electron micrographs were kindly provided by Dr. Malcolm J. Fraser, Jr., University of Notre Dame.

A distinctive feature of the baculoviruses is the large size (0.15 to 15 μm) and polyhedral or oval shape of the OV particles (see Fig. 1). The OV mediates virus transmission between insect larvae, the developmental stage most susceptible to viral infection. On ingestion by a larva, the OV protein matrix is dissolved by the alkaline pH of the midgut, releasing the occlusion-derived virions (ODVs), which initiate infection of the midgut epithelium. Within the OV particle, these virions are embedded in a crystalline matrix consisting of a single 29-kd protein, designated polyhedrin or granulin for the NPVs and GVs, respectively. Both matrix proteins are closely related. Within the matrix of NPVs (see Fig. 1A and Fig. 1B), either a single nucleocapsid (*S*NPVs) or multiple nucleocapsids (*M*NPVs) are bundled together and surrounded by a membrane envelope with virus-encoded proteins (88). The intranuclear membranes used for envelopment may be synthesized *de novo* or represent a modified form of the nuclear membrane (29,250). On their surface, mature OVs have an additional covering of protein and carbohydrate, known as the polyhedron envelope or calyx.

The BV form of baculoviruses consists of a nucleocapsid surrounded by a loose-fitting membrane envelope acquired by budding at the plasma membrane surface of the host cell (see Fig. 1C). The membrane envelope of BVs is thus distinct from that which envelops nucleocapsids embedded within OV. BV is the infectious unit responsible for cell-to-cell transmission within the insect and in cell culture. The envelope fusion protein (EFP) gp64 is the major virus-specific protein associated with the BV envelope of some NPVs (272). Antiserum to EFP gp64 neutralizes BV infectivity (275), suggesting that this protein participates in host cell–receptor interaction. Indeed, EFP gp64 is required for cell-to-cell infectivity (190). Envelope proteins unrelated to gp64 appear to mediate infectivity of other NPVs (211).

Baculovirus Genome Structure

The baculovirus genome is a large (90 to 160 bp) covalently closed, supercoiled circle of double-stranded DNA. To date, the complete nucleotide sequence of six baculoviruses has been reported, including that of *Autographa californica M*NPV (Ac*M*NPV), *Bombyx mori S*NPV (BmNPV), *Orgyia pseudotsugata M*NPV (Op*M*NPV), *Lymantria dispar M*NPV (Ld*M*NPV), *Xestia c-nigrum* granulovirus (XcGV), and *Cydia pomonella* granulovirus (CpGV) (2,3,95,126,163,200). Extensive transcriptional mapping of several baculoviruses has provided a broad picture of gene organization and regulation of expression. Ac*M*NPV is the best studied and represents the prototype NPV.

The AcMNPV genome (133,894 bp) consists almost entirely of unique DNA sequences, encoding 337 open reading frames (ORFs) of 150 nucleotides or more (3). The ORFs are closely spaced on both DNA strands with no apparent organization with respect to temporal expression during infection. Early, late, and very late genes are interspersed throughout the genome. Most ORFs are separated by only two to 200 nucleotides. These intergenic regions have a high A+T content and constitute the promoter and termination sequences for each gene (reviewed in 216). Illustrative of the economy of gene organization, the translational termination codon (usually **UAA**) often overlaps the polyadenylation signal, AA**UAA**A. There also are examples of overlapping ORFs. However, because splicing of baculovirus RNA is rare, there are few if any introns in the genome. An example of splicing involves expression of the *ie*-0/*ie*-1 gene (see later), which encodes the principal transcriptional regulator of baculoviruses (45,157,212). Frequently transcripts of one AcMNPV gene initiate from within or extend through an adjacent gene, a phenomenon especially prevalent among viral RNAs late in infection (81,179). Thus numerous genes are transcribed into bi- or multicistronic RNAs in which the upstream ORF is translated. In addition, there are multiple examples of the transcription of overlapping, antisense RNAs. The potential regulatory role of such antisense RNAs is unclear. Evidence exists that the interspersion of different temporal classes of transcripts may have functional significance. For example, activation of the very late promoter of *polh*, the gene encoding the major OV protein polyhedrin, down-regulates overlapping, antisense RNAs initiated downstream of *polh* (204). However, no evidence of this type of promoter interference occurs for a different set of overlapping RNAs that are all transcribed in the same direction (104).

A distinguishing feature of the baculovirus genome is the presence of multiple copies of interspersed repetitive sequences, known as homologous regions (*hrs*) (51,108). The *hrs* function as transcriptional enhancers (108,112) and are likely origins of viral DNA replication (154,210). Ac*M*NPV contains eight *hrs*, ranging in size from 30 to 800 bp and accounting for 3% to 4% of the genome. The *hrs* have a complex modular organization consisting of 60-bp repeats, each with a highly conserved 28-bp imperfect palindrome (28-*mer*). The 28-*mer* is the minimal sequence required for orientation- and position-independent enhancement of promoter activity and DNA replication (169,231). The *hrs* bind host- and virus-specific proteins. In particular, the transcriptional activator IE1 binds as a dimer to the palindromic 28-*mer*, which is required for IE1-mediated stimulation of enhancer activity (156,169,232). Deletion of a single *hr* (*hr*5) from the Ac*M*NPV genome reduces transcription of proximal genes, but has no obvious effect on virus replication, suggesting that these elements are functionally redundant (231). Nonetheless, the novel distribution and repetition of the *hrs* or *hr*-like elements within multiple baculovirus genomes suggest that these sequences play a critical role in the virus life cycle.

Stages of Baculovirus Replication

Primary and Secondary Infection

Baculovirus multiplication in the insect larva is divided into primary and secondary stages to describe the initial infection of midgut cells and the subsequent infection of secondary tissues, respectively (Fig. 2A and Fig. 2B). In both stages, infection is initiated by the binding of virus to the host cell. However, multiple aspects of primary and secondary infections differ. Secondary infection most closely resembles that which occurs in cultured cells after inoculation with BV, a process that is better understood with respect to individual replication events. Thus we first describe the known details of

Ac*M*NPV replication in a high-multiplicity infection of cultured SF21 (or SF9) cells, a well-studied and fully permissive cell line derived from the nocturnal moth, *Spodoptera frugiperda* (Lepidoptera; Noctuidae). Subsequently, aspects unique to primary infection in the midgut of permissive caterpillars are described. It should be noted that the timing of replication events varies with the virus and insect host.

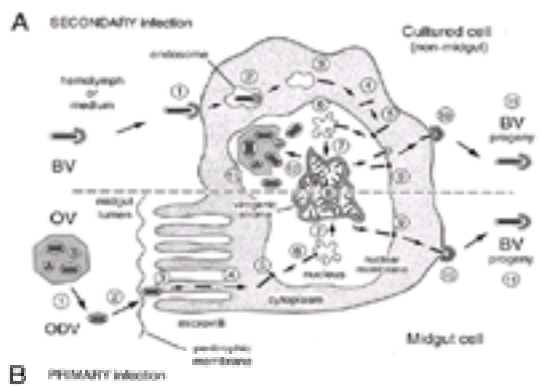

FIG. 2. Multiplication cycle of a baculovirus (*M*NPV). **A:** Infection of a cultured or nonmidgut cell by BV (secondary phase of infection). Enveloped BV attaches to receptors on the cell surface *(step 1)* and enters by endocytosis (*step 2*). As the endosome acidifies, virus and endosomal envelopes fuse (*step 3*), releasing nucleocapsids into the cytoplasm. Nucleocapsids proceed to the nucleus (*step 4*), where they interact end-on with the nuclear pore (*step 5*). On entering the nucleus, the DNA is released from the virion (*step 6*), and transcription begins (*step 7*). In association with the newly formed virogenic stroma, viral DNA is replicated and packaged into nucleocapsids (*step 8*). During the late phase, nucleocapsids exit the nucleus (*step 9*), migrate to the plasma membrane, and bud (*step 10*), thereby acquiring virus envelope proteins and producing infectious BV (*step 11*). During the very late phase, nucleocapsids are retained in the nucleus, acquire an envelope (*step 12*), and are embedded within a crystalline matrix of polyhedrin (*step 13*) to form OV particles. Mature OV are released by cell lysis. **B:** Infection of a midgut epithelial cell by OV (primary phase of infection). The polyhedrin matrix of an ingested OV particle dissolves in the midgut lumen *(step 1)*, releasing occlusion-derived virions (*ODV*), which crosses the peritrophic membrane (*step 2*) to gain access to the columnar epithelial cells. The enveloped ODV fuses with the microvilli membranes (*step 3*), releasing nucleocapsids into the cytoplasm, whereupon they migrate to the nucleus (*step 4*). The remaining replication events (*steps 5 to 11*) are similar to those in cultured cells (**A**).

Attachment, Endocytosis, and Uncoating

BV enters the host cell (see Fig. 2A) by what appears to be receptor-mediated endocytosis (reviewed in 280). However, the participating host-cell receptor(s) has not been identified. A second, less efficient, membrane-fusion mechanism also may allow virus entry (273). The major glycoprotein of BV, gp64 EFP, is required for receptor interaction and fusion with the endosomal membrane (25,127,274). After release within the cytoplasm, nucleocapsids migrate to the nucleus in conjunction with virus-induced actin polymerization (41). Ac*M*NPV nucleocapsids interact end-on with the nuclear pore, enter the nucleus, and uncoat. In this process, the capsid sheath of the nucleocapsid is released from the nucleoprotein core (268). It is unknown whether the 6.9K protamine-like core protein remains associated with the viral chromosome, but phosphorylation by a virus-encapsidated protein kinase may induce its release (284). Uncoating occurs rapidly because new synthesis of viral RNAs can be detected within the first 15 minutes after inoculation (45,113,140,160,195,260).

Early Phase

By definition, the early replication phase (from 0 through 6–9 hours) precedes virus DNA replication. During this period, baculoviruses express genes encoding transcriptional activators, a virus-specific RNA polymerase activity, DNA replication factors, apoptotic suppressors, and others. These early gene products prepare the cell for the enormous burden imposed by the synthesis of viral nucleic acid and structural components that can constitute more than a third of the infected cell's mass (Fig. 3A). The level and timing of both early and late gene expression is orchestrated to ensure proper temporal assembly of infectious BV and OV. Early viral gene products also block cell-cycle progression, causing infected cells to accumulate in S and G_2/M phases (28,142). In addition, the cell's cytoskeletal structure is dramatically rearranged. Both filamentous actin and microtubules are redistributed, leading to a characteristic hypertrophy of the nucleus and cell rounding during infection (40,41,234).

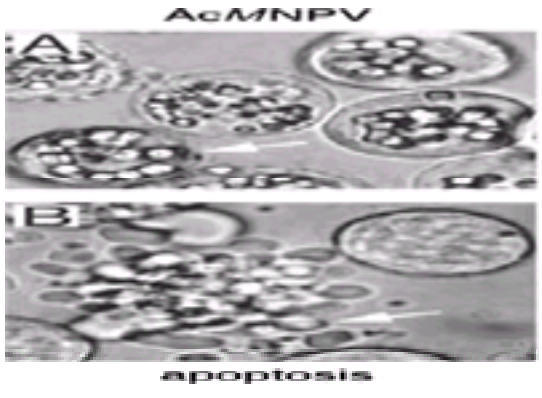

FIG. 3. Ac*M*NPV-infected SF21cells and apoptosis. **A:** Infection with wild-type Ac*M*NPV. Very late in infection the highly refractile OV particles *(arrow)* accumulate in the hypertrophied nucleus of each cell. **B:** Late stages of apoptotic blebbing. A single cell has undergone apoptosis forming a cell mass surrounded by membrane-enveloped apoptotic bodies

(arrow). Magnification, 200x. Micrographs provided by Gulam Manji, University of Wisconsin-Madison.

Baculovirus gene expression is regulated primarily at the level of transcription and involves a highly coordinated cascade of gene-activation events (recently reviewed in 80 and 178). Transcription of strictly defined early genes usually peaks between 6 and 12 hours after infection and declines thereafter, as late viral transcription accelerates. During this early time, the viral DNA genome adopts a nucleosome-like structure (286). The level of viral early RNAs is usually lower than that of late RNAs, which are transcribed by a novel virus-encoded RNA polymerase (RNA pol) specific for late genes. Suggesting that early transcription is mediated by host RNA pol II, early RNA synthesis is inhibited by a-amanitin (106,141), and early promoters are active in cell-free transcription extracts from uninfected cells (21,93,135,223). Moreover, the structure of early viral promoters resembles that of host RNA pol II promoters, complete with a consensus TATA element located ~30 bp upstream from the RNA start site (22,61,110,159,175,223,260). A tetranucleotide CAGT motif found at the RNA start site is common to early promoters and functions as an initiator element (21,222). These core promoter elements also cooperate with upstream activating elements or more distal transcription enhancers (*hr*s) to interact with sequence-specific transcription activators. The cis-acting transcriptional control elements for multiple Ac*M*NPV early genes have been studied in detail, including those for *ie-1, gp64* EFP, *pp31* (39K), *he65*, and *p35*. Viral DNA devoid of protein is infectious, indicating that viral structural proteins are not required for early gene expression. However, many early promoters are highly responsive to virus-encoded transactivators, including the multifunctional regulatory protein IE1 or its spliced gene product IE0 (reviewed in 80). Although it is likely that many host transcription factors also participate in promoting viral transcription, few cellular factors have been identified (92,151,159,228).

IE1 is the principal transcriptional regulator of early baculovirus genes. When assayed by plasmid transfections, IE1 stimulates early, but not late baculovirus promoters (22,110,111,158,162,175,195,209,229,260). This highly conserved, 67-kd transregulator has a modular structure consisting of an acidic transactivation domain(s) within its N-terminal half and DNA binding and oligomerization domain(s) at its C terminus (156,233,244). IE1 also augments expression of genes that are cis-linked to the *hr* elements by interacting with the 28-bp palindromes within these enhancers (108,112,156,169,195,232). By virtue of its interaction with the *hr*s, the co-localization of IE1 and DNA replication factors (202), and the requirement for IE1 in plasmid replication assays (see later), it is postulated that IE1 also contributes to viral DNA replication. However, the exact functions of IE1 during infection are still unclear (229).

Baculoviruses encode additional transcription activators, including IE0, IE2, and PE38. Although these proteins are conserved among baculoviruses, their role during infection is poorly understood. Derived by RNA splicing, IE0 is identical to IE1, except for 54 additional residues at its N terminus. It therefore has regulatory activities similar to those of IE1 (45,158,212,232). IE2 is a 47-kd leucine zipper, RING finger-containing transactivator that is also conserved among baculoviruses (35,261,293). Ac*M*NPV mutants containing loss-of-function *ie-2* alleles are viable, but exhibit delays in virus replication (218). On overexpression in transfected cells, *ie-2* causes cell-cycle arrest (220), but the significance of this activity is unknown. IE2 and the transregulator PE38 co-localize to punctate nuclear structures in transfected cells (161). PE38, which also contains a leucine zipper and RING finger, is capable of promoter-specific transactivation in plasmid transfection assays (160,175,209).

In general, the promoters for the immediate early baculovirus genes are highly active in the absence of virus proteins (158,161,223,261). As a consequence, several of these promoters including those for IE1 and IE2 have been used extensively for high-level gene expression in diverse lepidopteran and dipteran insects by stable or transient transfection protocols.

Late Phase

The late phase of the baculovirus life cycle is initiated by viral DNA replication, which begins between 6 and 12 hours after infection. The synthesis of new genomic DNA and the expression of late structural genes are necessary for the production of BV, the predominant infectious form generated during this period. Viral late gene expression is dependent on proper viral DNA replication. For example, inhibition of viral DNA synthesis by using a temperature-sensitive (*ts*) mutant in the helicase *p143* gene (see later) blocks DNA replication at the nonpermissive temperature and abrogates late gene expression and BV production (96). Likewise, treatment of infected cells with aphidicolin, which inhibits viral and host DNA polymerases, prevents viral DNA synthesis and blocks late viral transcription (230). The molecular basis for the coupling of late gene expression to DNA replication is unknown, but is common among large DNA viruses. At least five baculovirus genes (*ie-1, p143, lef-1, lef-2,* and *lef-3*) are required for DNA replication (Table 2). These genes were identified by using transient DNA replication assays conducted with plasmids containing an *hr* element/origin (152,177). The essential function of several replication genes during infection has been confirmed through the use of conditionally lethal mutants (see Table 2). Replication factors include a DNA-binding helicase (p143), a putative primase (LEF-1), a primase-associated protein (LEF-2), and a single-stranded DNA binding protein (LEF-3). The transactivator IE1 may stimulate transcription of the early replication genes and act as a DNA origin (*hr*)-binding protein (176). Five other genes (*dnapol, ie-2, lef-7, pe38*, and *p35*) directly or indirectly stimulate replication in this transient replication assay (reviewed in 176). A virus-specific DNA polymerase activity has been characterized (120,267), but the exact role of virus-encoded *dnapol* during infection is unclear. Viral factors localize to centers of viral DNA replication within the virogenic stroma appearing with the nucleus (see later) (202).

Gene	DNA replication	LATE expression	Function/Homology	Virus mutants
ie-1	+	+	Transcription transactivator; DNA-origin binding protein	tsB901
ie-2	+	+	Transcription transactivator; cell line–specific cell cycle regulator	
p47	–	+	Late RNA pol component	ts51-7
p143	+	–	Helicase; DNA binding; ATP binding motif	tsB
dnapol	?	+	DNA polymerase; 5′→3′ exonuclease	
pp31	–	+	Tumigenic virions association	
p35	+	–	Apoptosis suppressor	
lef-1	+	+	Primase homology (MIYDAD motif); LEF2 association	
lef-2	+	+	Primase-associated protein? Late, *trans* expression	tsL5-H
lef-3	+	+	ssDNA binding, p143 association	
lef-4	–	+	Late RNA pol component; guanyl transferase; 5′ triphosphatase	tsG30
lef-5	+	–	Unknown	
lef-6	+	–	Vaccinia virus RNA pol homology	
lef-7	+	+	Cell line–specific DNA replication	ref-7-KO
lef-8	–	+	Late RNA pol component	tsG1
lef-9	–	+	Late RNA pol component	
lef-10	–	+	Unknown	
lef-11	–	+	Unknown	
lef-12	–	+	Unknown	
p6.9	+	+	Transactivator of p143	
hcf-1	+	+	Cell line–specific, late, and VEL expression	
lef-3	–	–	ssDNA expression, nuclease/helicase/primase homology	tsB901?

TABLE 2. *Baculovirus DNA replication and late expression factors*

The mechanisms of baculovirus DNA replication are less well understood. Although the *hr* sequences are likely origins of viral DNA replication (154,169,210), it remains to be demonstrated that they act as origins during infection. The *hr*s are functionally redundant and do not affect late gene expression (210,229,231). Other non-*hr* sequences within the genome also have been implicated as replication origins (153,167,288). As suggested by the presence of multiple unit-length genome fragments and concatamers of defective genomes in cells (167,207), the large DNA genome may be replicated by a rolling-circle mechanism. Newly replicated, unit-length circles of DNA are packaged within nucleocapsids. During the late phase, the viral DNA adopts a nucleoprotein organization distinct from the host DNA that remains in a typical nucleosomal structure (286). The replicative or transcriptional function of this viral nucleoprotein structure is unknown.

Nineteen baculovirus genes are required for late gene expression (see Table 2), as first determined for Ac*M*NPV (173,177,227). These genes, designated late expression factors (*lef*s), were identified by their ability to support high-level expression of a reporter gene placed under control of a virus late promoter and cis-linked to an *hr* origin/enhancer element (209). The function and role of the *lef*s in baculovirus replication is the subject of ongoing research in this field (reviewed in 178). Because of the link between DNA replication and late gene expression, several genes required for late gene expression (*ie-1, p143, lef-1, lef-2*, and *lef-3*) are required DNA replication factors (see Table 2). Multiple *lef*s (*ie-2, lef-7*, and *hcf-1*) confer tissue or species specificity, because they are dispensable for late gene expression in certain cell lines. In addition, a variety of viral genes contribute to host range, including helicase *p143* and host range factor-1 (*hrf-1*) (42,53,148). Several *lef*s function directly or indirectly at the level of transcription or mRNA stabilization (see Table 2). Of these genes, four (*p47, lef-4, lef-8*, and *lef-9*) have been shown to encode components or subunits of the viral RNA polymerase (114) specific for late and very late gene expression (see later). The role of transcription-specific *lef*s during infection also has been characterized by using conditionally lethal mutations (see Table 2).

Unique among the nuclear-replicating DNA viruses, the baculoviruses switch from host RNA pol II for early transcription to a novel RNA polymerase for selective transcription of late and very late genes. The virus-encoded RNA polymerase retains its specificity for late virus promoters when assayed by using *in vitro* transcription extracts and is distinguished from other host RNA polymerases by its resistance to a-amanitin and tagetitoxin, inhibitors of RNA pol II and III, respectively (87,93,140,289). Chromatographic analyses of the late RNA polymerase activity indicated that the core of the complex comprises p47, LEF-4, LEF-8, and LEF-9, and is associated with additional proteins (13,114).

Late RNA transcripts initiate from a nucleotide motif containing the sequence (A/G/T)TAAG, which is the primary element for late and very late promoter activity (reviewed in 178). All genes encoding proteins synthesized in abundance during the late phase, including the major capsid protein vp39, the 6.9K basic core protein, and gp64 EFP, possess this late promoter motif. Nucleotide substitutions within the TAAG motif cause a dramatic loss of late promoter activity (191). Moreover, fewer than 18 nucleotides surrounding this initiation site are sufficient to direct high-level late gene expression. This simple promoter organization is reminiscent of yeast mitochondrial promoters and the T-odd bacteriophage promoters. Interestingly, certain late genes have multiple TAAG motifs, each serving as an independent RNA initiation site. For example, the *vp39* capsid gene is transcribed from three autonomous TAAG motifs at –57, –105, and –321 relative to the ORF (264). Such an arrangement may boost transcription levels needed for highly expressed genes. It is noteworthy that some early genes (*p35, gp64, pp31*, and *ie-1*) are also transcribed late in infection. This late transcription is most often accomplished by the use of late TAAG-containing elements that overlap the early promoter elements (22,110,195,222).

Very Late Phase

The final, very late stage of infection is characterized by the hyperexpression of occlusion-specific genes and the production of mature OV from 18 through 76 hours after infection or until cell lysis (Fig. 3A and Fig. 4). The very late phase is marked by a dramatic increase in transcription of *polh*, which encodes the major matrix protein of the OV. The temporally regulated hyperexpression of *polh* and its nonessential nature for BV production were the basis for development of the baculoviruses as highly efficient and productive vectors for foreign gene expression (reviewed in 144,155,186, and 199). In early vectors, foreign genes were placed under control of the *polh* promoter replacing the *polh* ORF to obtain high levels of expression very late in infection of cultured cells or whole larvae (180,215,245). More recently, the expression system has been extended to include other promoters, including that of the *p10* gene (see later).

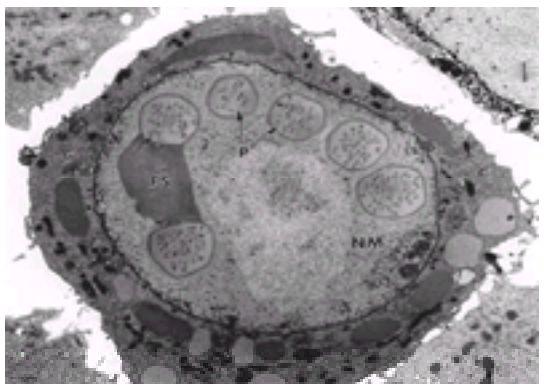

FIG. 4. The very late, occlusion stage of Ac*M*NPV infection. During the very late, occlusion phase, multiple OV particles of polyhedrin (*P*) form on the inside edge of the enlarged nucleus, defined by an intact nuclear membrane (*NM*). Dense fibrillar structures (*FS*) often form in the nucleus and the cytoplasm (*C*). Electron micrograph was provided by Dr. Peter Faulkner and Dr. Gregory Williams, Queens University.

Very late genes also are transcribed by the baculovirus a-amanitin-insensitive RNA polymerase. The promoters of these hypertranscribed genes, which include *polh* and *p10*, contain the late TAAG motif, which is the critical transcriptional element as shown by mutational analyses. However, these very late promoters also are positively regulated by the 50 nucleotides constituting the noncoding leader of their gene (191,205,279). This region between the TAAG and the ORF is responsible for the very late burst of transcriptional activity that distinguishes very late genes from late genes. Interestingly, insertion of the “burst” sequences immediately downstream from a late promoter was not sufficient to convert it to a very late promoter (191). These sequences may interact with activation factors responsible for the stimulation of transcription at this late time. Genetic evidence (184) suggests that virus-encoded very late factor-1 (VLF-1) is a likely candidate for the positive activator (see Table 2). VLF-1 forms a complex with the burst sequences, but the mechanism of transcriptional enhancement is not known (292). Host factors also may participate in transcription of very late genes (92).

The p10 gene is also the other hyperexpressed during the very late phase (reviewed in 196). It encodes a small coiled coil-domain protein (P10) that associates with expansive fibrillar structures that assemble in the nucleus and cytoplasm late in infection (see Fig. 4). P10 is nonessential for NPV replication, including OV formation (271,281). However, it may contribute to disruption of the nuclear membrane and may function at the tissue or organismal levels.

Virus Assembly, Budding, and Occlusion

Nucleocapsids assemble during the late and very late phases of infection. New capsids appear at the edge of the stromal matte located in the virogenic stroma (see Fig. 1D), a virus-specific nucleoprotein structure centered within the nucleus (123,294). Partially filled nucleocapsids with DNA strands connecting the core with the virogenic stroma have been observed, suggesting that the virogenic stroma may be the site of viral DNA replication, condensation, and encapsulation (77,294). A major viral protein associated with the virogenic stroma is phosphoprotein pp31, which is capable of DNA binding by a phosphorylation-regulated mechanism (30,31). RNA also may serve as a structural component of the virogenic stroma (294). Little else is known about this critically important virus-replication center. Newly assembled nucleocapsids exit the nucleus by budding or by transport through nuclear pores (see Fig. 2) (reviewed in 280). Nucleocapsid maturation is sensitive to the actin-depolymerizing drug cytochalasin D, suggesting a critical role for actin in this morphogenic process (40,201). Although enveloped nucleocapsids have been observed in the cytoplasm, the nuclear envelope is removed when the plasma membrane is reached. By interacting end-on with the plasma membrane that is associated with the envelope fusion protein EFP gp64, single nucleocapsids bud from the cell surface to produce extracellular BV (see Fig. 1C). EFP gp64 is required for budding of Ac*M*NPV (206). The rate of BV release from Ac*M*NPV-infected cells increases exponentially from 10 to 20 hours and then declines through 36 hours (166). The kinetics of BV production varies between baculoviruses.

OV particles accumulate in the nucleus of Ac*M*NPV-infected cells (see Fig. 3A and Fig. 4) starting ~18 hours after infection. OV production accelerates as BV production shuts down. Virion occlusion involves a number of processes, including virus-induced modification of the nuclear membrane and nuclear transport of polyhedrin, the OV matrix protein (145,280). Nucleocapsids align along nuclear membrane segments and acquire an envelope before condensation of polyhedrin, which encases the enveloped virions (see Fig. 1E). OV formation begins on the inside edge of the infected nucleus (see Fig. 4). Time-lapse video microscopy has indicated that the number of OV particles per cell is established early, and with time, each particle increases in size (181). Maturation of the OV includes deposition of the polyhedron envelope (calyx) over the particle's surface. OV is released from the nucleus on cytolysis very late in infection. Multiple virus genes are likely involved in OV production. For example, loss of function of the 25K protein gene of Ac *M*NPV causes the easily recognized “few polyhedra” (FP) phenotype, which is characterized by reduced OV accumulation, limited intranuclear envelopment of nucleocapsids, and increased production of BV (10,27,124). The exact function of the cytoplasmic 25K protein remains unknown. A gene involved in calyx formation also has been identified (94).

Disease Progression in the Insect

Horizontal transmission of baculoviruses occurs through the OV, the form of the virus that is most stable and resistant to environmental degradation. Primary infection occurs in the midgut epithelium of the insect larva (reviewed in 69). Infection is initiated by larval ingestion of virus-contaminated food. On entry into the midgut lumen (see Fig. 2B), the OV particles dissolve in response to the alkaline environment, thereby releasing the ODV. These virions pass through the peritrophic membrane, facilitated by the activity of virus-encoded proteases (enhancins), first discovered in the GVs (170). ODVs subsequently bind to the brush-border membrane of columnar epithelial cells and enter, apparently by direct

fusion with the plasma membranes (see Fig. 2B). Infection proceeds in a manner similar to that of BV-infected cell cultures, with the interesting exception that formation of OV in midgut cells of most lepidopteran hosts is rare (76). In addition, there is a distinct polarity in the intracellular transport of EFP gp64, which is directed primarily to the basal membrane side of the midgut cell (149). This directionality likely dictates nucleocapsid budding to the basal lamina, allowing access of BV to the hemocoel and tracheal epithelium for rapid systemic spread. Certain baculoviruses, such as the mosquito (Diptera) NPVs, are restricted to the midgut.

Secondary infection is achieved by BV produced in midgut cells (see Fig. 2A). Virus is spread by hemocytes (blood cells), the epithelial cells lining the tracheal network, or both (65,101). With highly susceptible hosts, secondary infection can affect virtually all the internal tissues of the larva (69). In the final phases, the larva is converted into a milky white liquid, consisting mostly of OV particles. This process, referred to as “melting” or “liquification,” is facilitated by a virus-encoded cathepsin and chitinase, which cooperate to break down the larval cuticle (skin) (125). In a typical Ac*M*NPV infection, more than 10^8 OV particles are produced per larva, constituting more than 10% of the dry weight of the insect. On rupture of the cuticular exoskeleton, OV is released into the environment for transmission to other insects.

It is noteworthy that not all baculoviruses are lethal. There are several reports of persistent or latent baculovirus infections in seeming healthy insects. Such viruses may be transmitted vertically. The most thoroughly described virus/host system is that of a *Mammestra brassicae* NPV that persists in a laboratory insect colony without causing significant mortality (139).

Baculovirus-Mediated Alterations of the Host

Baculoviruses have dramatic effects on the host cell, altering both cytoskeletal and nuclear structure (see earlier) and causing shutdown of host protein and RNA synthesis (36,203). However, these viruses also can control their insect hosts at the physiologic and behavioral levels (reviewed in 196). For example, infected larvae often display the abnormal behavior of wandering away from their food supply or climbing to the top of the vegetation, where they succumb hanging from a leaf or branch. This strategy may facilitate virus dispersal. In another example, baculoviruses arrest development of their larval hosts by controlling the activity of ecdysone, the steroid hormone that triggers molting (197). The baculovirus *egt* gene encodes an ecdysteroid uridine diphosphate (UDP)-glucose/galactose transferase, which is secreted from infected cells and transfers glucose or galactose to the hydroxyl group at position C22 of these ecdysteroids. Evidence exists that viral *egt* blocks larval molting (reviewed in 196). Larval developmental arrest is correlated with increased virus production, because on deletion of *egt*, infected larvae attempt to molt, but die sooner and produce less virus (198). The overall effect of *egt* depends on virus dose and the developmental stage at the time of inoculation.

Apoptosis and Apoptotic Suppressors

The replicative success of baculoviruses depends on active suppression of host-cell apoptosis, a process that may represent an antivirus defense strategy by the host. Apoptosis or programmed cell death (PCD) is a highly conserved mechanism for cellular self-destruction that is critically important in normal development, tissue homeostasis, and virus pathogenesis. To counteract the apoptotic suicide response and prolong cell viability, the baculoviruses encode novel apoptotic suppressors, which block virus-induced apoptosis (reviewed in 47 and 187). Because these same proteins function in phylogenetically diverse organisms, baculoviruses have provided important insight into the biochemical components of PCD and its regulation.

Ac*M*NPV mutants that lack PCD suppressors cause widespread apoptosis (48,49,129). Apoptosis of cultured *Spodoptera frugiperda* SF21 cells, a model system for studies of invertebrate PCD, is characterized by fragmentation of cellular and viral DNA and dismemberment of the infected cell into extracellular vesicles called apoptotic bodies (see Fig. 3B) (48,164,181). SF21 cells are highly sensitive to a variety of apoptotic stimuli, including UV radiation, actinomycin D, calcium ionophores, okadaic acid, and hydrogen peroxide (Fig. 5A). In cultured cells, apoptosis reduces the yield of infectious virus by as much as 10,000-fold (49,129). Moreover, the infectivity of apoptosis-causing Ac*M*NPV mutants in larvae is 25- to 1,000-fold lower than that of wild-type virus (49), suggesting that apoptosis impedes baculovirus multiplication in larvae. Interestingly, baculovirus-induced apoptosis is tissue or species specific. For example, cultured *Trichoplusia ni* TN368 cells fail to undergo apoptosis when infected by Ac*M*NPV mutants that cause apoptosis of SF21 cells (49,129). In *T. ni* larvae, the infectivity of these mutants is comparable to that of wild-type virus. The molecular basis of this cellular resistance to virus-induced apoptosis is not understood.

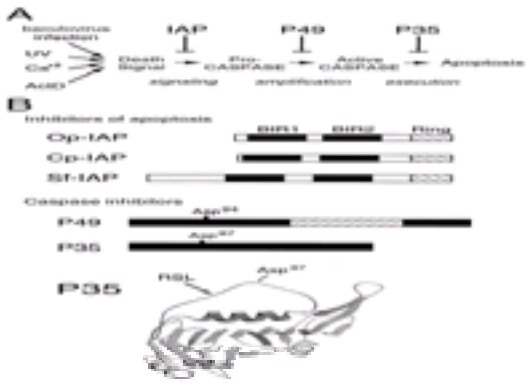

FIG. 5. Baculovirus suppressors of apoptosis. **A:** The apoptotic pathway. Apoptosis of S. *frugiperda* (SF21) cells is signaled by baculovirus infection and other agents which cause proteolytic cleavage of the inactive procaspases to their active forms. P35 functions to inhibit active caspases, including *Sf*-caspase-1, whereas P49 functions upstream to inhibit an apical caspase. Baculovirus IAP functions upstream of P49 to block procaspase activation. **B:** Comparison of baculovirus apoptotic regulators. The IAPs contain two BIRs (baculovirus inhibitor of apoptosis repeats) motifs and a C-terminal Ring finger motif. Viral IAPs, Op-IAP and Cp-IAP, closely resemble Sf-IAP, a cellular IAP from host

lepidopteran *S. frugiperda.* Caspase inhibitors P49 and P35 are 49% identical and contain aspartate residues (Asp ^{94} and Asp^{87}) required for caspase cleavage. P49 contains a 120 residue insertion (crosshatched) unrelated to P35. The P35 crystal structure (bottom) illustrates its reactive site loop (RSL) in which Asp ^{87} is located at the apex for caspase cleavage and interaction.

It is likely that multiple mechanisms are responsible for triggering apoptosis during baculovirus infection. Virus binding to cellular receptors is not sufficient. Rather, viral gene expression is required (50,164). After Ac*M*NPV infection, the earliest of detected apoptotic events (see Fig. 5A) is the activation of host-cell caspases (16,165). The caspases are a highly conserved family of **c**ysteinyl **asp**artate–specific prote**ases** that are critical and necessary effectors of apoptosis (reviewed in 265). Proteolytic activation of the proenzyme form of *Sf*-caspase-1, the principal executioner caspase in SF21 cells, coincides with the initiation of virus DNA replication (164,165,182,242). Thus apoptotic signaling must occur at or before this time, suggesting that viral DNA replication, late gene products, or shutdown of host RNA or protein synthesis may trigger apoptosis (50,164). Early gene expression also can contribute to apoptotic signaling (164). In particular, transactivator IE1 is sufficient to induce limited apoptosis in SF21 cells on overexpression by plasmid transfection (219). However, the mechanism by which IE1 induces apoptosis and its role in baculovirus-induced apoptosis are unclear (229).

The baculoviruses encode two mechanistically distinct types of apoptotic suppressors (see Fig. 5B), the inhibitors of apoptosis (IAPs) and the caspase inhibitors (P35 and P49). These proteins prevent premature host-cell death and thereby promote virus multiplication (reviewed in 47 and 187). Identification of functional *iap genes* in lepidopteran insects (see Fig. 5B) suggests that baculoviruses originally acquired these apoptotic regulators from the host cell (138,243). This possibility is consistent with the strong selective advantage conferred to the virus by the capacity to prevent virus-induced apoptosis (172). Although baculoviruses encode multiple apoptotic suppressors, usually one is sufficient per genome. For example, Ac*M*NPV encodes one functional copy of *p35* and two copies of *iap* (*iap1* and *iap2*), which are nonfunctional for blocking virus-induced apoptosis (50,103). Lacking *p35,* Op*M*NPV encodes one functional (*iap3*) and three nonfunctional *iap*s (19).

Baculovirus IAPs were the first discovered members of the IAP family, which now includes related proteins from invertebrates and vertebrates (reviewed in 47,59, and 187). IAPs are distinguished by their highly conserved Cys/His-containing motif called the BIR (**b**aculovirus **i***ap* **r**epeat) (see Fig. 5B). This defining ~65-residue motif coordinates a Zn atom and is required for IAP antiapoptotic function. Baculovirus Op-IAP (31 kd) and Cp-IAP (31 kd) from Op*M*NPV and CpGV, respectively, contain two BIRs and a C-terminal RING finger motif (19,54). Suggesting that they function at a conserved step in the apoptotic pathway, the viral IAPs prevent apoptosis induced by diverse signals in insect and mammalian cells (47,187). The BIR motif is required for interaction with cellular proapoptotic factors, including Reaper, Hid, and Grim from *Drosophila melanogaster* (276,277). In addition, the BIRs mediate homo-oligomerization of Op-IAP, which appears to be required for antiapoptotic activity (137). However, the molecular mechanism by which the BIRs contribute to viral IAP antiapoptotic activity is still unclear. More is known about mammalian IAPs, which directly inhibit activated caspases (59). Consistent with an anticaspase mechanism, Op-IAP prevents the appearance of caspase activity *in vivo* and blocks the proteolytic activation of *Sf*-caspase-1 by an upstream, apical caspase (165,182,242). Thus Op-IAP may function at or upstream of the step at which the caspases are activated in insects (see Fig. 5A).

First discovered in Ac*M*NPV (48), P35 is a universal suppressor of apoptosis. Ectopic expression of the *p35* gene prevents PCD in nematodes, flies, moths, and mice, as well as cultured human cells (37,50,58,133,143,224,225,257,270). Accounting for its broad effectiveness, P35 (35 kd) functions as a substrate inhibitor of the caspases. To block virus-induced apoptosis, P35 must be synthesized early in infection before the activation of host caspases (130). P35 is cleaved by the targeted caspase at Asp^{87} and forms a stable, stoichiometric complex (16,32,298). The 2.2-Å crystal structure of P35 reveals that the Asp^{87} cleavage site is located at the apex of a novel solvent-exposed reactive site loop (see Fig. 5B), the orientation of which is critical to P35's anticaspase activity (72,300). Identified in *Spodoptera littoralis* NPV, baculovirus P49 also blocks virus-induced apoptosis (63). At the amino acid level, P49 is 49% identical to P35 and contains a predicted reactive site loop with a cleavage site at Asp ^{94} (see Fig. 5B). Although P49 functions as a substrate inhibitor, it targets apical caspases that are upstream of and distinct from those inhibited by P35 (301). Thus baculoviruses have evolved multiple caspase inhibitors with different target specificities. Moreover, baculoviruses have evolved mechanisms to block virus-induced apoptosis at multiple steps in the death pathway (see Fig. 5A). No cellular homologs of *p35* or *p49* have been identified.

Host Transposons

The baculoviruses are one of the few families of animal viruses that accommodate the frequent and spontaneous insertion of host-derived transposable elements (reviewed in 79). By virtue of their nuclear replication and flexibility with respect to size of their DNA genome, baculoviruses are vulnerable to the insertion of resident transposons. Because of their relative abundance and mobility, arthropod transposons represent important insertional mutagens and can have a significant influence on virus and host evolution. Transposon insertion provides genetic diversity and potentially novel genes to the recipient virus. The baculovirus' capacity to act as a landing platform for these elements has led to the identification of new families of lepidopteran transposons.

Baculovirus mutants with transposon insertions are often distinguished by their altered plaque morphology, especially the “few polyhedra” (FP) phenotype, which exhibits reduced OV accumulation (see earlier). Several FP-causing lepidopteran transposons, including IFP2, IFP2.2, IFP1.6, TFP3, and hitchhiker, have been identified by their insertion at or near the FP locus that encodes the 25K protein gene (9,10 and 11,38,78). These middle to highly repetitive elements are characterized by their small size and terminal inverted repeats that sometimes flank a transposase-like ORF. Significantly, IFP2 (also called PiggyBac) is a 2.5-kb autonomous transposon from the moth *T. ni,* which is capable of stable germline transformation of the Mediterranean fruit fly from the order Diptera (119). Thus PiggyBac and other

lepidopteran elements have the potential for gene transfer in nondrosophilid insects.

Also discovered as a baculovirus insertion, TED (transposable element D) is a 7.5-kb, middle-repetitive retrotransposon of *T. ni* (82,185). TED has a retrovirus-like organization with *gag, pol,* and *env* genes that are flanked by long terminal repeats, and thus is a member of the gypsy family of retroelements (79). Unlike the smaller lepidopteran transposons, TED assembles virus-like *gag*-containing particles, complete with protease and reverse transcriptase activities (115,171). Moreover, the TED *env* gene encodes a membrane-associated glycoprotein that could function as a viral envelope protein (208). Thus TED and other *env*-carrying gypsy elements are likely insect retroviruses. As such, integration within the baculovirus genome could facilitate interspecies shuttling of these passenger viruses (79,185).

Nudiviruses

Classification and Structure of Nudiviruses

The nudiviruses were previously categorized as “nonoccluded” baculoviruses, but are currently unclassified. Like the baculoviruses, they have rod-shaped, enveloped nucleocapsids that contain a large circular, double-stranded DNA genome (recently reviewed in 33). The envelope is acquired in the nucleus, and in some cases, a second unit membrane is obtained by budding from the plasma membrane of the infected cell. In contrast to the baculoviruses, the nudiviruses lack an occluded form. This difference limits their survival outside the host and may contribute to their persistence or latency in infected insects. Because of the paucity of nucleotide sequence information, the relatedness between individual nudiviruses or baculoviruses is unknown. The nudiviruses could be an aggregate of genetically diverse viruses.

Nudivirus Transmission and Persistence

Nudiviruses can exert dramatic effects on insect populations. Oryctes virus, a nudivirus infecting the rhinoceros beetle *Oryctes rhinoceros,* causes a potentially fatal infection that initiates in the midgut of adult beetles and their larvae (295,296). This virus has been enormously successful as a control agent of the rhinoceros beetle in coconut plantations in the South Pacific (297). Virus transmission occurs primarily through contaminated food sources, but also can occur through mating. Another nudivirus, Gonad Specific Virus (GSV), infects gonadal tissue (ovarian and testicular organs) of adult moths and causes sterility (116,226). GSV appears to be transmitted by asymptomatic carriers within the insect population and can be vertically transmitted from eggs, probably in a persistent or latent state. Virus replication is hormonally activated in adult gonadal tissue. Hormonal or developmental activation also occurs with other viruses, including the polydnaviruses (see later). GSV can be propagated in cell culture, and persistently infected cell lines have been established (34).

Hz-1 is the most extensively studied nudivirus at the molecular level. This complex, nonoccluded virus has provided a useful model for insect virus persistence and latency (reviewed in 33). Hz-1 was originally isolated from a persistently infected cell line established from adult ovarian tissue of the corn earworm *Heliothis zea* (102). It has an unusually large (230 kbp) circular, double-stranded DNA genome. Hz-1 establishes persistent infections of cultured cells where replication occurs at low levels and produces defective interfering particles. Virus from persistent infections can cause lytic infection of naive cells not previously exposed to virus. The genome of persistently infected cells can harbor stably integrated Hz-1 DNA (174). The establishment or maintenance of viral persistence is associated with the synthesis of a single 2.9-kb RNA transcript from Hz-1, referred to as the persistency-associated transcript (PAT1) (39). The function of PAT1 and whether it encodes a protein(s) is unknown. Hz-1–infected cells also are resistant to superinfection. This immunity is not due to an acquired resistance to virus-induced apoptosis (168).

Polydnaviridae

Classification and Structure of Polydnaviruses

The polydnaviruses are distinguished by their obligate and mutualistic association with their host, the endoparasitic wasps (Order Hymenoptera). The family *Polydnaviridae* derives its name from the taxonomically characteristic “polydisperse” DNAs composing its multi-segmented genome. Virions contain numerous double-stranded, supercoiled DNA molecules with sizes ranging from 2 to 28 kbp (reviewed in 248 and 278). Depending on the virus, there are 15 to 30 different DNA molecules with an estimated genomic complexity of 75 to 200 kbp. Virion DNA is derived from proviral DNA integrated within the host wasp, where the virus is transmitted vertically. Current evidence indicates that the proviral DNA is also polydisperse within the host genome where certain DNAs are the linear equivalent of circular segments packaged within virions (55,74,105,290). Because polydnaviruses are not known to replicate outside the host wasp, it is not yet clear that virion DNA represents the entire virus genome.

The only characterized polydnaviruses are from endoparasitic wasps. These predatory insects lay their eggs inside the bodies of other living insects, often in the larval stage, where the eggs hatch and the young parasites develop. Polydnaviruses have been isolated from the Ichneumonidae and Braconidae families of wasps and are correspondingly divided into two genera, the ichnoviruses and bracoviruses (278). Although polydnavirus-like particles have been observed in other parasitoids, they remain unclassified.

The ichnoviruses and bracoviruses are morphologically distinct. The only feature shared by the two genera may be their polydisperse virion DNA and their novel life cycle. The ichnovirus virion is complex, resembling that of the ascoviruses (see later). The virions are ellipsoid or quasi-cylindrical, with a uniform size of 90 × 300 nm (Fig. 6A and Fig. 6B). The nucleocapsid is enveloped by two unit membranes, one derived from the nucleus during virion morphogenesis and the other by budding from the plasma membrane of the host cell. Resembling the baculoviruses, bracovirus nucleocapsids are rod-shaped with a uniform diameter (35–40 nm) and variable length (30–200 nm). They have a single membrane envelope, which is derived from the nucleus and surrounds one or more nucleocapsids (see Fig. 6C). Polydnavirus particles contain 20 different polypeptides. The minimal genetic information needed to encode these structural proteins is

about 30 kb. However, evidence exists that some structural proteins may be produced by the expression of integrated, proviral DNA, rather than virion DNA (278).

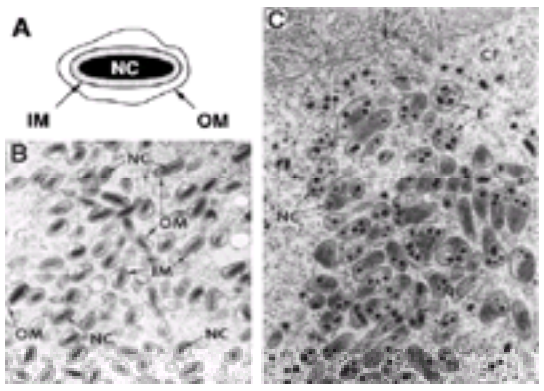

FIG. 6. Morphological features of polydnaviruses. **A:** Schematic view of the ichnovirus structure. The nucleocapsid (*NC*) is surrounded by an inner (*IM*) and outer (*OM*) membrane. **B:** Ichnovirus preparation. Lenticular nucleocapsids (*NC*) of uniform size are enveloped by inner and outer membranes (*IM* and *OM*). **C:** Bracoviruses in the calyx fluid (*CF*) of an adult female parasitoid wasp. Nucleocapsids (*NC*) are observed end-on and in lateral view. Multiple nucleocapsids are surrounded by a unit membrane envelope (*E*). An epithelial cell (*EC*) of the calyx is also observed. Electron micrographs provided by Dr. Donald B. Stoltz, Dalhousie University. Modified with permission from (251).

Obligate Mutualism of Virus and Host

The polydnaviruses play a critical role in the life cycle of their host wasp. This mutualistic participation is central to the multiplication strategy and genetic organization of these novel viruses. The polydnaviruses replicate asymptomatically in the oviducts of female wasps, as a normal step in the development of the reproductive tract (Fig. 7). Proviral DNA is present as dispersed, integrated segments and is inherited in a mendelian fashion (249). On replication, polydnavirus particles accumulate to high density in the calyx fluid of the oviduct. On parasitization, virus and the wasp's egg is delivered to the recipient caterpillar (see Fig. 7). Normally, the caterpillar mounts an immune response that is mediated in part by hemocytes of the open circulatory system, which encapsulate the intruding egg, thereby destroying it. However, in the case of polydnavirus-carrying ichneumonid and braconid wasps, encapsulation is counteracted or repressed by the accompanying virus. As a result, development of the parasitic egg is ensured. Demonstrating a definitive role for virus-mediated abrogation of the host immune response, the wasp egg is destroyed within the larva when introduced in the absence of virus (64). Thus the relationship between polydnavirus and wasp is mutualistic. The wasp requires the virus to provide protection against the immune response of the parasitized insect, and the virus requires the wasp for replication and survival of its genome.

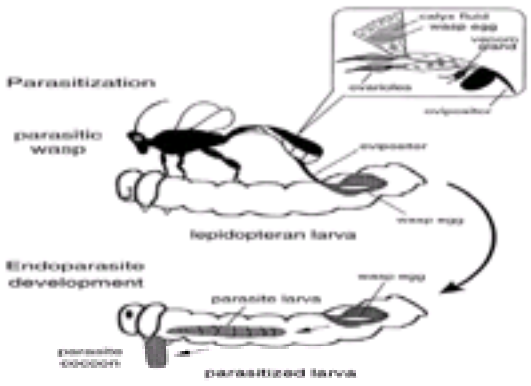

FIG. 7. Polydnavirus life cycle. Polydnavirus particles form in the epithelial cells of adult female ovaries and are released into the calyx fluid where they accumulate to high densities (*top inset*). As the first step in parasitization (*top*), the wasp egg along with virus and venom are injected into a lepidopteran larva during oviposition. During endoparasite development (*bottom*), polydnavirus activity suppresses the larval immune response allowing the wasp egg to develop within the parasitized larva. After development, the wasp larva emerges, spins a cocoon, pupates, and emerges as an adult to repeat the process in a new host. From Dr. Bruce A. Webb, University of Kentucky; modified with permission.

Polydnavirus Genome Organization

The polydnavirus genome is highly complex. Virion DNAs (designated by letters) are nonequimolar, polymorphic in length, and present in multiple topologic forms (superhelical, relaxed circular, etc.) (reviewed in 278). For example, the genome of *Campoletis sonorensis* polydnavirus (CsPDV), the ichnovirus prototype, consists of 28 to 30 different DNAs, ranging in size from 5.5 to 21 kbp, with a collective size of 200 to 250 kbp. It is not known how many viral DNAs are packaged within each virion or whether each virion contains all or a subset of DNA segments. Particles of CsPDV (see Fig. 6) have a uniform size and density and thus may have similar DNA contents. In contrast, bracovirus virions vary in length and may contain different quantities of DNA. In addition, certain ichnovirus DNA segments are likely derived from recombination events within larger segments, which are referred to as “nested” segments (55,290). The presence of nested segments may reduce the effective complexity of virion DNA. However, complete determination of genetic

complexity will require characterization of all genomic DNA segments.

From the few cases in which the relationship between virion and proviral DNA is known, the largest or “master” DNA segments within the wasp genome are flanked by direct repeats. The 16-kbp integrated W segment of CsPDV has long terminal repeats of 1.2 kb (55). Additional 350-bp repeats within this segment are apparently responsible for generating nested R and M segments through homologous recombination during amplification of circular DNA segments in the female wasp. Within the wasp genome, the termini of CsPDV segment B are flanked by 59-bp direct repeats and are removed during excision and circularization of this DNA (74). This finding and others suggest that proviral segments are excised from the wasp genome by recombination before amplification (105). Other sequences are repeated between CsPDV DNA segments, but may not be involved in recombination (262).

Virion DNA from the polydnaviruses carry genes that participate in suppression of the immune response of parasitized caterpillar. Several gene families have been identified (23,60,256,290). One family within CsPDV encodes proteins with sequence similarity to omega-conotoxins of marine snail venoms (60). One of the conotoxin-like proteins has been implicated in the suppression of the encapsulation response (reviewed in 278). Moreover, a functional relationship between the viral toxins and wasp venom peptides may explain the independence of the ichnoviruses from venom gland secretions of the wasp for immune suppression. Another gene family with sequence similarity to epidermal growth factors has been identified in *Microplitis demolitor* polydnavirus (MdPDV) (256). The nature and function of these gene products are unclear. It also is unknown whether virions contain all the genes required for virion assembly, because only a few polydnavirus structural genes have been characterized.

Polydnavirus Life Cycle and Host Effects

The formation of polydnavirus virions occurs primarily, if not exclusively, in the nuclei of epithelial calyx cells composing the oviducts of female wasps (see Fig. 7). Virus replication is under hormonal control and is first detected at a specific stage in wasp pupal development (reviewed in 278). Proviral DNA segments may be amplified in an “onion skin” fashion from within the wasp chromosome and then circularized. Alternatively, proviral DNA may be excised first, circularized, and then amplified. The presence of chromosomal sites lacking proviral DNA in tissues supporting viral replication is consistent with the latter mechanism (105). In mature females, the virions are released from the calyx cells into the oviduct lumen, either by budding (ichnoviruses) or by cell lysis (bracoviruses). The calyx fluid contains massive numbers of polydnavirus particles (see Fig. 6C), which are deposited along with the egg and wasp secretions such as venom from accessory glands during oviposition.

Despite the presence of high concentrations of virions, polydnaviruses cause no obvious pathology in wasps. RNA transcripts from some genomic segments have been detected in wasp ovaries, and there is evidence that some of the viral RNAs produced in wasps differ from those produced in parasitized hosts (23,262). Although virus particles are confined to the female reproductive tract, viral DNA also is present in many tissues of adult females and males (75). The predominant form of the viral DNA in males is the integrated proviral form, but a minor component of extrachromosomal DNA also has been detected.

The most obvious physiologic effect of the polydnaviruses is in the parasitized insect host, where larval immunity and development are altered (reviewed in 254 and 278). The mechanisms of virus-mediated immune suppression are not yet understood. Polydnavirus suppression of encapsulation involves physiologic changes in hemocytes that participate in capsule formation, including granulocytes and plasmatocytes (252). On virus entry, viral gene expression occurs in hemocytes and possibly other tissues. Many hemocytes survive throughout parasitization and continue to support virus gene expression. Some viral gene products are secreted and are thought to affect other hemocytes and tissues. In MdPDV, virus gene products induce apoptosis in a specific subclass of hemocytes, which are involved in the encapsidation response (255). Other aspects of larval physiology also are affected, either directly by polydnavirus-specific proteins or indirectly as result of infection of normal cells.

There is no evidence for polydnavirus replication in the parasitized larva. Neither synthesis of virion DNA nor assembly of virions has been detected. Nonetheless, virion DNA is long-lived, and viral RNA transcription occurs throughout parasitization. In the ichnovirus CsPDV, 12 different polyadenylated RNAs have been identified in parasitized or virion-injected larvae (23,24). Some of these viral RNAs are spliced. CsPDV transcripts are detected within 2 hours and persist throughout development and emergence of the parasite wasp 9 days after oviposition. Several virion gene products have been detected (reviewed in 278). A similar strategy of gene expression and persistence of the bracovirus MdPDV occurs in parasitized and virus-injected *Pseudoplusia includens* larvae (253,256). Viral DNA persists for 6 days, but is not amplified. At least six different classes of MdPDV RNA are synthesized primarily in hemocytes, which may be the principal target for immune suppression. The identification and functional characterization of polydnavirus gene products that modulate the lepidopteran immune system remain the areas of intense interest.

Ascoviridae

Classification and Structure

First discovered in the 1970s, the ascoviruses are classified as a single genus, ascovirus, within the family *Ascoviridae* (reviewed in 70 and 188). The name ascovirus is derived from the Greek word *askós*, meaning sac, to describe the large membrane-bound vesicles that are associated with virus development. The formation of these virion-containing vesicles is unique among viruses and represents the distinguishing feature of *Ascoviridae* (67). The virions are complex, double-enveloped particles having an allantoid (kidney-shaped), ovoidal, or bacilliform shape, depending on the species (Fig. 8A). The virions (~400 × 130 nm) have an electron-dense core that is surrounded by two unit membrane envelopes of unknown composition (see Fig. 8B). At least 12 different proteins, ranging in size from 11 to 200 kd, are present in virions (71).

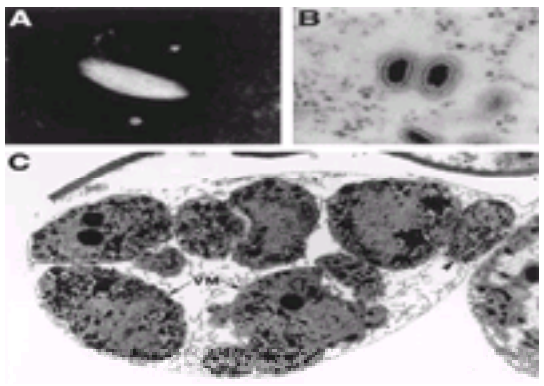

FIG. 8. Ascoviruses. **A:** An individual kidney-shaped nucleocapsid of the ascovirus from the moth *Trichoplusia ni.* The surface is reticular in appearance. **B:** Cross-section of two adjacent virions of the *Scotogramma* ascovirus. A multi-layered membrane envelope surrounds the nucleocapsid. **C:** Remnants of an ascovirus-infected cell. Dark-staining bodies are membrane-bound vesicles (*VM*) that contain *Autographa precationis* ascovirus particles (arrowheads). Different-sized vesicles are collectively bordered by a basement membrane. Provided by Dr. Brian A. Federici, University of California-Riverside, and Dr. J. J. Hamm, USDA-ARS, Tifton, GA; modified with permission from refs. 68 and 70.

Ascoviruses have a large, double-stranded DNA genome of ~100 to 180 kbp, as estimated by restriction fragment analyses (67,71). Evidence exists that the DNA genome is circular (18,44), but such forms have not been confirmed by electron microscopy. Limited nucleotide sequence information is available. Sequence comparisons of the *dnapol* gene of *S. frugiperda* ascovirus (SAV) with that of other viral *dnapol*s suggest that the ascoviruses are a unique virus family that is most closely related to the iridoviruses (214). Short imperfect repeats also have been identified within the ascovirus genome (18).

Replication Stages

Studies on ascovirus replication have been limited to cytologic observations in tissues of infected moth larvae (188). The first sign of infection is nuclear and cellular hypertrophy, in which the diameter of the infected cell increases from fivefold to 10-fold (67). As replication proceeds, the nucleus fragments, and the cell separates into 20 to 30 membrane-bound vesicles that contain assembling virions (see Fig. 8C). This unusual process involves extensive invagination of the plasma membrane, similar to that of a cell undergoing apoptosis. Once formed, the vesicles dissociate from the cell and are released into the hemolymph. As the vesicles accumulate, basement membranes surrounding the tissue are disrupted, and the hemocoel becomes filled with ~10^8 vesicles/mL, a process that turns the hemolymph a milky white color.

Ascovirus Transmission and Disease Progression

In the laboratory, ascovirus transmission is accomplished by pricking the host with a fine pin contaminated with virus-containing vesicles. A dose of 10 vesicles is sufficient to infect more than 90% of inoculated insects. In nature, ascoviruses are probably transmitted by female endoparasitic wasps through virus contamination of their ovipositor during egg laying. For example, *Diadromus pulchellus* ascovirus (DpAV) is vectored by the ichneumonid wasp *Diadromus pulchellus* during oviposition of leek moth pupae, where the virus multiplies during parasitization (18). DpAV can be found in the wasp reproductive tract, but appears to replicate poorly there. DpAV DNA is found in both male and female wasps. A mutualistic relationship between the ascovirus and its wasp vector is suspected, because survival of *D. pulchellus* wasps in the laboratory is positively correlated with the presence of DpAV (17). The host range of ascoviruses may include only a few closely related species or may extend to species in different families (117).

Ascoviruses cause a slow, chronic infection in lepidopteran (moth) larvae or pupae. The disease causes reduced feeding, aberrant development, and death within 2 to 6 weeks (reviewed in 188). During the early stages, there is little obvious pathology. In the later stages, the most notable disease symptom is developmental arrest. Some larvae exhibit a milky discoloration. Different ascoviruses exhibit different tissue tropisms. For example, SAV selectively multiplies in fat body, whereas other viruses multiply in diverse tissues.

Nodaviridae

Classification of Nodaviruses

The *Nodaviridae* are small riboviruses with a single-stranded, positive-sense genome of two RNAs. The bipartite genome is packaged within a single, nonenveloped virion (~30 nm diameter) with T=3 icosahedral symmetry (recently reviewed in 8,146, and 238). The genome organization and replication strategy of the nodaviruses is among the simplest of known viruses (Fig. 9). As such, the nodaviruses are powerful models for exploring strategies of virus replication, host interactions, and virion assembly.

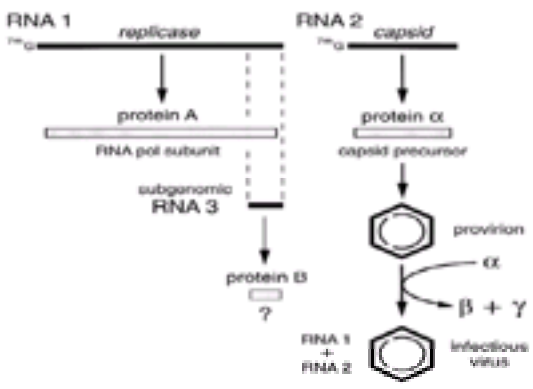

FIG. 9. Nodavirus replication strategy. The two genomic RNA segments (RNAs 1 and 2) encode the replicase (protein A) and capsid precursor protein (protein a), respectively. RNA 1 also specifies subgenomic RNA 3 which encodes protein B of unknown function. Assembled from capsid precursor a, provirions undergo a maturation cleavage producing capsid proteins b and k. Infectious virions contain both genomic RNAs.

The nodaviruses are divided into two genera (alpha and beta), which infect insects and fish, respectively. The family name originated from Nodamura virus, the first discovered family member isolated from mosquitoes near the Japanese village of Nodamura (236). The best-studied insect nodaviruses include Nodamura virus (NoV), black beetle virus (BBV), and flock house virus (FHV), each of which has been fully characterized at the molecular level. Other alpha members include New Zealand virus, Boolarra virus, Manawatu virus, and gypsy moth (*Lymantria ninayi*) virus. Most members of the alpha genus were isolated from insects of Australasia. NoV is the only nodavirus with the capacity to multiply in vertebrates (8). Nonetheless, on transfection of genomic RNA, nodaviruses can replicate in mammalian, yeast (*Saccharomyces cerevisae*), and plant cells (5,217,240).

Virion Structure of the Nodaviruses

The nodaviruses have provided enormous insight into icosahedral virus assembly and maturation. The structures of BBV, FHV, and NoV have been determined at atomic resolution (73,136,299). Each virion contains 180 copies of the same capsid protein (Fig. 10). Sixty triangular units, consisting of three similarly folded capsid proteins, form an icosahedral lattice with T=3 symmetry and a radius of 156 Å (recently reviewed in 146 and 238). The three capsid proteins form a prominent peak at the quasi-threefold axis (see images at www.bocklabs.wisc.edu/virusviz1.html). At the twofold axes, conserved C-terminal residues of the capsid protein make contact with duplexed genomic RNA that is highly ordered and stabilize the capsid protein interface (73). C-terminal residues of the capsid protein also are required for RNA encapsulation (237). At the fivefold axes, the capsid proteins form a pentameric helical bundle that has been proposed to participate in release of the genomic RNA on virus penetration into the host cell's cytosol (43).

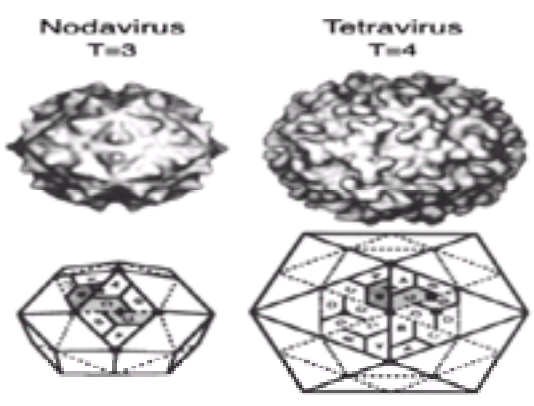

FIG. 10. Comparison of nodavirus and tetravirus structures. *Top:* Image reconstructions of the virion of a nodavirus (Flock House virus, *left*) and a tetravirus (Nudaurelia omega virus, *right*). The average particle diameter for the nodaviruses and tetraviruses is 320 Å and 415 Å, respectively. *Bottom*: Diagrammatic illustration of the subunit assembly of the T=3 nodavirus (*left*) and the T=4 tetravirus (*right*) virions. Each subunit (A, B, C, and D) is indicated by a trapezoid. Nodaviruses contain 60 subunits of three similarly folded capsid proteins that form a prominent peak at the quasi-three-fold axis (*top*). In contrast, tetraviruses contain 240 capsid protein subunits, twelve of which comprise each triangular face of the virion. Structural images are available at http://www.bocklabs.wisc.edu/virusviz1.html at the Institute for Molecular Virology, University of Wisconsin-Madison. Adapted with permission from Dr. John E. Johnson, Scripps Research Institute, La Jolla, CA.

The nodavirus provirion is assembled from 180 copies of the ~43-kd capsid precursor a. During virus morphogenesis (see Fig. 9), a is cleaved very near its C terminus to generate capsid proteins b and g (84,91,136). For FHV, this postassembly cleavage occurs autocatalytically between Asn^{363} and Ala^{364}, located on the inside surface of the virion. This cleavage is required for infectivity and virion stability (91,239). In addition, the maturation cleavage may be necessary for an undefined event occurring between cell attachment and cytosolic release of the RNAs.

Nodavirus genome organization

The nodavirus genome consists of two single-stranded, messenger-active RNAs (RNA 1 and 2) that are ^{7m}G-capped, but not polyadenylated (see Fig. 9). An unknown structure or factor blocks the 3' ends. RNA 1 (~3.1 kb) encodes the

functions required for RNA transcription and replication, whereas RNA 2 (~1.4 kb) encodes capsid precursor a. Both RNAs are required for infectivity and are packaged within the same virion (241). Infectious RNA transcripts from full-length cDNAs of the nodavirus genomic RNAs have been generated (57), and genetic functions have been determined by *in vitro* translation of the messenger-active RNAs and expression of cDNAs in heterologous systems, including baculovirus and vaccinia virus vectors and yeast cultures (5,62,84,217).

RNA 1 carries the information for at least two polypeptides, proteins A and B (see Fig. 9). Protein A (~112 kd) contains known RNA polymerase motifs and is required for nodavirus RNA replication. Most likely, protein A is an RNA-dependent RNA polymerase (RdRp) or a subunit thereof (7,90,109,217,287). En-coded by the 3' end of RNA 1 (see Fig. 9), protein B (~12 kd) is translated from subgenomic RNA 3 that is abundant in infected cells, but not packaged into virions (83,107). Although its exact function is unknown, protein B may play a role in RNA replication (8). RNA 1 encodes all the information necessary for autonomous replication (90). In contrast, RNA 2 encodes only capsid protein a. Thus the functions necessary for genome replication and virus transmission are segregated onto different genetic elements.

Stages of Replication

FHV and closely related BBV multiply prolifically in *Drosophila melanogaster* cell lines (86,91,241), thereby providing a highly tractable system by which to dissect virus replication. The mechanisms of nodavirus attachment and entry are unknown. Virus replication is cytoplasmic. Uncoated genomic RNA 1 is translated to produce the protein A–containing RdRp, which is insensitive to actinomycin D. Newly synthesized viral RNAs are detected by 2 hours after inoculation and continue to accumulate through 20 hours, eventually composing up to 50% of the total cellular RNA (84,85,91). Despite the presence of an equimolar ratio of RNA 1 and 2 throughout infection, synthesis of capsid protein a predominates because of the ability of RNA 2 to outcompete RNA 1 for rate-limiting translation factors (85). Nodavirus RNA synthesis also is regulated. RNA 1 and 2 replication is coupled, ensuring the production of an equal ratio of both genomic RNAs. During infection, RNA 1 must be generated before RNA 2 (6), which subsequently represses synthesis of subgenomic RNA 3 (90). Cis-acting sequences required for (+) and (–) strand RNA transcription and RNA 3 suppression have been identified (reviewed in 8). Virion assembly co-packages an equimolar ratio of RNA 1 and 2 by an unknown mechanism. Owing to the segmented genome, reassortment of genomic RNAs has been detected on mixed infections of cultured cells. Moreover, the nodaviruses can generate defective interfering particles at high multiplicities of infection and can establish persistent infections in cell cultures that are resistant to superinfection (56).

Tetraviridae

Classification of Tetraviruses

The tetraviruses, formerly known as the Nudaurelia b virus (NbV) group, contain a single-stranded, positive-sense RNA genome that is packaged into an nonenveloped, icosahedral virion. The virions (~40 nm diameter) have T=4 symmetry, which forms the basis of the family name (“tetra” from Greek *tettares,* meaning “four”). The tetraviruses are the only known nonenveloped viruses with T=4 symmetry (reviewed in 97,128, and 146). All tetraviruses have been isolated from insects of the order Lepidoptera (moths and butterflies). Nine viruses have been assigned to the family on the basis of serologic relatedness or the presence of a similar-sized capsid protein of more than 62 kd (97). Ten other viruses are likely members. The family is divided into betatetravirus and omegatetravirus genera. The genome of the betatetraviruses consists of a single (monopartite) RNA of ~5.5-kb, whereas the genome of the omegatetraviruses consists of two (bipartite) RNAs of ~2.5 and 5.5 kb. For example, the betatetravirus NbV has a single RNA, whereas the omegatetraviruses Nudaurelia omega virus (NwV) and *Helicoverpa armigera* stunt virus (HaSV) have two RNAs.

Virion Structure

Cryo-EM reconstructions have distinguished the basic structural features of the T=4 symmetry of the tetraviruses (see Fig. 10) (recently reviewed in 146). In addition, the structure of NwV has been resolved in atomic detail (193,194), providing the first structure of a T=4 virus. Tetravirus particles are composed of 240 capsid protein subunits. Twelve chemically identical capsid proteins compose each triangular face of the virion (see Fig. 10). The NwV capsid precursor is cleaved after Asn^{570} near the C terminus in a postassembly mechanism that is analogous to the cleavage of nodavirus capsid precursors required for virus infectivity (see earlier). The T=4 capsid protein arrangement of tetraviruses (~40 nm diameter) is readily distinguished from the T=3 arrangement of the nodaviruses (30 nm diameter), which have 60 fewer capsid proteins per particle (see Fig. 10). Nonetheless, the tertiary structure of capsid proteins of both virus families is strikingly similar. This conservation and the requirement for a postassembly cleavage of capsid proteins suggests that the tetraviruses and nodaviruses evolved from a common ancestor (146).

Tetravirus Genome Structure and Replication

The tetravirus RNA genome is either mono- or bipartite. The genomic RNAs are capped at their 5' end and have a unique tRNA-like structure at their 3' end (1,122). The genomes of several members of the beta and omega genera have been sequenced.

The 6,625-nucleotide NbV genome RNA contains two large ORFs (99). The 5' proximal ORF has the potential to encode a 214-kd protein containing domains characteristic of an RNA-dependent RNA polymerase with methyltransferase, nucleotide binding/helicase, and RNA polymerase motifs. The proteolytic processing steps of this predicted polyprotein are unknown. The 66-kd NbV capsid protein is encoded by the 3' proximal ORF, which is almost entirely overlapped by the replicase ORF, but in a different (+1) reading frame. It is therefore likely that the capsid protein is translated from a 2.5-kb subgenomic RNA that has been detected in preparations of virion RNA (99). *Thosea asigna* virus (TaV), a related betatetravirus, synthesizes a 2.5-kb subgenomic RNA, which also encodes the capsid protein (221).

The omegatetravirus HaSV contains two genomic RNAs of 5,300 and 2,478 nucleotides (98,122). RNA1 possesses a single ORF (1,704 codons) covering 96% of the RNA and likely encodes the RNA replicase. RNA2 encodes the 71-kd

HaSV capsid protein, which is closely related (66% identical) to the capsid protein of NwV (1). During assembly, the capsid precursor is cleaved near its C terminus to generate a 62-kd capsid protein and a smaller 7-kd sister polypeptide. RNA2 of HaSV also contains a 5' proximal ORF, which encodes a 17-kd protein of unknown function (122). It is not known whether both RNAs 1 and 2 of the omegatetraviruses are packaged within the same particle.

Stages of Replication

Tetravirus replication occurs in the cytoplasm of infected cells, and crystalline arrays of virus particles accumulate within cytoplasmic vesicles (128). However, because of the lack of permissive cell cultures, the stages of virus replication are unknown (97). Nonetheless, it is likely that tetravirus replication strategies resemble those of the nodaviruses and alphaviruses.

Tetravirus Transmission, Pathology, and Ecology

The tetraviruses are the only known RNA viruses restricted to insects, specifically those within the order Lepidoptera. Infection of larvae can be initiated by the ingestion of virus-contaminated foods (121). Virus multiplication is most often restricted to the foregut and midgut cells, even on injection of infectious virus into the hemolymph of larvae. Virus-mediated killing of midgut cells may account for the stunting pathology associated with HaSV. In general, susceptible insect larvae exhibit a wide range of pathogenic effects that include rapid death, an extended wasting disease, or a delay in pupation (97). NbV also has been isolated from pupae and adult moths. Larval death occurs within 4 to 7 days and is usually accompanied by discoloration, flaccidity, and sometimes liquefaction that resembles baculovirus-mediated melting. Tetravirus pathogenesis can be influenced by the presence of other viruses, latent or otherwise.

Tetravirus infections occur sporadically in natural populations. Thus ecologic aspects of virus spread and the existence of virus reservoirs are poorly understood. Nonetheless, these insect viruses function as natural biopesticides and have participated in natural control of certain insect pests. *Darna trima* virus and *Thosea asigna* (or *Setothosea asigna*) virus have been successfully used as pest-control agents in oil palm plantations. Although tetraviruses have been only isolated from insects, antibodies cross-reacting with some tetraviruses have been detected in wild and domestic animals and humans. Thus far, development of these viruses as biopesticides has been limited (97).

Cricket Paralysis–Like Viruses

Classification

The cricket paralysis–like viruses are small, nonenveloped riboviruses with icosahedral symmetry. Because their biophysical properties resemble those of the vertebrate picornaviruses, they were originally classified as members of *Picornaviridae* (recently reviewed by 46). However, more recent nucleotide sequence determinations (147,259,283) indicated that these invertebrate viruses are members of a taxonomically distinct family that remains unclassified (see Table 1). The best characterized members include Cricket paralysis virus (CrPV) and serologically related *Drosophila* C virus. Because of its ability to cause paralysis of the hindlimbs of early-instar cricket nymphs, CrPV is appropriately named. Other members of the CrPV-like virus family include *Plantia stili* intestine virus, himetobi P virus, and *Rhopulosiphum* virus (46).

Virion Structure

The physicochemical properties of the virions of the cricket paralysis–like viruses are strikingly similar to those of the vertebrate picornaviruses. These icosahedral riboviruses (<40 nm diameter, r =1.35 to 1.37 g/mL) contain four capsid proteins (VP1, VP2, VP3, and VP4) that are arranged in a pseudo T=3 lattice (259). The 2.4-Å resolution crystal structure of CrPV reveals a capsid conformation and virion morphology that is nearly identical to that of the vertebrate picornaviruses (259). However, unlike the human entero-viruses, CrPV lacks the distinguishing deep depression (canyon) at the fivefold axis or a VP1 pocket. These differences suggest that the mechanism of receptor binding is distinct from that of the picornaviruses. Interestingly, the proteolytic processing of VP0 ® VP3 + VP4 appears to be autocatalytic, which suggests that CrPV capsid assembly and processing more closely resemble those of the insect nodaviruses and tetraviruses than of the vertebrate picornaviruses (259).

Genome Organization and Novel Translation Initiation

CrPV and DCV possess single-stranded, messenger-sense RNA genomes of 9,185 and 9,264 nucleotides, respectively (147,283). The genomes are divided into two major ORFs (Fig. 11), which when translated generate two separate polyproteins that undergo proteolytic processing. Preceded by a 5' UTR, ORF1 encodes proteins with predicted RNA helicase, picornavirus 3C–like protease, and RNA-dependent RNA polymerase activities. ORF2 is preceded by an intergenic UTR (~200 nucleotides) and encodes the virion capsid proteins. Thus unlike the vertebrate picornaviruses, the capsid proteins are encoded within the 3' half of the genome, whereas nonstructural replication proteins are encoded within the 5' half (see Fig. 11).

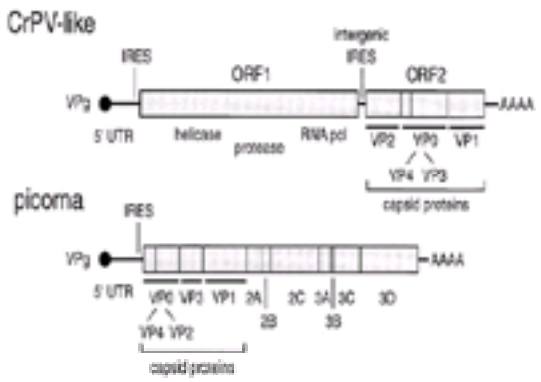

FIG. 11. Genome organization of the Cricket paralysis-like riboviruses. The single-stranded RNA genome of CrPV and DCV possess two open reading frames (ORF1 and ORF2) separated by a ~200 nucleotide spacer. Each ORF is preceded by an internal ribosome entry site (IRES). ORF1 encodes replicative functions (helicase, protease, and RNA-dependent RNA polymerase), whereas ORF2 encodes capsid proteins VP0, VP1, and VP2. VP3 and VP4 are generated by processing of precursor VP0 (259). VPg and an untranslated region (5' UTR) are located at the 5' end of the genomic RNA. The genome organization of the vertebrate picornaviruses differs from the CrPV-like viruses by possessing a single ORF which encodes capsid proteins and replicative functions at the 5' and 3' ends, respectively.

During infection, CrPV and DCV capsid proteins are produced in significant excess compared with the nonstructural proteins (46), a phenomenon that differs from that of the picornaviruses, which produce equimolar amounts of both structural and nonstructural proteins from their single ORF. Accounting for the differential levels of expression, CrPV possesses two internal ribosome entry sites, each located upstream from the nonoverlapping ORFs (283). Thus the CrPV genome represents a rare but naturally occurring bicistronic messenger RNA in eukaryotes. Most interestingly, ORF2 begins with a noncognate CCU triplet rather than AUG, suggesting a novel mechanism for translation initiation (283). Recent evidence indicates that the IRES within the intergenic UTR (see Fig. 11) can assemble an 80S ribosome in the absence of initiator Met-tRNA$_i$ and canonic initiation factors to initiate protein synthesis from the second triplet (GCU), which is positioned within the A site of the ribosome (235,282). This novel mechanism for translation initiation appears to involve the participation of a pseudoknot-like structure within the IRES that can substitute for the usual interactions between Met-tRNA$_i$ and the P-site initiator codon.

CrPV-like Virus Ecology and Transmission

CrPV was originally isolated in 1970 from Australian crickets *Teleogryllus oceanicus* and *T. commodus.* It has one of the widest experimental host ranges of the insect viruses and is capable of infecting invertebrate species of diverse orders, including the Diptera, Lepidoptera, Orthoptera, Hymenoptera, and Hemiptera (46). However, little is known of the distribution of CrPV in nature. Experimental inoculation by injection leads to virus multiplication and death of a number of insect hosts. CrPV transmission also can occur *per os* through contaminated food sources. In contrast to CrPV, DCV has a more restricted host range. DCV has been isolated only from wild or laboratory strains of *Drosophila melanogaster* (46). DCV can be transmitted *per* os to adult flies or larvae, causing death. In addition, DCV is transmitted horizontally between infected and uninfected adults.

This chapter is dedicated to the memory of Lois K. Miller, a friend and mentor, pioneer in baculovirology, and champion for studies of insect viruses and their application.

CHAPTER 21 Viruses of Yeasts, Fungi, and Parasitic Microorganisms

Reed B. Wickner

Prions, retroviruses, ds (double-stranded) RNA viruses, ss (single-stranded) RNA viruses, and dsDNA viruses have all been found in simple eukaryote hosts, and the experimental advantages of these systems has made some of these the most thoroughly characterized of their viral classes. This is an overview of these infectious entities and their unique aspects, with some emphasis on recent developments.

One feature common to all the viruses, prions, and retrotransposons (or retroviruses) of yeast and fungi is their wholly intracellular life cycles. These viruses have forsaken the extracellular route of transmission, being passed from cell to cell either vertically or by cytoplasmic mixing, such as occurs in mating, or in hyphal anastomosis (fusion) of filamentous fungi. They resemble, in this regard, the plant cryptoviruses and the intracisternal A type particles (retroelements) and LINEs (retroposons) of mammals. It has been argued that the high frequency of mating and hyphal fusion of fungi in nature makes an extracellular phase dispensible for these viruses, and it is difficult to find strains of *S. cerevisiae* that lack either the L-A or L-BC dsRNA viruses or any of the Ty retrotransposons. Nor is the direct cell-to-cell route of infection completely neglected by mammalian viruses, those of the herpes group and human immunodeficiency virus being prime examples.

However, this mode of transmission means that these viruses must balance the need to spread and propagate against consideration for the viability of their host. Furthermore, the fact that most of these elements are widespread means that the hosts have been selected for the ability to protect themselves. This is clearly seen in the Ty elements, which tend to target sites that can tolerate an insertion. The Ty elements, particularly Ty3, regulate their transcription such that most transposition occurs on mating. This design optimizes the chances of infecting the potentially unoccupied genome of the mating partner. The copy numbers of several of the RNA replicons (L-A dsRNA, L-BC dsRNA, and 20S RNA) are repressed by the host Ski proteins acting in translation (185,226,259,285). Likewise, Ty1 retrotransposition is negatively controlled by the *RTT* genes, which appear to control particle and DNA stability and the structure of the chromatin target (54,138,148,167,175,219).

Most of the viruses and prions discussed here can best be viewed as selfish RNA or DNA (or selfish protein), but the killer satellite dsRNAs clearly benefit their hosts by allowing them to kill competitors. The [Het-s] prion of *Podospora* is unique among prions described to date in being necessary for a normal cellular function, namely, heterokaryon incompatibility (57).

It is striking that most of the viruses and retro-elements discussed use some form of ribosomal frame-shifting to make a Gag-Pol fusion protein. This is not surprising for the retroelements, but it was not expected for the dsRNA genomes. Ribosomal frameshifting (in contrast to splicing or RNA editing) provides a mechanism for viruses whose mRNA is their genome to obtain two proteins with overlapping sequence from one mRNA without producing mutant genomes (140). Other translational tricks used include readthrough of stop codons, and internal ribosome entry.

The use of *S. cerevisiae* as a model host for viruses of plants and insects promises to facilitate the understanding of

these viruses (141,218), but it will not be dealt with here.

DOUBLE-STRANDED RNA VIRUSES

The fungal dsRNA viruses were first detected in 1948 as “La France” disease of cultivated mushrooms in Pennsylvania, and its study led to the first description of fungal viruses in 1962. The antiviral agents helenine and statolon, discovered in *Penicillium* in the 1950s, later proved to be fungal virus dsRNA that was inducing interferon secretion (reviewed in ref. 31).

The dsRNA viruses are found in many fungal species (Table 1), and include the single-segment *Totiviridae*, the oligosegmented *Partitiviridae*, the potyvirus-like *Hypoviridae* that limit the virulence for chestnut trees of the chestnut blight fungus *Cryphonectria parasitica*, and reoviruses of the same species.

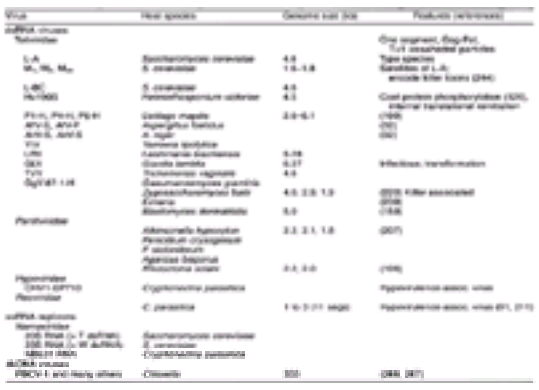

TABLE 1. *The dsRNA, ssRNA, and dsDNA viruses of simple ukaryotes*

L-A Virus of *S. cerevisiae*, Type Species of the *Totiviridae*

Some strains of *S. cerevisiae* secrete a protein toxin that is lethal to other strains, but to which they themselves are immune (Fig. 1) (182). This “killer character” of some strains is inherited as a non-Mendelian genetic element, and its study led to the discovery of the L-A dsRNA virus and its satellites M_1, M_2, M_{28}, and so on, each M encoding a different toxin-immunity specificity.

FIG. 1. The killer phenomenon of *S. cerevisiae*. A sensitive strain of yeast was spread as a lawn, and streaks of a killer strain (*above*) or a nonkiller strain (*below*) were applied. After 2 days' incubation, the lawn of the sensitive strain has not grown in a zone around the killer strain. The secreted protein killer toxin, and immunity to the toxin, are encoded by M_1, a satellite dsRNA of the L-A dsRNA virus.

L-A Virion Structure

P>The icosahedral structures of L-A and the *Ustilago* virus P4 are unusual in that they combine T=1 symmetry with 120 coat protein molecules per particle (Fig. 2) (35,41,98). This same symmetry has been found in the cores of all other dsRNA viruses examined, including reovirus, rotavirus, bluetongue virus, aquareovirus, and bacteriophage p6 (see Chapter 22 and Chapter 52, Chapter 53, Chapter 54, Chapter 55 and Chapter 56). Because sequence data suggest that dsRNA viruses arose independently from ssRNA viruses (161), rather than one being descended from the other, their common structure suggests that there is something about this structure that is well adapted to the intraviral replication pattern of dsRNA viruses.

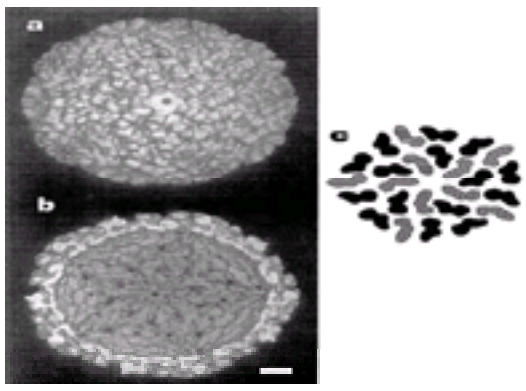

FIG. 2. L-A dsRNA virus capsid reconstruction at 16-Å resolution from cryoelectron microscopy (35). View of the outer (**a**) and inner (**b**) surfaces of the full capsid, viewed along a fivefold axis of symmetry. The internal contents were computationally removed to expose the inner surface (35). Bar = 50 Å. Schematic diagram (**c**) of the arrangement of Gag subunits around the fivefold axis. Note that solid and hatched subunits are identical in primary structure, but occupy distinct, nonequivalent environments (35).

The combination of 120 subunits and T=1 icosahedral symmetry implies that individual coat protein monomers can be in either of two environments. This expectation has been verified as subtly different morphology of the nonequivalent Gag protomers (35) (see Fig. 2). The packing of the dsRNA within the particles is less dense than is typical for dsDNA viruses, possibly reflecting the fact (see later) that in both replication and transcription, the genome must translocate sequentially past the RNA-dependent RNA polymerase immobilized on the particle wall, and this requires more space than is required by the static DNA genomes (35). The L-A virions also have 10- to 15-Å pores, which allow entry of nucleotides and exit of (+) strand transcripts but do not allow the dsRNA genome to exit or degradative enzymes to enter (35).

L-A Genome Structure

The L-A (+) strand has two overlapping open reading frames (ORF) (Fig. 3A) (140). They are *gag*, encoding the 76-kd major coat protein, and *pol*, encoding the 100-kd Pol domain of the Gag-Pol fusion protein (111,140). The pol ORF includes the consensus amino acid sequence patterns typical of viral RNA-dependent RNA polymerases. Three *in vitro* single-stranded RNA binding domains have also been localized to Pol (111,223,224), the central one cryptic unless an adjacent inhibitory region is deleted (see Fig. 3A). Pol residues 67 to 213 are necessary for packaging of the viral (+) strands (109,224). Neither 5' cap structure nor 3' poly(A) has been found on either strand of genomic L-A dsRNA or M_1 dsRNA (30), but there is, at each 3' end, an uncoded base that can be either A or G (24).

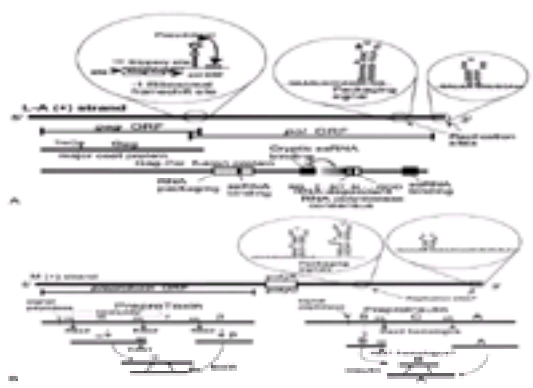

FIG. 3. A: Sites and encoded proteins of the L-A (+) strand. The sites responsible for –1 ribosomal frameshifting, (+) ssRNA packaging, and replication are shown. The pseudoknot makes the ribosome pause over the slippery site, where the tRNAs can unpair from the mRNA and re-pair in the –1 frame with correct base pairing of the nonwobble bases. Functional domains in the Pol region are also indicated. 7mGp indicates the cap-binding site at His154 of Gag. **B:** Coding and cis sites of M1 (+) strand. The analogous and homologous processing of the K1 preprotoxin encoded by M1 is compared to that of preproinsulin.

The M dsRNAs each encode, in their 5' portion, a preprotoxin protein (22,72,178,237) (see Fig. 3B). The M_1 (+) strand has an internal encoded polyA region whose length shows frequent clonal variation, presumably due to transcriptase stuttering (130), and a substantial 3' region that encodes no protein but contains essential *cis* sites (97,107,124,234,242). As will be detailed later, sites on the L-A and M_1 (+) strands necessary for packaging and (–) strand synthesis have been determined (see Fig. 3), and some limits have been set on the possible transcription signals.

Stages in the Replication Cycle

The L-A replication cycle and the closely related cycle of its satellites are shown in Figure 4 (98,108). L-A dsRNA-containing viral particles synthesize (+) ssRNA in a conservative reaction (108,134), and these new (+) strands are then extruded from the particle (98). There, they serve as mRNA for the production of the Gag and the Gag-Pol fusion proteins. These proteins then assemble with a viral (+) strand to form new particles. The newly assembled viral particles carry out the synthesis of (–) strands on the (+) strand template to form dsRNA and complete the cycle (108).

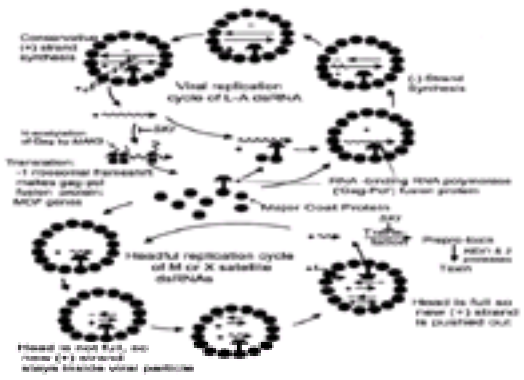

FIG. 4. Replication cycles of L-A virus and its satellite dsRNAs, M and X. The packaging region of the Pol domain of Gag-Pol binds to the packaging site of (+) strands as the Gag domain associates with other Gag molecules. This ensures packaging of viral plus strands (76,111). L-A particles have only one dsRNA molecule per particle. But the smaller M or X dsRNAs replicate within the viral coat until they fill the head (98,99).

In addition to their appropriating viral proteins from L-A, the replication cycle of the satellite dsRNAs, M_1, S (deletion mutants of M_1), and X [a 530- basepair (bp) deletion mutant of L-A] are similar to that of L-A itself except that they replicate more than once within the viral particle until it is full (see Fig. 4). Only a single (+) ssRNA is packaged per particle (107), so L-A and M are separately encapsidated. Because the particle capacity is determined by the structure of Gag to be sufficient to accommodate one full-length L-A dsRNA molecule, and the M and X dsRNAs are much smaller, new M or X (+) strand transcripts are often retained within the viral particles, where they are converted to new dsRNA molecules. Then, all new (+) strands are extruded from the now full particle (98,99). This is called the *headful replication mechanism* (in contrast to the headful packaging mechanism of many DNA bacteriophage) (98,99). This implies that extrusion of the transcripts is a mechanical consequence of the head being full, rather than an active process. Both (+) and (–) strands are synthesized within the viral particles, but at different points in the cycle, so the replication is conservative, intraviral, and asynchronous, and it fills the capsid (headful mechanism).

Transcription Reaction ((+) Strand Synthesis)

As in the *Reoviridae*, the transcription reaction for L-A is conservative (108,286), resulting in the overall process of viral replication being conservative (204). However, in *Aspergillus foetidus* slow virus and *Penicillium stoloniferum* slow virus (32), dsRNA transcription is semiconservative. The difference between conservative and semiconservative reactions concerns whether or not there is re-pairing of the template (–) strand with the parental (+) strand that was (in either case) displaced during the synthesis.

A template-dependent *in vitro* transcription reaction method has been developed for the L-A dsRNA virus (113). When L-A dsRNA-containing particles are treated with very low ionic-strength conditions, they rupture, releasing the dsRNA. These opened empty particles can be reisolated free of RNA and carry out a dsRNA template-dependent reaction that is, like the *in vivo* reaction, conservative (113). This reaction is highly template specific, using only L-A, M, and X dsRNAs (all physiologic templates), but not L-BC, p6, or rotavirus dsRNAs. Because X dsRNA retains only 25 bp of the end of L-A from which the transcription reaction starts (99), the signal recognized by the transcriptase is most likely within this region, perhaps within the terminal 6 bp that are in common among L-A, M_1, and M_2 (129,258). The template-dependent transcription reaction requires very high concentrations of polyethylene glycol (20%), suggesting that the transcriptase has a low affinity for the dsRNA template (113). Because the dsRNA is normally formed within and stays inside the viral particles, the RNA polymerase sees a very high effective concentration and need not have a particularly high affinity.

Translation

The translation apparatus is a prime battleground for the fight between an RNA virus and its host. For example, interferon acts primarily by blocking viral translation. This can also be seen in picornaviruses, where cleavage of a cap-binding component inactivates host translation (see Chapter 23), or influenza virus cap-stealing and antiinterferon measures (see Chapter 46). Studies of the replication mechanisms of the L-A virus and its satellites have likewise led to the suggestion that translation of viral proteins is the critical event determining the balance between virus and host.

Ribosomal Frameshifting. The *gag* and *pol* ORFs of L-A overlap by 130 nucleotides (nt), and the Pol protein is expressed only as a fusion protein with the major coat protein, Gag (see Fig. 3A) (111,140). The mechanism of formation of this Gag-Pol fusion protein is a –1 ribosomal frameshift (74), very similar to those described in Rous sarcoma virus, many mammalian retroviruses, coronaviruses, and several plant viruses (142, and reviewed in refs. 101,125).

There are two features of the mRNA that determine the frequency of –1 ribosomal frameshifts (see Fig. 3A). The “slippery site” is a sequence of the form X XXY YYZ, where the *gag* reading frame is shown. This sequence allows the tRNAs reading XXY and YYZ to each move back one base on the mRNA and still have their nonwobble bases correctly paired (142). X can be any base, but Y can be only A or U, probably because the frequency with which unpairing of the tRNAs from the 0 frame codons (XXY and YYZ) is also important, and because A site-pairing is stronger than P site-pairing (26,74). Z can be any base but G, suggesting that specific tRNAs are more able to frameshift than others (37,133). The second component determining frameshift efficiency is the presence of a strong secondary structure, usually an RNA pseudoknot, just downstream of the slippery site, to slow ribosomal movement at this point (25,142). The location of this secondary structure is particularly critical (27), and a pseudoknot is far more effective in promoting frameshifting than a simple stem-loop of the same overall melting energy. The pseudoknot, more than the simple stem-loop, should resist

melting of the first few bases of the stem, precisely positioning the ribosome with the slippery site in the A and P sites.

The efficiency of –1 frameshifting, and thus the ratio of Gag-Pol fusion protein to Gag protein produced, is critical for viral propagation (76), as is the efficiency of +1 frameshifting for Ty1 retrotransposition frequency (see later). A twofold change away from L-A's normal 1.9% efficiency results in failure to propagate the M_1 satellite dsRNA. L-A propagation is less sensitive, but the antibiotics sparsomycin, which increases ribosomal frameshifting, and anisomycin, which has the opposite effect, can cure L-A (75). The Gag-Pol to Gag ratio is likely to be important for viral assembly. Excess Gag-Pol (high frameshift efficiency) may result in starting too many particles and winding up with too little Gag to complete any of them. In contrast, excess Gag might result in particles closing before the packaging domain of Pol has had a chance to find a viral (+) strand (76).

Host genes affecting the efficiency of –1 frameshifting are called *MOF* (maintenance of frame) (76,77) and are expected to encode ribosomal components or translation factors. The differential effects of specific host mutations on frameshifting at specific slippery sites suggests that drugs similarly affecting frameshifting might target specific viruses (77). *MOF9* has been shown to be the 5S rRNA, showing a role for this 60S subunit component in maintenance of reading frame (78). *MOF4* is *UPF1*, one of the components of the nonsense-mediated decay system (61), and thus Upf1p plays roles in both monitoring reading frame and in the destabilization of mRNAs with premature termination codons. *MOF2* proved to be identical to *SUI1* [encoding a subunit of translation initiation factor 3 (eIF3)], and, like MOF4, it has effects on both nonsense mediated decay and maintenance of reading frame (62).

60S Subunits—Critical to Viral Propagation. Mutations in any of 20 chromosomal genes (called *MAK* for maintenance of killer) that result in diminished levels of free 60S ribosomal subunits also produce loss of M dsRNA and decreased copy number of L-A dsRNA (85,208). Mutations diminishing the supply of free 40S subunits generally had no such effect (208). The deficiency of 60S subunits results in selectively decreased rates of translation of mRNAs which, like L-A mRNA, lack 5' cap and 3' poly(A) (85). These *mak* mutations are suppressed by the *ski* mutations that derepress translation of non-poly(A) mRNAs (261).

Gag Decapping Activity—Necessary for M Expression. The L-A and L-BC Gag proteins each covalently bind the 5' cap from any RNA *in vitro* (17). L-A Gag covalently attaches ^{7m}GMP from the cap to His154 in a reaction that requires only Mg^{2+} (18). Modification of His154 on an L-A cDNA expression clone destroys Gag's ability to covalently bind cap, but it does not prevent the clone's ability to propagate the M_1 satellite virus (18). However, expression of the killer toxin encoded by M_1 is impaired by the His154 mutation. Mutation of the *SKI1*/*XRN1* gene encoding the 5' to 3'exoribonuclease, specific for uncapped RNAs and responsible for the major mRNA decay pathway (137), results in restoration of expression of killer toxin in spite of the mutation of His154 of Gag (185). It has been proposed that the virus decaps cellular mRNAs to decoy the Ski1p exoribonuclease from degrading the capless viral mRNA (185).

SKI *Antiviral System Blocks Translation of Viral [Non-poly(A)] mRNA.* The sole essential function of four of the SKI genes of *S. cerevisiae* is the repression of viral copy number, particularly control of M (14,15,222,226,245,259,285). The SKI proteins repress three unrelated viral systems: L-A and its satellites, L-BC (a dsRNA virus), and the ssRNA replicon called 20S RNA (10,188,259). Detailed studies of the *SKI2* gene suggested that the system acts by limiting translation of viral mRNA (285). Because all of these are cytoplasmic replicons, and none was known to have either 5' caps or 3' polyA structures, it was speculated that the *SKI* system recognized the absence of one or both of these structures typical of eukaryotic cellular mRNAs (285). That *SKI2* also represses translation of RNA polymerase I transcripts (probably lacking cap and/or polyA) supports this idea (285).

Electroporation of mRNAs into spheroplasts shows that the Ski2, Ski3, Ski6, Ski7, and Ski8 proteins inhibit the translation of mRNA specifically if it lacks a 3' polyA structure (13,14,185). Kinetic studies indicate that both the initial rates and the duration of translation are affected by the Ski proteins.

The *SKI2*, *SKI3*, *SKI6*, *SKI7*, and *SKI8* genes have been characterized, and only *SKI6* is essential for growth in the absence of M dsRNA (13,14,189,222,245,285). Ski2p has helicase motifs, a glycine-arginine-rich domain and it is highly homologous to two mammalian genes (205,285). Ski3p has the TPR an amino acid repeat pattern (222) while Ski8p has a different sequence repeat first identified in b-transducin (189). Ski2p, Ski3p, and Ski8p form a cytoplasmic complex (29). Ski6p is homologous to RNAse PH, a tRNA-processing enzyme (14), and it is part of a nuclear complex of exoribonucleases thought to have a role in rRNA processing (196). Indeed, *ski6* mutants produce abnormal 60S ribosomal subunits (13) and show abnormalities in processing of 5.8S rRNA (13). Ski7p has homology to EF1-a, an elongation factor, suggesting that it is involved in the translation process.

Recently, a yeast homolog of *SKI2* (called *YGR271w* or *SLH1*) has been found whose deletion (*slh1*D) depressed L-A copy number as does *ski2*D (184). The *ski2*D *slh1*D double mutants show dramatically in-creased L-A, L-BC and M_1 dsRNA copy numbers, but grow normally in the abscence of the L-A and M_1 viruses (238). Remarkably, the *ski2*D *slh1*D cells show the same *in vivo* translation kinetics of non-poly(A) mRNA as they do for poly(A)+ mRNA, in spite of the presence of normal amounts of competing poly(A)+ mRNA (238). Thus, the translation apparatus is indifferent to the 3' poly(A) structure except for the action of the Ski proteins and Slh1p. This suggests that the role of the eukaryote 3' poly(A), like that of Ski2p and Slh1p, is to allow cells to distinguish their own mRNAs from those of invading viral genomes.

Posttranslational Modification

KEX1, KEX2 *Proteases and Discovery of Prohormone Proteases.* The *kex1* and *kex2* mutants were first isolated because of their inability to produce the “killer” toxin encoded by the M_1 satellite dsRNA (KEX, from killer expression) (282). The *kex2* mutants were noted to have a defect in mating that was specific to cells of the a mating type, and *kex2*/*kex2* homozygous diploids were defective for sporulation (170). The a-specific mating defect was partially explained by the finding that the cells failed to secrete the a pheromone (170), a peptide that prepares cells of the opposite (**a**) mating type

for mating by arresting them in the G1 phase of the cell cycle. The failure to secrete killer toxin and a pheromone was explained by the finding that *KEX2* encodes a protease that cleaves C-terminal to pairs of basic amino acid residues (145), and that *KEX1* encodes a carboxypeptidase that can remove the pair of basic amino acids (55,79). These were the cleavages needed to convert the toxin and a pheromone proproteins to their mature forms (see Fig. 3B).

The specificities of the Kex proteases are the same as those needed to process preproinsulin (see Fig. 3B), preproopiomelanocortin, and other mammalian prohormones, but the enzymes responsible for these maturation cleavages had been elusive. Several genes and enzymes with homology to Kex2p were identified, and evidence that they are involved in these prohormone processing steps is accumulating (reviewed in ref. 246).

There is also evidence that the Kex2p-homologous enzymes are involved in the proteolytic processing of some mammalian viral proteins. Mutant CHO cells resistant to Sindbis virus and Newcastle disease virus were made sensitive by expression of the Kex2p-homolog, mouse furin, or by expression of Kex2p itself (197).

N-*Acetylation of* gag *by Mak3p—Necessary for Assembly. MAK3* is one of the three chromosomal genes known to be necessary for the propagation of the L-A dsRNA virus. Its sequence shows homology with *N*-acetyltransferases, particularly with the rimI protein of *Escherichia coli*, which acetylates the N-terminal of ribosomal protein S18 (256). In fact, the L-A Gag protein is normally blocked (presumably acetylated) and is unblocked in a *mak3* mutant host, resulting in failure of viral assembly (257). Mak3p recognizes the N-terminal four amino acid residues of Gag (255), and this signal can be transferred to b-galactosidase, producing *MAK3*-dependent N-terminal acetylation. Like L-A, the major coat proteins of Rous sarcoma virus, tobacco mosaic virus, turnip yellow mosaic virus, alfalfa mosaic virus, and potato X virus are N-terminally acetylated, but the enzymes responsible have not been identified, nor can the role of acetylation for these viruses be examined without altering the primary protein sequence.

Recently, a complex of Mak3p, Mak10p, and Mak31p has been detected (227). Mak10p, Mak31p, and Mak3p are the only three proteins known to be necessary for L-A propagation (16,169,260), and this indicates that Mak10p and Mak31p are also involved in *N*-acetylation of the coat protein. Both *mak3* and *mak10* mutants show slowed growth on glycerol or ethanol, further supporting the idea that their functions are related (73,169,255).

Viral Assembly

The headful replication mechanism implies that the coat protein determines the structure of the head, not the genome. This is typical of isometric viruses, and it has now been confirmed by the finding that expression of the Gag protein alone produces empty particles that are morphologically indistinguishable from normal L-A virions (109). Normal L-A particles have a T=1 icosahedral structure with an asymmetric unit consisting of a dimer of Gag (35; see preceding). Each particle has only one or two Gag-Pol fusion proteins (perhaps as a dimer). The requirement for the Mak3p-catalyzed *N*-acetylation of Gag for assembly suggests that the Mak3/10/31 complex is involved in this process (226).

The existence of a Gag-Pol fusion protein, the ssRNA binding activity of its Pol domain, and the fact that (+) ssRNA is the species encapsidated to form new viral particles, led to a model of assembly and packaging that has been supported by subsequent findings (Fig. 4) (111). The Pol domain of the Gag-Pol fusion protein recognizes and binds to a packaging site on the viral (+) strands. Then (or concomitantly), the Gag domain of the fusion protein associates with the free Gag protein. This leads to encapsidation of a single (+) strand per particle if there is only one Gag-Pol fusion protein (or one dimer) per particle.

In vivo, Pol residues 67 to 213 of the Gag-Pol fusion protein are necessary for packaging of (+) strands, but not for assembly of morphologically normal viral particles (109,224). One of the three single-stranded RNA binding domains of Pol is located within this region and is necessary for the packaging (224) (see Fig. 3A).

The *packaging site* recognized is an internal stem-loop sequence with an A residue bulging from the 5' side of the stem (see Fig. 3A) (107). This site, located about 400 nt from the 3' end of the L-A (+) strand, was first identified as necessary for binding of X (+) ssRNA to the opened empty particles (97). Binding requires the stem structure but not the sequence of the stem. In contrast, the sequence of the loop is important. The protruding A residue must be present and must be an A (107). A similar site, similarly located on the M_1 (+) strand, was found (107) by examining the predicted folded structure of the M_1 sequence (124), and another was found by studying sequences involved in exclusion of M_1 (242). Either the L-A (X) or M_1 stem-loops are sufficient for binding, but the addition of 10 bp from the 5' side of either one improves the binding substantially (107,242). Both the L-A and M_1 sites contain direct repeat sequences whose significance has not yet been determined. A site with the same structure has also been found in a similar location in the M_{28} satellite dsRNA (236).

The L-A and M_1 sites can each serve as a portable packaging signal *in vivo*, directing packaging of heterologous transcripts by L-A virus or by proteins produced from the L-A cDNA clone (107,109). The heterologous transcripts were packaged alone in viral particles, confirming the prediction of the headful replication model that a single (+) strand is initially packaged per particle.

The ratio of Gag-Pol fusion protein to Gag can be altered *in vivo* by adjusting the efficiency of ribosomal frameshifting and, as discussed, this ratio is important for M_1 satellite dsRNA propagation but less so for L-A itself (75,77). Whereas M_1 or X particle assembly can fail in a Gag-poor cell, an L-A (+) strand could be its own supply of Gag that will not be exhausted until completion of the particle makes the L-A (+) strand no longer available to the ribosomes. This form of *cis*-packaging could explain the differential effect of frameshift efficiency on M_1 and L-A propagation.

Replication [(–) Strand Synthesis]

Newly assembled viral particles contain an L-A (+) strand and are capable of converting it to the dsRNA form when

supplied with nucleoside triphosphates (108). The particles formed in this reaction have all the properties of mature L-A particles and can carry out the transcription reaction (110).

To study the detailed mechanism of the replication reaction, it was necessary to establish a template-dependent *in vitro* reaction. The opened empty particles, when supplied with viral (+) strands, Mg^{2+}, nucleoside triphosphates, and a low concentration of polyethylene glycol, carry out (–) strand synthesis to form dsRNA (112). Only L-A, M, or X (+) strand templates are active in this reaction, supporting the notion that it accurately reflects the *in vivo* reaction.

A maximally active template requires both sequences at the 3' end of the L-A (or X) plus strand and internal sequences (the internal replication enhancer) overlapping the packaging signal (97). The 3' end of L-A (+) strands has a stem-loop whose structure is necessary for template activity. While the sequence of the loop and that of the 3' terminal four nucleotides are important, that of the stem is not. In spite of the requirements for these structures and sequences in the context of L-A, the 3' terminal 33 nucleotides of M_1's (+) strand can substitute for the L-A 3' end, although there is little or no similarity between the two sequences (see Fig. 3) (97). The internal replication enhancer and the 3' end site must be bound together for optimal template activity in the replication reaction (114). However, they need not be covalently attached and can simply be hydrogen bonded. This suggests that the RNA polymerase binds first to the internal site and is thus brought close to the 3' end site where polymerization is to begin.

Because the RNA-dependent RNA polymerase consensus domains defined by Kamer and Argos (147) have since been found in essentially all (+) ssRNA and dsRNA viruses examined, the detailed mutagenesis of the most highly conserved of these regions was carried out using the L-A cDNA clone (225). This has defined the extent of the domains necessary for the propagation of the M_1 satellite dsRNA. Interestingly, homologous regions from Reovirus or Sindbis virus RNA polymerases could partially substitute for that of L-A (225).

Other Factors Affecting L-A, M, and L-BC Replication. Mutation of either *POR1*, encoding the major mitochondrial outer membrane porin, or *NUC1*, encoding the major mitochondrial nuclease, results in derepression of L-A copy number (73,177). A similar effect results from mutation of *scs1*/*lbc2* (122), encoding a subunit of serine palmitoyltransferase. *MKT1* is necessary for M_2 propagation, but not for M_1 (278,279). Several natural variants of L-A have been described based on their interactions' with *MKT1*, M_2 dsRNA, and *mak* mutations affecting levels of free 60S ribosomal subunits, but the mechanisms of these interactions have not yet been determined (reviewed in ref. 280).

Totiviridae *Using Internal Initiation to Make RNA Pol.* The 190S virus of *Helminthosporium victoriae* (Hv190SV) is a totivirus that does not make a coat protein–RNA polymerase fusion protein and does not use ribosomal frameshifting in its gene expression. Instead, the termination codon for the coat protein overlaps with the initiation codon for the RNA polymerase, the sequence being . . .GGA CA**A TG A**GT G. . . (139). The RNA polymerase is detected only as a separate protein, and it is suggested to be translated by the occasional reinitiation of ribosomes that have just terminated at the end of the coat protein part of the mRNA.

Two viruses of the filamentous fungus *Sphaeropsis sapinea*, a pathogen of pine trees, are closely related to Hv190SV in sequence, and they apparently use the same translation strategy to express their RNA-dependent RNA polymerase (217).

Leishmania dsRNA Viruses

Leishmania is a flagellated protozoan that causes cutaneous, visceral, or mucosal infections of man. *Leishmania* virus (LRV1-1) was first discovered as an RNA species associated with cytoplasmic, 32 nm virus particles (252). A similar virus (LRV1-4) was found in another strain and shown to be associated with an RNA polymerase activity (283). A survey of 71 *Leishmania* isolates showed related viruses present in 12, all of which were *L. braziliensis* or *L. guyanensis* originating in the Amazon basin (128). These species cause cutaneous and mucocutaneous forms of leishmaniasis, but not all such isolates carry the virus, nor is there evidence that the virus affects pathogenicity.

The replication cycle of LRV appears to be quite similar to that of the L-A virus of *S. cerevisiae* (276). The structure of LRV likewise closely resembles L-A (248). The two major ORFs, ORF2 and ORF3, overlap by 71 nt, with ORF3 in the +1 frame relative to ORF2 (Fig. 5) (248). ORF2 encodes the major coat protein (33), and ORF3 has the consensus patterns typical of viral RNA-dependent RNA polymerases. This suggests that a Gag-Pol fusion protein might be made (248), and an *in vitro* translation product of the predicted size (33) is a candidate for this protein. The sequence of the overlap region suggests a possible Ty1-like +1 shift site or a pseudoknot-promoted hop (248). The similarity of the LRV1 *pol* amino acid sequence with that of L-A of *S. cerevisiae* is striking, and it is far beyond that simply because they share the RNA polymerase consensus domains (248).

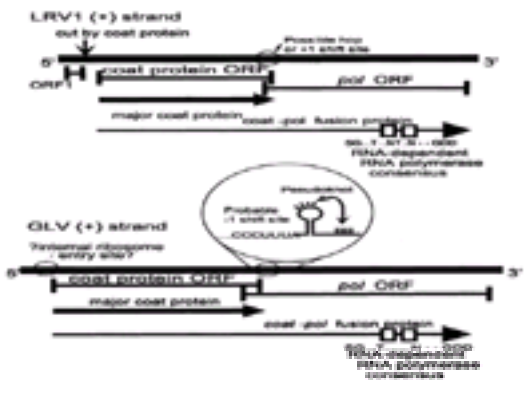

FIG. 5. Genome structure and expression of *Leishmania* virus, LRV1 (248), and the *Giardia* virus, GLV (273). There are several similarities of these viruses to each other and to the *Saccharomyces* virus, L-A, which has led to their

classification together as totiviruses.

A small ORF of 228 nt (ORF1) is present upstream of ORF2 in LRV1-1 (248), and two such small upstream ORFs are found in the closely related LRV1-4 (235). The absence of the spliced leader sequence common to all Leishmania cellular mRNAs suggests that this upstream region may be untranslated.

The capsid protein of LRV has an endonuclease activity that cuts viral (+) strands at GAUC*CG, 320 nt from the 5' end in LRV1-4 (180). The role of this unique activity is not yet clear.

Giardia lamblia Virus

The Giardiavirus (GLV) is an infectious totivirus, with a single-segment, 6.1 kb double-stranded RNA genome (271). Its host, *Giardia lamblia*, is a primitive eukaryote with two nuclei but no mitochondria, Golgi, or endoplasmic reticulum. This protozoan is a flagellated intestinal parasite of mammals with a wide distribution.

Unlike other known viruses of fungi or parasites discussed here, GLV is found in the culture supernatant and readily infects *G. lamblia* cells. Infected cells contain 36 nm isometric particles composed of a major 100-kd protein and a minor 190-kd protein (194). Purified viral (+) ssRNA can be reintroduced into a virus-free strain by electroporation, and a new infection can be initiated in this way (116). Inserting luciferase within an *in vitro* transcript of a cDNA clone of GLV, replacing most of the Gag ORF, and electroporating the hybrid RNA into GLV-infected *Giardia* trophozoites, resulted in stable expression of luciferase in the recipient cells and the production of viral particles able to transmit luciferase expression to newly infected cells (67).

The structure of the GLV genome (see Fig. 5) (271) has several features in common with other *Totiviridae* and with certain animal viruses. There are two major ORFs: The 5' ORF encodes the 100-kd major coat protein. The 3' ORF has the typical RNA-dependent RNA polymerase motifs, and it is expressed only as a fusion protein with the 5' ORF (271). Thus, expression in GLV resembles that of retroviruses, the *Saccharomyces* L-A virus, and the *Leishmania* dsRNA virus LRV-1 in forming a gag-pol fusion protein. The structure of the 210 nt overlap region of the *gag* and *pol* ORFs strongly suggests that the mechanism of fusion protein formation is by the same –1 ribosomal frameshift as that used by many animal retroviruses and the yeast L-A dsRNA virus. A slippery site C CCU UUA (*gag* frame shown) is followed closely by a predicted pseudoknot, as has been shown to be essential in these systems and in coronaviruses for programmed frameshifting.

The 5' noncoding region of the GLV genome has seven AUG codons, each followed by a very short reading frame (271). This feature appears to be common among the *Cryphonectria* hypoviruses, LRV1, and GLV. The 5' and 3' UTRs are necessary for replication of the luciferase hybrid viruses, but the 5' 265 nt of the Gag coding region further promotes expression of luciferase in these hybrids without affecting transcript levels, indicating a translational control mechanism (68). The results are consistent with an internal ribosome entry site bypassing the small upstream ORFs.

Trichomonas Virus and Host Phenotypic Variation

Many strains of *Trichomonas vaginalis* carry 33 nm viral particles composed of an 85-kd major coat protein and containing 5.5 kb dsRNA (272). This 5.5 kb dsRNA in fact consists of three distinct dsRNA species that do not cross-hybridize (152). Sequence analyses of two of the species indicate that each has a typical totivirus structure with overlapping 5' Gag and 3' Pol ORFs (250). Like the LRV1 totivirus, the Pol ORF is in the +1 frame relative to Gag (250).

Remarkably, the presence of the virus is correlated with a phenotypic variation of the host cells (270). Expression of a major surface antigen switches on and off in cells carrying the virus, but its transcription is always off in virus-free strains (153). Cells often lose the virus on serial passage, and loss of the virus is always accompanied by loss of phenotypic variation (270).

Partitiviridae

The *Partitiviridae* have a bipartite genome with the two segments separately encapsidated in particles containing the proteins encoded by both segments. This group includes viruses of the filamentous fungi *Penicillium*, and *Aspergillus*, and the mushroom *Agaricus*, as well as many other fungi. It also includes a large group of plant cryptoviruses (20,202), whose genome is dsRNA and whose biology is much like that of the systems discussed in detail here.

Atkinsonella hypoxylon *Partitivirus 2H.* This isolate of *Atkinsonella hypoxylon* strain 2H has three dsRNA segments of 2180, 2135, and 1790 nt. Segment 1 encodes an RNA-dependent RNA polymerase, and segment 2 encodes a 74-kd protein that may be the major coat protein (207). The third segment does not appear to encode a protein (207).

VIRUSES REDUCING VIRULENCE OF *Cryphonectria parasitica*

The American chestnut tree was devastated by the accidental introduction, in 1905, of the pathogenic fungus *Cryphonectria parasitica*, along with an oriental variety of the chestnut tree (reviewed in ref. 206). The fungus virtually eliminated the upper parts of the chestnut trees in the eastern United States, but the root systems are not killed and shoots continue to emerge, only to have their growth limited by the reattack of the fungus. *C. parasitica* had a similar effect in Europe, but in the 1950s, the emergence of fungal strains in Italy with markedly reduced virulence to the trees was noted. These “hypovirulent” strains (Fig. 6), later also found in Michigan, could transmit their hypovirulence by hyphal anastomosis to virulent strains, and this was used successfully for the biologic control of chestnut blight in

Europe. Hypovirulent strains also show decreased asexual spore formation, decreased production of laccase (a phenol oxidase possibly involved in pathogenesis), and reduction in pigment formation (reviewed in 206).

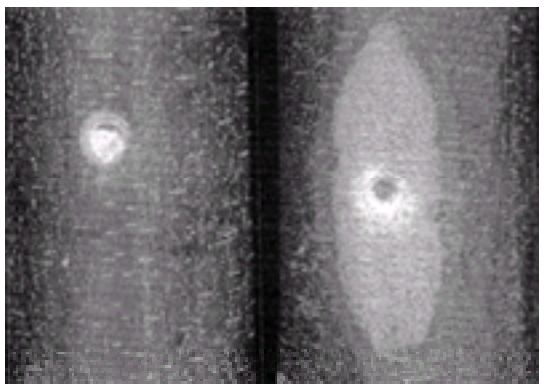

FIG. 6. Virulent (uninfected, *right*) and hypovirulent (virus-infected, *left*) *Cryphonectria parasitica* (chestnut blight fungus) inoculated into chestnut trees. Infection of the fungus by any of several hypoviruses attenuates its virulence toward the trees. (Photo courtesy of Dr. Donald Nuss.)

The cytoplasmically inherited factor that reduces the pathogenicity of the fungus and produces these hypovirulence-associated traits was identified as any of several apparently unrelated dsRNA replicons found in the hypovirulent strains and not in the virulent strains (6,66,135). Curing the dsRNAs by growth in the presence of cycloheximide was accompanied by the return of virulence (115).

Genome Structure

The most thoroughly studied hypovirulence-producing virus is CHV1-EP713, the L-dsRNA of hypovirulent *C. parasitica* strain EP713, a 12,712-bp molecule whose (+) strand has two long ORFs, ORFA and ORFB (Fig. 7) (240). Each ORF encodes a papain-like cysteine protease in its N-terminal portion that self-cleaves the primary translation products at least once, as shown in Figure 7 (49,241). The presence of related papain-like proteases and helicase domains, as well as RNA-dependent RNA polymerase motifs, has led to the suggestion that L-dsRNA of *C. parasitica* is related to the potyviruses, a group of (+) ssRNA viruses of plants (162).

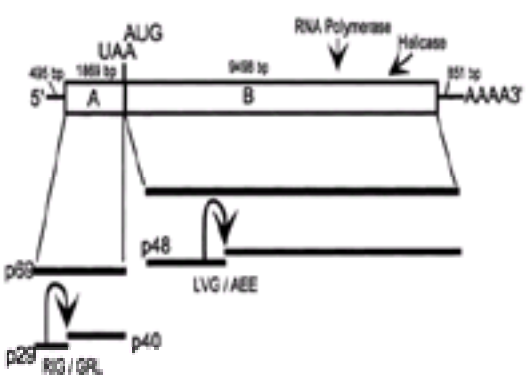

FIG. 7. Coding information and protein processing of the *Cryphonectria parasitica* virus, L. (Adapted from ref. 206, with permission.) The sites of action of the p29 and p48 proteases are indicated. This virus is now designated CHV1-EP713, the type member of the *Hypoviridae*.

The ORFA and ORFB overlap by a single nucleotide, with the UAA termination codon of the first overlapping with the AUG codon of the second (240). The mechanism by which ORFB is expressed has not yet been defined, but this structure implies that the mechanism will not involve ribosomal frameshifting or termination codon read-through. Rather, reinitiation is the most likely mechanism. The translation of ORFA also poses an interesting problem, as the 5' noncoding region contains six short ORFs (240). Whether ribosomes initiate internally as in the case of picornaviruses (see Chapter 23) or use these tiny ORFs for regulatory purposes, as in the GCN4 gene of *S. cerevisiae* (136), is not yet clear.

Virus Replication in Intracellular Vesicles

Unlike other mycoviruses, most of the *C. parasitica* dsRNAs described to date are not associated with virus particles. Rather, they are found in intracellular vesicles (80,131). These vesicles have an RNA polymerase activity that produces both ssRNA and dsRNA (100). Most of the label is incorporated into viral (+) strands (100). This is reminiscent of the membrane association of *in vivo* RNA synthesis of many (+) strand RNA viruses, supporting the notion that this virus is not closely related to other fungal viruses.

Virus Induction of Hypovirulence

CHV1-EP713 has very specific effects on certain genes. For example, the laccase gene encodes a phenol oxidase believed to be involved in pathogenesis. Transcription of the laccase gene is repressed by CHV1-EP713 infection (46,228), an effect that can be produced by expression of just the p29 protease encoded by part of ORFA (48). Although

p29 is sufficient to alter fungal phenotypes, it is neither necessary nor sufficient to cause hypovirulence (60). Deletion of p29 from the virus results in decreased induction of the hypovirulence-associated traits, but no decrease in hypovirulence itself. Moreover, it is not the protease activity of p29 that produces hypo-virulence (60). The symptom-determining domain of p29 has now been localized to the interval Phe25 to Gln73 of p29 (25). The effect of CHV1-EP713 on laccase appears to be transmitted by an influence on the inositol triphosphate–calcium signal transduction system of the fungus, possibly explaining the multiple phenotypic effects of hypovirulence (165).

Cryparin, a hydrophobic cell-surface protein, is also reduced in hypovirulent strains, an effect mediated at transcription (295). Another gene, *Vir2*, was isolated based on its decreased transcription in a hypovirulent strain. Although no effect was seen on virulence itself, deletion of this gene partially mimics some of the hypvirulent-associated traits, with decreased asexual sporulation and fruiting body formation and impaired sexual crossing ability (294). The hypovirulence-associated traits are thus caused by specific effects of viral gene products, rather than by the presence of a replicating dsRNA.

Recently, G protein signaling has been implicated in the induction of hypovirulence by CHV1-EP713. Hypo-virus infection leads to decreased expression of the host Gia (a inhibitory subunit of G protein) and a concomitant increase in cAMP levels (40,45). Moreover, disruption of *cpg-1*, the gene for Gia, results (in an uninfected strain) in elevated cAMP levels, total loss of virulence, and the development of the same associated phenotypes seen on virus-induced hypovirulence (118).

Infectious cDNA Clones and Biologic Control of Chestnut Blight

Introduction of complete cDNA clones of L-dsRNA under control of the *C. parasitica* glyceraldehyde-3-phosphate dehydrogenase promoter resulted in both a complete hypovirulence phenotype of the fungus and the launching of the RNA replicon in a form transmissible to other strains (47). In addition to its usefulness in studying the mechanism of the effects of CHV1-EP713 dsRNA on the cell, this infectious cDNA clone method is an important advance in attempts to control chestnut blight. Although artificial inoculation of trees with hypovirulent fungal strains in Europe resulted in spread of the hypovirulence dsRNAs to virulent strains and control of the blight, this approach has not succeeded in the United States. CHV RNA spreads by fusion of the growing fungal cells with other cells, a process called hyphal anastomosis, but not by sexual crosses (4). Hyphal anastomosis requires that strains have identical alleles at several different loci determining compatibility. The number of compatibility groups is apparently much greater in the United States, limiting the spread of the hypovirulence dsRNA.

In contrast, infectious cDNA incorporated into the *C. parasitica* genome, while generating dsRNA replicons, will also naturally spread to other mating and vegetative compatibility groups through sexual transmission (47,205). It is thus expected to be more effective in the biologic control of chestnut blight than the natural virus, and early results support this expectation (5).

A Reovirus of *Cryphonectria*

Two strains of *C. parasitica* have been found carrying reovirus-like elements (91,211), one of which (C18) is associated with hypovirulence (91). Strains C18 and 9B-2-1 each have 11 dsRNA segments ranging in size from about 1 to about 3 kb and associated with 60 nm virus particles, unlike the vesicles in which the potyvirus-like *Hypoviridae* are found. These 11 segments are present in equimolar amounts and transmission studies show that either all or none of the segments are transmitted, suggesting that they are parts of a single viral genome. Blotting experiments suggest that the C18 and 9B-2-1 genomes are not closely related, but both apparently cause hypovirulence. This system adds new dimensions to the study of both hypovirulence and the *Reoviridae*.

SINGLE-STRANDED RNA REPLICONS

20S RNA

In 1971, a stable species of RNA, intermediate in size between 18S and 25S rRNAs, dubbed 20S RNA, was found to appear specifically in cells exposed to the condition used to induce meiosis and sporulation—namely, when acetate is supplied as the carbon source in the absence of a nitrogen source (146). The ability to produce 20S RNA was then found to be inherited as a non-Mendelian genetic element, distinct from other known elements (123). It was not connected with meiosis, except that the same culture conditions are used to induce both (123). 20S RNA was finally proven to be an independent RNA replicon whose copy number is inducible in acetate (188). Its sequence shows that its 2,500 nucleotides encode a single 95-kd protein with some similarities to the RNA-dependent RNA polymerases of RNA phages and RNA viruses (190,230). W dsRNA, a minor species inducible by growth at high temperature (277), proved to be the replicative form of 20S RNA (190,230). Electron micrographs of purified 20S RNA showed about 50% circular molecules (188), but biochemical experiments indicate that the RNA itself is not circular (231). Recently, the terminal sequences of 20S RNA were shown to be 5'GGGGC . . . . . GCCCC-OH3' (232), suggesting that a circular structure may have been formed by hydrogen bonding.

20S RNA is an apparently naked cytoplasmic replicon with no coat protein (284). The 91-kd RNA polymerase is found bound specifically to the 20S RNA genome (119), and these complexes have RNA polymerase activity—that is, synthesizing 20S RNA and its complementary strand (120). Replication intermediates of 20S RNA include W dsRNA, which is a unit-length molecule, and larger, apparently double-length species (190). Single-stranded molecules of approximately dimer length have also been detected on denaturing gels (190).

23S RNA

T dsRNA was discovered as a minor species of dsRNA easily detected in cells lacking L-A and L-BC, and shown to be, like W dsRNA, an independent replicon inducible by growth of cells at high temperature (277). T is the replicative form of

23S ssRNA (96). 23S RNA has substantial homology with 20S RNA, and likewise appears to encode an RNA-dependent RNA polymerase (96), with which it is associated in extracts (95). All strains known to have T dsRNA also have W dsRNA, but many strains with W lack T (277). Whether T depends on W is not clear.

Control of 20S and 23S RNA Replication

The copy numbers for 20S RNA and 23S RNA are controlled by media conditions, requiring acetate as the carbon source and the absence of a nitrogen source for their 10,000-fold induction (96,146,188,277). Both are also induced by growing cells at 37°, and at least 20S is repressed by the *SKI* system (188,277). The *SKI* effect apparently reflects the absence of 3' poly(A) on 20S mRNA (see preceding).

The *Cryphonectria parasitica* Mitochondrial Replicon NB631 dsRNA

Polashock and Hillman (216) have described a mitochondrial dsRNA species in *C. parasitica* strain NB631. If one assumes the mitochondrial genetic code (UGA = Trp), then the NB631 dsRNA has a single long ORF that encodes an RNA-dependent RNA polymerase. This RNA polymerase is most closely related to those of 20S and 23S RNAs, and all are more closely related to RNA phage such as Qb, than to RNA viruses of higher organisms (215,229). The degree of similarity is such that these elements must be very close relatives. Nevertheless, 20S RNA and 23S RNA are primarily ssRNA replicons with small amounts of the dsRNA replicative form found in cells, whereas NB631 has been identified as a dsRNA element.

NB631 dsRNA is transferred by hyphal anastomosis, like other *C. parasitica* RNA replicons, but unlike those, and other viruses of filamentous fungi, it is also efficiently transmitted by meiotic spore formation if the female parent had the virus (215).

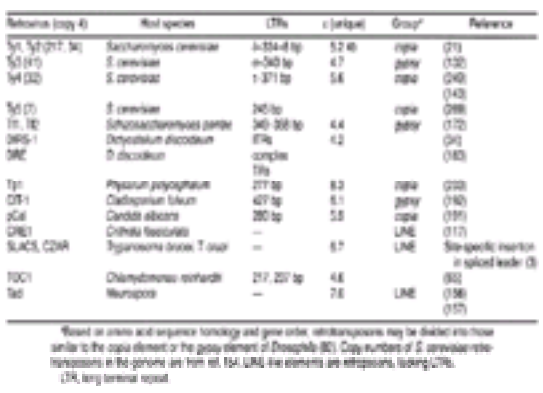
A dsRNA in *Rhizoctonia solani* Also Found as Chromosomal DNA

The M_2 dsRNA of the plant pathogen *Rhizoctonia solani* is a 3,750-bp molecule with a single ORF, and with a high similarity to the NB631 dsRNA. Some of the RNA-dependent RNA polymerase motifs are found, and the results indicate that this protein is an RNA-dependent RNA polymerase (RDRP) (164). Remarkably, the same sequences are present in the DNA genome of the fungus, and the original hypovirulent isolate carrying M_2 derives from a virulent strain having the DNA copy but lacking the free dsRNA (164).

RETROVIRUSES (RETROELEMENTS)

Retroviruses, Retrotransposons, Retroposons, and Retrointrons

Retroelements (Table 2) all share their use of reverse transcriptase in their propagation. The retrotransposons (Table 3) of fungi and parasitic microorganisms resemble mammalian retroviruses in all essentials except for their lacking an *env* (envelope) gene and, in part for this reason, are restricted to propagation without leaving the intracellular environment (Fig. 8). Nonetheless, the frequency with which these cells mate in nature is so high that most of these elements are widely distributed in their respective species. The retroposons are one step further removed in that they lack the long terminal repeat (LTR) structure, and their transposition process differs from those of the other groups. These elements resemble the mammalian LINE elements, but they have the advantage of readily detectable transposition and facile host genetics for their study. For example, Tad, of *Neurospora*, can retrotranspose between nuclei of a heterokaryon (156,157).



Element	*env*	LTRs	RT	Examples
Retrovirus	+	+	+	RSV, HIV
Retrotransposon	–	+	+	Ty1–5
Retroposon	–	–	+	LINEs, Tad
Retrointron	–	–	+	intron al1 of *COX1*

LTR, long terminal repeat; RT, reverse transcriptase; RSV, respiratory syncytial virus; HIV, human immunodeficiency virus.

TABLE 2. *Retrotransposons of simple eukaryotes*

TABLE 3. *Groups of retroelements*

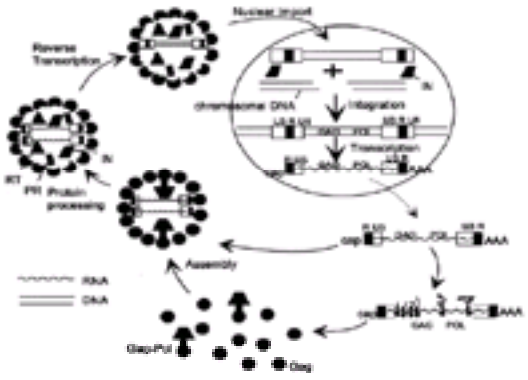


FIG. 8. The Ty replication cycle. It is likely that all retrotransposons follow this cycle.

A group of reverse-transcriptase-encoding introns in mitochondrial DNA of *S. cerevisiae* has also been identified (151). These are introns aI1 and aI2 of the COX1 (cytochrome oxidase subunit I) gene. These introns are capable of retrotransposition both into their normal location and into heterologous locations, both *in vitro* (151) and *in vivo* (199). These retroelements lack LTRs and have only a single ORF. Their properties suggest that introns may have begun as parasitic elements.

The retrotransposons are also divided based on amino acid sequence homologies and gene order in the *pol* domain into the *copia*-like and the *gypsy*-like elements. *Copia* and *gypsy* are retroelements of *Drosophila*. Because Ty3 is more similar to gypsy than to Ty1 (132,290), it is likely that Ty3 and Ty1 entered the yeast genomes at different times, and thus that horizontal transfer of these elements does occur.

Structure of Tys and Other Retroelements

The Ty elements of *S. cerevisiae* each have LTRs of 245 to 371 bp, separated by a unique region (called e) of 4.7 to 5.6 kb (Fig. 9 and Fig. 10) (21,51,132). The major Ty RNA transcript begins within the 5' LTR (at base 241 from the 5' end in Ty1) and ends at base 289 of the 3' LTR, 45 bp from the 3' end of the element (see Fig. 10) (90). This provides the basis for the conventional division of retroviral LTRs into the U3 region (present only at the 3' end of the Ty RNA, but located at the 5' end of the LTR), the R region (repeated at both ends of Ty RNA), and the U5 region (present only at the 5' end of Ty RNA, but at the 3' end of the LTR).

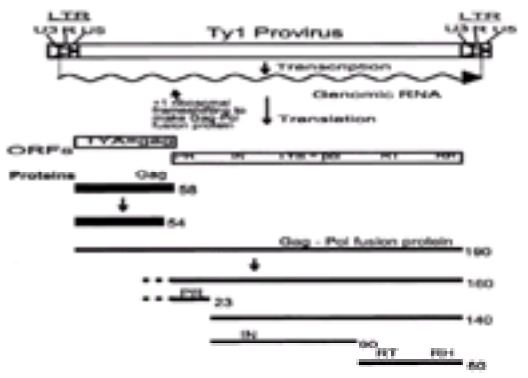

FIG. 9. Genome structure and expression of Ty1. Gag and Gag-Pol are the primary translation products, which are processed by cleavage with the viral protease to form the proteins shown. (Adapted from ref. 121, with permission.)

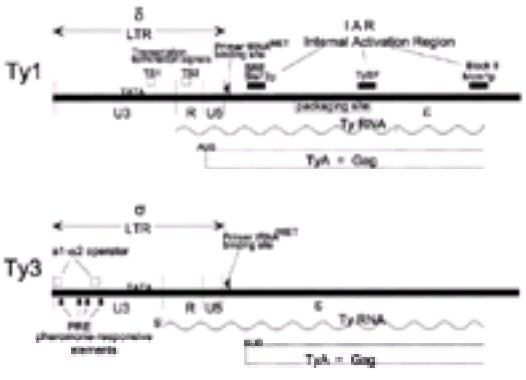

FIG. 10. Structure and functional regions of the Ty1 and Ty3 long terminal repeats (LTRs). Although the LTRs of Ty1 and Ty2 are similar, the control sequences within e, the unique regions, are different. SRE, Site-responsive element; TyBF, Ty binding factor site; Block II, the Mcm1p binding site. Ty38s control sequences are apparently all within the LTR, its primer binding site is two bases from the LTR, and its Gag protein initiation codon is within the unique region, not in the

LTRs.

Ty1 through Ty4 all have two overlapping ORFs, TYA, corresponding to *gag*, and TYB, homologous to the *pol* of mammalian retroviruses. Like mammalian retroviruses and *gypsy*, Ty3 has the gene order protease (PR)–reverse transcriptase (RT)–RNase H (RH)–integrase (IN) in the *pol* ORF (132), whereas Ty1 and Ty2 have the *copia* order PR-IN-RT-RH (51,275).

Replication Cycle of *S. cerevisiae* Ty Elements

The Ty replication cycle resembles that of mammalian retroviruses except that it begins and ends with the integrated form of the genome (see Fig. 8). Ty transcripts made with RNA polymerase II are translated to make the Gag (TYA) and Gag-Pol fusion (TYA-TYB) proteins. These proteins assemble, packaging the Ty RNA to make particles that are homologs of the core particles of retroviruses. The reverse transcriptase and RNase H make a dsDNA copy of the genome, and integrase inserts this into the genome, producing a short repeat of the chromosomal integration site.

Reverse Transcription

The reverse transcriptase and RNase H–homologous domains are present in the Ty1 particles as a 60-kd protein that is produced by proteolytic processing of the 190-kd Gag-Pol fusion protein (see Fig. 9) (121). Isolated Ty1 particles have reverse transcriptase that is active on either the endogenous Ty1 RNA or externally added templates. The Ty particles are also open to externally added enzymes, indicating that they are not impermeable shells but have pores. This porous structure may help explain how pseudogene formation can occur (71).

The mechanism of reverse transcription of Ty RNA is largely the same as that for mammalian retroviruses (but see ref. 166). The primer for reverse transcription is $tRNA_i^{Met}$, with 10 nucleotides of the 3' acceptor stem complementary to a site on the Ty1 (+) strand just 3' to the 5' LTR, called the (–) primer binding site (–PBS) (39). This tRNA is specifically packaged in viral particles (39). Interestingly, although the primer function of the initiator tRNAMet depends on its complementarity with the –PBS, its packaging is independent of this complementarity (39). This indicates that the $tRNA_i^{Met}$ is recognized by some other component of the Ty virus particle, and that it is probably not the acceptor stem of the tRNA that is recognized.

Integration

Ty3 shows a tight specificity for target sites, integrating 16 or 17 bp upstream of the 5' ends of tRNA coding regions (29,36). The DRE element of *Dictyostelium discoideum* and the spliced leader-specific elements SLACS, CZAR, and CRE1 of trypanosomes have a similar integration target specificity (3,117,183). Other genes transcribed by RNA polymerase III, such as 5S ribosomal RNA and U6 small nuclear RNA, are similarly targets for Ty3 (36). However, no common consensus sequence could be deduced for the insertion sites, suggesting that the integration apparatus was recognizing some aspect of chromatin structure or the RNA polymerase III transcription apparatus itself at these sites. Substitution of four purines with pyrimidines at the site of transcription initiation without moving the promoter did not change the site of Ty3 insertion. Eliminating transcription by destroying the promoter (box B inside the tRNA gene) eliminated target activity. But leaving the original transcription initiation site and Ty3 insertion site intact and moving box A of the promoter to a new site moved the site of transcription initiation and changed the Ty3 insertion site to a comparable position (36). This indicates that the integration apparatus recognizes the transcription apparatus but not the transcription initiation site or the promoter itself.

Other Tys are capable of insertion at many different sites, with Ty1 producing a five-bp duplication of the target DNA (102), but these sites tend to be within 750 bases of a tRNA gene or other RNA polymerase III–transcribed gene (144,154). Ty1 insertions in RNA *pol* II–transcribed genes tend to be in the 5' part of the *URA3*, *LYS2*, and *CAN1* genes (86,175,201), with control regions targeted far more often than the ORFs. Ty5 specifically targets regions of silent chromatin, such as the telomeric regions or the silent mating type loci (296).

An *in vitro* integration system has been established for Ty1 using Ty1 viral particles produced from an element carrying a copy of the *E. coli supF* gene and, as target, l DNA from a multiple amber mutant suppressible by *supF* (87,88). Using this system, it has been shown that linear double-stranded DNA substrates carrying the terminal 12 bp at each end of the LTR are sufficient for the integration reaction to occur at normal efficiency (88). There are also no nucleotide requirements. The substrate DNA must have 3' hydroxyls, suggesting that the reaction involves covalent attachment of these 3' ends to the target DNA. Unlike mammalian retroviruses, Ty1's IN does not remove two terminal bases in the process of integration (88), probably because in Ty1 the –PBS is immediately adjacent to the U5 part of the LTR. Ty3, however, resembles mammalian retroviruses in this regard (S. Sandmeyer, personal communication).

In fact, the purified IN protein is capable of carrying out an integration model reaction without other components of the viral particle (198). This suggests that it may be sufficient for IN and the reverse transcript to enter the nucleus for integration.

Expression

Control of Transcription

Ty1 transcription is controlled by MAT, the yeast mating type locus. MATa/MATa diploid cells have 20-fold lower Ty1 transcript levels than MATa or MATa haploid cells or MATa/MATa or MATa/MATa diploids (89). Exposure of cells to

mating pheromones, a step that immediately precedes mating itself, produces a posttranscriptional blockage of Ty1 transposition (293). Is this a control strategy adopted by Ty1 or imposed by the host, and why?

DNA damage, induced by ultraviolet irradiation or 4-nitroquinoline-1-oxide also induce Ty1 transposition by inducing transcription of the element (24). Is this effect adaptive for Ty1 as a first step in finding a new home, or is it a consequence of a failure of the host anti-Ty system?

Retroelements all must cajole the cellular RNA polymerase II into transcribing their proviral form to make viral RNA. They are constrained, however, to place the controlling sequences inside the limits of the element. While most mammalian retroviruses have enhancers in their LTRs upstream of the start site of transcription, Ty1 and Ty2 elements have major transcriptional control sequences downstream of both the transcript start site and the translation start site, most of them inside the unique region e (see Fig. 10). Ty1 has two major downstream sites responsible for its haploid-specific transcription: the sterile-responsive element (SRE) binds Ste12p, and another site (block II or PRTF) binds Mcm1p (53,92) (see Fig. 10). Ty2 has one upstream activation site (174), and at least two downstream activation regions, one of which (DAS1) responds to Gcn4p (103,264). Ty2 also has several downstream repression sites (DRS) (104).

Transcription of both Ty3 and Ty5 are, like that of Ty1, much higher in haploid cells than in diploids. Moreover, its transcription and transposition are derepressed by exposure of cells to the mating pheromones (52,150,265). Ty3 transposition is, in fact, induced in mating cells and Ty3 transposing from the genome of one mating partner to that of the other occurs at high rates (158). Ty3 transcription is induced before mating and repressed after mating by mating type control, but the particles synthesized before mating are sufficient to give a burst of transposition from one genome into the other (158). Here, the interpretation of preparation to transpose into the potentially Ty3-free genome of the mating partner seems clear.

In diploid *Saccharomyces* cells, the MATa1-MATa2 protein complex (encoded by the mating type locus) represses haploid-specific cellular genes. The regulation of Ty3 transcription involves two a1-a2 consensus recognition sites, determining mating type repression, and three PRE sequences, determining pheromone responsive expression, all located within the 5' LTR of the Ty3 element (16,265). An upstream repression sequence (URS) is located at the junction of the 5' LTR and the adjacent tRNA gene (16). Thus, in contrast to Ty1 and Ty2, most of whose control regions are located within the unique region downstream of the transcription and translation start sites, Ty3's transcription control regions are largely upstream within the U3 region of the LTR (see Fig. 10).

Effect of Ty Insertion on Cellular Genes

Insertion of Ty elements into the control regions of cellular genes can activate, inactivate, or alter the control of the target gene (93,287; reviewed in 21). The Ty insertions often move the normal regulatory sequences 5 kb away from the target gene, eliminating the normal regulation. Insertions of Ty whose 5' end is close to the 5' end of the target gene impose the Ty transcriptional control on the target gene. This produces a divergent transcription of the Ty element and the target gene, but both are under mating type control because of the effect of the Ty control region.

Chromosomal Genes Regulating Ty Transcription

Mutant cellular genes which have come under control of Ty1 have been used extensively to investigate the cellular genes affecting the transcription of Ty1 itself (50,288,289). Second-site mutations (suppressors) that restore the normal expression of the target genes have defined a large group of genes, called *SPT*, that include the TATA binding factor TFIID, the genes encoding histones, and many general transcription factors with effects on many genes (e.g., *SNF2*, *SNF5*, *SNF6*, *GAL11*, *SIN1*). In addition, the control of the target genes by mating type and mating pheromones have led to studies of effects of the mating type and pheromone control pathway genes on Ty itself. For example, *STE12* controls Ty1 transcription, as do the genes upstream of *STE12* in the mating type control kinase cascade (93,94).

+1 Ribosomal Frameshifting

Like mammalian retroviruses, Ty elements direct the synthesis of a Gag protein and a Gag-Pol fusion protein (Fig. 11). For reasons that are not yet clear, each of the *Saccharomyces* Ty elements uses +1 ribosomal frameshifting, whereas animal retroviruses all use –1 frameshifting (or readthrough of a terminator) to make Gag-Pol (reviewed in 101,125). As shown by studies of the L-A dsRNA virus, yeast can perform –1 ribosomal frameshifts by the same simultaneous slippage mechanism used by retroviruses.

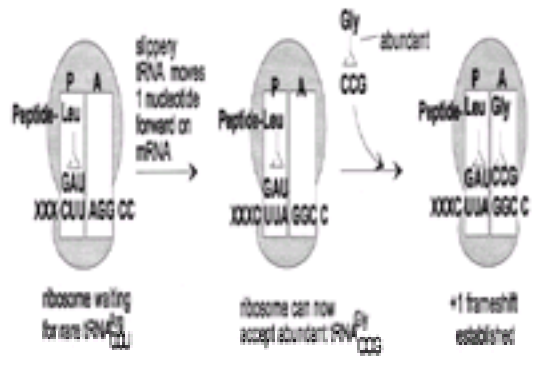

FIG. 11. Mechanism postulated for +1 ribosomal frameshifting of Ty1. (Adapted from ref. 12, with permission.) Ty3 frameshifting involves the new tRNA pairing in the +1 frame without a shift of the peptidyl tRNA as for Ty1 (268).

The mechanisms of the +1 frameshifts in Ty1 or Ty2 (see Fig. 11) and Ty3 all involve the combination of starvation for a rare tRNA and an unusual tRNA able to perform the frameshift (13,105). In the case of Ty1, the slippery site on the mRNA is CUU-AGG-C. The ribosomes are slowed by the AGG codon at the A ribosomal site. This codon is recognized by a $tRNA^{Arg}$ that is present in low abundance in yeast, so it is called a hungry codon. The $tRNA^{Leu}$, located at the P site while the A site is waiting for the AGG codon to be occupied, has as its anticodon UAG, and it is capable of pairing with either the 0 frame CUU codon or the +1 frame codon UUA. When it slips into the +1 frame, the GGC codon can be easily recognized by an abundant $tRNA^{Gly}$ species, and the ribosomes then continue in the +1 pol reading frame to make Gag-Pol fusion protein (13).

The efficiency of the Ty1 +1 ribosomal frameshift depends on the scarcity of the $tRNA^{Arg}$ recognizing the AGG codon. Thus, artificially oversupplying this tRNA lowers frameshift efficiency (13) and also lowers transposition frequency (291). Likewise, deletion of the gene for this $tRNA^{Arg}$ increases the efficiency of frameshifting and lowers the frequency of transposition (149). Starvation of cells for spermidine elevates the efficiency of Ty1 +1 ribosomal frameshifting and results in decreased transposition efficiency (8). Like the similar experiments done with the L-A dsRNA virus of *S. cerevisiae*, these results suggest that drugs affecting frameshifting efficiency might be useful as antivirals.

The Ty3 frameshift site is GCG-AGU-U, and, like that of Ty1, it is based on a hungry codon in the ribosomal A site, namely AGU (105). AGU is recognized by a low-abundance $tRNA^{Ser}$, so the ribosome pauses at this point. But the $tRNA^{Ala}_{CGC}$ that decodes the GCG codon in the P site cannot slip +1 and re-pair. Rather, it is believed that the valine tRNA simply pairs out of frame (268).

Proteolytic Processing and Phosphorylation

Ty1 Gag is expressed as a primary translation product of about 58 kd, most of which is processed by the Ty1 protease to form the 54-kd major particle protein (1). Gag is phosphorylated (193), and this phosphorylation is increased concomitant with the inhibition of transposition that occurs when cells are treated with mating pheromone (293). After Pol is synthesized as a 190-kd Gag-Pol fusion protein, it is processed through several intermediates to form a 23-kd protease, the 90-kd integrase, and the 60-kd reverse transcriptase–RNase H (see Fig. 9) (121).

Packaging: RNA Sites and Protein Requirements

The Ty1 RNA site determining packaging has been localized to within a 381-nt region between nt 239 and 620 (see Fig. 10) (292). The RNA structure recognized and the parts of TYA or TYA-TYB proteins that recognize this region have not yet been determined.

Debranching Enzyme and Ty1

Mutation of *DBR1*, encoding the enzyme that debranches the lariat structure produced by intron excision by cleaving the 2'-5' linkage at the branchpoint, results in a ninefold decrease in Ty1 transposition efficiency (38). However, the explanation of this unexpected finding remains unclear.

Host Limitations on Ty Transposition Efficiency

Although normal cells have about 35 chromosomal copies of Ty1, most of which are probably transposition competent (64), transposition is a relatively rare event. Most studies of the mechanism of transposition have used a high-copy plasmid with a GAL1-promoted Ty1 carrying a marker (such as *HIS3*) included in the Ty1 to facilitate detection of transposition (21). When Ty1 transposition is induced with such a plasmid, although Ty1 RNA is increased only a few fold over that derived from the normal chromosomal Ty1 copies, the frequency of transposition increases about 100-fold (63). One point at which transposition is blocked in uninduced cells is at the processing of viral proteins, particularly the PR and IN proteins encoded by TYB (63). Several host genes have been identified whose mutation derepresses Ty1 transposition, analogous to the effect of ski mutations on RNA virus copy number (see preceding).

Mutation of the cellular *rad6* gene, encoding a ubiquitin-conjugating enzyme, increases the frequency of Ty transposition at either *URA3* or *CAN1* (214). This effect was not caused by altered Ty transcript levels, and it was seen even when retrotransposition from a GAL1-promoted Ty1 was studied. The *rad6* mutation is believed to alter chromatin structure by failing to ubiquitinate histones, suggesting that its effect on Ty1 transposition is on the nature of the target. Indeed, Ty1's target-site specificity for gene control regions is apparently eliminated by the *rad6* mutation (148,175).

Another case of target-level regulation of Ty1 retrotransposition is found on mutation of *CAC3*, encoding a subunit of chromatin assembly factor, and *HIR3*, a histone transcription regulation gene (218). Here again, both the frequency of integration and the distribution of insertions is affected by alterations of the structure of the target (138).

Mutation of the *FUS3* mitogen-activated protein kinase (MAP kinase) results in an over 20-fold increased Ty1 transposition frequency (54). Ty1 transcript levels and primary translation products were not affected by *fus3*, but virus particle–associated processing products of TyB and Ty cDNA were each elevated 10-fold or greater in the mutant. The Fus3 kinase is activated by exposure to the mating pheromones via a cascade of kinases, so this explains the inhibition of Ty1 transposition by exposure to mating pheromones (293). Although Fus3 may act indirectly to block Ty1 transposition, several observations suggest a direct action (54). TyA is normally phosphorylated, but it is hyperphosphorylated when cells are treated with a pheromone, which is known to activate Fus3 (293). TyA has several consensus sites for Fus3 phosphorylation.

Also inhibiting Ty1 retrotransposition are components of the nucleotide excision repair/transcription factor TFIIH (167). *SSL2* and *RAD3* encode DNA helicases with roles in both nucleotide excision-repair and in the basal transcription factor

TFIIH. Mutants in either of these genes show elevated frequencies of Ty1 retrotransposition without alterations of the distribution of integration sites (167). There is no elevation of Ty1 proteins, but the level of Ty1 cDNA is elevated in either mutant (167). These results indicate that Ssl2p and Rad3p either inhibit reverse transcription or, perhaps more plausibly, destabilize Ty1 cDNA (167).

It is thus apparent that the host has several levels of defense against Ty1 attack: stability of viral particles, stability of cDNA, and structure of the target sites.

Schizosaccharomyces pombe Retroelements

The Tf1 and Tf2 elements of *S. pombe* are unusual in that a single ORF encodes both Gag and Pol (172). From the primary 140-kd translation product, the viral protease cleaves the proteins that form the viral particles (173). In view of the strict requirement for the ratio of Gag to Gag-Pol in Ty1 (149,291) and retroviruses, the assembly process in Tf1 and Tf2 must be significantly different. In log phase cells, the ratio of Gag to IN in particles is close to 1, whereas in stationary cells, it is quite high (7). Selective degradation of the non-Gag protein components alters the ratio after particle formation (7).

The priming mechanism of Tf1 is also unique. Instead of tRNA-priming as for other retrotransposons and retroviruses, Tf1 (–) strand DNA synthesis is primed by the first 11 nucleotides at the 5' end of the viral RNA, which is complementary to the primer-binding site (171,176). A hairpin is formed, which is nicked to separate the first 11 nucleotides from the 5' end of the RNA and give it a 3'OH that can serve as a primer for strong-stop DNA synthesis.

Candida albicans Retrotransposon as a Plasmid

Most retrotransposons have minute amounts of cDNA present in normal strains, but that of *C. albicans* (pCal) produces 50 to 100 copies per cell of linear dsDNA in a particular strain of *Candida* (191). pCal is a member of the Ty1/*copia* group found in integrated form in most strains, and the basis for its high free levels is not yet known. pCal is also unique among retrotransposons in that it uses readthrough of a stop codon to make its Gag-Pol fusion, as in murine leukemia virus (191).

Summary of Retroelements

The mating type and pheromone control of Ty transcription is clearly adapted to maximize transposition activity at the time when a potentially unoccupied genome becomes available (mating), and to minimize potential damage to the host, whose health is indispensable for survival. Posttranslational mechanisms, determined by the host, also limit transposition.

Among the many interesting questions about Ty elements are, Why do all Ty's use +1 frameshifting, but mammalian retroviruses use –1 frameshifting or termination readthrough to make their Gag-Pol fusion proteins? How does RNA polymerase II know to stop in the 3' LTR, but to keep going in the identical sequence in the 5' LTR? What does Dbr1, the debranching enzyme, do for Ty1? The bewildering array of retroelements continues to amaze.

DNA VIRUSES: *CHLORELLA* VIRUSES

Chlorella is a unicellular eukaryotic alga with a rigid cell wall and a single chloroplast (reviewed in ref. 266). Most *Chlorella* species are free-living, but several, called collectively zoochlorellae, live as endosymbionts (intracellular symbionts) of *Hydra* or *Paramecium*.

An attempt to isolate zoochlorellae free of their *Hydra* or *Paramecium* host often induces multiplication of a virus that grows and kills the zoochlorellae. These viruses are called HVCV (for *Hydra viridis Chlorella* virus) or PBCV (for *Paramecium bursaria Chlorella* virus) (reviewed in refs. 266,267). Hundreds of *Chlorella* viruses have been isolated directly from fresh water and are found throughout the world. They are grown on cultured zoochlorellae and form lytic plaques on agar plates.

Chlorella viruses are large (150 to 230 nm), polyhedral particles containing 5% to 10% lipid. The dsDNA genome of PBCV-1, the best studied *Chlorella* virus, is 333 kb, one of the largest viruses known. PBCV-1 DNA is linear with (a) terminal inverted repeats of 2.2 kb, (b) terminal hairpin structures, and (c) shorter direct repeats within the inverted terminal repeats (245). All three characteristics are in common with the poxviruses, vaccinia virus and African swine fever virus. Some other features are shared with the iridoviruses.

Chlorella virus DNA is heavily methylated, with 5-methylcytosine accounting for as much as 47% of C residues and 6-methyladenine for up to 37% of A residues. Surprisingly, the *Chlorella* viruses encode their own methylases. They also have been found to encode a variety of restriction endonucleases, similar in properties and, in many cases, in specificity to bacterial type II restriction endonucleases. The variety of such methylases and restriction endonucleases has only begun to be explored, but it is clear that a wide variety of specificities will be found (203). The function of these enzymes is completely unclear, and there is evidence against their being required for either degradation of host DNA or exclusion of other co-infecting viruses (reviewed in ref. 203).

It is not surprising to find glycosylated viral proteins, and the 54-kd major capsid protein of PBCV-1 has a carbohydrate component of about 5 kd. What is unexpected is that the virus encodes products that determine the glycosylation of Vp54 (274). Antivirus monoclonal antibodies directed against the carbohydrate moiety of Vp54 were used to select resistant mutants. The resulting virus mutants had altered glycoprotein moieties, but unaltered Vp54 amino acid sequence, indicating that the virus encodes either its own glycosyl transferases or products that control the host enzymes.

The complete sequence of PBCV-1 showed that the 330,742-bp genome encodes enzymes for synthesis of hyaluronic acid, aspartate transcarbamylase (uracil biosynthesis), an EF-3 homolog (translation elongation factor), 10 tRNA genes, genes with self-splicing type I introns, and numerous enzymes involved in nucleic acid metabolism.

Large DNA viruses of marine brown algae have also been described (reviewed in ref. 267).

PRIONS OF *SACCHAROMYCES* AND *PODOSPORA*

The concept of an infectious protein arose in studies of the transmissible spongiform encephalopathies, such as scrapie of sheep, mad cow disease, and Creutzfeldt-Jakob disease of humans (see Chapter 90). Based on genetic evidence (Fig. 12), two non-Mendelian genetic elements of *S. cerevisiae*, [URE3] and [PSI], were identified as prion (infectious protein) forms of Ure2p and Sup35p, respectively (281). This conclusion is supported by extensive further evidence and both appear to be transmissible amyloidoses, a remarkably close parallel to the mammalian disease.

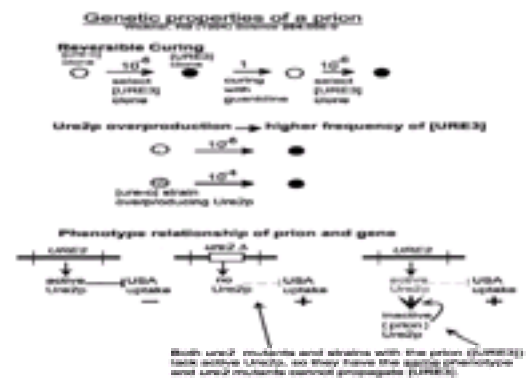

FIG. 12. Three genetic criteria for a prion. These are unusual features, expected of a prion but not of a nucleic acid replicon. (Adapted from ref. 281, with permission.)

[URE3]—A Transmissible Amyloidosis of Ure2p

In 1971, Lacroute described a non-Mendelian genetic element of *S. cerevisiae* called [URE3], which allowed cells to take up ureidosuccinate in spite of the presence of a rich nitrogen source such as ammonia (163). Ureidosuccinate is normally produced by aspartate transcarbamylase in the uracil biosynthesis pathway, and its uptake from the medium by Dal5p is repressed by ammonium. Chromosomal *ure2* mutants have the same effects as [URE3], but in addition they fail to propagate the [URE3] genetic element (2,281). Ure2p is inhibited by Mks1p (84) and posttranslationally inhibits the transcription activator, Gln3p (56). Gln3p positively regulates many genes in nitrogen metabolism, including *DAL5*, whose product is necessary for ureidosuccinate uptake (195,221):

NH_3—|Mks1p—|Ure2p—|Gln3p ® N catabolism genes

Genetic Evidence That [URE3] Is a Prion

Three lines of genetic evidence indicate that [URE3] is actually an altered form of Ure2p that has lost its activity in repressing nitrogen metabolic enzymes through Gln3p but has acquired the ability to convert the normal Ure2p to this altered form (see Fig. 12) (281). First, [URE3] is curable by growth of cells on guanidine HCl, but the curing is reversible in that [URE3] derivatives may again be selected from the cured strain (281). Second, overproduction of Ure2p leads to a 20- to 100-fold increase in the frequency with which [URE3] arises *de novo* (281). Third, the requirement of Ure2p for propagation of [URE3] and the identical phenotypes of *ure2*D and [URE3] are easily explained by the prion model, but not if [URE3] were a nucleic acid replicon—a virus or plasmid (281).

Ure2p is partially protease resistant in extracts of [URE3] strains, indicating that the Ure2 protein is altered, as predicted by the prion model (187). Deletion analysis showed that the part of Ure2p responsible for nitrogen regulation is residues 90 to 354, while the part responsible for the prion change is the N-terminal 80 residues (181,187) (Fig. 13A;. Moreover, the generation and propagation of [URE3] was unaffected by the repression or derepression of nitrogen regulation, eliminating some alternative models. [URE3] truly does arise *de novo*, and it is the Ure2 protein, not the *URE2* mRNA or the copy number of the *URE2* gene that induces [URE3] to arise (185).

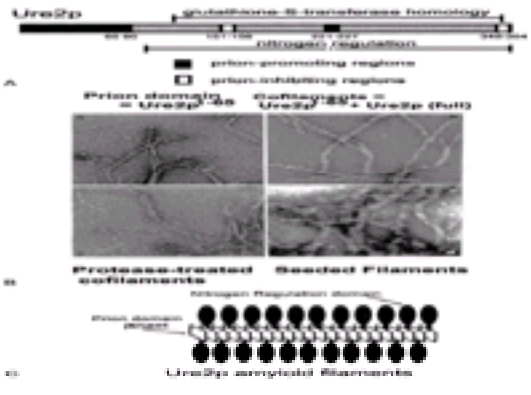

FIG. 13. A: Domains of Ure2p (181,186). **B:** Amyloid formation by Ure2p *in vitro* (253). **C:** Model of Ure2p amyloid structure (253).

Amyloid Formation In Vitro by Ure2p Promoted by the Prion Domain

Ure2p–green fluorescent protein fusions were found to be aggregated in [URE3] cells, indicating that aggregation is involved in the [URE3] change (83). Recent *in vitro* studies have shown that the Ure2p prion domain synthetic peptide can form amyloid, and that it can direct the conversion of the full-length native Ure2p into amyloid (see Fig. 13B) (253). The product of this reaction can seed further amyloid filament formation *in vitro*, suggesting that the [URE3] phenomenon is a transmissible amyloidosis of yeast (253). It appears that the conversion of Ure2p to amyloid inactivates the protein, and at the same time provides a seed for the further polymerization of newly synthesized Ure2p. It is proposed that the amyloid formed by Ure2p consists of a b-sheet core of the prion domain with the C-terminal nitrogen regulation domain attached as shown in Figure 13C.

[PSI]—A Transmissible Amyloidosis of Sup35p

In 1965, Cox described [PSI], a non-Mendelian genetic element of *S. cerevisiae* that increases the efficiency of nonsense suppression by classical tRNA suppressors (58,59). Like [URE3], [PSI] is reversibly curable, in this case either by guanidine or by high-osmotic-strength media (42,179,243,262). Overexpression of Sup35p increases the frequency with which [PSI] arises by 100-fold (42), like the induction of [URE3] appearance by Ure2p overproduction (see preceding). Finally, the phenotype of [PSI] is like that of *sup35* mutants, and *SUP35* is necessary for propagation of [PSI] (81,252), as *URE2* is necessary for propagation of [URE3]. This logical parallel with [URE3] led to the suggestion that [PSI] is also a prion form of Sup35p (281).

In support of the prion model for [PSI], it was shown that Sup35p is aggregated in [PSI+] strains, but not in [psi–] strains (210,212). Further, it was found that it was the overproduction of the Sup35 protein, not the *SUP35* mRNA or the gene in high copy number, that caused the *de novo* appearance of [PSI] (70).

Chaperone Involvement in [PSI] Propagation

Chernoff found that either overproduction of Hsp104p or deletion of the *HSP104* gene resulted in the inability of cells to propagate [PSI] (Fig. 14) (43,44). This finding is important because it at once supported the prion model for [PSI], it was the first proof of involvement of a chaperone in a prion phenomenon, and it provides a potential pathway to treatment of prion diseases. Because Hsp104 disaggregates denatured proteins *in vivo* (209), overproduction of Hsp104 probably cures [PSI] by disaggregating the aggregated Sup35p (see Fig. 14). Whether deficiency of Hsp104 results in loss of [PSI] because Hsp104 participates in the conversion of the normal to the prion form of Sup35p or because Hsp104 must partially disaggregate the prion form of Sup35p to ensure its segregation to both daughter cells remains unclear.

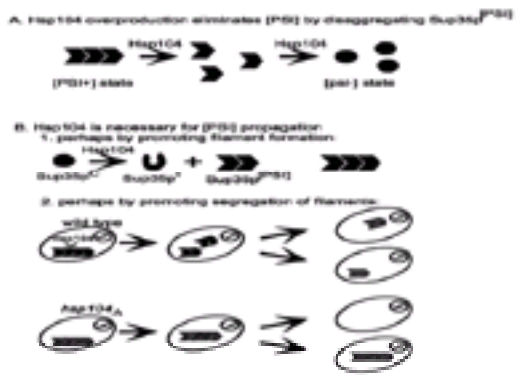

FIG. 14. Role of chaperone Hsp104 in propagation of the [PSI] prion of *S. cerevisiae* (43,44). Overproduction of Hsp104 cures the [PSI] prion by renaturing aggregates of Sup35p. Normal levels of Hsp104 are needed for [PSI] propagation, perhaps because it has a role in catalyzing Sup35p filament (aggregate) formation or in breaking up aggregates to ensure that each daughter cell gets at least one aggregate.

Amyloid Formation by Sup35p In Vitro

The *in vitro* aggregation of native soluble Sup35p seeded by the prion form from [PSI+] cells will continue indefinitely as long as fresh native Sup35p is supplied (213). Further, synthetic prion domain peptide spontaneously forms amyloid *in vitro* (155). In addition, the full-length Sup35p, made in *E. coli*, forms b-sheet-rich filaments spontaneously when diluted out of denaturant, a process that can be accelerated specifically by an extract from [PSI+] cells (127).

[Het-s]—A Prion of *Podospora* Responsible for a Normal Function

When two colonies of the same strain of filamentous fungus meet, they fuse their cellular processes (called hyphae) in a process called hyphal anastomosis or vegetative fusion. This allows exchange of cytoplasm and even nuclei and allows cooperation between the colonies in obtaining nutrients. However, a virus initially present in only one colony will spread

throughout the other colony, so the process is tightly controlled, requiring identity of the two strains at 6 to 10 special chromosomal loci, called *het* loci in *Podospora anserina*. Fusion of two strains that differ at a *het* locus begins, but it is quickly arrested with death of the few fused hyphae and formation of a barrier to further hyphal fusion. This is called the heterokaryon incompatibility reaction (Fig. 15) (11,229; reviewed in 10).

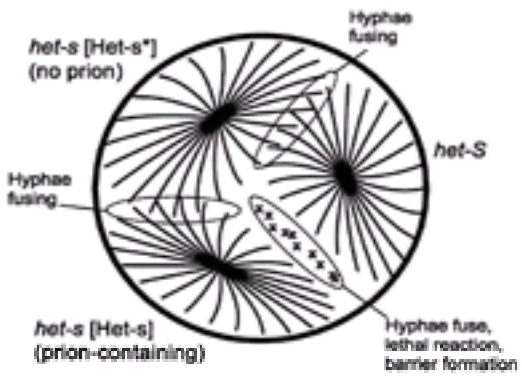

FIG. 15. The [Het-s] prion of *Podospora anserina* is required for heterokaryon incompatibility. (Reprinted from ref. 57, with permission.)

One of the het genes of Podospora is *het-s*, with alleles *het-s* and *het-S* encoding a 289-residue protein differing at 14 positions (263), although the difference at residue 33 is sufficient to trigger the incompatibility reaction (69).

Rizet found that *het-s* strains could show the incompatibility reaction only if they also carried a non-Mendelian genetic element, called [Het-s] (229). [Het-s] could be "cured" from a male strain by mating, but from the cured strain, [Het-s] cells arose at a frequency of about 10^{-7} (12). This is the *reversible curing* criteria for a prion.

Coustou et al. have made the case that [Het-s] is a prion of the protein encoded by *het-s* (57). They showed that overproduction of the Het-s protein increased the frequency with which [Het-s] arose, and that the Het-s protein is relatively protease resistant in strains carrying [Het-s]. Moreover, deletion of the *het-s* gene makes a cell unable to propagate the [Het-s] non-Mendelian genetic element (57).

Beyond its obvious interest as a new prion, [Het-s] is particularly important because it is the first case in which a prion appears to be responsible for a normal cellular function. Heterokaryon incompatibility is observed in most filamentous fungi, usually controlled by chromosomal genes that have no particularly unusual features. In this case, it requires the [Het-s] prion to be observed. This suggests that other prions may be found responsible for normal cellular functions.

PERSPECTIVE

The discovery of prions of yeast and fungi has resolved the debate over whether prions could exist at all and widened the scope of this concept, showing that it is not unique to a single mammalian protein. The possibility is now open for exploring the mechanisms of amyloid and prion generation and propagation using yeast, and using these systems to devise approaches to the many heretofore intractable amyloid diseases.

CHAPTER 22 Bacteriophages

Allan M. Campbell

HISTORY

Bacterial viruses (generally called bacteriophages or simply phages) were discovered independently by Twort and d'Herelle as filtrable, transmissible agents of bacterial lysis (21,68). Although their relevance to animal and plant viruses was not universally accepted, phages proved so tractable to experimentation that information about their nature was soon forthcoming. For example, their ability to form isolated plaques on bacterial lawns was noted, and d'Herelle correctly attributed the linearity of plaque assays to the self-replicating nature of the phage particles (as expected for a subcellular pathogen) rather than to the cooperative effect of many particles (as expected for a typical poison).

The early hope that phage might be used to combat pathogenic bacteria (either therapeutically or in decontamination of the environment, such as in purifying water supplies) did not materialize at that time, although efforts toward that goal have been renewed (51). Starting in the 1920s, phages were widely used in the typing of bacterial strains of medical interest.

A new era in phage research was initiated in the early 1940s by Max Delbrück, Salvador Luria, and their disciples. Their efforts laid the groundwork for the use of phage in the fundamental experiments of molecular biology, but the work itself is notable for its deemphasis of biochemistry and its focus on basic biologic information relevant to the mechanism of self-replication. The techniques used were simple, mainly microbiologic, and some of the questions investigated had already received indicative answers in the previous two decades. What was new was an emphasis on sharp, incisive answers, quantitative where appropriate, and the development of a few standardized systems.

Conditions were determined for the rapid, reproducible attachment of phage to bacterial cells, allowing synchronous infection of all the cells in a culture, with the resulting “one-step” growth. The effect of varying the ratio of phage to bacteria (multiplicity of infection) was analyzed as a problem in random statistics. It was also shown that infected cells pass through an eclipse phase, where infectious phage is unrecoverable from infected cells, and that infectious particles appear at a later time (3). The ability of one phage to exclude another, and of coinfecting phage to interact productively either genetically (by recombination) or phenotypically (by complementation or phenotypic mixing) or both (as in the production of viable phage from cells multiply infected with radiation-damaged particles) was rigorously documented. Quantitative analysis at a comparable level was introduced into animal virology, with the development of plaque assays on tissue monolayers. Thus, the foundations of modern animal virology (independent of its molecular aspects) go back to the phage work of the 1940s.

Central to the quantitative analysis of phage experiments is the random (Poisson) distribution, which states that, when a mean number s of objects (such as virions) are distributed randomly among containers (such as infected cells), then the fraction of containers with exactly r objects is $Pr = s^r e^{-s}/r!$, where e is the base of natural logarithms (2.718...) and $r! = 1 \times 2 \times ...(r\text{-}1)r$, with 0! = 1. Although s can be any nonnegative number, r is restricted to integral values (a cell cannot be infected with half a virion).

Of particular interest is the zero term $P_0 = e^{-s}$. Thus we expect that, when phage and bacteria are mixed at a ratio of 2:1, the fraction of infected cells should be e^{-2}, or about 0.14. To be exact, this calculation requires that every cell have the same large number of surface sites for viral attachment. Although this is not precisely true, the calculation accords fairly well with experiment.

The distribution also applied to the single burst experiment, where infected cells, before lysis, were diluted and distributed so that each tube received, on average, less than a single cell. For example, with an average number of 0.2 infected cells per tube, the fraction P_0 of sterile tubes is $e^{-0.2}$, or 0.818; the fraction P_1 of tubes with exactly one infected cell is $0.2e^{-0.2}$, or 0.162; the fraction with two infected cells is $0.2^2/2e^{-0.2}$, or 0.0162, and so on. Aside from pipetting errors or confounding factors like cell clumping, this calculation is precise.

Studies of phage genetics started in the 1940s with the construction of recombinational maps (36) and continued in the

1950s with Benzer's analysis of fine structure genetics of the T4 *r*II genes (10) and with the discovery and use of conditionally lethal mutations in l and T4, which allowed dissection of the developmental programs of phages (13,26). The rII work depended conceptually on the prior discovery of phenotypic mixing (54), which showed that when mutants of the same phage co-infect a cell, phage gene products are drawn from a common pool. And the later conditional lethal studies depended on the operational protocol laid out in the rII studies.

Serious phage biochemistry was initiated in the 1930s, when Schlesinger determined that phage particles were about 50% DNA and 50% protein (62). It did not enter into the mainstream of phage work until the 1950s, when Hershey and Chase showed by radiolabeling that the phosphorus (DNA) entered the cell during T2 infection but that most of the sulfur (protein) did not (35). The experiment followed the demonstration of the eclipse phase, and the use of electron microscopy to show that empty phage heads remain attached to the cell envelope and that the DNA of virions could be separated from the protein shell by osmotic shock (2). Concurrently, the enzymology of T4 infection was developed in detail, clearly indicating that the phage was introducing instructions for proteins present neither in the uninfected cell nor in the virion.

It was reported in the 1920s that many bacterial strains harbored phage permanently and secreted it into the medium, so that every culture contained phage. Such strains are called lysogenic. The Luria-Delbrück school initially chose to ignore lysogeny, in part because of the possibility that the phenomenon might be explainable simply by the adherence of extracellular phage particles to the bacterial surface and their occasional detachment from it. Increased rigor was introduced by Lwoff et al. around 1950 in a series of experiments showing first, that when individual cells were allowed to divide and daughter cells separated into different drops of liquid by micromanipulation, both daughters retained the ability to produce phage; second, that an occasional cell lysed and liberated a burst of phage (so that it was unnecessary to postulate secretion by living cells); and third, that certain treatments (such as ultraviolet light or other agents that induce the SOS response) induce mass lysis and phage liberation by all cells of the culture (49). As with infected cells in the eclipse phase, no infectious phage were found when lysogenic cells were artificially disrupted.

Phages capable of producing lysogenic complexes are called temperate, and the noninfectious form in which phage genetic information is transmitted is called prophage. Of the temperate phages, coliphage l has been studied most intensively, partly because it grows in the K-12 strain of *Escherichia coli*, for which conjugational and transductional mapping were possible by the 1950s. It was soon shown that prophage has a specific location on the bacterial map, and later that its genome is linearly inserted into the continuity of the bacterial chromosome (16,44).

From 1950 onward, the virtues of a simple identifiable genome with rigorous genetics that could be simultaneously introduced into (or induced to replicate in) all the cells of a culture made phage the favored experimental material for many of the classic experiments of molecular biology, such as the demonstration of DNA breakage and joining during genetic recombination, and the proof of the triplet code. In the 1960s, l, in particular, became the model for study of the genetic hierarchy controlling a simple developmental program. Although the initial investigations on conditionally lethal mutations were pursued in far more depth with T4 than with l, l had some inherent advantages: The initiation of the entire program of the lytic cycle from two promoters directly controlled by repressor, the uniformity of the DNA molecules extracted from virions, and the specific probes for different parts of the genome provided by specialized transducing phages and deletions or substitutions (whose locations could be seen via heteroduplex mapping) made the effects of genetic manipulation on molecular events readily interpretable; and the existence of alternative pathways toward lysis or lysogeny added to the interest.

Since 1970, phage work has merged with the rest of biology because artificial cloning allows the application to many systems of the techniques early available for phage. The background data on phage systems, plus their facile manipulation, continue to allow their study at a high level of sophistication.

VIRULENT PHAGES

Like viruses in general, phages can be divided into those with RNA genomes (mostly small and single stranded), those with small DNA genomes (generally less than 10 kilobases, mostly single stranded), and those with medium to large DNA genomes (30 to 200 kb). The last group includes most of the temperate phages, as well as the first virulent phages to be studied intensively.

Large DNA Phages

The classic T coliphages selected for study by the Luria-Delbrück school fall into four groups: T1 (about 50 kb); T2, T4, and T6 (about 170 kb); T3 and T7 (40 kb); and T5 (about 130 kb). The members of a group have similar virion morphology and can produce viable recombinants in mixed infection.

Phage T4

Virion

T4 was the object of many classic experiments. More than 200 T4 genes were identified through mutational studies. The virion contains 43 phage-encoded proteins, of which 16 are located in the head that encapsidates the DNA, and 27 form the tail through which DNA passes into the cell during infection. The head is an elongated T=13 icosahedron with an extra equatorial row of capsomeres. The tail consists of a hollow core (surrounded by a contractile sheath) that terminates in a baseplate to which are attached six fibers. The whole apparatus functions to inject phage DNA into the interior of the cell. The tips of the tail fibers make initial contact with lipopolysaccharide surface receptors on the bacterium. Once the phage is anchored by tail fiber attachment, random motion brings the baseplate into contact with the cell surface. Either this contact or the tail fiber attachment itself triggers conformational changes in the tail: The center of the baseplate opens like a shutter, allowing the tip of the core to pass through, and the sheath contracts, driving the core through the cell envelope, after which DNA is released into the cell. The double-stranded DNA is distinctive in containing

hydroxymethylcytosine (HMC) (heavily glucosylated) rather than cytosine. It is cyclically permuted and terminally repetitious—that is, the sequences of various molecules can be represented as ABCDEFGHAB, DEFGHABCDE, GHABCDEFGH, and so on. This is most simply demonstrated by allowing the DNA to separate into single strands and then reannealing with complementary strands from other virions, generating circular duplexes with single-stranded tails (Fig. 1).

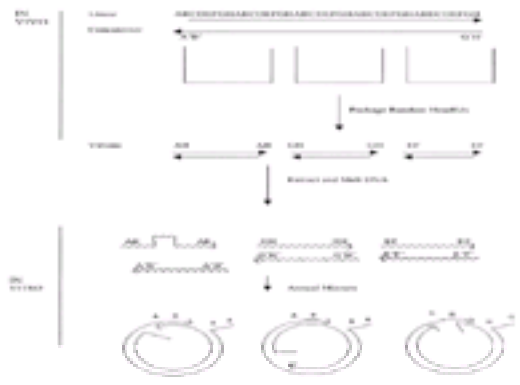

FIG. 1. Genesis (*in vivo*) and demonstration (*in vitro*) of circular permutation of T4. Within infected cells, replication generates a DNA network with linear concatemeric segments. From these, headfuls of DNA, cut randomly, are packaged. Thus DNA extracted from virions has random endpoints. When single strands reassociate, the complementary strands in general have different starting points and thus pair as shown.

DNA Transactions

Infection triggers a massive degradation of cytosine-containing host DNA with subsequent enzymatic conversion of deoxycytosine monophosphate to deoxyhydroxymethylcytosine monophosphate. The phage encodes enzymes that perform these and other conversions of deoxyribonucleotides, which are then used in phage replication. Bidirectional replication is initiated at several origins along the DNA, and elongation is performed by a complex of phage-encoded enzymes, leading- and lagging-strand synthesis proceeding coordinately from a single replication complex. Because there is no mechanism for priming synthesis at the extreme 5' end of the lagging strand, this first round of replication produces linear molecules with protruding 3' ends.

Soon after infection, these early replication origins cease to function (because replication there requires priming by RNA made by host RNA polymerase, whose promoter recognition specificity is altered). Late replication initiates at recombination intermediates formed by invasion of 3' ends into homologous double-stranded DNA. Because of the terminal redundancy, such homologous sequences are available, even in single infection. As replication proceeds, repeated invasions of this kind generate a complex network of intracellular viral DNA, which includes end-to-end concatemers (the preferred packaging substrate for T4). In packaging, empty heads are first assembled, then filled with DNA. Cutting is coordinated with packaging, so that headful lengths are cut to size after the head is filled. The packaging length exceeds the genome length, hence the terminal redundancy. The position of molecular ends along the concatemer is close to random.

This picture of the DNA transactions has genetic consequences; in fact, much of it was inferred from genetic studies that preceded the biochemistry and molecular biology. First, the recombination rate in T4 infection is very high, producing a linkage map thousands of centimorgans in length. It was early noted that this corresponded to about one recombination per replication cycle. Second, the linkage map is circular, as expected if virion DNA has random endpoints. Third, when cells are infected with phages of two different genotypes, some of the progeny particles can carry different information within the terminal duplication; for example, in a mixed infection between T4 and T4 *h*, some progeny plaques contain phage of both *h* and *h*+ genotypes. Another mechanism that generates mixed plaques is packaging of heteroduplex DNA recombination intermediates. Both types of heterozygous progeny are demonstrable (65).

Finally, there are genetic implications of headful packaging. If the length of the terminal overlap represents the difference between packaging length (determined by head size) and genome length, then that length should change in a predictable manner if either packaging length or genome length is deliberately altered. The first test was to alter genome length with a nonlethal deletion. The prediction that this would increase the length of the terminal overlap (and therefore the fraction of particles heterozygous for any locus in the genome) was fulfilled (67). Later experiments with other phages that use headful packaging, such as P22, showed that increasing the genome length by insertion of extra DNA has the reverse effect of decreasing the terminal overlap.

The opposite experiment, where genome length remains constant but packaging length changes, was accomplished through examination of virions with abnormal morphology. Preparations of T4 contain a small fraction of virions whose heads are isometric rather than elongated, separable from the majority type by ultracentrifugation. Certain treatments (such as phage development in the presence of amino acid analogs) induce formation of giant particles with the same diameter as normal virions but additional rows of capsomeres, approaching helical tubes in shape. Missense mutations in the major capsid protein can increase the proportion of both isometric and giant particles. Both types of abnormal particle inject their DNA into cells. The packaging capacity of isometric particles is about 67% that of normal virions; accordingly, single infection is unproductive, but multiple infection allows a normal cycle through recombination between molecules of less than genome length with random endpoints. Giant particles have longer than normal DNA (up to several genome lengths) and a correspondingly high degree of heterozygosity when coming from mixed infection. They are also highly resistant to ultraviolet light because of complementation and recombination between damaged genomes.

Regulation

The genes whose products are needed for phage DNA synthesis and host DNA breakdown, including those mediating nucleotide metabolism and the seven proteins of the replication complex, are all expressed immediately after infection, being transcribed from promoters recognizable by *E. coli* RNA polymerase with s70. With time, early synthesis shuts off and other genes that code for virion components and lysis genes are activated. The shutoff of early genes is effected at both the transcriptional and the translational levels. Translational control is sometimes autogenous, as for the DNA polymerase gp43 and the single-stranded binding protein gp32; many other early genes are controlled by a dedicated translational repressor, the product of the *regA* gene, itself an early gene subject to autogenous control (4,71). (In phage work, gp means gene product, not glycoprotein, as elsewhere in this book.)

Transcriptional control operates on three different types of T4 promoters. The early promoters have sequences approximating the consensus for *E. coli* s70 (with a small but apparently real difference in consensus). Middle promoters require *E. coli* polymerase with s70, in addition to the T4-specified positive regulators MotA and AsiA (1). Their hallmark is a sequence TGCTT at around –32. Late promoters follow –12 consensus TATAAATA. They are transcribed by *E. coli* holoenzyme, with a phage-coded s factor (gp55) replacing s70. In normal infection, late promoter activation requires concurrent DNA replication. *In vitro*, activation can be achieved by nicks or gaps on the nontranscribed strand near the promoter; treatments that create damage *in vivo* can also induce some replication-independent transcription.

In vitro, activation of late transcription by nicks or gaps requires three replication proteins, gp45 and gp44/62, which form a sliding clamp that loads at the nick or gap and moves along the DNA (29). An RNA polymerase-associated protein, gp33, is also required, as well as gp55. Transcription cannot be stimulated by bringing the DNA interruption spatially close to the promoter through catenation of DNA molecules; enhancement is seen only when all signals are on the same DNA double helix, as expected from the sliding clamp model. The exact relationship between these *in vitro* results and the *in vivo* dependence of late transcription on replication is unknown.

Some other ancillary changes during infection may reinforce the temporal sequence but are not essential for it. For example, the a subunit of RNA polymerase becomes adenosine diphosphate (ADP)-ribosylated a few minutes after infection by the action of either of two phage gene products: gp *alt*, which is activated during virion assembly and injected along with the DNA, and gp*mod*. ADP-ribosylation modifies polymerase specificity, but both successful infection and shutoff of host promoters occur in its absence (in *alt*/*mod* double mutants), perhaps because of a multiplicity of functionally overlapping shutoff mechanisms. Shutoff of host transcription is also effected by a T4-encoded transcriptional terminator protein (Alc), which recognizes cytosine-containing DNA.

Thus the chemical marking of phage DNA by HMC is used as a passover signal: Transcription of the host's cytosine (C)-containing DNA is first reduced by the Alc protein (39) and then C-containing DNA is degraded. T4 also has some noteworthy features with no known regulatory role, such as genes that are discontinuous because of intron splicing or ribosomal skipping (8,72).

Assembly

Once late genes are expressed, the stage is set for assembling virions. The T4 virion was the first biologic structure of comparable complexity whose pathways of assembly were worked out, from a combination of physical and genetic knowledge. The major technical factors facilitating the study were, first, the availability of conditionally lethal mutations in genes for individual virion proteins; second, the fact that the final steps of the pathway were readily executed *in vitro* so that reactions in the pathway could be distinguished from irrelevant interactions or side reactions that do not contribute to the yield of functional plaque-forming particles; and third, the facility of operations by then standard in phage work, such as assay for complexes stable to dilution.

The results of these studies suggested several general principles whose rationalization as effective strategies and extension to other phages has been subsequently assessed and updated. One of these is the repeated use of subassembly pathways rather than a single linear pathway. Thus, heads, tails, tail fibers, and soluble protein (gp63) catalyzing tail fiber addition are all made separately. Heads and tails combine first to form complexes that are both visible by electron microscopy and stable to dilution, and finally tail fibers are added to the complex. The tail consists of a baseplate (to which the fibers attach) composed of a central hub surrounded by six wedges. Hub and wedges are made separately, then combined to form the baseplate (Fig. 2). Likewise, in tail fiber assembly, the distal and proximal segments are assembled separately, then combined immediately before addition to the head–tail complex. The most obvious advantage of subassembly pathways is that mistakes in assembly can be rejected for each pathway separately, rather than ruining entire virions.

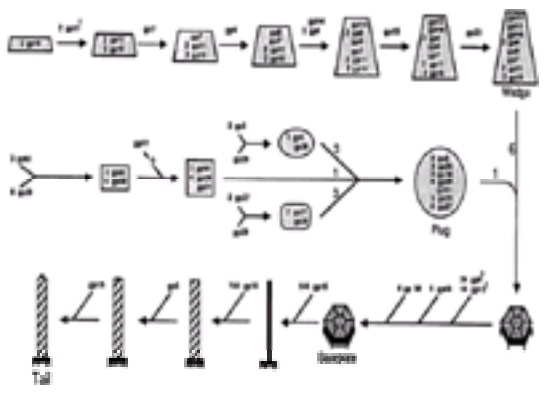

FIG. 2. Assembly pathway of T4 tails. Proteins must be added in the indicated order, except that gp11, gp12, and gp9

(indicated by †) can be added at later times as well. (From ref. 17, with permission.)

A second general rule is that linear elements are built from the end in (toward their junction with the rest of the virion). In tail assembly, baseplates are made first, then the core and sheath are added to them. Likewise, wedges are formed by adding different protein units successively, beginning with one of the outermost units, and finishing with the one that interacts with the hub. This strategy ensures that the intermediates of the subassembly pathway cannot compete with the final product for assembly into the virion. The order of assembly of the wedges themselves may be prescribed by allosteric changes on addition to the complex or by the recognition of binding sites that contain elements of more than one of the proteins already present. In fiber addition to head-tail complexes, fibers do not add efficiently to base plates until heads and tails are joined, apparently because the bend in the fibers contacts the head–tail junction and interacts with it. A protein (gp*wac*) in the collar serves this function *in vitro*, although it is not essential for plaque formation *in vivo*. In free virions, fibers are frequently wrapped around the tail sheath, becoming extended only under specific conditions.

The joining of fibers to head–tail complexes attracted attention early because it proceeds by catalysis of a noncovalent interaction. The catalyst (gp63) also functions as an RNA ligase that apparently acts during (but is not essential for) DNA synthesis. Protein catalysis of a one-step noncovalent interaction was novel at the time, and its discovery was too far in advance of later work on chaperonins to have wide impact.

Tail assembly raised the question of length determination. The core and sheath are both formed by polymerization of single protein species. Core assembly is initiated through nucleation on the baseplate, followed by addition of subunits to build the structure. How is the number of subunits counted, so as to ensure the observed uniformity among virions? The answer (better documented for l than for T4) is by use of a linear measuring stick protein that is embedded within the core and eliminated when assembly is complete (40).

The T4 tail fiber is a bent, linear structure with several specific protein monomers or dimers arranged end to end, terminating in a dimer of gp37. This protein at the tip of the tail fiber is so arranged that its amino acid sequence (and hence its genetic map) is colinear with the fiber axis (7). The specificity for host cell receptors and neutralizing antibodies lies in the distal portion, near the tip, which is also the location of mutations for altered host range.

The pathway of capsid formation in T4 (as for isometric capsids of any virus) is still understood in less depth than tail assembly, but several established features are noteworthy. Some of these are better understood for other phages (l, P22) and inferred for T4. The capsid is synthesized first, and it is filled with DNA later. This fits with the determination of DNA content by head size, but it is more directly established by the association of capsids assembled early with DNA made late in infection (47). Second, capsids are not built directly into their final form; rather, capsid proteins associate with an internal scaffolding protein, which fills the interior of the prohead and is later extruded through holes in the protein shell, which expands to its final shape before DNA enters. Both scaffolding protein (gp24) and the major head protein (gp23) have a shape-determining role [inferred from the aberrations in shape caused by certain missense mutations (12)]. Probably both proteins are added to the structure concurrently. How these proteins actually determine the elongated icosahedral shape is unknown, and the intermediate states are no better understood than for any other closed lattice. After the prohead expands and assumes a more obviously icosahedral shape, two decoration proteins, gp *hoc* and gp*soc*, are added at regular positions in the lattice; neither protein is essential for formation of functional virions. Third, assembly requires nucleation from one vertex, in which minor capsid proteins, noncapsid proteins, and host chaperonins (*gro*EL) all participate. This unique vertex becomes the portal vertex through which DNA enters the virion and to which the tail later attaches. DNA packaging requires two phage proteins (gp16 and gp17) that probably act at the portal vertex but are not present in the final virion. Protein gp17 has been identified as the endonuclease that cuts the DNA from the concatemer during packaging (11). Another packaging gene, gp49, is needed for processing the DNA substrate. Only linear DNA is packaged, but intracellular T4 DNA becomes highly branched during replication and recombination; gp49 cleaves Holliday junctions and other branched structures, creating packageable lengths of linear DNA (11). Fourth, processing of gp23 takes place concurrently with assembly. Figure 3 presents the general scheme for virion assembly in double-stranded DNA phages.

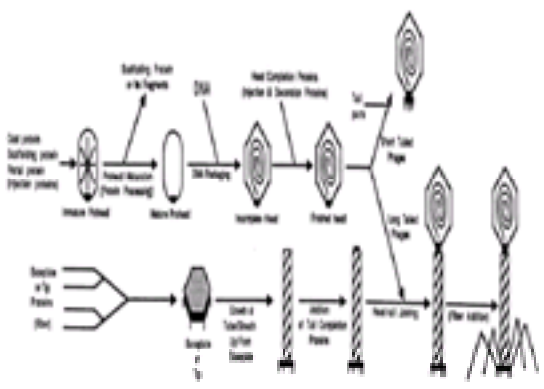

FIG. 3. Generalized assembly pathway for dsDNA phages with tailed virions, such as T4 and l. (From ref. 17, with permission.)

Lysis

The final stage of the T4 cycle is cellular lysis, releasing virions into the medium. Lysis requires two gene products: a

lysozyme (gpe), which attacks the bonds joining *N*-acetylglucosamines in the rigid murein layer, and a holin (gpt), which creates holes in the inner membrane, allowing the lysozyme to reach its substrate. Other genes affect the timing of lysis. The status of gpt as a holin is not fully established and rests largely on analogy to l gpS (75). In *e t*+ mutants, the cell dies and the membrane potential collapses at the normal time of lysis, whereas in *e*+ *t* mutants, the cell continues to produce lysozyme and intracellular phage long after the normal time of lysis.

It is clearly desirable to coordinate the time of lysis with the rest of the lytic cycle, but no regulatory system serving this function has been identified. The timing of lysis appears to be determined largely by the accumulation of gpt, formed coordinately with other late proteins. One genetic system that regulates time of lysis under certain conditions is the *r*II locus. T4*r* mutants were discovered by their ability to form larger than normal plaques, and the *r*II mutants have the related property of inability to plate on strains expressing the *rex* genes of l [which provided the selective conditions for Benzer's classical studies on fine structure genetics (9)]. However, their effect on lysis and plaque size is attributable to the absence, in *r*II mutants, of lysis inhibition. When a cell infected with T4 *r*+ is superinfected before lysis by another T4 particle, lysis is delayed and intracellular phage development continues, for a period of up to several hours beyond the normal latent period of 24 min. The rIIA and rIIB membrane proteins must mediate this response and must likewise destroy membrane damage inflicted by the l *rex* system in response to superinfection, but their mechanism of action is unknown.

Phage T7

Each group of T phages has unique properties. This brief account of phage T7 is intended to indicate some major differences from the T4 paradigm. The phage T7 virion contains 39,936 base pairs (bp) of linear double-stranded DNA (completely sequenced). It is terminally redundant (like T4) but not cyclically permuted. The length of the terminal overlap is 160 bp (25). Immediately after infection, host RNA polymerase initiates transcription from a promoter near the left end of the molecule, whose products include an antirestriction factor, a protein kinase that phosphorylates and inactivates *E. coli* RNA polymerase, a new T7-specific RNA polymerase, and a DNA ligase. After a few minutes, T7 polymerase replaces host polymerase and all transcription takes place on the 81% of the genome toward the right end. The first genes transcribed by T7 polymerase (nearer to the left end) include a DNA polymerase and recombination genes. Later, after replication ensues, the late genes encoding virion components and at least one lysis gene are expressed. Late gene expression does not require replication, as it does in T4, and the host polymerase is replaced rather than reprogrammed. Even without inactivation of host polymerase, the T7 RNA polymerase competes so effectively for nucleoside triphosphates that it redirects almost all transcription to T7 promoters, a feature that has been exploited in the design of T7-based expression vectors for DNA cloning.

The first cycle of DNA replication proceeds bidirectionally from a unique origin of the linear monomer. As with T4, concatemers are probably generated through strand invasion of terminal segments into other molecules within the 160-bp terminal repeat. Replication then generates concatemers in which the unique 39,616 viral sequences alternate with single copies of the 160-bp repeat. If complete virion DNA molecules with repeats at both ends were cut and packaged from such concatemers, half of the genomes would lack terminal repeats. It was suggested that T7 might solve the problem by cutting the DNA in opposite strands at the two ends of the repeat, creating protruding 160-base 5' ends, followed by DNA synthesis to produce flush ends.

The actual solution is apparently more complicated and wasteful. Replication of one strand initiated from a nick near the 160-bp segment proceeds leftward through the 160-bp segment to a reverse repeat beyond the segment. The displaced strand is then nicked at the end of the reverse repeat, which folds back and initiates synthesis rightward through the 160-bp segment. Thus, two copies of the 160-bp segment are present, which can be trimmed to size and packaged (19). Packaging proceeds from right to left processively along the concatemer (66). Because T7 packages the DNA between two specific sites, the amount of DNA per head is not fixed by head size. From study of T7 variants with deletions or duplications, the packaging limits of T7 are about 85% to 103% of normal genome length (F. W. Studier, personal communication).

Small DNA Phages

Some phages package small covalently closed circles of (+) strand genomic DNA in their virions. There are two groups: isometric and filamentous. Although the two groups are not detectably related in sequence and differ in modes of attachment, packaging, and egress, their replication mechanisms are similar.

Isometric Phages

The prototype is f × 174. The virion (25 to 35 nm) has an icosahedral T=1 capsid, composed of three polypeptide species: gpF (60 copies), gpG (60 copies), and gpH (12 copies). gpG and gpH are considered spike proteins and can be physically removed without disrupting the integrity of the capsid. The spike proteins are necessary for attachment to cells, and gpH enters the infected cell with the DNA and participates in phage development. Such participation is not essential for all productive infection, because transfection by pure (+) strand DNA from virions leads to some phage production.

Once within the cell, the DNA becomes coated with single-stranded binding protein (Ssb), then begins to replicate. The first cycle [parental single strand ® double-stranded replicative form (RF)] is mediated entirely by host enzymes. Transcription by host DNA–dependent RNA polymerase at a unique site near a DNA hairpin provides a primer, which is extended by the host replication complex and then digested away. At completion of the cycle, the new DNA strand is ligated to give a covalently closed circle (the RF). Transcription from RF by host RNA polymerase leads to production of phage proteins, among them a dimeric protein gpA, which works only in *cis* (i.e., an A- mutant cannot be complemented in *trans*, perhaps because the protein binds rapidly and irreversibly to DNA near the site of transcription). Rolling circle replication is initiated when gpA binds to RF at a specific origin site and nicks its parental (+) strand, which is then extended by the action of a host-specified DNA helicase (Rep) followed by the host elongation complex. The displaced 5' end is not free but remains bound to the growing point through the gpA dimer. The displaced strand is coated with Ssb

and remains single stranded (no lagging-strand synthesis). When one genome length of DNA has been synthesized and the growing point comes to the origin, the displaced DNA is cut from the newly synthesized DNA and its ends are ligated, giving a single-stranded circle and a double-stranded (RF) circle, both of which can recycle through further rounds of replication. Thus, a fraction of the (+) strands in infected cells are linear and from monomer to dimer length, whereas both (+) and (–) strands are present as monomer circles.

With time, virion proteins accumulate and form empty proheads, and concurrently a phage-specified DNA-binding protein (gpC) is made. On some of the (+) strands, gpC competes with Ssb for binding to the Rep-gpA complex, and these interact with proheads to become encapsidated into virions. Thus, the DNA is directed toward packaging before it encounters the prohead (5). The replicating pool then ceases to expand as (+) strands are packaged (Fig. 4). The multiplication cycle ends with lysis, mediated by the phage gpE protein. The mode of gpE action is uncertain, but it does not involve either a lysozyme or a holin (75).

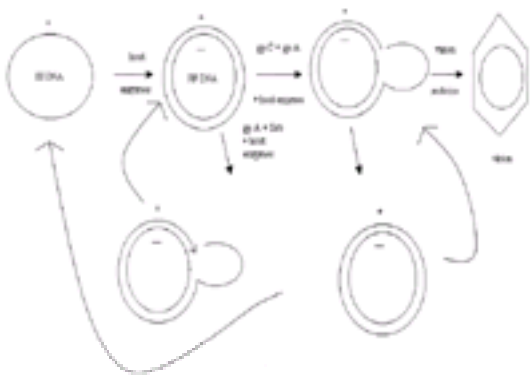

FIG. 4. Replication of fX174. The DNA injected from the virion as a closed ring of single-stranded (+) DNA is first replicated by host enzymes to give the supercoiled double-stranded replicating form (RF). Early after infection (*left*), the (+) strand is cleaved by the phage-coded gpA, and rolling circle replication is initiated. One cycle of replication produces one SS and one RF DNA. At late times, interaction with gpC initiates rolling circle replication, but here the SS DNA is packaged into virions. In early replication, SS DNAs are coated with the host single-strand binding protein Ssb; in late replication, they are coated with gpC until packaging.

Filamentous DNA Phages

The virions of filamentous phages, of which phage fd is the prototype, differ from those of most helical viruses in that the capsid surrounds a DNA molecule that is not linear but circular and therefore is doubled back on itself, although unpaired. The replication cycle of the filamentous DNA phages is similar to that of the isometric phages. Infection is initiated by adsorption of the end of a virion to the terminus of an F-coded pilus, used during bacterial conjugation. The details of DNA entry are obscure. As with f×174, ssDNA formed at late times is coated with a phage-specified DNA-binding protein (gp5) that directs the DNA to packaging rather than to recycling. Packaging is concomitant with egress. The major coat protein (gp8) is embedded in the cell membrane. As phage DNA enters the membrane, gp5 is exchanged for a helical capsid of gp8. Subunits of gp8 are proteolytically processed as they are added to phage DNA, and virions are extruded through the cell envelope without loss of cell viability. Except for a few enveloped phages, these are the only phages whose egress does not require lysis.

The filamentous phages (especially M13) are popular as cloning vectors because of their high yields, the absence of a packaging limit, and the single-strandedness of the product. Cloning is generally accomplished through cutting and ligation of RF DNA, followed by transfection. Filamentous phages have also had extensive use in phage display libraries.

RNA Phages

The common RNA phages have isometric T=1 virions, each containing a single linear single-stranded RNA molecule about 4 kb in length, encoding three to four genes and capable of assuming extensive secondary structure. They enter bacterial cells by attachment to the sides of F pili (rather than the ends, as with the filamentous DNA phages). Like the filamentous phages, they are only able to infect bacteria that harbor the F plasmid. The four genes of phage MS2 encode the coat protein (C), an RNA-dependent RNA polymerase (P), a lysin (L), and a fourth protein (A, for assembly) present in one copy per virion. The genes are arranged in the order 5'A-C-(L)-P3', where the L gene overlaps the 3' end of C and the 5' end of P.

In these phages, there is no known distinction between replication and transcription. All RNA copies are full length, and gene expression is controlled at the translational level. Nevertheless, they have developed a program of temporal control exquisitely tailored to their needs. The *A* gene at the 5' end is available for translation only in nascent RNA that has not yet folded into its most stable secondary configuration, a reasonable strategy for obtaining one copy per virion. The *C* gene, on the other hand, is available for translation at all times. The *P* gene is under a more complex control. Translation of the *C* gene is needed to open the secondary structure that otherwise sequesters the *P* ribosome binding site; but coat protein itself, binding to the RNA upstream of the *P* gene, inhibits polymerase translation. The first control delays the onset of phage replication whenever conditions for protein synthesis are poor; the second means that, as with T4 or T7, synthesis at late times is diverted to virion components (in this case, coat protein), with minimal competition from polymerase synthesis. The *L* gene lacks a ribosome binding site of its own. Lysin synthesis results from reattachment of ribosomes that initiated at the ribosome binding site for *C*, then disengaged as a result of high-frequency frameshifting and reattached at the AUG for L (41). By tying the accumulation of lysin to the rate of coat protein synthesis, this

arrangement should help coordinate the time of lysis with the rest of phage development.

In broad outline, the mechanism of RNA synthesis is similar to that of most linear single-stranded RNA viruses. RNA phage replication enjoys the distinction of being the first system in which *in vitro* replication of a nucleic acid was shown to initiate at a specific origin (33). In conjunction with three host proteins (elongation factors Tu and Ts and ribosomal protein S1, all part of the machinery for host protein synthesis), the phage polymerase initiates replication at the 3' end of a (+) strand. Generally, several subsequent initiations take place at the same end before the first (–) strand is completed. When completed (–) strands dissociate from their (+) strand templates, they are used in a similar manner as templates for (+) strand synthesis.

Because of their small size and rapid mutation rate, RNA phage genomes have been used in studies of *in vitro* evolution, where enzyme is supplied and those RNA molecules structurally capable of the most rapid rate of multiplication are selected (37). The most consistent result was selection for much smaller molecules, which always include the terminal sequences recognized by the polymerase. The results are instructive with respect to the defective interfering particles that accumulate *in vivo* during the high-multiplicity passage of many viruses. In the absence of added template, the replicase can also create short sequences *de novo* and copy them.

TEMPERATE PHAGES

Temperate phages are mostly large (>20 kb) double-stranded DNA viruses. Three prototypes can be distinguished based on their modes of establishment of lysogeny. The first, represented by coliphage l, inserts DNA into the chromosome at one or a few preferred sites. The second, represented by phage Mu-1, inserts it anywhere in the host chromosome by use of a phage-coded transposase. In the third, represented by phage P1, prophage DNA is not inserted into the chromosome but instead is maintained as a plasmid. Some other phages, such as satellite phage P4, can be maintained either as inserted prophages or as plasmids. The inserted state can be stably maintained only if the phage genes for autonomous replication are repressed, whereas in the plasmid state some viral functions are expressed without killing the cell.

Phage l

The development of l has become a paradigm for gene control in developing systems. An infected cell has one of two options: either to lyse and produce viral progeny or to survive as a lysogen. Once a cell is committed to one of these pathways, there are several safeguards to stabilize the decision.

The l virion is isometric, with a T=7 configuration of capsomeres and a long tail terminating in a single fiber. The virion DNA is a 48,502-bp linear molecule with complementary 12-base 5' overhangs. Once injected into the cell, the DNA ends pair and are ligated by host ligase to generate a covalently closed circle. Figure 5 shows a genetic map of l in its circular form.

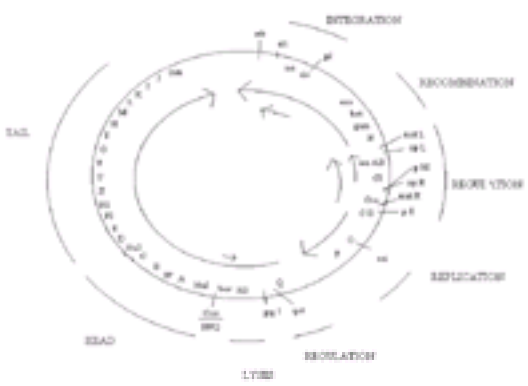

FIG. 5. Genetic map of l in its circular (replicating) form. Genes are shown inside the circle; sites are outside. Transcripts are shown inside the circle. Genes are clustered according to function in the phage life cycle. The *bor* and *lom* genes affect host phenotype in lysogens. Functions of most other phage genes and sites are discussed in the text. Some genes with minor or unknown functions are not shown.

Commitment

After infection, host RNA polymerase initiates transcription at three promoters: *p*L, *p*R, and *p*R'. The *p*L and *p*R transcripts each contain one gene (*N* and *cro*, respectively). The *p*R' transcript contains no genes. The Cro protein binds to the operators controlling *p*L and *p*R and represses transcription from them; however, because *cro* itself is transcribed from *p*R, the Cro concentration never reaches a level where repression is complete. The gpN protein is an antiterminator, which allows transcription at *p*L and *p*R to read through ordinary termination signals. The seminal early observations leading to this conclusion were, first, that the l gene *exo*, which is downstream of *N*, requires for expression both a functional gpN (suppliable in *trans*) and a derepressed *p*L (in *cis*), and second, that terminators of ordinary bacterial operons such as *trp* are read through when placed downstream of *p*L in the presence of gpN (28,48).

Antitermination by gpN is effected by binding to specific RNA sequences (*nut* sites) that are generated early in the transcripts from *p*L and *p*R. The *nut*R RNA includes a binding site (*boxA*) for host protein NusA, and a stem-loop sequence (*boxB*) specific for l's gpN. NusA (the principal elongation factor for *E. coli* RNA polymerase) is the product of one of the *nus* genes, isolated by screening for mutants with an "*N* undersupply" phenotype, so that even lN^+ behaves

like an N⁻ mutant on *nus* mutants. Various l-related phages have distinct N specificities determined by the sequence in the *boxB* loop. The gpN–NusA complex bound to *nut* RNA interacts with the RNA polymerase that has passed the *nut* site and is transcribing downstream from it and modifies transcription so that normal termination signals are no longer recognized. The complex N⁻NusA–RNA polymerase –nut^R site is stabilized by interaction with other host factors: NusB, NusG, and ribosomal protein S10 (50).

The result of antitermination is that both leftward and rightward transcription proceed beyond the primary terminators (*t*L1 and *t*R1, respectively). The leftward transcript includes several genes whose functions are not essential to either lytic or lysogenic development, although some of them play ancillary roles in DNA replication (*exo*, b) or lysogenization (*cIII*). The rightward transcript includes *cII* (whose product promotes lysogenization), replication genes *O* and *P*, and gene *Q*, the antiterminating positive regulator of late transcription.

The CII protein is a positive effector of transcription initiating at site pE within *cII* and proceeding leftward beyond *p*R through genes *cI* and *rexAB*. The CI protein (repressor) binds to the same operator sites as Cro and represses transcription from *p*L and *p*R, thus stopping all transcription characteristic of the lytic cycle.

If CII were formed at high concentration in all infected cells, they all should become lysogenic. In fact, among cells under the same ambient conditions, some commit to lysis and others to lysogeny, presumably because of stochastic fluctuations in early molecular events. Mathematical modeling with measured kinetic parameters adequately predicts the observed proportions of cells committed to the two pathways as a function of the phage-to-bacterial ratio (6). The critical biochemical players are CII (which is metabolically unstable because of proteolysis; CIII (which stabilizes CII in a manner dependent on the phage-to-bacterial ratio); and Cro, which accumulates with time and represses synthesis of CII. Cro accumulation thus functions as a developmental clock; when its concentration becomes high, CII decays and the cell is committed to lysis.

In those cells where repression is established, further events are needed to ensure stable lysogeny. First, repressor synthesis must continue in the lysogen so that the lytic cycle functions are shut off permanently. Once repression is established, *p*R transcription stops and CII disappears. Repressor does not disappear as well, because *cI* transcription commences from the maintenance promoter pM immediately to the left of *o*R.

The *o*R and *o*L operators are tripartite, with three binding sites separated by short spacers. Both repressor and Cro recognize these binding sites, but with different relative affinities. Cro binds most tightly to *o*R3 (which represses leftward transcription from *p*M) and less tightly to *o*R2 and *o*R1 (repressing rightward transcription from *p*R). Repressor, on the other hand, binds tightly and cooperatively to oR2 and oR1, which both represses transcription from pR and stimulates transcription from pM. At high repressor concentration (unsustainable in the steady state) repressor also binds to oR3 and represses its own synthesis (Table 1). Thus, once a high concentration of repressor is achieved through transcription from pE, repression is self-sustaining (58). The inhibition by Cro of spontaneous initiation at pM reinforces the decision to follow the lytic pathway.

Leftward transcription from pM	oR3	oR2	oR1	Rightward transcription from pR

TABLE 1. *Gene regulation by repressor (R) and Cro (C) at one oR*

Commitment to lysogeny requires not only repression of lytic cycle genes but also insertion of phage DNA into the host chromosome. Insertion is mediated by the phage-coded integrase (Fig. 6). The structural gene for integrase, *int*, is transcribed from two promoters: the major leftward promoter *p*L and a CII-activated promoter *p*I. The latter is the important promoter for lysogenization. Its control by CII ensures that insertion occurs in those cells where repression is established.

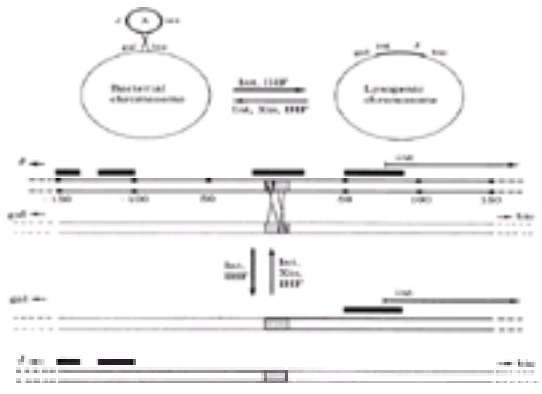

FIG. 6. Insertion of l DNA into the bacterial chromosome. **Top:** Overall process. **Bottom:** Detail of action at the crossover

point. The 15-bp identity between phage and host DNA is *stippled.* The *heavy bars* overlying the phage DNA are Int-binding sites. The 3' end of the *int* gene overlaps the right site. (Reproduced from ref. 14, with permission.)

Integrase promotes reciprocal recombination between sites on phage and host DNA, which inserts the phage DNA into the continuity of the host chromosome. The recombination occurs within a 15-bp sequence that is identical in phage and host. Both *in vivo* and *in vitro*, the minimal length of specific sequence required in the *attB* partner is 21 bp, and that in the *attP* partner is about 240 bp. A linear *attB* molecule functions *in vitro*, but *attP* must be supercoiled for optimal activity.

Integrase has two DNA binding sites. The strong binding sites (in the N-terminal part of the molecule) recognize arm sites, which are located on *attP* at positions –130, –80, +60, +70, and +80 (where 0 is the center of the 15-bp identity) (Fig. 7). Integrase molecules bound to these sites on DNA, bent appropriately by the host-encoded DNA bending integration host factor (IHF) protein, are so positioned that they can bind (in their C-terminal domains) to core sites, which are symmetrically disposed about the crossover point and approach the consensus 5'CAACTTNNT3'. Core sites are present in both *attP* and *attB*. The actual crossover then takes place by an exchange on the left between the “top” strands of the two double helices to create a Holliday junction, and resolution by exchange between the bottom two strands. The nicking site in the top strands is 7 bp to the left of the nicking site in the bottom strands. The process was once imagined to require branch migration of the Holliday junction between the two sites. However, recent data favor strand swapping between nicking and sealing, so that the Holliday structure exists only at the midpoint between the two sites (55). The left-right orientation here is determined by the positions of the arm sites on the *attP* partner, not by the core sequences themselves (41). Host and phage sites are aligned by protein–protein and DNA–protein interaction, and DNA–DNA recognition is restricted to the 7-bp overlap segment where branch migration occurs.

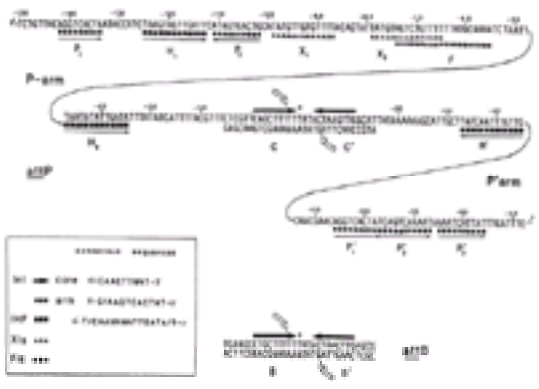

FIG. 7. Sequence of l *attP* and l *attB*, showing binding sites for proteins required for insertion and/or excision. P_1, P_2, P_1', P_2', P_3' (arm binding sites for Int); C, C', B, B' (core binding sites for Int); H_1, H_2, H' (IHF binding sites); X1, X2 (Xis binding sites); FI (Fis binding site). *Curved arrows* indicate portions of strand exchange in core. (Reproduced from ref. 43, with permission.)

Commitment to lysogeny is further reinforced by a third CII-activated promoter *p*AQ, located within gene *Q* reading leftward. By inhibiting *Q* translation, this antisense transcript apparently minimizes *Q*-promoted late gene transcription characteristic of the lytic cycle.

Lysogeny

Once established, the lysogenic state is quite stable. Lysogenic cells divide to give lysogenic progeny. Lysogeny can break down either through spontaneous switching to the lytic cycle (which happens about once every 10^4 cell divisions in an actively growing culture) or by spontaneous loss of prophage with cell survival (which happens less than once every 10^6 cell divisions). As long as repressor is present, *cI* transcription from *p*M continues, and more repressor is made. If repressor concentration rises so high as to saturate *o*R3, then repressor synthesis ceases until it returns to a lower level. Likewise, once the prophage is stably inserted into the chromosome, it remains so; there is a low rate of integrase synthesis from the *p*I promoter (not activated by CII) but essentially no excisionase (a phage-coded protein required for excision, though not for insertion).

Some ancillary factors reinforce this stability. One of these is the need for antitermination by gpN to initiate lytic development. This requirement puts a double lock on the system, because any transcripts made during a momentary unblocking of the operator sites will not get anywhere until the gpN that has been made by the first transcript can extend other transcripts. Because gpN is unstable and accidents should be rare, this will seldom happen. Stabilization of lysogeny is one reason that has been suggested for the use by l of antitermination (rather than simply mutating the termination sites). Poising the lysis/lysogeny decision to depend on molecular fluctuations may be another reason.

Escape from Lysogeny

About once every 10^4 cell divisions, stability breaks down. Detailed knowledge of what happens in those rare cells is unavailable, but the rate is strongly depressed in *recA*$^-$ hosts. This fact suggests that these spontaneous transitions to lytic development have the same primary basis as the mass induction of this transition by exposure to ultraviolet light or other DNA-damaging agents. In that case, the initial event is the activation of the proteolytic activity of RecA protein by products of DNA degradation, such as single-stranded DNA. RecA is not a conventional protease, but it accelerates the

specific cleavage of the host LexA protein, which can autocatalyze the same cleavage under extreme conditions. LexA is a repressor for many DNA repair functions, and RecA-promoted LexA cleavage turns these genes on. Like LexA, l repressor is sensitive to RecA-enhanced autoproteolysis (45).

RecA activation is one means of inducing the switch to lysis in almost all cells of a lysogenic culture. Another method makes use of l *cIts* mutants, which form a thermolabile repressor. With an appropriate mutant, lysogeny is quite stable at 30°C, but a shift to 43°C rapidly inactivates repressor in all cells. After derepression, transcription initiates from *p*L and *p*R. One early consequence of *p*L transcription is excision of the prophage from the chromosome. Whereas insertion requires only one phage-coded protein, integrase, excision requires a second protein, excisionase, as well. Excisionase is encoded by a gene *xis*, upstream from *int* and overlapping it by 20 bp. The CII-dependent *p*I promoter used during lysogenization lies at the 5' end of *xis*, and the start site is within *xis* so that the *p*I transcript makes only integrase. From the *p*L transcript, *int* and *xis* are expressed coordinately.

The mechanism of excisionase (Xis) action is not fully understood. Excisionase binds to two specific sites in the left arm of *attR*, bends the DNA, and interacts with integrase; one of the two excisionase molecules can be replaced by a host DNA-bending protein, Fis. Conventional enzymes are pure catalysts, and the nature of the catalysts cannot determine the direction of the reaction. Superficially, excisionase appears to reverse the integrase reaction; however, in excision as in insertion, cutting and resealing on the left precede cutting on the right; therefore, excision is not a true reversal of insertion. What remains unsolved is why integrase alone fails to promote the true reversal.

The *p*L transcript is subject to posttranscriptional control. In infected cells, either before commitment or after commitment to lysis, *int* and *xis* are cotranscribed; however, little integrase is made. This is because of exonucleolytic (3' ® 5') degradation of the transcript after cleavage by host enzyme RNase III at a site (*sib*) downstream of *att*. This process (retroregulation) prevents untimely or wasteful synthesis of integrase. Retroregulation does not affect *p*L transcripts made from a derepressed prophage, because the *sib* site is at the other end of the prophage. It also does not affect *p*I transcripts, which terminate within *sib* and therefore are resistant to RNase III. Because the *p*L transcript is made by an RNA polymerase molecule operating in the antitermination mode and reading through *sib*, it is degraded; this is another function for antitermination in the l life cycle. Despite the elegance and apparent utility of the retroregulation mechanism, deletion or mutation of the *sib* site has no observed effect on l development as normally studied in the laboratory.

The potentiality of controlling insertion and excision differentially provides a rationale for the use of arm sites by l integrase. Some related site-specific recombinases recognize only core sites, but in those cases there is no recognition of directionality.

When lytic development is induced in a lysogen, a small fraction (about 10^{-5}) of the particles produced result from abnormal excision that follows from breakage and joining of DNA at sites other than the *att* sites. If the excised DNA includes the *cos* sites and is within the packaging limits of the l virion, it can be packaged and used to infect other cells. Thus, a lysate produced by induction can transfer host genes that lie close to the l insertion site (such as *gal* or *bio*) into recipient cells. This specialized transduction is a form of natural cloning. The transduced bacterial DNA segment need not replace its homolog in the recipient; instead, the cell becomes lysogenic for the specialized transducing phage and is diploid for the transduced segment (Fig. 8 and Fig. 9).

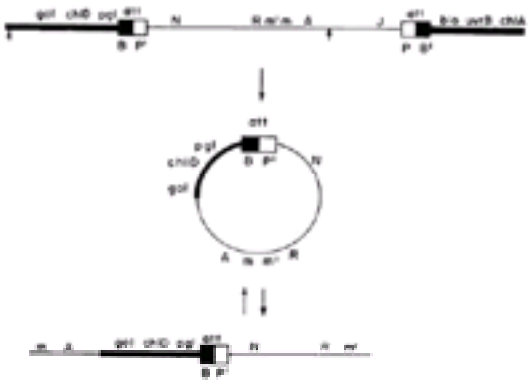

FIG. 8. Genesis of l *gal* specialized transducing phage. *Arrows* indicate positions of breaking and joining of heterologous DNA in a particular isolate. The m and m' indicate the ends of mature l DNA (equivalent to *cos*). (Reproduced from ref. 14, with permission.)

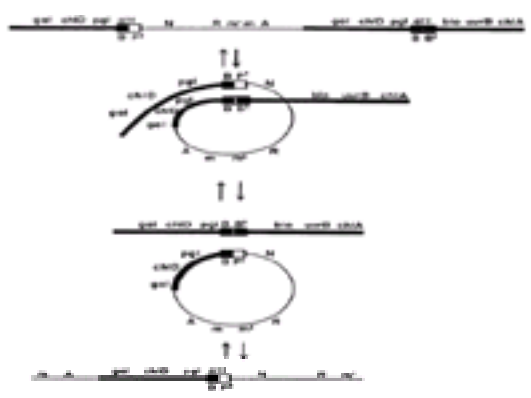

FIG. 9. Lysogenization by l *gal* (*bottom line*) to produce a heterogenote with two copies of *gal* separated by l DNA. (Reproduced from ref. 14, with permission.)

The genesis of specialized transducing phages may be comparable to the acquisition of oncogenes by retroviruses. Although the mechanisms may differ substantially, specialized transduction has provided a useful model because the entire process can be followed in the laboratory. With retroviruses, until very recently the critical events have generally occurred in nature from progenitors of inferred structure.

Lytic Development

Lytic development can be studied either in infected cells or in derepressed lysogens. Because of the high degree of synchrony obtainable, the method of choice has usually been thermal induction of lysogens carrying *cIts* prophages. The genetic program and its readout are well understood. At early times, most transcription is from *p*L and *p*R. The only protein of the *p*L transcript that is essential for lytic development is gpN. The pR transcript contains three important genes: *O* and *P* (replication) and *Q* (late gene activation). As time proceeds, gpQ accumulates and causes antitermination of the short transcript starting at *p*R' (downstream from *Q*). The mechanism of antitermination differs from that performed by gpN. The recognition elements for antitermination overlap the promoter. *Q* antitermination also requires a pause site close to the start site. The gpQ binds to the complex of DNA and paused s70-containing RNA polymerase, and it replaces s70 in the complex. The gpQ-containing polymerase then transcribes downstream DNA without stopping at ordinary termination signals (60).

At any rate, as gpQ accumulates, transcription of genes for lysis and virion formation becomes increasingly rapid. Concurrently, the rate of transcription from *p*L and *p*R decreases as Cro accumulates, producing an orderly transition from early gene expression to late gene expression.

Bidirectional DNA replication initiates from an origin within gene *O*. The gpO protein recognizes the origin and also recognizes gpP, which in turn recruits the host DnaB helicase into the initiation complex. Disassembly of the initiation complex to leave an elongation complex requires three host heat shock proteins (DnaJ, DnaK, and GrpE). Elongation proceeds, as in the host, by the combined action of DnaB helicase, DnaG primase, and Pol III holoenzyme, the polymerase. Theta-form replication can reproduce monomer circles, but a switch to rolling circle replication occurs in some molecules. l rolling circle replication (which predominates at late times) differs from that of fX in two major respects. First, the tails are double stranded rather than single stranded because lagging-strand synthesis takes place on the displaced strand. Second, tails can grow to multigenomic lengths rather than stopping when a single genome has been spun off.

Multigenomic tails are the primary substrates for l packaging. Empty proheads are first assembled, composed mainly of the major capsid protein gpE. Later, DNA enters the prohead, which increases in size and becomes more conspicuously icosahedral, and the smaller decoration protein gpD is added to the shell, with gpD hexamers interspersed among gpE trimers in a T=7 arrangement.

Efficient DNA packaging requires the presence of specific sequences (called *cos*, for cohesive site) at both ends of the packaged genome; hence, multigenomic tails or multimeric circles are good packaging substrates and monomer circles are poor ones. Cutting at *cos* is effected by a heterodimeric protein, terminase, whose subunits are encoded by l genes *Nul* and *A*. DNA molecules are packaged from left to right so a DNA monomer can be cut from the concatemer at its left end early in packaging and at its right end after the DNA has entered the virion. The *cos* site (about 200 bp in length) has three components: a binding site (*cos*B), recognized by gpNul before the DNA is cut at either end; a nicking site (*cos*N), at which DNA is cut at sites 12 bp apart in the two strands to generate the packaged single-strand overhangs of virion DNA; and a termination site (*cos*Q), required for the final nicking at the right end (20). Packaging is processive. After one genome is packaged, the next genome to the right can be packaged with no requirement for recognition of *cos*B on the second or subsequent genomes (27).

Because l packages the DNA between two *cos* sites, the amount of DNA per head can be changed by deletions or insertions (as in T7). The packaging limits are from about 79% to 110% of normal l length. Internal *cos* sites artificially placed within l at less than or near the lower limit can be packaged uncut, as though scanning for *cos* sites becomes more efficient as the head fills. l-based *in vitro* packaging systems have been used for efficient delivery of *cos*-containing plasmid-cloning vectors (cosmids) into *E. coli* cells.

Table 2 indicates the packaging limits for some phages described in this chapter. Those with headful packaging are listed with the same upper and lower limits. In fact, there is some random variation around the mean value. Alternative forms with different head sizes, such as the isometric and giant particles of T4 or the l virions formed by D $^{-}$ mutants, are not considered.

Phage	Packaging substrate	First cut	Second cut	Packaging limits (% of genome)
T4	Concatemer	Random	Head(full	102
P22	Concatemer	pac site	Head(full	109
λ	Concatemer	cos site	cos site	78-110
T7	Concatemer	Terminal overlap	Terminal repeat	85-103
φX174	Dimer ss of rolling circle	Replication origin	Replication origin	Limited
M13	Dimer ss of rolling circle	Replication origin	Replication origin	Unlimited
Mu-1	Inserted monomer	Near left end	Head(full	105
P1	Concatemer	pac site	Head(full	110

TABLE 2. *DNA cutting and packaging*

Genome Organization

The functional clustering of genes on the l map is notable. Not only do genes acting in a single pathway (head formation, tail formation, replication) lie together on the map, but genes for DNA binding lie close to their target sites, products of adjacent genes in a cluster frequently interact directly, and even within genes determinants are ordered so that they lie close to the elements with which they interact. For example, the *cos*B site is at the end of *cos*, next to the *Nul* gene whose product recognizes *cos*B; *Nul* in turn lies next to *A*, whose product forms the terminase heterodimer with gpNul. In both head and tail clusters, the same tendency is observed, the tail fiber gene *J* being most distal from the head cluster. The *att* site is adjacent to the *int* gene, and *cI* and *cro* are close to their target sites. The N-terminus of gpO recognizes the *ori* site that lies within the 5' end of *O*, whereas the C-terminus interacts with the product of the adjacent *P* gene. The clustering of major functional groups could increase regulatory efficiency, but the finer orderings may be more related to the disruptive effect of recombination on coevolved functions.

Phage Mu-1 as a Model Transposon

Mu-1 first attracted attention as a phage capable of inducing bacterial mutations at a high rate. The mutations proved to be insertions of Mu-1 into random sites on the host chromosome, disrupting the genes or operons into which it inserted.

Like l, Mu-1 can follow two alternative developmental pathways, leading on the one hand to a transcriptionally quiescent prophage and on the other to a lytic cycle with replication, packaging, and lysis. In l, the DNA transactions in these two pathways are distinct. Insertion plays no role in l replication, which proceeds normally if either the *int* gene or the *att* sites are deleted. With Mu-1, on the other hand, replication and insertion are minor variations of a common pathway, transposition. In Mu-1 replication, transposition happens many times during each cycle of infection, which has made it a system of choice for studying the biochemistry of transposition (compared with most bacterial transposons, which transpose naturally at rates such as 10^{-6} per cell division).

Mu-1 DNA is inserted into host DNA at all stages of its life cycle, even in the virion. When linear DNA from the virion is injected into a cell and the Mu-specific transposase is made, the first step in replication is transposition of Mu-1 DNA into the chromosome. Among bacterial transposons, the transposition mechanism may be either replicative (generating transposon copies in both the donor and the target site) or conservative (excising the transposon from the donor and inserting it into the target site). In cells destined to become lysogenic, the initial transposition is conservative rather than replicative. In cells destined to lyse, Mu-1 undergoes repeated rounds of replicative transposition.

The initial steps of replicative and conservative transposition are the same. The 3' end of the two transposon strands undergo strand transfer reactions with target DNA at positions displaced by five base pairs. Replication then initiates from the recessed 3' ends of the target DNA. In conservative transposition, the nicked donor DNA adjacent to the transposon is cut in the other strand and digested away; replication fills the gap, and ligation incorporates the parental transposon bodily into the target site (Fig. 10). In replicative transposition, the donor strands remain attached to the 5' transposon ends, and replication proceeds through the transposon with ligation to the free 5' donor ends at the opposite end of the transposon. This produces two semiconserved transposon copies, each joined to donor DNA at one end and target DNA at the other (52). Replicative transposition from a chromosomal donor produces two inserted copies accompanied by chromosomal rearrangement (inversion or excision); if replicative transposition happened from a linear infecting molecule (unaccompanied by subsequent recombination), it would linearize the chromosome.

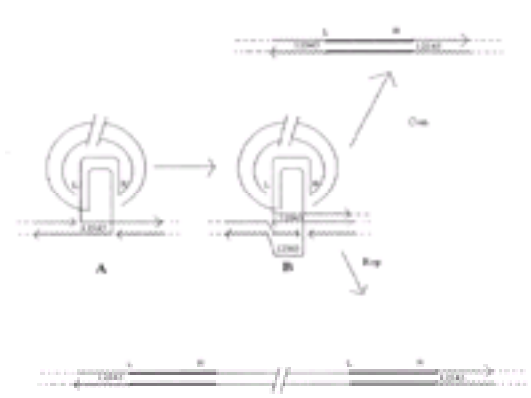

FIG. 10. Transposition of Mu phage. **A:** The stage immediately following strand transfer. **B:** The oligonucleotide sequence (12345) of the target molecule has been replicated. In conservative transposition (Con), the donor DNA is digested away and the Mu DNA is inserted into the target DNA, flanked by a direct oligonucleotide repeat; this is the usual fate of infecting DNA, where the donor is linear DNA (Mu and some flanking host sequence). In replicative transposition (Rep), replication from the 3' ends shown in (**B**) continues through the Mu, terminating with ligation to the free 5' end of donor DNA. This is the mechanism of Mu replication in the infected cell, where donor and target DNAs (both circular) are derived from the host chromosome. Mu DNA, with left and right ends indicated; , donor DNA; , target DNA.

In Mu-1 packaging, the left end of the inserted DNA is recognized, and cutting takes place within the flanking DNA, 50 to

150 bp to the left of the left end. Packaging is then by headfuls, and the headful length is longer than the genome length. Therefore, 500 to 3,000 bp of DNA on the right end of the virion molecule is host DNA. Thus virion DNA molecules have random segments of host DNA at their termini. When virion DNA is separated into single strands and reannealed, the host sequences are visibly unpaired when viewed in the electron microscope.

An internal segment of Mu-1 DNA about 3 kb in length is invertible through the action of a phage-coded integrase, so reannealed molecules are sometimes unpaired in this segment as well. The gene for the tail fiber protein spans one boundary of the invertible segments so that two types of tail fibers with different host specificities can be formed, depending on the orientation. Thus, if Mu-1 grown on *E. coli* K-12 encounters an alternative host such as *Citrobacter*, the rare particle that attaches to *Citrobacter* can invade and replicate. The rate of inversion is about 10^{-5} per generation. Certain other phages, such as P1, have related invertible segments.

In lysogens, inserted Mu-1 can occasionally transpose without induction of a full lytic cycle. Thus, inserted Mu-1 behaves in all respects as a bacterial transposon.

Phage P1 as a Model Plasmid

The P1 virion contains about 100 kb of linear double-stranded DNA in an isometric T=16 capsid. As in T4, the DNA is cyclically permuted and terminally redundant. Unlike T4 (but like *Salmonella* phage P22, a relative of l), processive packaging does not initiate at random but instead at specific *pac* sites. After infection, reciprocal recombination within the terminal overlap creates a circular DNA molecule of about 90 kb. Some of this recombination is mediated by a site-specific recombinase (Cre) whose target site (*lox*) is close to the *pac* site. The Cre–*lox* system has proven useful for generating controlled deletions and rearrangements during development of multicellular eukaryotes.

The cell can now enter either a lytic cycle or a lysogenic cycle. Unlike l or Mu-1, the lysogenic alternative entails replication of the circular P1 DNA as a plasmid and therefore requires expression of phage-coded replication genes. In lysogens, P1 is maintained at low copy number (about one per chromosome) and has an efficient partitioning mechanism so that both daughters of a dividing cell receive a P1 copy. The mechanism is similar to that used by other stringently controlled low copy number plasmids, such as the fertility factor F, and in some respects to that of the bacterial chromosome. The partitioning mechanism could potentially become ineffective if homologous recombination created a dimeric molecule, which could not pass into both daughter cells; this problem is greatly diminished by the site-specific *lox*–Cre recombination, which rapidly and reversibly equilibrates monomers with dimers. The elements for replication and partitioning (except *lox*–Cre) are localized in 1.5 kb of P1 DNA that can replicate as a plasmid when circularized; it includes a specific replication origin (*oriR*), its cognate replication initiator (*repA*), and a DNA sequence (*incA*) that controls replication by binding and sequestering *repA* (72).

In cells destined to lyse, P1 DNA replication (like that of l) proceeds in both a theta form and a rolling circle mode, the latter providing the packaging substrate. The replication origin used is distinct from the plasmid origin *oriR*. Rare mistakes lead to occasional packaging of random fragments of host DNA instead of phage DNA. Such fragments are responsible for the generalized transduction of bacterial genes. Generalized transduction at detectable frequencies is observed for most phages that use headful packaging, but not by wild-type l, probably because in l both cutting (at both ends) and injection require the specific *cosN* sequence, whereas in P1 or P22 initial cutting at sequences resembling *pac* sites can initiate processive packaging. Mutations that relax the specificity and thereby increase the frequency of transduction have been isolated in both P22 and P1 (63,71).

DEFECTIVE PHAGES AND PHAGELIKE OBJECTS

The fact that Mu-1 can behave as a transposon and P1 as a plasmid underscores some of the commonality between phages and nonviral elements. Transposable elements are common in bacteria, and most of them seem to use a biochemistry similar to that of Mu-1. Most bacterial transposons are smaller than Mu-1, going down to simple insertion sequences a few hundred base pairs long; and typical transposons carry genes affecting conspicuous bacterial traits such as antibiotic resistance (15). Transposition is usually conservative for some elements, replicative for others. Those using replicative transposition frequently resolve the resulting cointegrate structures through use of a site-specific recombinase that acts on a sequence internal to the element. Some transposons integrate and excise by a recombination mechanism similar in some respects to l insertion (64).

Bacterial plasmids fall into two general groups: elements with small genomes, present in many copies per cell and replicating randomly with respect to the cell division cycle, and larger elements similar in size to phage P1, present in one or a few copies per cell and partitioned regularly at cell division. Conjugative plasmids resemble viruses as autonomous elements capable of infecting cells, but they differ from them in the absence of an extracellular phase.

DNA sequences closely related to those of temperate phages are found in the genomes of many natural bacteria. For example, Southern hybridization of enteric bacteria with l DNA usually turns up some l-related sequences (59). Most of these are probably defective prophages: remnants of previous lysogenization that have since lost phage function through deletion or mutation. The K-12 strain of *E. coli* is naturally lysogenic for l but also harbors four l-related elements: DLP12, Rac, e14, and Qin. Such elements could in principle be of some value to the host or could even be precursors rather than descendants of complete phages; however, each defective prophage contains an array of genes from different functional clusters of the phage genome, frequently in the same order found in active phages, so that a role as host elements seems contrived. Defective lysogens arise from active lysogens in the laboratory by prophage mutations, and they frequently retain superinfection immunity, SOS-induced lysis, and production of structures resembling phage heads, tails, or complete virions.

Many natural strains liberate (or produce on induction) such phagelike or phage-related particles, which have not been shown to be infectious. Many bacteria also produce proteins (bacteriocins) that are toxic to other strains of the same bacterial species but not to the producing strain. Bacteriocins are sometimes encoded on plasmids and act through

diverse mechanisms. Operationally, some phagelike objects qualify as bacteriocins.

For example, many natural strains of *Bacillus subtilis* and several other *Bacillus* species harbor a prophage-like element, phage of *Bacillus subtilis* (PBS), that has been localized on the chromosome. After SOS induction, the cells lyse and liberate many virion-like particles with tails and DNA-filled heads. This is not simply a phage whose sensitive host remains to be discovered, because the large majority of particles contain random segments of host DNA with no significant preference for packaging prophage DNA. Like a bacteriocin, these particles kill other *Bacillus* cells. The producing strain is resistant, at least sometimes because the particles fail to be adsorbed. There are several varieties of PBS, each with a different killing specificity (76).

PBS has some similarity to mutants of generalized transducing phages that have lost (in this case, completely) their extreme preference for initiating packaging at phage-specified *pac* sites. Its wide distribution and the variety of killing specificities suggest that the bacteriocin-like activity confers a selective advantage to the host. Inasmuch as some bacteriocins are single protein molecules, a DNA-filled virion seems an especially clumsy and expensive kind of bacteriocin to have been so successful in evolution.

EVOLUTION AND NATURAL BIOLOGY OF PHAGES

For historical reasons, the coliphages have become workhorses of molecular biology and remain among the most thoroughly understood biologic objects. Phages are found throughout the prokaryotic world in a variety comparable with that of eukaryotic viruses, including enveloped virions with double-stranded RNA genomes (69), linear DNA genomes with protein covalently bound to their 5' ends (61), and satellite viruses like P4 [which forms virions with the capsid protein of its helper virus P2, induces late gene function from P2 prophage, lysogenizes P2 lysogens using its own integrase but can establish a plasmid state in P2 nonlysogens, and represses its own genes by the use of antisense RNA rather than a protein repressor (45)]. Compared with our knowledge of phage development in infected cells, little is known about their natural ecology or population biology. Some aspects are worthy of note.

Abundance

In some natural environments, phagelike particles are much more numerous than one might suspect from plaque assays on susceptible hosts. In estuaries, concentrations as high as 10^8 have been reported. If most of these are infectious (and they may very well not be), they potentially could play a major role in the natural cycling of the biosphere (31).

Host Defense Mechanisms

Bacteria have evolved mechanisms for phage resistance, and phages have evolved counterstrategies, presumably indicating in some measure the significant impact that phage infection can have. A host defense mechanism unique to prokaryotes is restriction/modification. Restriction enzymes damage DNA that has not undergone chemical modification at specific sites (most frequently methylation) by cleaving it either at those sites or nearby; nonspecific exonucleases then degrade the resulting linear fragments. Cells protect their own DNA from the restriction enzymes they make by modifying it. A phage that escapes restriction becomes modified and is fully infectious on a restricting host in the next cycle; so the strategy can be effective for the host only if the strains sensitive to a given phage have various restriction specificities. A strain with a rare restriction specificity will exclude almost all phage it encounters and will be favored over one with a common specificity; so eventually the rare specificity will become common. The recognition sites for restriction enzymes are frequently symmetrical, even if the cleavage takes place at a variable distance from the recognition site; this allows the modification of either strand to prevent cleavage, which ensures that, during semiconservative replication, a new strand that has not yet been modified is protected from destruction.

Phages have many strategies for avoiding restriction. The first level is a paucity of recognition sequence. Phages of *Bacillus*, where many known restriction enzymes recognize four-base palindromes, have few such palindromes in their DNA; coliphages are deficient in six-base palindromes, which are sites for some of the enzymes they naturally encounter (38). Various phages also have enzymes that destroy 5-adenosylmethionine, a cofactor for restriction (T3), expedite modification of phage DNA before restriction enzymes can cleave (l), or block recognition sites by wholesale nonspecific DNA modification (T4).

Some restriction enzymes are encoded by chromosomal genes, but many are encoded by phages or plasmids. Many resistance mechanisms contributing to defense of the host may in fact be manifestations of competition between extrachromosomal elements preserving their cellular territories.

One element may exclude others by diverse mechanisms, and in many cases exclusion may be an incidental side effect of the phage life cycle. The repressors of temperate prophages (essential for the internal stability of lysogens) render the lysogens immune to superinfection by phage of the carried type, and this superinfection immunity probably selects for diversification of repressor specificities. Certain phages, such as the e phages of *Salmonella*, encode enzymes that alter the polysaccharide surface receptors used in phage attachment, so that lysogens not only are immune but also cannot be penetrated by DNA of the same type. The alteration also takes place during the lytic cycle and reduces phage loss from attachment to fragments of cell envelope after lysis. The l-related phage HKO22 has a variant of the l *N* gene that competes with l*N* when l infects an HKO22 lysogen and causes termination rather than antitermination of early l transcripts (55). The l Rex proteins trigger a collapse of membrane potential when a l lysogen is infected with certain other phages (such as T4 *rII* mutants), preventing the production of viral progeny (57). The Lit protease (encoded by the defective l-related prophage e14) is activated by the major head protein of T4 to hydrolyze its specific substrate, elongation factor Ef-Tu (30). These last three mechanisms do not protect the infected cell but may protect other cells in a colony by impeding viral replication.

Natural Recombination

Third, the study of natural isolates has provided some perspectives on variation and the recombination among phages in nature. The l-related (lambdoid) phages are a good example.

The way that phage workers have approached taxonomy differs substantially from the method used by many medical virologists. In medical virology, once a virus such as measles is identified as a disease agent, many isolates from different clinical sources are examined, and those sharing some acceptable degree of similarity to the type virus are classified as measles virus. For epidemiology, some such approach is necessary. Phage workers are not epidemiologists, and their interest in natural variation is relatively recent. Many investigators have been more interested in developing highly defined experimental systems. To that end, each isolate is given its own name. l refers only to the prophage present in *E. coli* K-12 and its laboratory descendants; K-12 refers to one bacterial isolate, not to other natural strains with similar properties. Workers with a different perspective might have classified all lambdoid phages as natural variants of l, and the same can be said of other phage groups such as T2, T4, and T6.

The lambdoid phages have a common genetic map and the ability to generate viable hybrids when crossed in the laboratory. They came from various sources (usually from lysogenic bacteria) isolated over the past 70 years from Europe, Asia, and the United States. Genetic variation among the lambdoid phages is apparent from both functional specificity and DNA sequence. For example, phages with at least a dozen repressor specificities have been isolated; where the sequences are known, homologies between heterospecific repressor genes are barely discernible. Phages with different repressors have corresponding differences in their *cro* genes and operator sites.

Lambdoid phages also exhibit major variations in virion structure. Those phages (such as l) that plate on *E. coli* K-12 have long, flexible tails terminating in a single fiber that attaches to the *malB* chemotaxis protein of the outer membrane. Phages such as P22 (from *Salmonella*) have short, stubby tails and attach to the lipopolysaccharide 0-antigen of smooth strains of *Enterobacteria*, including *E. coli* (22). And in certain phage heads (such as HK97's), morphologically similar to that of l, the major capsid proteins are covalently joined into multimers that are catenated to create an indissoluble chainmail configuration (24).

If the l sequence is compared with that of any other lambdoid phage (or, equivalently, if heteroduplexes of the two phages are constructed), the general result is that the sequences match closely in some parts of the genome, whereas homologies are weak or absent in others. This is not because some sequences are highly conserved, because another phage pair shows a different set of matching segments; instead, the whole pattern strongly indicates that it is generated by frequent natural recombination so that in any phage pair, some portions of their genomes are of recent common ancestry. When defective prophages are compared with known lambdoid phages, they likewise are closely related to different phages in different segments. For example, the defective prophage DLP12 has an *int* gene and a partially deleted *xis* gene related to phage P22, followed by segments homologous to l's *exo* and P/*ren* genes, followed by analogs (*qsr*') of l QSR unrelated to any known l phage, followed by *cos* DNA similar to l's. Thus, all the lambdoid phages, including the defective prophages, seem to be drawn from a common gene pool.

Among the lambdoid phages, some genes that may serve viral functions have been borrowed from outside the l pool. Gene 12 of P22 occupies the same position in the genome as l gene P, but gene 12 is a homolog of the bacterial *dnaB* gene, and l gpP recruits the host DnaB helicase to participate in phage replication. Wild-type l has a gene for side tail fibers (*stf*) that facilitate phage attachment. (In the l commonly used in laboratories, *stf* has been inactivated by a frameshift.) The *stf* gene is closely related to tail fiber genes of other groups of coliphages (32). Most lambdoid phages encode a true lysozyme that hydrolyzes glycosidic bonds; l makes instead a transglycosylase that attacks the same bonds but has no detectable homology to lysozyme (75). The l lysozyme may have been appropriated from some external source, as yet unidentified.

Sequence comparisons of a wide variety of phages and prophages indicate that most double-stranded DNA phage genomes are chimeric products of both ongoing and ancient gene exchange (34). Thus, even apparently unrelated phages seem to have occasionally drawn genes from a common pool.

The natural function of genetic recombination is not obvious. In l, as in sexual eukaryotes, it is clear that recombination has a substantial evolutionary impact. But that does not tell us at what level natural selection acts to preserve recombination as a process, or whether recombination is an accidental byproduct of gene activities selected to function in repair or replication. One classic argument for the value of recombination is that an asexual line deteriorates through accumulation of deleterious mutations, which can be corrected by recombination with other lines that are the wild type for the loci of those particular mutations (53). The first experimental demonstration of this Muller's ratchet effect came from phage f6 (18); corroborative evidence from animal viruses has since appeared (23). Muller's ratchet may be central to the evolution of certain human viruses such as influenza, where the clonally selected epidemic strains are eventually replaced by reassortants with avian viruses.

In their natural ecology, phages exhibit many of the same features observed in eukaryotic viruses, and they will probably find increasing use as model systems.

PHAGE-BORNE GENES FOR BACTERIAL TOXINS AND OTHER PROTEINS AFFECTING HOST PHENOTYPE

In the prototypical temperate phages (l, Mu), most of the genome (especially genes needed for lytic growth) is strongly down-regulated in the prophage. For this reason, lysogeny is generally not an overt property of a bacterial strain, and many natural bacteria harbor prophages that remain unrecognized unless they show inducible lysis (not seen with all temperate phages) or unless a phage-sensitive bacterial host is available. However, lysogeny by some phages markedly affects host phenotype—a phenomenon known as lysogenic conversion.

Lysogenic conversions frequently entail changes in the bacterial surface, and they sometimes affect the virulence of

pathogenic bacteria. Their existence raises the questions of how the relevant genes became phage-associated, what advantage (if any) they confer on the phage, and how expression of the acquired genes is influenced by the phage's biology.

Gene Acquisition

The genesis of transducing phages by abnormal excision (see Fig. 8) is one way that a phage may acquire host genes. This mode places the acquired genes next to the phage *att* site. Other genes (such as those for antibiotic resistance) may enter the phage genome in transposons. The phage-borne genes for some bacterial toxins (diphtheria, cholera) are adjacent to *att* sites, whereas others, such as Shiga toxin, are not.

Selective Value for the Phage

Some conversions (such as those described earlier by the l phages of *Salmonella*) may benefit a phage by altering phage receptors on the bacterial surface. Some lambdoid phages have a gene (*nmpC*) with homology and partial functional equivalence to the major *E. coli* outer membrane protein gene *ompC* (whose product is a receptor for many phages). NmpC may replace OmpC, altering the cell's adsorption characteristics. Both these changes affect the antigenic specificity of the lysogen and could influence its ability to survive in a human host.

Phage l makes two proteins (Bor and Lom) that may increase a lysogen's ability to colonize the human intestine, thereby indirectly expanding the phage's habitat.

Relation to Phage Biology

Most of the genes described previously are expressed in lysogens, using promoters distinct from those that transcribe phage genes. Thus the *bor* gene (see Fig. 5) is transcribed in the opposite direction from the l late operon in which it is embedded. Transcription of the genes for diphtheria and cholera toxins is controlled by host transcription factors and is responsive to cues such as iron concentration.

Unlike most other temperate phages, the cholera phage (CTXf) is a single-stranded filamentous DNA phage similar to M13. Toxin expression from the integrated prophages is controlled by host factors (ToxR and ToxT). However, when phage replication is induced, the excised phage genome makes large amounts of toxin independently of ToxR and ToxT. The genes for Shiga toxin are in a lambdoid phage downstream of pR' (see Fig. 5). Although they can be expressed in the prophage from an iron-regulated promoter, high-level expression requires induction of the phage lytic cycle with concomitant Q-mediated antitermination. Phage-mediated lysis may also promote the liberation of toxin into the medium (70). Thus the phage lytic cycle may contribute significantly to the pathogenesis of toxin-producing bacteria.

CHAPTER 23 *Picornaviridae:* The Viruses and Their Replication

Vincent R. Racaniello

The Picornaviridae are nonenveloped viruses with a single-stranded RNA genome of positive polarity. This virus family contains many important human and animal pathogens, including poliovirus, hepatitis A virus, foot-and-mouth disease virus, and rhinovirus. The name of the virus family was intended to convey the small size of the viruses (pico, a small unit of measurement [10^{-12}]) and the type of nucleic acid that constitutes the viral genome (RNA).

Picornaviruses have played important roles in the development of modern virology. Foot-and-mouth disease virus was the first animal virus to be discovered, by Loeffler and Frosch in 1898 (193). Poliovirus was isolated 10 years later (182), a discovery spurred by the emergence of epidemic poliomyelitis at the turn of the 20th century. Forty years later, the discovery that poliovirus could be propagated in cultured cells led the way to studies of viral replication (84). The plaque assay, an essential method for quantification of viral infectivity, was developed with poliovirus (80). The first RNA-dependent RNA polymerase identified was that of mengovirus (20), a picornavirus, and the synthesis of a precursor polyprotein from which viral proteins are derived by proteolytic processing was first identified in poliovirus-infected cells (297). The first infectious DNA clone of an animal RNA virus was that of poliovirus (259), and the first three-dimensional structures of viruses determined by x-ray crystallography were those of poliovirus (142) and rhinovirus (272). Poliovirus RNA was the first messenger RNA (mRNA) shown to lack a 5' cap structure (139,231). This observation was subsequently explained by the finding that the genome RNA of poliovirus, and other picornaviruses, is translated by internal ribosome binding (155,244), a process now known to occur on cellular mRNAs (158,195).

Because they cause such serious diseases, poliovirus and foot-and-mouth disease virus have been the best-studied picornaviruses. Research on poliovirus has led to the development of two effective vaccines, and it is likely that poliomyelitis will be eradicated from the globe within the first 5 years of the new millennium. The World Health Organization has established a future goal of cessation of vaccination, at which time all poliovirus stocks must be destroyed. As a result, all research on this virus will cease. Poliovirus is truly a virus with a brilliant past, but with no future.

CLASSIFICATION

The family Picornaviridae consists of six genera: aphthovirus, cardiovirus, enterovirus, hepatovirus, parechovirus, and rhinovirus (Table 1), which all contain viruses that infect vertebrates. Other picornaviruses of invertebrates, such as cricket paralysis virus and *Drosophila* C virus, have not been assigned a genus.

Genus	Number of serotypes	Type species	Other members
Aphthovirus	7	Foot-and-mouth disease virus O	Foot-and-mouth disease viruses A and C, Asia 1, SAT 1, SAT 2, SAT 3
Cardiovirus	2	Encephalomyocarditis virus[a]	Theiler's murine encephalomyelitis virus
Enterovirus	100	Poliovirus 1	Polioviruses 2 and 3 Bovine enteroviruses 1 and 2 Human coxsackieviruses A1–A22,[b] and A24 Human coxsackieviruses B1–B6[c] Human echoviruses 1–7,[d][e] 9,[e] 11–21, 24–27,[f] 29–33 Human enteroviruses 68–71[c] Porcine enteroviruses 1–13 Simian enteroviruses 1–18 Vilyuisk human encephalomyelitis virus
Hepatovirus	2	Human hepatitis A virus[g]	Simian hepatitis A virus
Parechovirus	2	Human parechovirus 1	Human parechovirus 2
Rhinovirus	100	Human rhinovirus 1A	Human rhinoviruses 2–100 Bovine rhinoviruses 1–3

[a]Strains of this virus include mengovirus, Columbia SK virus, and mouse Ellerfeld virus.
[b]Coxsackievirus A23 was shown to be echovirus 9.
[c]Swine vesicular disease virus is similar to coxsackievirus B5.
[d]Echovirus 8 was shown to be echovirus 1.
[e]Echovirus 10 was shown to be reovirus 1.
[f]Echovirus 22 and 23 have been moved to a separate genus, Parechovirus, and renamed parechovirus 1 and 2; echovirus 28 was shown to be rhinovirus 1A.
[g]Formerly enterovirus 72.
SAT, South African type.

TABLE 1. *Members of the family Picornaviridae*

The aphthoviruses (foot-and-mouth disease virus) infect cloven-footed animals, such as cattle, goats, pigs, and sheep,

but rarely infect humans. Seven serotypes of this virus have been identified, and within each serotype are many subtypes. These viruses are highly labile and rapidly lose infectivity at pH values of less than 7.0.

There are two “clusters” of cardioviruses. The encephalomyocarditis-like viruses (encephalomyocarditis virus, Columbia SK virus, maus Elberfeld virus, and mengovirus) are murine viruses but can also infect other hosts, including humans, monkeys, pigs, elephants, and squirrels. The second cluster includes the Theiler's murine encephalomyelitis viruses. Strains such as GDVII cause a disease in mice that resembles poliomyelitis. The TO strains are less virulent and cause a chronic demyelinating disease that resembles multiple sclerosis. Vilyuisk human encephalomyelitis virus, or Vilyuisk virus, originally classified as an enterovirus, was recently transferred to the Theiler's cluster of the cardioviruses. Vilyuisk virus is believe to cause a neurodegenerative disease among the Yakuts people of Siberia and was originally isolated from the cerebrospinal fluid of a patient with a chronic case of encephalomyelitis (191). Nucleotide sequence analysis of Vilyuisk virus RNA indicates that it is a divergent Theiler's virus (258), justifying its transfer to the cardioviruses.

As the name implies, enteroviruses replicate in the alimentary tract, and as might be expected, they are resistant to low pH. This genus includes poliovirus (3 serotypes), coxsackievirus (23 serotypes), echovirus (28 serotypes), human enterovirus (4 serotypes), and many nonhuman enteric viruses. Formerly a member of the enterovirus genus, human hepatitis A virus (1 serotype) has been reclassified into a separate genus, hepatovirus. This reclassification was based on a number of unique properties of the virus, including nucleotide and amino acid sequence dissimilarity with other picornaviruses, replication in cell culture without cytopathic effect, and the existence of only one serotype.

The parechovirus genus contains two serotypes of human parechovirus that were previously classified as echoviruses types 22 and 23. Studies of the nucleotide sequence of the viral genome revealed no greater than 30% amino acid identity with other picornaviruses. In addition, the capsid consists of three, not four, capsid proteins. These and other differences led to the reclassification of these viruses (294).

There are 103 serotypes of rhinoviruses, so named because they replicate in the nasopharynx. These viruses, which are important agents of the common cold, are extremely acid labile.

VIRION STRUCTURE

Physical Properties

Picornavirus virions are spherical in shape with a diameter of about 30 nm (Fig. 1). The particles are simple in that they are composed of a protein shell surrounding the naked RNA genome. The virus particles lack a lipid envelope, and their infectivity is insensitive to organic solvents. Cardioviruses, enteroviruses, hepatoviruses, and parechoviruses are acid stable and retain infectivity at pH values of 3.0 and lower. In contrast, rhinoviruses and aphthoviruses are labile at pH values of less than 6.0. Differences in pH stability are related to the sites of replication of the virus. For example, rhinoviruses and aphthoviruses replicate in the respiratory tract and need not be acid stable. As discussed later, the acid lability of these viruses plays a role in uncoating of the viral genome. Cardioviruses, enteroviruses, hepatoviruses, and parechoviruses pass through the stomach to gain access to the intestine and therefore must be resistant to low pH. The structural basis for the acid lability of foot-and-mouth disease virus is partly understood (see Entry by Endocytosis).

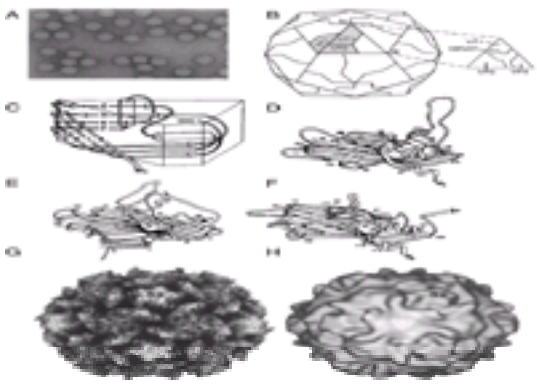

FIG. 1. Structural features of picornaviruses. **A:** Electron micrograph of negatively stained poliovirus, magnification 270,000. (Courtesy of N. Cheng and D. M. Belnap, National Institutes of Health.) **B:** Schematic of the picornavirus capsid, showing the pseudoequivalent packing arrangement of VP1, VP2, and VP3. VP4 is on the interior of the capsid. The biologic protomer (*gray*) is not the same as the icosahedral asymmetric subunit (*triangle expanded at right*). **C:** Diagram of how the eight b-strands of each capsid protein form a wedgelike structure with loops connecting the strands. These loops decorate the surface of the particle and give each subunit distinctive morphology and antigenicity. In many picornaviruses, the neutralizing antigenic sites are located in the BC loops of VP1 and VP3 and in the EF loop of VP2. These loops can accommodate extra amino acids without affecting the framework of the capsid (45). **D to F:** Ribbon diagrams of polioviruses VP1, VP2, and VP3, showing the common b-barrel structure that is also common to many other viral capsid proteins. The N- and C-termini of each capsid protein are separated by almost 50 angstroms. (C-F, adapted form ref. 142, with permission.) **G:** Model of poliovirus type 1, Mahoney, based on x-ray crystallographic structure determined at 2.9 Å (142). The model is highlighted by radial depth cuing so that portions of the model farthest from the center are bright. The 5-fold axis of symmetry is marked; it is characterized by a prominent star-shaped mesa. Surrounding the 5-fold axis is the canyon, which is the receptor-binding site. At the 3-fold axis is a propeller-shaped feature. **H:** Model of poliovirus type 1, Mahoney, made by image reconstruction from cryoelectron microscopy data. The resolution is 20 Å. The star-shaped mesa, canyon, and propeller are clearly visible.

The buoyant densities of picornaviruses are quite different (Table 2). Cardioviruses and enteroviruses have a buoyant

density of 1.34 g/mL, that of foot-and-mouth disease virus is 1.45 g/mL, and rhinoviruses have an intermediate value (1.40 g/mL). The reason for the difference lies in the permeability of the viral capsid to cesium. The capsid of poliovirus does not allow cesium to reach the RNA interior; hence, the virus bands at an abnormally light buoyant density (90). In contrast, aphthovirus capsids contain pores that allow cesium to enter (2). The rhinovirus capsid is permeable to cesium, but the presence of polyamines in the capsid interior limits the amount of cesium that may enter, explaining the intermediate value (90).

Genus	pH stability	Virion buoyant density	Sedimentation coefficient
Aphthovirus	Labile, d	1.43–1.45	145–146S
Cardiovirus	Stable, 3–9	1.34	160S
Enterovirus	Stable, 3–9	1.34	160S
Hepatovirus	Stable	1.34	160S
Rhinovirus	Labile, d	1.40	160S

TABLE 2. *Physical properties of some picornaviruses*

Ratio of Particles to Infectious Viruses

The ratio of particles to infectious virus is determined by dividing the number of virus particles in a sample (determined by electron microscopy or spectrophotometric measurements) by the plaque titer, yielding the particle-to-plaque forming unit ratio. This ratio is a measurement of the fraction of virus particles that can complete an infectious cycle. The particle-to-plaque forming unit ratio of poliovirus ranges from 30 to 1,000, and that of other picornaviruses is in the same range. The high particle-to-plaque forming unit ratio may be caused by the presence of lethal mutations in the viral genome. This explanation, however, probably does not apply to all picornaviruses; it has been shown that the infectivity of aphthovirus RNA approaches one infectious unit per molecule. An alternative explanation is that all viruses do not successfully complete an infectious cycle because they fail at one of the many steps—attachment, entry, replication, and assembly—that a virus must go through to complete the infectious cycle.

High-Resolution Structure of the Virion

The capsids of picornaviruses are composed of four structural proteins: VP1, VP2, VP3, and VP4. The exception is the parechoviruses, which contain only three capsid polypeptides: VP1, VP2, and VP0, the uncleaved precursor to VP2 + VP4. In the 1960s, Caspar and Klug, elaborating the principles of virus structure, concluded that the best way to build a shell with nonidentical subunits is to arrange the proteins with icosahedral symmetry (51). An icosahedron is a solid composed of 20 triangular faces and 12 vertices (see Fig. 1). The smallest number of subunits that can be used to compose such a solid is 60. The results of x-ray diffraction studies, electron microscopic observations, and biochemical studies of virus particles and their dissociation products led to the hypothesis that the picornavirus capsid contains 60 structural proteins arranged into an icosahedral lattice (274). Our understanding of the structure of picornaviruses took an enormous leap in 1985 when the atomic structures of poliovirus type 1 (142) and human rhinovirus 14 (272) were determined by x-ray crystallography. Since then, the high-resolution structures of many other picornaviruses have been determined.

The basic building block of the picornavirus capsid is the protomer, which contains one copy each of VP1, VP2, VP3, and VP4. The shell is formed by VP1 to VP3, and VP4 lies on its inner surface. VP1, VP2, and VP3 have no sequence homology, yet all three proteins have the same topology: they form an eight-stranded antiparallel b-barrel (also called a b-barrel jelly roll or a Swiss-roll b-barrel) (see Fig. 1). This domain is a wedge-shaped structure made up of two antiparallel b-sheets. One b-sheet forms the wall of the wedge, and the second, which has a bend in the center, forms both a wall and the floor. The wedge shape facilitates the packing of structural units to form a dense, rigid protein shell. Packing of the b-barrel domains is strengthened by a network of protein–protein contacts on the interior of the capsid, particularly around the 5-fold axes. This network, which is formed by the N-terminal extensions of VP1 to VP3 as well as VP4, is essential for the stability of the virion. VP4 is quite different from the other three proteins in that it has an extended conformation. This protein is similar in position and conformation to the NH2-terminal sequences of VP1 and VP3 and functions as a detached NH2-terminal extension of VP2 rather than an independent capsid protein.

The main structural differences among VP1, VP2, and VP3 lie in the loops that connect the b-strands and the N- and C-terminal sequences that extend from the b-barrel domain. These amino acid sequences give each picornavirus its distinct morphology and antigenicity. The C-termini are located on the surface of the virion, and the N-termini are on the interior, indicating that significant rearrangement of the P1 precursor occurs on proteolytic cleavage.

Resolution of the structures of poliovirus and rhinovirus yielded a great surprise: the b-barrel domains were strikingly similar in structure to those of plant viruses whose structures had been solved 5 years earlier, southern bean mosaic virus and tomato bushy stunt virus. Yet the capsid proteins of these viruses bear no sequence homology with those of the picornaviruses. It has since become apparent that similar protein topology is found in the capsid proteins of many plant, insect, and vertebrate positive-stranded RNA viruses as well as in the DNA-containing papovaviruses and adenoviruses. These findings suggest that either the polypeptides evolved from a common ancestor or that the b-barrel domain is one of the few ways to allow proteins to pack to form a sphere.

Surface of the Virion

Resolution of the structures of poliovirus and human rhinovirus revealed that the surfaces of these viruses have a corrugated topography; there is a prominent star-shaped plateau (mesa) at the 5-fold axis of symmetry, surrounded by a deep depression (“canyon”) and another protrusion at the 3-fold axis (see Fig. 1). It was originally proposed that the canyon is the receptor binding site, and this hypothesis has been proved for poliovirus and rhinovirus. However, not all picornaviruses have canyons. The surfaces of aphthoviruses and cardioviruses lack canyons and are much smoother in appearance. As discussed later, other features of these viruses serve as receptor-binding sites.

Interior of the Virion

A network formed by the N-termini on the interior of the capsid contributes significantly to its stability. At the 5-fold axis of symmetry, the N-termini of five VP3 molecules form a cylindrically parallel b-sheet. This structure is surrounded by five three-stranded b-sheets formed by the N-termini of VP4 and VP1. The myristate group attached to the N-terminus of VP4 mediates the interaction between these two structures (61). Interactions among pentamers are stabilized by a seven-stranded b-sheet, composed of four b-strands of the VP3 b-barrel and one strand from the N-terminus of VP1 that surround a two-stranded b-sheet made from the N-terminus of VP2 from a neighboring pentamer (86).

An extra 1500 nucleotides can be added to the poliovirus genome and successfully packaged, indicating that the interior of the capsid is not completely full (7). It has been suggested that picornaviral capsids are stabilized by interactions with the RNA genome, based on findings with bean pod mottle virus, which is related to picornaviruses. In this virus, ordered RNA can be observed at the 3-fold axis, and packaging of viral RNA stabilizes subunit interactions (58,188). Unfortunately, little information is available about the arrangement of the RNA genome of picornaviruses because the nucleic acid is usually not visible. Nevertheless, a few nucleotides have been tentatively identified in a similar location in the structures of P3/Sabin and rhinovirus type 14 (18,86). In the atomic structure of poliovirus P2/Lansing, RNA bases have been observed stacking with conserved aromatic residues of VP4 (185). This interaction could play a role in capsid stability or uncoating.

The Hydrophobic Pocket

Within the core of VP1, just beneath the canyon floor of many picornaviruses, is a hydrophobic tunnel or pocket. In poliovirus types 1 and 3, the pocket is believed to contain sphingosine (86); an unidentified lipid has been found in human rhinoviruses types 1A and 16, and a C16 fatty acid has been modeled in the pocket of coxsackievirus B3 (127,168,225). In contrast, the pocket of human rhinovirus type 14 is empty (18).

The same hydrophobic pocket is also the binding site for antipicornavirus drugs such as the WIN compounds produced by Sterling-Winthrop (290) as well as similar molecules produced by Schering-Plough (Kenilworth, NJ) and Janssen Pharmaceutica (Titusville, NJ) (13,68). Some of these drugs have been evaluated in clinical trials (1). These hydrophobic, sausage-shaped compounds bind tightly in the hydrophobic tunnel, displacing any lipid that is present. As discussed later, such drugs inhibit either binding or uncoating. Drug-dependent mutants of poliovirus spontaneously lose infectivity at 37°C, probably because they do not contain lipid in the pocket (224).

Myristate

Myristic acid (*n*-tetradecanoic acid) is covalently linked to glycine at the amino-terminus of VP4 of most picornaviruses (61). This residue is an integral part of the viral capsid. The N-termini of VP3 intertwine around the 5-fold axis to form a twisted tube of parallel b-structure (142). The five myristyl groups extend from the N-termini of VP4 and cradle the twisted tube formed by VP3 (61). The myristyl groups interact with amino acid side chains of VP4 and VP3. Mutagenesis of VP4 has revealed a role for myristic acid modification in virus assembly and in the stability of the capsid (14,196,197 and 198,220).

Neutralizing Antigenic Sites

As shown in Table 1, there are many different serotypes in the picornavirus family. Although the atomic structures of many picornaviruses have been solved, they provide no insight into why some picornaviruses, such as rhinovirus, occur in so many serotypes, whereas there are only three serotypes of poliovirus. However, serotype is determined by the connecting loops and C-termini of the capsid proteins that decorate the outer surface of the virion. These contain the major neutralization antigenic sites of the virus. Such sites are defined by mutations that confer resistance to neutralization with monoclonal antibodies directed against the viral capsid (213,214,286).

GENOME STRUCTURE AND ORGANIZATION

General Features

The genome of picornaviruses, a single positive-stranded RNA molecule, is infectious because it can be translated on entry into the cell and produce all the viral proteins required for viral replication. The picornavirus genome is unique because it is covalently linked at the 5' end to a protein called VPg (virion protein, genome linked) (88,184). VPg is covalently joined to the 5'-uridylylate moiety of the viral RNA by an O4-(5'-uridylyl)-tyrosine linkage. All picornavirus genomes are linked to VPg, which varies in length from 22 to 24 amino acid residues. The tyrosine that is linked to the viral RNA is always the third amino acid from the N-terminus. VPg is encoded by a single viral gene in all picornaviruses except the genome of foot-and-mouth disease virus, which encodes three VPg genes (89). VPg is not required for infectivity of poliovirus RNA; if it is removed from viral RNA by treatment with proteinase, the specific infectivity of the viral RNA is not reduced. VPg is not found on viral mRNA that is associated with cellular ribosomes and undergoing

translation; these mRNAs contain only uridine 5'-phosphate (pU) at their 5' ends. The lack of VPg is the only difference between poliovirus virion RNA and mRNA (230,249). VPg is removed from virion RNA by a host protein called *unlinking enzyme* (9). It is not known whether removal of VPg is a prerequisite for association with ribosomes or is a result of that association. Although VPg RNA can be translated in cell-free extracts, it is possible that VPg is rapidly cleaved from the RNA such that only RNAs lacking VPg are translated (112,217,316). VPg is present on nascent RNA chains of the replicative intermediate RNA and on negative-stranded RNAs, which has led to the suggestion that poliovirus RNA synthesis uses VPg as a primer (229,248). The role of VPg in viral RNA synthesis figures prominently in recent models of poliovirus RNA replication and is discussed in subsequent sections.

Nucleotide sequence analysis of many picornavirus RNAs has revealed a common organizational pattern (Fig. 2). The genomes vary in length from 7,209 to 8,450 bases. The 5'-noncoding regions of picornaviruses are long (624 to 1,199 nucleotides) and highly structured (Fig. 3). This region of the genome contains sequences that control genome replication and translation (see Genome Replication and mRNA Synthesis). The 5'-noncoding region contains the internal ribosome entry site (IRES), an element that directs translation of the mRNA by internal ribosome binding. Based on the RNA structure, two major classes of IRES elements have been defined (see Fig. 3). The 5'-untranslated regions of aphthoviruses and cardioviruses contain a poly(C) tract that varies in length among different virus strains (80 to 250 nucleotides in cardioviruses, 100 to 170 nucleotides in aphthoviruses). Among cardioviruses, longer poly(C) length is associated with higher virulence in animals (79,129).

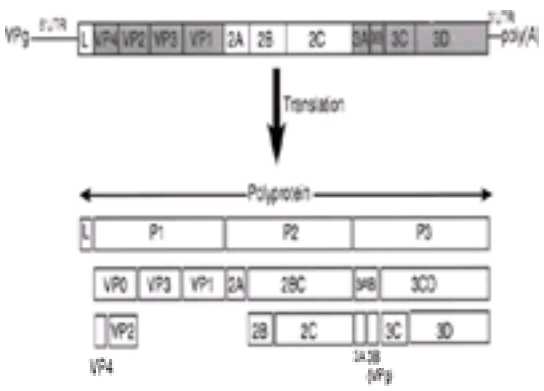

FIG. 2. Organization of the picornavirus genome. **Top:** Diagram of the viral RNA genome, with the genome-linked protein VPg at the 5' end, the 5' untranslated region, the protein coding region, the 3' untranslated region, and the poly(A) tail. L is a leader protein encoded in the genomes of cardioviruses and aphthoviruses but not other picornaviruses. Coding regions for the viral proteins are indicated. **Bottom:** Processing pattern of picornavirus polyprotein. The coding region has been divided into three regions, P1, P2, and P3, which are separated by nascent cleavage by two viral proteinases, 2A and 3C. Intermediate and final cleavage products are indicated. The proteinase responsible for cleavage of VP0 has not been identified. Proteins L and 2A carry out cleavages described in Figure 10. The remaining cleavages are carried out by $3C^{pro}$ and its precursor, $3CD^{pro}$.

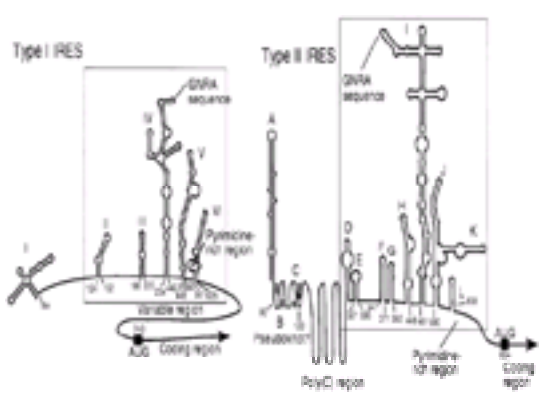

FIG. 3. Two major classes of picornavirus internal ribosome entry site (IRES). **Left:** The 5' untranslated region of poliovirus. **Right:** The same region from encephalomyocarditis virus. The IRES is indicated by a box. Predicated secondary and tertiary structures (RNA pseudoknots) are labeled. The poliovirus IRES is a type I IRES, also found in the genomes of other enteroviruses and rhinoviruses. The genomes of cardioviruses and aphthoviruses contain a type II IRES. The GNRA loop and pyrimidine-rich region are features that are conserved in both the type I and type II IRES. The IRES of hepatoviruses differs from the type I and type II IRES and probably constitutes a third class. (Adapted from Stewart SR, Semler BL. RNA determinants of picornavirus cap-independent translation initiation. *Semin Virol* 1997;8:242,243,244,245,246,247,248,249,250,251,252,253,254 and 255, with permission.)

The 3'-noncoding region of picornaviruses is short, ranging in length from 47 nucleotides for human rhinovirus 14 to 125 bases for encephalomyocarditis virus. This region also contains a secondary structure, notably a pseudoknot, that has been implicated in controlling viral RNA synthesis (154). The entire 3'-noncoding region of poliovirus and rhinovirus is not required for infectivity, although RNA lacking this sequence has low infectivity, and the resulting viruses replicate poorly (301). Both poliovirus virion RNA and mRNA contain a 3' stretch of poly(A) (326). Negative-stranded RNA contains a 5' stretch of poly(U), which is copied to form poly(A) of the positive strand (325). The average length of the poly(A) tail varies from 35 nucleotides in encephalomyocarditis virus to 100 nucleotides in aphthoviruses (5). Viral RNA from which the poly(A) tract is removed is noninfectious (293).

The results of biochemical studies of poliovirus-infected cells had predicted the presence of a single, long, open reading frame on the viral RNA that is processed to form individual viral proteins (297). This hypothesis was proved when the nucleotide sequence of the poliovirus genome was determined, which revealed a single open reading frame in the viral RNA (173,260). A similar strategy, in which a single polyprotein is synthesized, is used by all picornaviruses. The polyprotein is cleaved during translation, so that the full-length product is not observed. Cleavage is carried out by virus-encoded proteinases to yield 11 to 12 final cleavage products. Some of the uncleaved precursors also have functions during replication.

To unify the nomenclature of picornavirus proteins, the polyprotein has been divided into three regions: P1, P2, and P3. Aphthoviruses and cardioviruses encode a leader (L) protein before the P1 region. The P1 region encodes the viral capsid proteins, whereas the P2 and P3 regions encode proteins involved in protein processing (2A ^{pro}, 3C^{pro}, 3CD^{pro}) and genome replication (2B, 2C, 3AB, 3B^{VPg}, 3CD^{pro}, 3D^{pol}).

Infectious DNA Clones of Picornavirus Genomes

Recombinant DNA techniques make it possible to introduce mutations anywhere in the genome of most animal viruses. Progress in virus research has been greatly expanded by the availability of infectious DNA clones—a double-stranded copy of the viral genome carried on a bacterial plasmid. Infectious DNA clones, or RNA transcripts derived by *in vitro* transcription, can be introduced into cultured cells by transfection to recover infectious virus. The first infectious DNA clone of an animal RNA virus was that of poliovirus (259). The mechanism for infectivity of cloned poliovirus DNA is unknown but might result from production of RNA in the nucleus, by cellular DNA-dependent RNA polymerase, from cryptic, promoter-like elements in the plasmid. The initial transcripts produced are longer than poliovirus RNA but can be translated and replicated. The extra sequences must be removed or not copied because viruses produced from cloned DNA have authentic 5'- and 3'-termini.

The infectivity of cloned poliovirus DNA (10^3 plaque-forming units per μg) is much lower than that of genomic RNA (10^6 plaque-forming units per μg). The development of plasmid vectors incorporating promoters for bacteriophage SP6, T7, or T3 RNA polymerase for the production of RNA transcripts *in vitro* enabled the production of infectious picornavirus RNA from cloned DNA (309). Such RNA transcripts have an infectivity approaching that of genomic RNA.

THE REPLICATION CYCLE

Replication of picornaviruses takes place entirely in the cell cytoplasm. The first step is attachment to a cell receptor (Fig. 4). The RNA genome is then uncoated, a process that involves structural changes in the capsid. Once the positive-stranded viral RNA enters the cytoplasm, it is translated to provide viral proteins essential for genome replication and the production of new virus particles. The viral proteins are synthesized from a polyprotein precursor, which is cleaved nascently. Cleavages are carried out mainly by two viral proteinases, 2A ^{pro} and 3C^{pro}/3CD^{pro}. Among the proteins that are synthesized are the viral RNA-dependent RNA polymerase and accessory proteins required for genome replication and mRNA synthesis. The first step in genome replication is copying of the input positive-stranded RNA to form a negative-stranded intermediate; this step is followed by the production of additional positive strands. These events occur on small membranous vesicles that are induced by several virus proteins. Once the pool of capsid proteins is sufficiently large, encapsidation begins. Coat protein precursor P1 is cleaved to form an immature protomer, which then assembles into pentamers. These assemble with newly synthesized, positive-stranded RNA to form the infectious virus. Empty capsids are also found in infected cells; these are likely to be a storage form of pentamers.

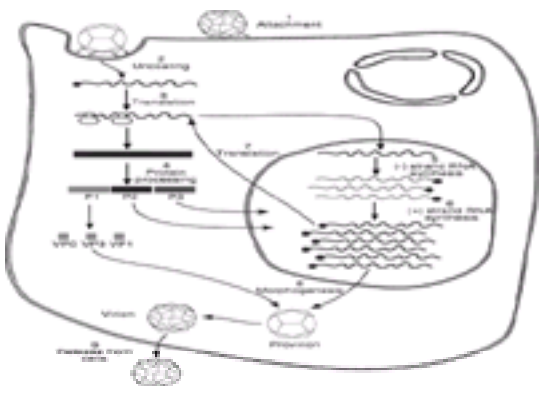

FIG. 4. Overview of the picornavirus replication cycle. Virus binds to a cellular receptor *(1)* and the genome is uncoated *(2)*. VPg is removed from the viral RNA, which is then translated *(3)*. The polyprotein is cleaved nascently to produce individual viral proteins *(4)*. RNA synthesis occurs on membrane vesicles (not drawn to scale in this diagram). Viral (+) strand RNA is copied by the viral RNA polymerase to form full-length (–) strand RNAs *(5)*, which are then copied to produce additional (+) strand RNAs *(6)*. Early in infection, newly synthesized (+) strand RNA is translated to produce additional viral proteins *(7)*. Later in infection, the (+) strands enter the morphogenetic pathway *(8)*. Newly synthesized virus particles are released from the cell by lysis *(9)*.

The entire time required for a single replication cycle ranges from 5 to 10 hours, depending on many variables, including the particular virus, temperature, pH, host cell, and multiplicity of infection. Many picornaviruses are released as the cell loses its integrity and lyses. Other picornaviruses, such as hepatitis A virus, are released from cells in the absence of cytopathic effect.

Attachment

Cellular Receptors and Coreceptors

Picornaviruses initiate infection of cells by first attaching to the host cell membrane through a host cell receptor. The nature of picornavirus receptors remained obscure until 1989, when the receptors for poliovirus and the major group rhinoviruses were identified (121,212,296). Since then, receptors for many other members of this virus family have been identified (Table 3). Examination of picornavirus receptor usage illustrates a number of important points. First, picornaviruses use a wide variety of cell surface molecules for cellular receptors. Second, many picornaviruses share cellular receptors. For example, the cell surface protein CD55 is a receptor for certain coxsackieviruses A and B, echoviruses, and enterovirus 70. Third, for some picornaviruses, a single type of receptor is sufficient for entry of viruses into cells. Viruses in this category include polioviruses and rhinoviruses. For other viruses, a second molecule, or coreceptor, is needed for virus entry into cells. For example, coxsackievirus A21, which attaches to CD55, requires intercellular adhesion molecule 1 (ICAM-1) for entry into cells (283). The precise role of coreceptors in picornavirus entry is not yet known.

TABLE 3. *Cell receptors for picornaviruses*

One Type of Receptor Molecule for Virus Binding and Entry

The poliovirus receptor (Pvr, CD155) was identified by DNA transformation (212). It was known that mouse cells are not susceptible to poliovirus infection because they lack cellular receptors (208). Mouse cells are permissive to poliovirus replication, however, because introduction of poliovirus RNA into these cells leads to the synthesis of infectious viruses (143,144). Poliovirus-susceptible mouse cells were produced by transforming mouse cells with human genomic DNA (211). Such cells were identified using a monoclonal antibody directed against the poliovirus receptor. Cloning of the human poliovirus receptor gene revealed that the receptor is a integral membrane protein and a member of the immunoglobulin (Ig) superfamily of proteins, with three extracellular Ig-like domains (212) (Fig. 5). The first Ig-like domain contains the site that binds poliovirus. This conclusion comes from three different types of experiments. First, cells expressing the first Ig-like domain of Pvr, either alone or as a hybrid with other Ig-like proteins, are susceptible to infection with poliovirus (177,218,280,281). Second, mutations in the first Ig-like domain of Pvr interfere with poliovirus binding (15,36,219). Mutations in the C'C'' loop, the C-terminus of the D-strand, and the DE and FG loops of Pvr domain 1 cause alterations in virus binding to the receptor. Third, models of the poliovirus–Pvr complex produced from cryoelectron microscopy data indicate that only domain 1 contacts the virus surface (32,136,323) (see Fig. 5). Mutations that affect receptor binding map to the virion–Pvr interface as determined by these structural studies.

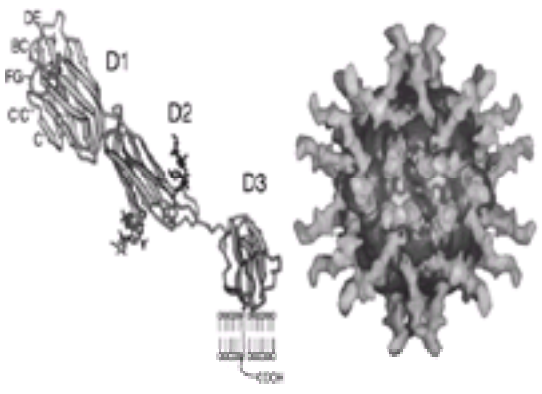

FIG. 5. Interaction of poliovirus with its cellular receptor. **Left:** Model of the poliovirus receptor produced from homology modeling and the density map from cryoelectron microscopy data of a virus-receptor complex (32). Immunoglobulin-like domains are labeled. The receptor contacts the virus only through domain 1; principal loops involved in the contact are labeled. Carbohydrate side chains have been modeled on domains 1 and 2. **Right:** Image reconstruction of poliovirus type 1 and a soluble form of Pvr, lacking the transmembrane and cytoplasmic domains (32). Domain 1 of Pvr binds in the canyon of the virus; no other receptor domains contact the particle. There are 60 receptor binding sites on each viral capsid; the complexes were produced with saturating amounts of Pvr, and all binding sites on the capsid are occupied.

A mouse model for poliomyelitis was developed by introducing the human Pvr gene into transgenic mice (179,262). Such

mice develop poliomyelitis after inoculation with poliovirus by different routes. Pvr expression in different tissues of transgenic mice is not always sufficient to permit virus replication. For example, Pvr is expressed in the kidney of transgenic mice, but the kidney is not a site of poliovirus replication (263). Furthermore, Pvr transgenic mice are not susceptible to infection by the oral route, the natural route of infection in humans, probably because of a postreceptor block to replication in mouse intestinal cells (332).

Expression of Pvr on cultured cells derived from different animal species leads to susceptibility to poliovirus infection. It therefore seems likely that Pvr is the only molecule required for poliovirus binding and entry. At one time, it was believed that the lymphocyte homing receptor, CD44, might be a coreceptor for poliovirus because a monoclonal antibody against this protein blocks poliovirus binding to cells (284,285). It was subsequently shown that CD44 is not a receptor for poliovirus and is not required for poliovirus infection of cells that express Pvr (43,93). It seems likely that Pvr and CD44 are associated in the cell membrane (94) and that anti-CD44 antibodies block poliovirus attachment by blocking the poliovirus-binding sites on Pvr.

The normal cellular function of Pvr is unknown. Sequence homologs of Pvr have been identified in humans (Prr1/Nectin-1 [81,194]), monkeys (Agm1 and Agm2 [178]), mice (Prr1, Mph/Prr2/Nectin-2, Nectin-3 [218,277]), and rats (pE4 [52]). Only Pvr, Agm1, and Agm2 encode proteins that can function as cell receptors for poliovirus (178,211,218; V. Racaniello, unpublished data, 1999). Pvr, Nectin-1, and Nectin-2 are coreceptors for alphaherpesviruses (102,287,321). Nectin-1 and Nectin-2 are homophilic adhesion proteins that interact with the actin cytoskeleton through a cytoplasmic linker protein called *afadin* (299). Mice lacking the Nectin-2 protein are sterile and produce sperm with cytoskeletal and nuclear defects (42). It is not known whether Pvr is also an adhesion molecule; it lacks the sequence in the cytoplasmic domain that is responsible for binding of Nectin-1 and Nectin-2 to afadin (299).

The cell surface receptor for the major group of human rhinoviruses (about 91 serotypes) was identified using monoclonal antibodies directed against the cellular binding site to isolate the receptor protein from susceptible cells. Amino acid sequence analysis of the purified protein revealed that it is ICAM-1, an integral membrane protein that is also a member of the Ig superfamily of proteins (121,296,303). The normal cellular functions of ICAM-1 are to bind its ligand, lymphocyte function–associated antigen 1 (LFA-1) on the surface of lymphocytes and to promote a wide range of immunologic functions (308). Erythrocytes infected with *Plasmodium falciparum* gain the ability to bind ICAM-1 on endothelial cells, allowing the parasite to become sequestered in tissues. ICAM-1 is expressed on the surfaces of many tissues, including the nasal epithelium, which is the entry site for rhinoviruses.

Mutagenesis of ICAM-1 DNA has revealed that the binding site for rhinovirus is located in the first Ig-like domain (204,261,295). The binding sites for two other known ligands of ICAM-1, LFA-1 and *Plasmodium falciparum*–infected erythrocytes, are also located in the first domain. A model of the rhinovirus–ICAM-1 complex produced from cryoelectron microscopy data, combined with x-ray structures of both components, confirms that only domain 1 of ICAM-1 contacts the virus surface (30,50,180,236). The residues of ICAM-1 that contact rhinovirus are located in the BC, CD, DE, and FG loops of the first aminoterminal domain. These findings agree with the results of mutational analysis that identify amino acids crucial for virus binding.

A comparison of the structures of virus–receptor complexes of two different picornaviruses reveals significant differences. The orientation of the receptors bound to their viruses are strikingly different. The long axis of ICAM-1 is perpendicular to the capsid surface, whereas Pvr binds at a glancing angle. In addition, the “footprint” of Pvr on poliovirus is significantly larger than that of ICAM-1 on rhinovirus, and the receptor sites on the poliovirus capsid are more exposed. The extra surface area on poliovirus includes the knob of VP3 and the C-terminus of VP1 from the fivefold-related promoter in the southeast corner of the road map describing the contact of Pvr on poliovirus. As discussed later, these differences may account for some of the differences in kinetic and affinity constants between the two virus-receptor complexes.

Receptors and Coreceptors Needed for Infection

Many enteroviruses bind to decay-accelerating factor (DAF, or CD55), a member of the complement cascade (see Table 3). For most of these viruses, however, interaction with CD55 is not sufficient for infection. For example, coxsackievirus A21 binds to CD55, but infection does not occur unless ICAM-1 is also present (283). Some coxsackie B viruses that bind CD55 may require $a_v b_6$-integrin as a coreceptor (4), whereas some echoviruses that bind integrin $a_2 b_1$ or CD55 are believed to require b_2-microglobulin as a coreceptor (320).

Alternative Receptors

Certain viruses bind to different cell surface receptors, depending on the virus isolate or the cell line (see Table 3). Foot-and-mouth disease virus A12 attaches to cells through the integrin $a_v b_3$ (226). However, the O strain of foot-and-mouth disease virus, which has been passaged many times in cell culture, cannot bind to $a_v b_3$; instead, this virus uses cell surface heparan sulfate (152). The type A12 strain cannot infect cells that do not express $a_v b_3$, even when heparan sulfate is present on the cell surface. It is believed that laboratory adaptation of foot-and-mouth disease virus in cultured cells expressing low levels of $a_v b_3$ leads to the selection of a virus that binds an alternative receptor.

How Picornaviruses Attach to Cell Receptors

As discussed previously, the capsids of picornaviruses are composed of four proteins arranged with icosahedral symmetry. Among the family members, the capsid proteins are arranged similarly, but the surface architecture varies. These differences account for not only the different serotypes but also the different modes of interaction with cell receptors. For example, the capsids of polioviruses, rhinoviruses, and coxsackieviruses have a groove, or canyon, surrounding each fivefold axis of symmetry. In contrast, cardioviruses and aphthoviruses do not have canyons.

The canyons of poliovirus and rhinovirus have been shown to be the sites of interaction with cell receptors. Mutation of

amino acids that line the canyons of poliovirus and rhinovirus can alter the affinity of binding to receptors (65,66 and 67,134,189). Models of the interaction of poliovirus and rhinovirus with their cellular receptors have been produced from cryoelectron microscopy and x-ray crystallographic data (30,32,50,136,180,236,323). As discussed previously, these models reveal that only domain 1 of Pvr or ICAM-1 penetrates the canyon of the respective virus. For both rhinovirus and poliovirus, the footprint of the receptor defined by structural models agrees with the results of mutational data. More detail is available about the ICAM-1–rhinovirus interaction because the x-ray crystallographic structure of ICAM-1 has been determined (30,50). This information, however, does not explain why major and minor group rhinoviruses recognize different receptors. Minor group rhinoviruses have no obvious amino acid sequence differences from members of the major group; indeed, the major group rhinoviruses 14 and 16 are more distantly related to each other than to the minor group rhinoviruses 1A and 2.

It was originally believed that the picornavirus canyons were too deep and narrow to allow penetration by antibody molecules, which contain adjacent Ig domains (271). This physical barrier was believed to hide amino acids crucial for receptor binding from the immune system. Structural studies of a rhinovirus–antibody complex, however, revealed that antibody does penetrate deep into the canyon, as does ICAM-1 (289). The shape of the picornavirus canyon is therefore not likely to play a role in concealing virus from the immune system.

Beneath the canyon floor is the hydrophobic pocket that opens at the base of the canyon and extends toward the fivefold axis of symmetry (see The Hydrophobic Pocket, earlier). The pocket appears to be occupied in many picornaviruses with a fatty acid or related compound. Certain antiviral drugs, such as the WIN compounds, displace the lipid and bind tightly within the pocket (290). Binding of such drugs to rhinovirus 14 causes conformational changes in the canyon that prevent attachment to cells (250). In contrast, drug binding to rhinoviruses 1A, 3, and 16 and to poliovirus causes smaller structural changes in the capsid (120,126,140). Inhibition of rhinovirus 16 binding by these compounds is probably not a consequence of altering the receptor binding site, but rather the result of preventing conformational changes required for receptor binding. Such compounds do not inhibit binding of poliovirus, but rather uncoating (209).

The capsids of some picornaviruses, including coxsackievirus A9 and foot-and-mouth disease virus, do not have prominent canyons. These viruses are believed to attach to cell receptors through surface loops. In foot-and-mouth disease virus, an Arg-Gly-Asp sequence in the flexible bG-bH loop of the capsid protein VP1 is recognized by integrin receptors on cells (91). Arg-Gly-Asp–containing peptides block attachment of foot-and-mouth disease virus (28), and alteration of this sequence interferes with virus binding (200). In coxsackievirus A9, the Arg-Gly-Asp sequence is present in a 17–amino acid extension of the C-terminus of VP1 and is also the site of attachment to cell receptors (53,268). Alteration of this sequence does not abolish binding to cells, however, suggesting that the virus can bind to another cell surface receptor (147).

As discussed previously, foot-and-mouth disease virus uses alternative receptors, either integrin or heparan sulfate, depending on the virus isolate. The binding site for heparan sulfate on cell culture–adapted foot-and-mouth disease virus is a shallow depression on the virion surface, where the three major capsid proteins, VP1, VP2 and VP3, are located (96). Binding specificity is controlled by two preformed sulfate-binding sites on the capsid. Residue 56 of VP3 is a critical regulator of receptor recognition. In field isolates of the virus, this amino acid is histidine. Adaptation to cell culture selects for viruses with an arginine at this position, which forms the high-affinity heparan sulfate–binding site.

Kinetics and Affinity of the Virus–Receptor Interaction

The affinity and kinetics of picornaviruses binding to soluble forms of their receptors have been studied by surface plasmon resonance. Such parameters are important because they describe the interaction of virus with receptor, which enables a better understanding of the reaction and its comparison to other systems. There are two classes of receptor-binding sites, with distinct binding affinities, on the capsids of poliovirus and rhinovirus (49,205,323). The association rates for the two binding classes are 25- and 13-fold higher for the poliovirus–sPvr interaction than for the rhinovirus–sICAM interaction at 20°C. The greater association rate of poliovirus and Pvr may be due, in part, to differences in the extent of contact between virus and receptor (see earlier). In contrast, whereas there are two dissociation rate constants for the poliovirus–Pvr interaction, only one has been reported for the rhinovirus 3–ICAM interaction. The dissociation rates for the poliovirus–sPvr interaction are 1.5-fold and 2.0-fold faster than for the rhinovirus–sICAM interaction, indicating greater instability of the former complex. The affinity constants for the poliovirus–sPvr interaction are 19-fold and 6-fold greater than those reported for the rhinovirus–sICAM-1 complex.

In contrast to the observations with poliovirus and rhinovirus, a single class of binding site was found on echovirus 11 for a soluble form of its receptor, CD55 (183). The affinity of this interaction is at least 4 times lower than either of the binding sites on poliovirus for sPvr. The association rate for the interaction between echovirus 11 and CD55 is faster than that of poliovirus–sPvr and rhinovirus–sICAM-1. One explanation for these findings is that the contact between echovirus 11 and CD55 is more extensive than that of the other two virus-receptor complexes. The binding site for CD55 on echovirus 11 may also be more accessible than those of Pvr and ICAM-1. The dissociation rate for the echovirus–CD55 interaction is at least 97 times faster than that of either the poliovirus–sPvr or the rhinovirus–sICAM-1 interaction. These findings are consistent with a more accessible binding site for CD55 on echovirus 11, compared with the receptor-binding sites on poliovirus and rhinovirus. Atomic interactions between CD55 and echovirus 11 may be weaker than between the other two viruses and their receptors. The faster dissociation rate of the echovirus 11–CD55 complex may be related to the finding that the interaction does not lead to structural changes of the virus particle (257), as occurs with poliovirus and rhinovirus.

Why do poliovirus and rhinovirus have two classes of receptor binding sites? The receptors for both viruses make contacts at two major sites on the virus surface, one in a cleft on the south rim of the canyon, and a second on the side of the mesa on the north rim. These two contact sites may correspond to the two classes of binding sites. Two classes of binding sites may also be a consequence of the structural flexibility exhibited by both viruses, which may cause exposure of different binding sites. Normally internal parts of the poliovirus and rhinovirus capsid proteins have been shown to be transiently displayed on the virion surface, a process called *breathing* (186,187). As discussed later, the interaction of poliovirus and rhinovirus with their cellular receptors leads to irreversible and more extensive structural changes. In

contrast to the findings with poliovirus and rhinovirus, binding of echovirus 11 with CD55 can be described by a simple 1:1 binding model. Such behavior, which would be expected for the interaction of two preformed binding sites, is consistent with the fact that the echovirus–CD55 interaction does not result in detectable structural changes in the capsid (257).

Entry Into Cells

Once picornaviruses have attached to their cellular receptor, the viral capsid must dissociate to release the RNA genome, which must enter the cytoplasm, the site of picornavirus replication. For some picornaviruses, interaction with a cell receptor serves only to concentrate virus on the cell surface; release of the genome is a consequence of low pH or perhaps the activity of a coreceptor. For other picornaviruses, the cell receptor is also an unzipper and initiates conformational changes in the virus that lead to release of the genome.

Formation of a Pore in the Cell Membrane

The interaction of poliovirus with its receptor, Pvr, leads to major structural changes in the virus. The resulting particles, called *altered,* or *A, particles,* contain the viral RNA but have lost the internal capsid protein VP4. In addition, the N-terminus of VP1, which is normally on the interior of the capsid, is on the surface of the A particle (95). This sequence of VP1 is hydrophobic, and as a result, the A particles have an increased affinity for membranes compared with the native virus particle. In one hypothesis for poliovirus entry, receptor binding leads to these conformational changes; the exposed lipophilic N-terminus of VP1 then inserts into the cell membrane, forming a pore through which the viral RNA can travel to the cytoplasm (Fig. 6). The finding that A particles, when added to lipid bilayers, induce the formation of ion channels supports this hypothesis (304). A model of the A particle produced from cryoelectron microscopy provides more insight into uncoating of the poliovirus genome (31). Compared with the native virus, capsid domains in the A particle have moved up to 9 Å, in a process that has been compared to the movements of Earth's tectonic plates. These movements produce gaps between the capsid subunits, and it is hypothesized that the gaps in the area where VP1, VP2, and VP3 meet could allow the emergence of VP4 and the N-terminus of VP1. In this model, VP4 and the VP1 N-terminus are extruded from the bottom of the canyon and are arranged around the mesa at the fivefold axis of symmetry. There, the five predicted amphipathic helices at the N-termini of VP1 would be in position to insert into the plasma membrane. A pore is formed, and then VP3, which forms a plug blocking the fivefold axis, is moved, allowing the RNA to exit the particle.

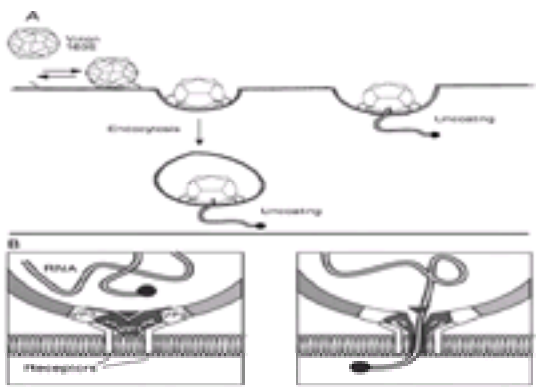

FIG. 6. Model for poliovirus entry into cells. **A:** Overview of poliovirus entry. The 160S native virus particle binds its cellular receptor, Pvr, and at temperatures greater than 33°C, undergoes a receptor-mediated conformational transition, leading to the production of altered *(A)* particles. These particles, which may be entry intermediates, are hydrophobic and have lost capsid protein VP4. The N-terminus of VP1, normally on the interior of the capsid, is translocated to the surface. The viral RNA, shown as a *curved line,* may exit the particle from the plasma membrane or from within endosomes. **B:** Hypothetical mechanism for translocation of poliovirus RNA across the cell membrane. At the left is a cross-section of a virus particle that has just bound Pvr at the cell surface. The viral RNA is in the capsid, and lipid occupies the hydrophobic pocket. Pvr docks on the capsid in the canyon, above the hydrophobic pocket. At right, the capsid has undergone the receptor-mediated conformational change. Docking of the receptor in the canyon leads to loss of the lipid in the hydrophobic pocket, allowing the capsid to undergo conformational changes. The extruded N-termini of VP1 form a pore in the cell membrane through which the viral RNA may pass. The dark triangle is the VP3 b-cylinder, which could move out of the way like a float valve (31).

The ultimate disposition of VP4 released from the viral capsid is not known, but it is clear that this protein is required for an early stage of cell entry. A virus containing a mutation in VP4 can bind to cells and be converted to A particles, but these are blocked at a subsequent step in virus entry (221). VP4 and VP2 are produced, during virus assembly, from the precursor VP0, which remains uncleaved until RNA encapsidation. Cleavage of VP0 can therefore be viewed as a way of priming the capsid for uncoating because cleavage separates VP4 from VP2.

Although the A particle has biochemical and structural properties consistent with an entry intermediate, its role in entry has been questioned by the results of experiments demonstrating that poliovirus can replicate at 25°C, a temperature at which A particle formation cannot be detected (77). Perhaps the A particle detected at higher temperatures is a stable end product and an exaggerated form of an uncoating intermediate. The uncoating intermediate may be unstable and difficult to detect. However, the A particle is likely to be similar to the uncoating intermediate, and thus warrants further study.

Although it is believed that poliovirus RNA crosses the cell membrane, it is not known whether that event occurs at the plasma membrane or from within endosomes (see Fig. 6). Drugs, such as bafilomycin A1, that block acidification of

endosomes through their inhibition of proton transport into the vesicles, do not inhibit poliovirus infection (245). These drugs effectively inhibit infection by viruses that enter the cytoplasm from acidic endosomes, such as influenza virus and Semliki Forest virus. Although it is likely that poliovirus RNA could enter at either the plasma or endosomal membrane, it is clear that endocytosis alone is not sufficient to trigger poliovirus uncoating. For example, antibody-coated poliovirus particles cannot efficiently infect cells expressing Fc receptors, which are efficiently endocytosed (16,199). This finding suggests that Pvr-mediated conformational changes in poliovirus are crucial to the uncoating process.

Entry by Endocytosis

Some picornaviruses, such as foot-and-mouth disease virus and rhinovirus, enter cells by receptor-mediated endocytosis, and uncoating is triggered by acidification of the endosomal, pH-dependent pathway (47,200). Infection of cells by these viruses is inhibited by weak bases and ionophores that block the acidification of endosomes (47,48). Consistent with this mechanism of entry, foot-and-mouth disease virus that has been coated with antibody can bind to and infect cells that express Fc receptors, in contrast to poliovirus (see earlier) (199). The cell receptor for foot-and-mouth disease virus is therefore a “hook”: it does not induce uncoating-related changes in the virus particle, but rather serves only to tether the virus to the cell and bring it into the endocytic pathway.

The mechanism by which low pH causes disassembly of the foot-and-mouth disease virus capsid has been illuminated by structural and genetic studies. At a pH of about 6.5, the viral capsid dissociates to pentamers, releasing the viral RNA (315). Examination of the atomic structure of the virus revealed a high density of histidine residues lining the pentamer interface (2). These residues confer stability to the capsid; because the pKa of histidine is 6.8, close to the pH at which the virus dissociates, protonation of the side chains of the histidines might cause electrostatic repulsion, leading to disassembly (70). To test this hypothesis, a histidine residue at position 142 of VP3 was changed to arginine by mutagenesis. The resulting capsids were more stable at low pH than wild-type capsids (83), supporting the proposed role of the histidine residue in acid-catalyzed disassembly.

Regulation of Uncoating by Cellular Molecules

The hydrophobic pocket located below each protomer surface appears to be a critical regulator of the receptor-induced structural transitions of poliovirus. In poliovirus type 1, each pocket is occupied by a natural ligand that is believed to be a molecule of sphingosine (Fig. 7) (86,324). The capsids of rhinoviruses 1A and 16 each contain lipids that are shorter than sphingosine (167,235), whereas that of coxsackievirus B3 has been modeled as a C16 fatty acid (225). The icosahedral symmetry of the capsid would allow each virion to contain up to 60 lipid molecules. In some picornaviruses, the pockets are apparently empty, such as in rhinovirus types 3 and 14 (18,333).

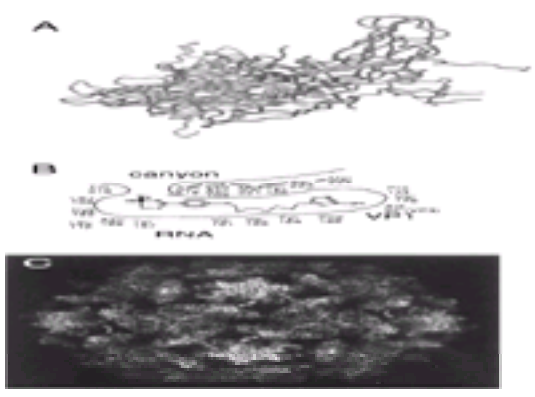

FIG. 7. The hydrophobic pocket in the picornavirus capsid. **A:** Cellular lipid bound in the hydrophobic pocket of poliovirus type 1. Side view of a protomer, consisting of one copy each of VP1, VP2, VP3, and VP4. RNA is below, and the 5-fold axis of symmetry is at the upper right. Gray spheres represent what is believed to be a molecule of sphingosine bound in the hydrophobic pocket. The lipid is just below the canyon floor. **B:** WIN52084 bound in the hydrophobic pocket. These drugs displace the lipid from the pocket, thereby blocking infectivity. **C:** Drug bound in the poliovirus pocket. R78206, a WIN-like compound, bound in the poliovirus capsid. The bound drug is the small white molecule at the base of the canyon. The drug appears to be exposed on the surface but is actually in the hydrophobic pocket. The capsid model is shown in a radial depth-cued representation, in which atoms are colored according to whether they are near the center of the virus (*black*) or far from the center (*white*). Residues at the bottom of the canyon are dark because they are at a position of low radius. The bound drug is not depth cued.

These lipids are thought contribute to the stability of the native virus particle by locking the capsid in a stable configuration and preventing conformational changes. Removal of the lipid is probably necessary to provide the capsid with sufficient flexibility to undergo the changes that permit the RNA to leave the shell. This hypothesis comes from the study of antiviral drugs, such as the WIN compounds, that displace the lipid and bind tightly in the hydrophobic pocket. These antiviral compounds block breathing of the rhinovirus capsid, the process by which normally internal parts of the capsid proteins are transiently displayed on the virion surface (186). Polioviruses containing bound WIN compounds can bind to cells, but the interaction with Pvr does not result in the production of A particles (92,331). WIN compounds appear to inhibit poliovirus infectivity by preventing Pvr-mediated conformational alterations that are required for uncoating. Additional support for the role of lipids in uncoating comes from the analysis of poliovirus mutants that cannot replicate unless WIN compounds are present (224). Such WIN-dependent mutants spontaneously convert to altered particles at 37°C, in the absence of the cell receptor, probably because of the absence of lipid in the hydrophobic pocket. The lipids can be considered to be switches that determine whether the virus is stable (lipid present) or will uncoat (lipid absent). It is not known what causes the lipid to be released from the capsid. Pvr docks onto the poliovirus capsid just above the hydrophobic pocket (see Fig. 6), which suggests that the interaction of the virus with receptor may initiate structural

changes in the virion that lead to the release of the lipid. Incubation of poliovirus with Pvr for short periods at low temperatures appears to result in release of the lipid (32).

Translation of the Viral RNA

Internal Ribosome Binding: The Internal Ribosome Entry Site

Once the picornavirus positive-stranded genomic RNA is released into the cell cytoplasm, it must be translated because it cannot be copied by any cellular RNA polymerase and no viral enzymes are brought into the cell within the viral capsid. Several experimental findings led to the belief that translation of the picornavirus genome was accomplished by an unusual mechanism. The positive-stranded RNA genomes lack 5'-terminal cap structures; although virion RNA is linked to the viral protein VPg, this protein is removed by a cellular “unlinking” enzyme on entry of the RNA into the cell (8). Furthermore, picornavirus genomes are efficiently translated in infected cells despite inhibition of cellular mRNA translation. Determination of the nucleotide sequence of poliovirus positive-stranded RNA revealed a 741-nucleotide 5'-untranslated region that contains seven AUG codons (174,260). Such 5'-noncoding regions, which were subsequently found in other picornaviruses, contain highly ordered RNA structures (265,288). These features led to the suggestion that ribosomes do not scan through the picornaviral 5'-untranslated regions, but rather bind to an internal sequence. The 5'-untranslated region of poliovirus positive-stranded RNA was subsequently shown to contain a sequence that promotes translation initiation by internal ribosome binding, or the IRES (Fig. 8).

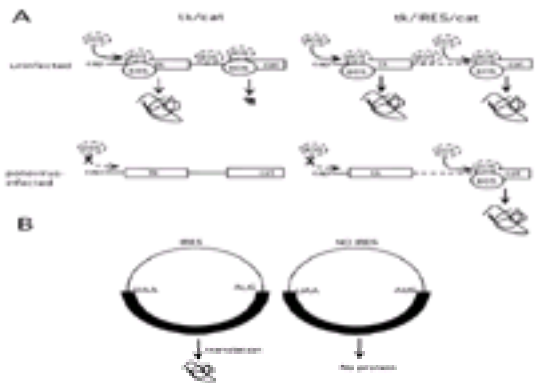

FIG. 8. Discovery of the internal ribosome entry site (IRES). **A:** Bicistronic mRNA assay used to discover the IRES (244). Plasmids were constructed that encode two reporter molecules, thymidine kinase (tk) and chloramphenicol acetyl transferase (cat), separated by an IRES (*solid line*) or a spacer (*dotted line*). After introduction into mammalian cells, the plasmids give rise to mRNAs of the structure shown in the figure. In uninfected cells (*top line*), both reporter molecules can be detected, although cat synthesis is inefficient without an IRES and is probably due to reinitiation. In poliovirus-infected cells, 5' end–dependent initiation is inhibited, and no proteins are detected without an IRES, demonstrating internal ribosome binding. **B:** Circular mRNA assay for an IRES. Circular mRNAs were constructed and translated *in vitro* in cell extracts. In the absence of an IRES, no protein is observed because 5'-end initiation requires a free 5'-end. Inclusion of an IRES allows protein translation from the circular mRNA, demonstrating internal ribosome binding (56).

The picornavirus IRES contains extensive regions of RNA secondary structure that is conserved within the type I (enteroviruses and rhinoviruses) and type II (cardioviruses and aphthoviruses) IRES (see Fig. 3). One sequence motif that is conserved among these two types of IRES is a GNRA sequence (N, any nucleotide; R, purine) in stem-loop IV of the type I IRES and in stem-loop I of the type II IRES. Another conserved element is an Yn-Xm-AUG motif, in which Yn is a pyrimidine-rich region and Xm is a 15- to 25-nucleotide spacer followed by an AUG codon. In the type II and hepatitis A virus IRES, this codon is the initiator AUG; in the type I IRES, the initiator is located 30 to 150 nucleotides further downstream. Translation initiation through a type 1 IRES involves binding of the 40S ribosomal subunit to the IRES and scanning of the subunit to the AUG initiation codon. The 40S subunit probably binds at the AUG initiation codon of a type II IRES.

Mechanism of Internal Ribosome Binding

Translation initiation directed by an IRES requires the same set of initiation proteins necessary for the translation of mRNAs by 5' end–dependent initiation. The exception was believed to be eIF4G, which is cleaved in picornavirus-infected cells, inactivating the translation of most cellular mRNAs. We now know that the C-terminal fragment of eIF4G, which contains binding sites for eIF3 and eIF4A (Fig. 9), stimulates IRES-mediated translation (44,234). In one model of the mechanism of internal ribosome binding, the 40S ribosomal subunit is recruited to the IRES through interaction with eIF3 bound to the C-terminal domain of eIF4G (see Fig. 9). Binding of eIF4G to the mRNA does not occur through eIF4E because picornavirus mRNAs are not capped. However, eIF4G may bind to the IRES either directly or through a “linker” protein (see Fig. 9). It has been reported that eIF4G mRNA contains an IRES (100,101), suggesting a mechanism for its synthesis in picornavirus-infected cells, in which 5' end–dependent translation initiation is inhibited. Stimulation of IRES function by the C-terminal proteolytic fragment of eIF4G may explain the observation that IRES activity is enhanced in cells in which the poliovirus protease $2A^{pro}$ is expressed (131). Protease $2A^{pro}$ is one of the picornaviral proteinases responsible for cleavage of eIF4G. Although the IRES of most picornaviruses functions with cleaved eIF4G, that of hepatitis A virus requires intact eIF4G (41).

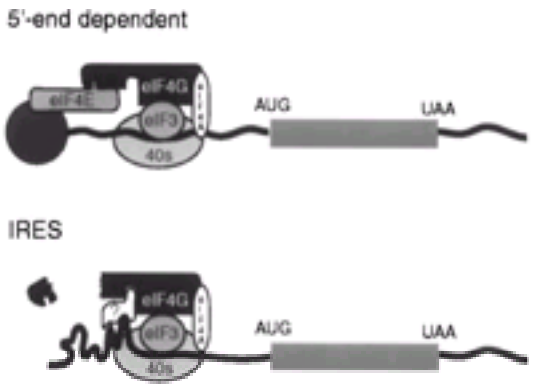

FIG. 9. Models for initiation complex formation. In 5'8 end–dependent initiation, the 40S subunit is recruited to the mRNA through its interaction with eIF3, which binds eIF4G. The latter initiation factor is part of eIF4F, which also contains eIF4A, a helicase to unwind RNA secondary structure, and eIF4E, the cap-binding protein. Binding of eIF4E to the cap thus positions eIF4E at the 5'-end and positions the 40S subunit on the mRNA. In IRES-dependent translation, a 5'-end is not required. The eIF3–40S complex is believed to be recruited to the RNA by the interaction of eIF4G with cellular IRES-binding proteins, marked by ?. No such universal IRES-binding protein has been identified.

Only one IRES, from cricket paralysis virus (322), has been shown to function *in vitro* in wheat germ extracts, and many IRESes function poorly in reticulocyte lysates; capped mRNAs can be translated efficiently in both types of extract. These observations may be explained if ribosome binding to the IRES requires cell proteins other than the canonical translation proteins, perhaps to link the IRES to eIF4G, as discussed previously. The search for such proteins has involved using mobility-shift assays to identify proteins that bind to the IRES and determining whether such proteins are necessary for IRES function in cell-free extracts. One host protein identified by this approach is the autoantigen La, a cellular protein that plays a role in the maturation of RNA polymerase III transcripts (210). It is present in low amounts in reticulocyte lysates; addition of the protein to such lysates stimulates the activity of the poliovirus IRES (210). La autoantigen is also required for efficient function of the encephalomyocarditis virus IRES (169).

Another protein that binds the picornavirus IRES is polypyrimidine tract-binding protein, a regulator of pre-mRNA splicing (138). Removal of this protein from a reticulocyte lysate with an RNA affinity column inhibits the function of the encephalomyocarditis virus IRES but does not affect translation by 5' end–dependent initiation (161). The deficiency in IRES function is restored by adding the purified protein back to the lysate. The depleted lysate, however, still supports the function of the IRES from Theiler's murine encephalomyocarditis virus, another picornavirus. It was subsequently shown that the requirement for polypyrimidine tract-binding protein by the encephalomyocarditis virus IRES depends on the nature of the reporter and the size of an A-rich bulge in the IRES (162). Polypyrimidine tract–binding protein is required for the function of the IRES of poliovirus and rhinovirus (149).

HeLa cell extracts also contain unr, an RNA-binding protein with five cold-shock domains that is required for IRES function (148). Recombinant unr stimulates the function of the rhinovirus IRES in the reticulocyte lysate and acts synergistically with recombinant polypyrimidine tract–binding protein to stimulate translation mediated by the rhinovirus IRES. However, unr does not augment the stimulation of the poliovirus IRES by polypyrimidine tract–binding protein.

Ribosome-associated poly r(C)–binding proteins bind at multiple sites within the poliovirus IRES (38,98). One binding site for these proteins has been identified within stem-loop IV of the poliovirus IRES (see Fig. 3) (38). Mutations in this region that abolish binding of poly r(C)–binding proteins cause decreased translation *in vitro.* Furthermore, depletion of poly r(C)–binding proteins from HeLa cell translation extracts results in inhibition of poliovirus IRES function (39). When this assay was used to survey a wide range of picornaviral IRES elements, it was found that poly r(C)–binding proteins are required for function of the type I, but not the type II, IRES (318). These results provide the first evidence of a difference in the manner in which the type I and type II IRES function. A second binding site for poly r(C)–binding proteins has been identified within a cloverleaf RNA structure that forms within the first 108 nucleotides of the positive-stranded poliovirus RNA genome (98,239). The interaction of poly r(C)–binding proteins with this part of the RNA has been proposed to regulate whether a positive-stranded RNA molecule is translated or replicated.

From the preceding discussion, it is clear that no single protein has been identified that is essential for the function of every IRES. It is certainly reasonable to propose that certain types of IRES have different requirements for cellular proteins. A different view is that cellular proteins, such as polypyrimidine tract–binding protein, may act as RNA chaperones, maintaining the IRES in a structure that permits it to bind directly to the translational machinery (151). IRESes that do not require such chaperones may fold properly without the need for cellular proteins. In support of this hypothesis, the IRES of hepatitis C virus, a flavivirus, has been shown to bind directly to eIF3 and the ribosomal 40S subunit, without a requirement for eIF4F (246).

Processing of the Viral Polyprotein

Picornavirus proteins are synthesized by the translation of a single, long, open reading frame on the viral positive-stranded RNA genome, followed by cleavage of the polyprotein by virus-encoded proteinases (Fig. 10; see Fig. 2). This strategy allows the synthesis of multiple protein products from a single RNA genome. The polyprotein is not observed in infected cells because it is processed as soon as the protease coding sequences have been translated. The polyprotein precursor is processed cotranslationally by intramolecular reactions (in *cis*) in what are called primary cleavages, followed by secondary processing in *cis* or in *trans* (intermolecular). Picornavirus genomes encode three proteinases: L^{pro}, $2A^{pro}$, and $3C^{pro}$, which carry out cleavage of the polyprotein.

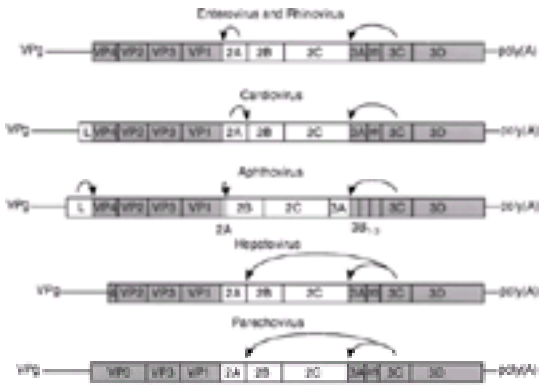

FIG. 10. Primary cleavages of picornavirus polyprotein. In cells infected with enteroviruses and rhinoviruses, nascent P1 is cleaved from P2 by $2A^{pro}$. In cells infected with cardioviruses and aphthoviruses, the P1–P2 junction is cleaved by $3C^{pro}$. The 2A proteins of these viruses are not proteinases, but they cause their own release at the junction with 2B. In all viruses shown, the P2–P3 cleavage is carried out by $3C^{pro}$. In hepatoviruses and parechoviruses, $3C^{pro}$ also carries out primary cleavage at the 2A–2B junction. The L^{pro} proteinase of foot-and-mouth disease virus catalyzes its release from VP4.

In contrast to other picornaviruses, the first protein encoded in the genome of cardioviruses and aphthoviruses is the L protein (see Fig. 2 and Fig. 10). The L protein of foot-and-mouth disease virus is a proteinase that releases itself from the polyprotein by cleaving between its C-terminus and the N-terminus of VP4. Based on sequence analysis, it was suggested that foot-and-mouth disease virus L^{pro} is related to thiol proteases (118). This prediction was supported by the results of site-directed mutagenesis, which showed that Cys-51 and His-148 are the active-site amino acids (252,266). The atomic structure of L^{pro} reveals that it consists of two domains, with a topology related to that of papain, a thiol proteinase (123) (Fig. 11). The active-site His is located at the top of the central a-helix, and substrate binds in the groove between the two domains (see Fig. 11). Besides releasing itself from the polyprotein, L^{pro} also cleaves the translation initiation factor eIF4G to effect inhibition of cellular translation (73). In cardioviruses, the L protein, which does not have proteolytic activity, is released from the P1 precursor by $3C^{pro}$ (238).

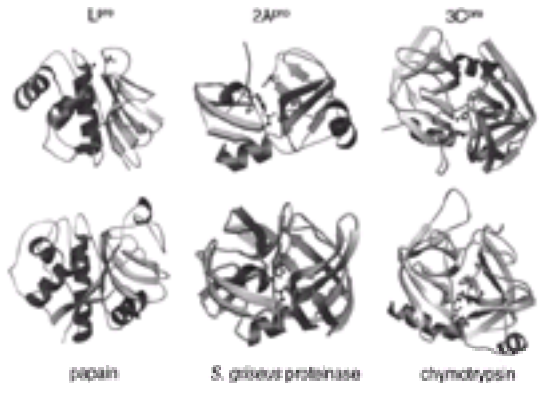

FIG. 11. Three dimensional structures of hepatitis A virus $3C^{pro}$, rhinovirus $2A^{pro}$, and L^{pro} of foot-and-mouth disease virus. Below each is the cellular proteinase that is structurally similar to each viral enzyme. Only the globular domain of L^{pro} is shown because the remaining residues have no counterpart in papain. Catalytic residues are drawn as *balls* and *sticks.* The rhinovirus $2A^{pro}$ structure is a model that was predicted before the crystal structure was solved. (Adapted from Seipelt J, Guarne A, Bergmann E, et al. The structures of piconaviral proteinases. *Virus Res* 1999;62:159,160,161,162,163,164,165,166,167 and 168), with permission.)

In cells infected with enteroviruses or rhinoviruses, the primary cleavage between P1 and P2 is mediated by $2A^{pro}$. In addition, $2A^{pro}$ cleaves the host cell protein eIF4G (see Cleavage of eIF4G). In the protein precursor of rhinovirus, poliovirus, and some other enteroviruses, the cleavage site for $2A^{pro}$ is between tyrosine and glycine. Other sites cleaved by $2A^{pro}$ include threonine-glycine and phenylalanine-glycine in certain coxsackieviruses and echoviruses. Based on sequence alignments, it was suggested that the structure of $2A^{pro}$ would resemble that of small bacterial chymotrypsin-like proteinases such as *Streptomyces griseus* proteinase A and would possess a catalytic triad consisting of His-20, Asp-38, and an active-site nucleophile of Cys-109 rather than serine (29). The results of site-directed mutagenesis and the resolution of the atomic structure of rhinovirus $2A^{pro}$ confirm that these residues compose the active site and that the fold of $2A^{pro}$ is very similar to that of *S. griseus* proteinase A (247,292,329) (see Fig. 11). However, $2A^{pro}$ differs from all known chymotrypsin-like proteinases in that the N-terminal domain is not a b-barrel, but rather a four-stranded antiparallel b-sheet. Another unusual feature of $2A^{pro}$ is a tightly bound zinc ion located at the beginning of the C-terminal domain. Biochemical and structural studies indicate that zinc is essential for the structure of the enzyme (247,291,317).

The 2A protein of hepatoviruses and parechoviruses does not have proteolytic activity and has no known function. The primary cleavage between the capsid protein precursor and the P2 region of these viruses is carried out by $3C^{pro}$ (see Fig. 10) (157,278,279).

The 2A protein of aphthoviruses and cardioviruses does not have proteolytic activity and is not related to other picornavirus 2A proteins. In cells infected with these viruses, the VP1/2A cleavage is not carried out by 2A, but rather by

3C^{pro} (238). Aphthovirus 2A protein is only 18 amino acids in length, yet this protein can catalyze autocleavage at the junction with 2B, even in heterologous polyproteins (275). The 2A protein of cardioviruses is 150 amino acids long, yet only the last 19 amino acids, plus the first amino acid from 2B, proline, are required for cleavage from 2B (76). Mutations within the conserved amino acid sequence Asn-Pro-Gly-Pro, which contains the cleavage site Gly-Pro, disrupt cleavage (238). The mechanism of aphthovirus- and cardiovirus 2A–mediated cleavage is not understood and represents a novel form of peptide bond scission probably involving a single turnover event.

All picornaviruses encode 3C^{pro}, which carries out a primary cleavage between 2C and 3A (see Fig. 10). In hepatoviruses and parechoviruses, 3C^{pro} also cleaves between 2A and 2B (see Fig. 10). Unlike the other picornavirus proteinases, 3C^{pro} also carries out secondary cleavages of the P1 and P2 precursors. Poliovirus 3C ^{pro} cleaves only at the Gln-Gly dipeptide; however, 3C^{pro} of other picornaviruses has less strict cleavage specificities and cleaves at other sites, including Gln-Ser, Gln-Ile, Gln-Asn, Gln-Ala, Gln-Thr, and Gln-Val. There are clearly other determinants of cleavage because not all such dipeptides in picornavirus polyproteins are cleaved by 3C ^{pro}. Additional determinants include accessibility of the cleavage site to the enzyme, recognition of secondary and tertiary structures in the substrate by the enzyme, and amino acid sequences surrounding the cleavage site. For example, efficient cleavage of poliovirus Gln-Gly pairs requires an Ala at the P4 position (Gln is residue P1, numbering is toward the N-terminus) (37).

Sequence comparisons with cellular proteinases led to the prediction that 3C ^{pro} folds similarly to the chymotrypsin-like serine proteinases (29,114,115,116 and 117). The putative catalytic triad was believed to consist of His-40, Asp-71 (aphthoviruses and cardioviruses) or Glu-71 (enteroviruses and rhinoviruses), and Cys-147 as the nucleophilic residue, in contrast to serine in cellular serine proteinases. These predictions have been confirmed by site-directed mutagenesis and by resolution of the atomic structures of rhinovirus, hepatitis A virus, and poliovirus 3C ^{pro} (55,122,132,166,201,222,247). The viral enzyme folds into two equivalent b-barrels like chymotrypsin (see Fig. 11) but differs in some of the connecting loops, the orientation of the catalytic residues, and in areas needed for transition-state stabilization. The acidic member of the catalytic triad, Glu or Asp, points away from the active-site His and is therefore not believed to assist in catalysis. However, 3C^{pro} also binds viral RNA (see Genome Replication and mRNA Synthesis), and this binding site is distal from the active site of the enzyme. The presence of this RNA-binding site imposes evolutionary constraints on 3C^{pro} that are not found in other proteinases.

Both 3C^{pro} and 2A^{pro} are active in the nascent polypeptide and release themselves from the polyprotein by self-cleavage. After the proteinases have been released, they cleave the polyprotein in *trans.* The cascade of processing events varies for different picornaviruses. In cells infected with rhinovirus and enteroviruses, the initial event in the processing cascade is the release of the P1 precursor from the nascent P2–P3 protein by 2A^{pro}. The activity of 2A^{pro} does not depend on whether it is cleaved from the precursor (137), but further processing of P1 by 3CD^{pro} does not occur unless 2A^{pro} is released from P1 (228,328). Next, 3CD^{pro} is released from the P3 precursor by autocatalytic cleavage; it is this proteinase, and not 3C^{pro}, which carries out secondary cleavage of glutamine-glycine dipeptides in poliovirus P1 (160,327). Both 3C^{pro} and 3CD^{pro} can process proteins of the P2 and P3 regions. 3D may be required to recognize structural motifs in properly folded P1, allowing efficient processing of the 3C ^{pro} part of the enzyme. The presence of multiple activities in a single protein is not found among eukaryotic proteinases and is an example of how the coding capacity of small viral genomes can be maximized. Not all picornaviruses require 3CD ^{pro} to process P1; aphthoviruses, cardioviruses, and hepatoviruses produce 3C ^{pro} that can cleave P1 without additional viral protein sequence.

An advantage of the polyprotein strategy is that expression can be controlled by the rate and extent of proteolytic processing. Alternative use of cleavage sites can also produce proteins with different activities. For example, because 3CD^{pro} is required for processing of the poliovirus capsid protein precursor P1, the extent of capsid protein processing can be controlled by regulating the amount of 3CD ^{pro} that is produced. Because 3CD^{pro} does not possess RNA polymerase activity, some of it must be cleaved to allow RNA replication.

A final processing step occurs during maturation, when VP0 is cleaved to form VP4 and VP2. This event is discussed later.

Genome Replication and mRNA Synthesis

In the 1950s, it was believed that the genome of RNA viruses was replicated by the cellular DNA-dependent RNA polymerase, through an intermediate DNA strand. The replication of RNA viruses was therefore thought to occur entirely in the cell nucleus. In the early 1960s, studies of mengovirus showed that virus infection results in the induction of a cytoplasmic enzyme that can synthesize viral RNA in the presence of actinomycin D (21). This observation suggested that viral genome replication occurred through a virus-specific RNA-dependent RNA polymerase because cellular RNA synthesis is DNA dependent, occurs in the nucleus, and is sensitive to actinomycin D. Shortly thereafter, a similar cytoplasmic, actinomycin D–resistant genome replication system was discovered in poliovirus-infected cells (19). Since then, most studies of picornavirus RNA synthesis have been carried out with poliovirus.

In poliovirus-infected cells, the positive-stranded genome is amplified through a negative-stranded intermediate, resulting in about 50,000 genomes per cell. Three forms of RNA have been identified in the cell: single-stranded RNAs, replicative intermediate (RI), and replicative form (RF). Single-stranded RNA is the most abundant form and is exclusively positive-stranded; free negative strands have never been detected in infected cells. RI is full-length RNA from which six to eight nascent strands are attached. RI is largely of positive polarity with nascent negative strands, although the opposite configuration has been detected. RF is a double-stranded structure, consisting of one full-length copy of the positive and negative strands. Viral RNA synthesis is asymmetric in that the synthesis of positive strands is 25 to 65 times greater than the synthesis of negative strands (106,232).

The Viral RNA-Dependent RNA Polymerase, 3D^{pol}

The first evidence for a viral RNA-dependent RNA polymerase activity came from experiments in which lysates from cells

infected with mengovirus or poliovirus were assayed for viral RNA polymerase activity by the incorporation of a radioactive nucleotide into viral RNA (21). Initial experiments demonstrated that the viral RNA polymerase is associated with a cellular membrane fraction, subsequently shown to be smooth membranes, which was called the *RNA replication complex* (109). A major component of the replication complex was a viral protein that migrated at 63,000 daltons on polyacrylamide gels (therefore called p63), which was suggested to be the viral RNA-dependent RNA polymerase. However, other viral and host proteins, including 2BC, 2C, 3AB, and 3C ^{pro}, were detected in the RNA replication complexes.

A limitation of this early work was that replication complexes did not respond to the addition of template RNA, but rather copied viral RNA already present in the complex. Therefore, attempts were made to purify a template-dependent enzyme from membrane fractions of infected cells, using a poly(A) template and an oligo(U) primer. A poly(U) polymerase activity was purified from poliovirus-infected cells, which could also copy poliovirus RNA in the presence of an oligo(U) primer. Highly purified preparations contained only p63, the major viral protein found in membranous replication complexes (87,310). This protein is the poliovirus RNA polymerase, now known as 3D ^{pol}. In the absence of an oligo(U) primer, 3D ^{pol} cannot copy poliovirus RNA. Recombinant 3D ^{pol} purified from bacteria or insect cells also requires the presence of an oligo(U) primer to copy poliovirus RNA (227,256). 3D^{pol} is therefore a template- and primer-dependent enzyme that can copy poliovirus RNA. Its molecular weight predicted from the amino acid sequence is 53 kd.

The structures of three of the four types of polymerases, DNA-dependent DNA polymerase, DNA-dependent RNA polymerase, and RNA-dependent DNA polymerase (reverse transcriptase), are characterized by analogy with a right hand, consisting of a palm, fingers, and thumb. The palm domain contains the active site of the enzyme. The first structure of an RNA-dependent RNA polymerase is that of poliovirus 3D ^{pol}, which was determined at 2.6 Å resolution by x-ray crystallography (133). The enzyme has the same overall shape as other polymerases, although the fingers and thumb differ (Fig. 12). The palm domain is similar to that of other polymerases and contains four conserved amino acid motifs that are found in other RNA-dependent polymerases. 3D ^{pol} also contains a fifth motif between the palm and thumb subdomains, which is found in RNA-dependent but not DNA-dependent polymerases.

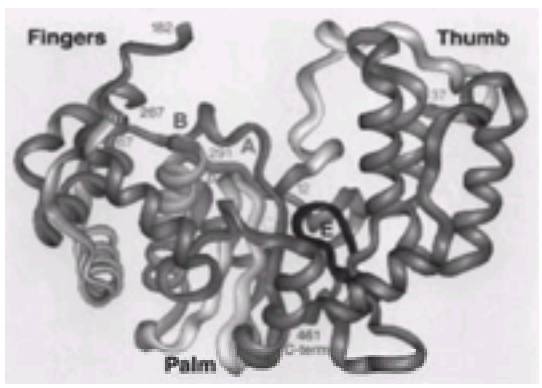

FIG. 12. Three dimensional structure of poliovirus 3D ^{pol}. Thumb, palm, and fingers subdomains are labeled. The two white regions have no counterparts in other polymerases. The region connecting these sequences is disordered (amino acids 33 to 66); hence, it is not known whether these residues are connected across the active site (considered unlikely) or whether amino acids 14 to 35 are from a separate molecule. If the latter is correct, such interactions may lead to oligomerization. (Adapted from ref. 133, with permission.)

In addition to its enzymatic activity, poliovirus 3Dpol is also a cooperative single-stranded RNA-binding protein and can unwind duplex RNA without the need for adenosine triphosphate hydrolysis (59,240). Consistent with these findings, two regions of polymerase–polymerase interaction have been observed in 3D ^{pol} protein crystals. The first, called interface I, is extensive and involves more than 23 amino acid side chains on two different surfaces of the protein (Fig. 13). This interaction occurs in a head-to-tail fashion and results in long fibers of polymerase molecules. When RNA is modeled into the 3D^{pol} structure based on the location of DNA in the crystal structure of DNA bound to human immunodeficiency virus type 1 reverse transcriptase, it falls along the fibers formed by interface I interactions. Interface II is formed by N-terminal polypeptide segments, which may lead to a network of polymerase fibers in combination with interactions at interface I. These N-terminal polypeptide segments may originate from different polymerase molecules. The N-terminus of 3D^{pol} is required for enzyme activity, which would support the idea that interface II interactions are of functional consequence. The viral nucleoproteins of negative-stranded RNA viruses are also cooperative single-stranded RNA-binding proteins. The function of these proteins is to allow multiple rounds of RNA synthesis by keeping the RNA single stranded and preventing base-pairing between template and product. The single-stranded RNA–binding properties of 3D^{pol} may have a similar function in infected cells.

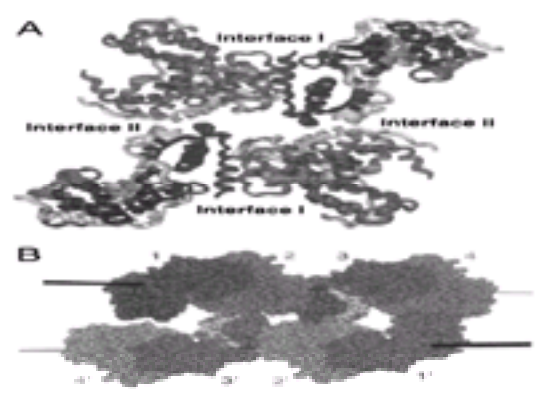

FIG. 13. Interactions among $3D^{pol}$ molecules in protein crystals. **A:** The manner in which four polymerase molecules interact is shown. Interface I, between the front of the thumb subdomain of one molecule and the back of the palm subdomain of another, leads to head-to-tail fibers of the enzyme. Interface II, formed by interactions between the two N-terminal regions of the polymerase (*white*), is a result of contacts between polymerase molecules in neighboring fibers. **B:** Model of how $3D^{pol}$ might oligomerize on RNA. Shown are two fibers formed by interface I interactions. Each fiber contains four polymerase molecules. The two fibers interact across interface II; the axis of each is shown in *black.* (Adapted from ref. 133, with permission.)

Viral Accessory Proteins

The poliovirus capsid proteins are not required for viral RNA synthesis; the region of the viral genome that encodes these proteins can be deleted without affecting the ability of viral RNA to replicate in cells (163). However, the capsid coding regions of rhinovirus, Theiler's virus, and mengovirus contain a cis-acting RNA sequence required for genome replication (192,206,207). A cis-acting RNA sequence required for RNA replication has also been identified in the poliovirus protein 2C coding region (113). Genetic and biochemical studies implicate most proteins of the P2 and P3 regions of the genome in RNA synthesis.

2A Protein

As discussed previously, $2A^{pro}$ protein is necessary for proteolytic cleavage of the polyprotein. Whether this is the sole requirement for this protein in viral replication was addressed by placing a second IRES element in the poliovirus genome before the $2A^{pro}$ coding region, effectively alleviating the need for the processing activity of the enzyme. Such viruses are viable (216). However, deletion of part of the coding region for $2A^{pro}$ is lethal. These results suggest that $2A^{pro}$ also plays a role in viral RNA replication, although its function in this process is not known.

2B Protein

Mutagenesis of 2B protein of poliovirus and coxsackievirus results in viruses with defects in RNA synthesis (159,311). The C-terminus of 2B contains a hydrophobic region and a conserved putative amphipathic a-helix that appear to be crucial to the function of the protein (312). However, the role of 2B in RNA synthesis is not known. Protein 2B has been shown to induce cell membrane permeability (6,276,313,314), which may play a role in release of virus from cells. Protein 2B is also partly responsible for the proliferation of membranous vesicles in infected cells, which are the sites of viral RNA replication. Because protein 3A has the same effect, it is not clear whether altered membrane proliferation is responsible for the RNA-defective phenotype in 2B mutants.

2C Protein

Mutations responsible for resistance of poliovirus and echovirus to guanidine hydrochloride, which blocks viral RNA replication, are located in the 2C protein (175,253,254). This compound has been shown to inhibit specifically the initiation of negative-stranded RNA synthesis and has no effect on initiation of positive-stranded RNA synthesis or on elongation on either strand (25). Protein 2C binds RNA, has nucleoside triphosphatase (NTPase) activity (267) that is inhibited by guanidine (251), and shares amino acid homology with known RNA helicases, proteins encoded by most positive-stranded RNA viruses with large genomes. These enzymes are believed to be necessary to unwind double-stranded RNA structures that form during RNA replication. Purified protein 2C, however, does not have RNA helicase activity (267). Alteration of conserved amino acids within the NTPase domain of 2C results in loss of viral infectivity. 2C may therefore have two functions during viral RNA synthesis: as an NTPase, and directing replication complexes to cell membranes. Expression of 2C leads to the formation of membrane vesicles and may contribute to the formation of the replication complex (60).

3AB Protein

Protein 3AB is believed to anchor VPg in membranes for the priming step of RNA synthesis. The purified protein greatly stimulates $3D^{pol}$ activity *in vitro* (241,255,264) as well as the proteolytic activity of $3CD^{pro}$ (215). 3AB interacts with $3D^{pol}$ and 3CD in infected cells and with $3D^{pol}$ in the yeast two-hybrid system (145). Mutations in $3D^{pol}$ that disrupt its interaction with 3AB result in viruses with defects in protein processing and viral RNA synthesis (104,105). A complex of 3AB and 3CD also binds the 3'-terminal sequence of poliovirus RNA. 3AB is therefore a stimulatory cofactor for $3D^{pol}$.

Cellular Accessory Proteins

Early studies of poliovirus replication using purified components suggested that a host cell protein is required for copying the viral RNA by $3D^{pol}$ in the absence of an oligo(U) primer (72). Although this protein was never identified, the concept of a host factor required for poliovirus replication endured, largely because there was ample precedent for the participation of host cell components in a viral RNA replicase. The best studied example is the RNA replicase of the bacteriophage Qb, which is a multisubunit enzyme consisting of a 65-kd virus-encoded protein and three host proteins: ribosomal protein S1 and translation factors EF-Tu and EF-Ts. The 65-kd viral protein has no RNA polymerase activity in the absence of the host factors but has sequence similarity with known RNA-dependent RNA polymerases. A subunit of the translation initiation factor eIF-3 is part of the polymerase from brome mosaic virus. Two different experimental systems have recently been used to provide additional evidence that poliovirus RNA synthesis requires host cell components.

When purified poliovirus RNA is incubated *in vitro* with a cytoplasmic extract prepared from cultured, permissive cells, the

viral RNA is translated, the resulting protein is proteolytically processed, and the genome is replicated and assembled into new infectious virus particles (217). When guanidine, an inhibitor of poliovirus RNA synthesis, is included in the reaction, complexes are formed, but elongation cannot occur (25). The preinitiation complexes can be isolated free of guanidine, and when added to new cytoplasmic extracts, RNA synthesis occurs. In the absence of cytoplasmic extract, preinitiation complexes do not synthesize viral RNA (24). These results indicate that one or more soluble cellular components are required for the initiation of viral RNA replication. A similar conclusion derives from studies in which poliovirus RNA is injected into oocytes derived from the African clawed toad, *Xenopus laevis.* Poliovirus RNA cannot replicate in *Xenopus* oocytes unless it is co-injected with a cytoplasmic extract from human cells (97).

Cellular poly r(C)–binding proteins are required for poliovirus RNA synthesis. These proteins bind to a cloverleaf-like secondary structure that forms in the first 108 nucleotides of positive-stranded RNA (Fig. 14). Binding of poly r(C)–binding protein to the cloverleaf is necessary for the binding of viral protein 3CD to the opposite side of the same cloverleaf (10, 11, 98, 239). Formation of a ribonucleoprotein complex composed of the 5' cloverleaf, 3CD, and a cellular protein is essential for the initiation of viral RNA synthesis (10). The human cell protein required for replication of poliovirus RNA in *Xenopus* oocytes has also been identified as poly r(C)–binding protein (98). A model of how these interactions lead to viral RNA synthesis is shown in Figure 14.

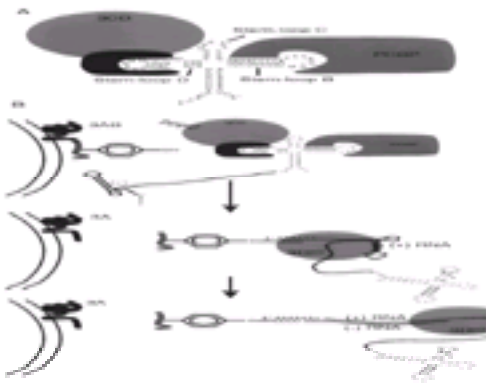

FIG. 14. Model for the synthesis of poliovirus (–) strand RNA. **A:** Schematic of the ribonucleoprotein complex that forms on a cloverleaf-like structure in the first 108 nucleotides of the viral (+) strand RNA. Binding of poly r(C) binding protein to stem-loop B is required for binding of viral 3CD to stem-loop D. This complex is required for synthesis of (+) and (–) strand RNA. **B:** Model for the initiation of (–) strand RNA synthesis. **Top:** the ribonucleoprotein complex has formed around the cloverleaf-like structure on the (+) strand and interacts with membrane-bound 3AB. Middle: 3AB is uridylylated and cleaved to release VPg-pUpU, and 3CD is cleaved to $3C^{pro}$ and $3D^{pol}$. Uridylylation and cleavage are carried out by 3CD. The $3D^{pol}$ then uses VPg-pUpU to prime RNA synthesis at the 3'-end of the viral (+) strand. A pseudoknot in the 3'-untranslated region may facilitate recognition of the 3'-end. **Bottom:** Elongation of a (–) strand RNA. Once this strand is complete, a cloverleaf forms at the 5'-end, leading to formation of another ribonucleoprotein complex and (+) strand RNA synthesis. Thus, many initiation reactions can occur on the original (+) strand RNA while (–) strands are being elongated.

Another candidate for a host protein that is involved in poliovirus RNA synthesis is Sam68 (Src-associated in mitosis, 68 kd), which is associated with $3D^{pol}$ in poliovirus-infected cells (203). Sam68 is normally located in the cell nucleus but becomes redistributed to the cytoplasm during poliovirus infection. Sam68 can also be isolated from infected cells using an antibody directed against viral protein 2C, which is present in membranous RNA replication complexes. These results suggest that Sam68 may have a role in poliovirus RNA synthesis, although no direct experimental support for this hypothesis has emerged.

A Protein-Linked Primer for RNA Synthesis

As discussed previously, poliovirus $3D^{pol}$ is a primer-dependent enzyme that will not copy poliovirus RNA *in vitro* without an oligo(U) primer. The discovery of VPg linked to poliovirus genome RNA, as well as to the 5' end of newly synthesized positive- and negative-stranded RNAs, suggested that VPg might be involved in the initiation of RNA synthesis. This hypothesis was supported by the finding that both VPg and a uridylylated form of the protein, VPg-pUpU, can be found in infected cells (69). Furthermore, VPg-pUpU can be synthesized *in vitro* in a membrane fraction from poliovirus-infected cells (300). It was also argued that a precursor of VPg, known as 3AB, is likely to participate in the initiation reaction. 3AB is a membrane-bound polypeptide and therefore an ideal candidate to act as a VPg donor in membranous replication complexes. Viruses containing a mutation in 3AB that decreases its hydrophobicity are defective in initiation of RNA synthesis, *in vitro* uridylylation of VPg, and *in vivo* synthesis of positive-stranded viral RNAs (104, 105). Because no protein larger than VPg has been detected linked to nascent RNA strands, it is likely that 3AB is rapidly cleaved by the proteinase $3C^{pro}$ to form VPg RNA. Additional evidence that VPg can serve as a primer for poliovirus RNA synthesis comes from experiments in which synthetic VPg is first uridylylated *in vitro,* then added to an *in vitro* polymerase reaction containing a poly(A) template and $3D^{pol}$ (242). The labeled, uridylylated VPg is extended to form poly(U). Thus, poliovirus RNA replication is primed by a genome-linked protein, a mechanism also involved in adenovirus DNA replication. A model for VPg priming of poliovirus RNA synthesis is shown in Figure 15.

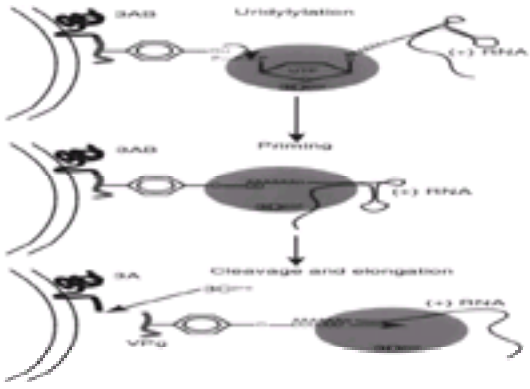

FIG. 15. Model for VPg priming of poliovirus RNA synthesis. 3AB is a hydrophobic, membrane-bound protein that is a precursor of VPg and probably participates in the initiation reaction. Uridylylation of membrane-bound 3AB is carried out by $3D^{pol}$ and is dependent on RNA template. Priming of RNA synthesis by 3AB-pUpU and cleavage to release VPg-pUpU probably occur in rapid succession because no protein larger than VPg linked to nascent RNA strands has been detected.

The Cellular Site of RNA Synthesis

Messenger RNA and genome synthesis of picornaviruses, like that of most RNA viruses, occurs in the cytoplasm of the cell. Cells infected with poliovirus accumulate small membranous vesicles that are the sites of poliovirus RNA synthesis (109,223). The accumulation of these vesicles is believed to be a result of the inhibition of membrane vesicle transport from the endoplasmic reticulum to the cell surface. Expression of the viral proteins 2B or 3A is sufficient to block the transport of glycoproteins to the cell surface, and it has been suggested that this inhibition leads to the accumulation of vesicles on which viral RNA synthesis occurs (74,75,314). Proteins 2BC and 2C might also contribute to the accumulation of such vesicles because expression of these proteins leads to membrane proliferation in cells (60).

Two other findings indicate the importance of vesicles in viral RNA synthesis. First, poliovirus RNA synthesis is inhibited by cerulenin, an inhibitor of lipid synthesis (124). Viral RNA replication is also inhibited by the fungal metabolite brefeldin A, which blocks the transport of proteins from the endoplasmic reticulum to the cell surface (150,202). Brefeldin A inhibits protein transport by blocking the movement of membrane vesicles from the endoplasmic reticulum to the Golgi apparatus and among the compartments of the Golgi. In the presence of brefeldin A, membranous vesicles derived from the endoplasmic reticulum do not accumulate in infected cells, leading to an inhibition of viral RNA synthesis. Poliovirus, therefore, appears to produce the membrane vesicles important for its replication by inhibiting an intracellular protein transport pathway. Because poliovirus is nonenveloped, its replication does not require the protein glycosylation and secretion functions of the endoplasmic reticulum and Golgi apparatus.

Two viral proteins, 2C and 3AB, bring the replication complex to membranous vesicles. As discussed previously, 3AB is a hydrophobic protein that anchors the protein primer VPg in the membrane for RNA synthesis. Protein 2C has an RNA-binding domain, which might anchor viral RNA to membranes in the replication complexes (82).

Translation and Replication of the Same RNA Molecule

The genomic RNA of picornaviruses is not only mRNA but also the template for synthesis of negative-stranded RNA. How does the viral polymerase, traveling in a 3' to 5' direction on the positive strand, avoid collisions with ribosomes translating in the opposite direction? Perhaps a mechanism exists to avoid the two processes occurring simultaneously. *In vitro* experiments using inhibitors of protein synthesis demonstrate that when ribosomes are frozen on the viral RNA, replication of the RNA is inhibited. In contrast, when ribosomes are released from the viral RNA, its replication is increased (26). These results suggest that replication and translation cannot occur on the same template simultaneously.

It has been proposed that the cloverleaf structure in the 5'-noncoding region of poliovirus positive-stranded RNA can regulate whether the RNA is translated or replicated (99). In this model, early in infection, binding of poly r(C)–binding protein to the cloverleaf structure stimulates translation. Once 3CD has been synthesized, it binds to the cloverleaf structure (see Fig. 14), represses translation, and stimulates RNA synthesis. Although this model has some experimental support, it does not account for the fact that viral RNA translation and RNA replication both occur for several hours in infected cells.

Whether there exist mechanisms to regulate translation and replication of an RNA, there is experimental evidence that some ribosome and RNA polymerase collisions do occur. This conclusion is based on the isolation of a poliovirus variant whose genome contains an insertion of a 15 nucleotide sequence from 28S ribosomal RNA (54). Apparently, the RNA polymerase collided with a ribosome, copied 15 nucleotides of rRNA, and then returned to the viral RNA template.

Discrimination of Viral and Cellular RNA

The RNA-dependent RNA polymerases of picornaviruses are template-specific enzymes. Poliovirus $3D^{pol}$ copies only viral RNAs, not cellular mRNAs, in infected cells. However, the purified enzyme will copy any polyadenylated RNA if provided with an oligo(U) primer. This observation has led to the suggestion that template specificity probably resides in the interaction of replication proteins with sequence elements in the viral RNA. The 3'-noncoding region of the viral positive-stranded RNA contains an RNA pseudoknot conserved among picornaviruses that is believed to play a role in the specificity of copying by $3D^{pol}$ (154). Disruption of the pseudoknot by mutagenesis produces viruses that have impaired RNA synthesis, indicating the importance of the structure in the synthesis of negative-stranded RNA. $3D^{pol}$ or 3CD cannot bind to the 3' end of poliovirus RNA unless 3AB is present. Thus, the $3AB–3D^{pol}$ complex may determine the

specificity of binding to the 3' pseudoknot. Despite experimental results that underscore the importance of the pseudoknot in RNA synthesis, polioviruses from which the entire 3'-noncoding region of the viral RNA has been removed are able to replicate, albeit inefficiently (301). It seems likely that there are other primary determinants of template selection by the polymerase, such as cis-acting RNA sequences within the coding region and membrane association of the RNA polymerase, which would lead to increased local concentrations of essential components. Template specificity may also be conferred by the position of the $3D^{pol}$ gene at the very 3' end of the viral RNA; translation places the polymerase at the 3' end of the genome, ready for initiation. Early in infection, the pseudoknot structure might facilitate template selection when few polymerase molecules are available and membrane association has not yet provided highly concentrated areas of replication components.

A cloverleaf-like structure that forms in the 5'-noncoding region also plays an important role in template specificity. The finding that a mutation in a cloverleaf-like structure in the 5'-noncoding region that affects RNA synthesis could be complemented by a suppressor mutation in 3C led to the suggestion that $3C^{pro}$ might bind the cloverleaf and play a role in viral RNA replication (12). It was subsequently found that 3CD binds the cloverleaf structure in the positive strand, together with a cellular protein, now known to be poly r(C)–binding protein, that is required for complex formation (see later) (10,11,239). The RNA-binding domain of 3CD is contained within the 3C portion of the protein, on the opposite face of the molecule from the site involved in proteolysis. Mutations within this domain abolish complex formation and RNA replication without affecting viral protein processing. 3CD, therefore, plays an important role in viral RNA synthesis by participating in formation of a ribonucleoprotein complex at the 5' end of the positive-stranded RNA. A role for these interactions in viral RNA replication is suggested in the model in Figure 14.

Recombination

Recombination, the exchange of nucleotide sequences among different genome RNA molecules, was first discovered in cells infected with poliovirus, and was subsequently found to occur with other positive- and negative-stranded RNA viruses. The frequency of recombination, which is calculated by dividing the yield of recombinant virus by the sum of the yields of parental viruses, can be relatively high. In one study of poliovirus and foot-and-mouth disease virus, the recombination frequency was 0.9%, leading to the estimation that 10% to 20% of the viral genomes recombine in one growth cycle. When poliovirus recombination is studied by quantitative polymerase chain reaction, obviating the necessity to select for viable viruses, the recombination frequency for marker loci 600 nucleotides apart was 2×10^{-3}, which is similar to estimates obtained using selectable markers (156). RNA recombination also occurs in natural infections. For example, intertypic recombinants among the three serotypes of Sabin poliovirus vaccine strains are readily isolated from the intestines of vaccinees; some recombinants contain sequences from all three serotypes (46). The significance of these recombinants is unknown, but it has been suggested that such viruses are selected for their improved ability to replicate in the human alimentary tract compared with the parental viruses.

Poliovirus recombination mainly occurs between nucleotide sequences of the two parental genome RNA strands that have a high percentage of nucleotide identity and is called base pairing dependent (Fig. 16). RNA recombination is believed to be coupled with the process of genome RNA replication: it occurs by template switching during negative strand synthesis, as first demonstrated in poliovirus-infected cells (172). The RNA polymerase first copies the 3' end of one parental positive strand, then switches templates and continues synthesis at the corresponding position on a second parental positive strand (see Fig. 16). Template switching in poliovirus-infected cells occurs predominantly during negative strand synthesis because the concentration of positive-strand acceptors for template switching is 25- to 65-fold higher than that of negative-strand acceptors. This template-switching mechanism of recombination is also known as *copy-choice.* A prediction of the copy-choice mechanism is that recombination frequencies should be lower between different poliovirus serotypes, a prediction that has been verified experimentally. For example, recombination between poliovirus types 1 and 2 occurs about 100 times less frequently than among type 1 polioviruses (the different poliovirus serotypes differ by about 15% in their nucleotide sequences) (170). The cause of template switching is not known, but it might be triggered by pausing of the polymerase during chain elongation.

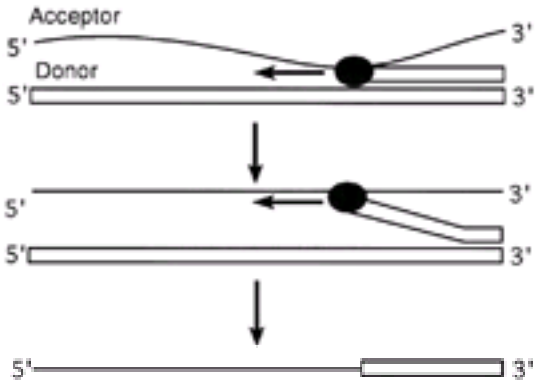

FIG. 16. RNA recombination. Schematic diagram of RNA recombination in picornavirus-infected cells by template switching, or copy-choice. Two parental genomes, the acceptor and donor, are shown as a *line* and *box.* The RNA polymerase, a *black oval,* is shown copying the 3' end of donor RNA and switching to the acceptor genome (middle). As a result of this template switch, the recombinant RNA shown at the bottom is formed.

Assembly of Virus Particles

Morphogenesis of picornaviruses has been studied extensively because the 60-subunit capsid is relatively simple and the assembly intermediates can be readily detected in infected cells (Fig. 17). During the synthesis of the P1 protein, the capsid protein precursor, the central b-barrel domains form, and intramolecular interactions among the surfaces of these

domains leads to formation of the structural units. Once P1 is released from the 2A protein, the VP0–VP3 and VP3–VP1 bonds are cleaved by proteinase $3CD^{pro}$. These cleavage sites are located in flexible regions between the b-barrels; there is considerable movement of the aminotermini and carboxyltermini after cleavage, but the contacts between b-barrels are not disturbed (142). In the mature capsid, the carboxyltermini of VP1, VP2, and VP3 are on the outer surface of the capsid, whereas the aminotermini are on the interior, where they participate in an extensive network of interactions among protomers. This process produces the first assembly intermediate in the poliovirus pathway, the 5S protomer, the immature structural unit consisting of one copy each of VP0, VP3, and VP1. Five protomers then assemble to form a pentamer, which sediments at 14S. Cleavage of P1 is probably required for assembly of the pentamer (237). This conclusion is supported by examination of the virion structure. The b-cylinder at the fivefold axis of symmetry is formed from the N-termini of neighboring VP3 molecules; the cylinder is surrounded by a bundle composed of the aminotermini of VP0 and VP1. For these interactions to occur, proteolytic cleavage of the capsid proteins must occur to allow movement of the aminotermini.

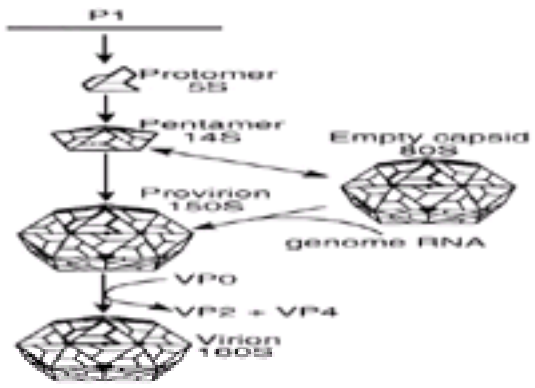

FIG. 17. Morphogenesis of picornaviruses. The capsid protein precursor, P1, folds nascently, is cleaved from P2, and then is further cleaved to VP0 + VP3 + VP1 by $3CD^{pro}$. Protomers (5S) self-assemble into 14S pentamers, and pentamers assemble into 80S empty capsids. In one model of encapsidation, RNA is threaded into the empty capsid, producing a 150S provirion in which VP0 is uncleaved. Another possibility is that pentamers assemble around the RNA genome and that empty capsids are storage depots for pentamers. Cleavage of VP0 is the final morphogenetic step that produces the infectious 160S virion. The proteinase responsible for the cleavage of VP0 is unknown. (Adapted from Hellen CUT, Wimmer E. *Human enterovirus infections.* Washington, DC: ASM Press, DC, 1995, with permission.)

Pentamers are important intermediates in the assembly of all picornaviruses (40,269). They can self-assemble *in vitro* or *in vivo* into 80S empty capsids; in one model of assembly, newly synthesized viral RNA is inserted into these particles to form the provirion (153), in which the capsid protein VP0 remains uncleaved. This assembly model would seemingly require an opening in the empty capsid through which the RNA can enter. Examination of the high-resolution x-ray crystallographic structure of these particles does not provide evidence for such an opening (27). This finding does not exclude this morphogenetic pathway because the pore might be dynamic and not observed in the crystals. In an alternative morphogenesis pathway, 4S pentamers assemble with virion RNA to form provirions. In this model, for which there is some experimental support (233), the empty capsids found in infected cells serve as storage depots for 14S pentamers.

The final morphogenetic step involves cleavage of most of the VP0 molecules to VP4 + VP2. The proteinase that carries out this final maturation cleavage has not been identified. The VP0 scissile bond is located on the interior of empty capsids and mature virions and is inaccessible to viral or cellular proteinases. The presence of a conserved serine in VP2 near one of the cleaved termini of VP2 led to a model that cleavage occurs by a novel autocatalytic serine protease-like mechanism in which basic viral RNA groups serve as proton abstracters during the cleavage reaction (17). However, replacement of ser-10 does not impair VP0 cleavage (135). More recently, it has been suggested that a conserved histidine in VP2 may be involved in catalysis, together with the viral RNA (27,71).

The structure of the 80S particle reveals differences in the network formed by the N-terminal extensions of the capsid proteins on the inner surface of the shell, compared with the native virion (27). In empty capsids, VP4 and the entire N-terminal extensions of VP1 and VP2 are disordered, and many stabilizing interactions that are present in the mature virion are not present. Thus, cleavage of VP0 establishes the ordered N-terminal network, an interlocking seven-stranded b-sheet formed by residues from adjacent pentamers. This network results in an increase in particle stability and the acquisition of infectivity.

The picornavirus encapsidation process is highly specific, resulting in packaging of only positive-stranded RNA, and not viral mRNA, negative-stranded viral RNA, or any cellular RNA (230,232). VPg is probably not an encapsidation signal because VPg-containing negative-stranded RNA is not packaged. The coupling of encapsidation to viral RNA synthesis may explain the selective packaging of viral positive-stranded RNA. In infected cells, newly synthesized RNA is packaged into virions within 5 minutes, whereas incorporation of capsid proteins in virions requires at least 20 minutes (22). The pool of viral RNA available for packaging is therefore small, whereas the pool of capsid proteins is large. If capsid formation is inhibited with *p*-fluorophenylalanine, the accumulated RNA cannot be packaged after removal of the inhibitor (130). These results suggest that packaging of the viral genome is linked to RNA synthesis, and would explain why only RNAs containing VPg are encapsidated.

During its synthesis, the P1 capsid protein precursor is linked to myristic acid at the aminoterminal glycine residue of VP4 that is exposed after removal of the initiation Met residue (61). The myristate groups, which form part of a network of interactions between subunits that form when protomers assemble into pentamers, cluster around the fivefold axis of symmetry and stabilize the b-cylinder that is made by the aminotermini of five copies of VP3. Mutagenesis indicates that

the myristate group plays a role in stabilizing pentamers and therefore virions (14,196,197 and 198,220).

Effects of Viral Multiplication on the Host Cell

Inhibition of 5' End–Dependent mRNA Translation

Cleavage of eIF4G

In cultured mammalian cells, poliovirus infection results in inhibition of cellular protein synthesis. By 2 hours after infection, polyribosomes are disrupted, and translation of nearly all cellular mRNAs stops and is replaced by viral mRNA translation (Fig. 18). Poliovirus mRNA, but not capped mRNAs, can be translated in extracts from infected cells. In such extracts, one translation initiation factor, eIF4F, has been inactivated by cleavage of the eIF4GI/II component (85,270,305). Cleavage of eIF4G prevents eIF4F from recruiting 40S ribosomal subunits to capped mRNAs because it releases the N-terminal domain of eIF4G, which binds eIF4E, which in turn binds the 5' cap of cellular mRNAs (Fig. 19). The synthesis of poliovirus proteins is not affected because the viral RNA is translated by internal ribosome binding, a process that does not require eIF4E. However, optimal function of the IRES does require the C-terminal fragment of eIF4G, which, as discussed previously, is necessary to anchor 40S ribosomal subunits to the IRES. Cleavage of eIF4G by picornaviruses inhibits cell translation and is also a strategy for stimulating IRES-dependent translation. Although both eIF4GI and eIF4GII are cleaved in poliovirus- and rhinovirus-infected cells, the kinetics of shutoff of host translation correlates with cleavage of eIF4GII and not eIF4GI (119,298).

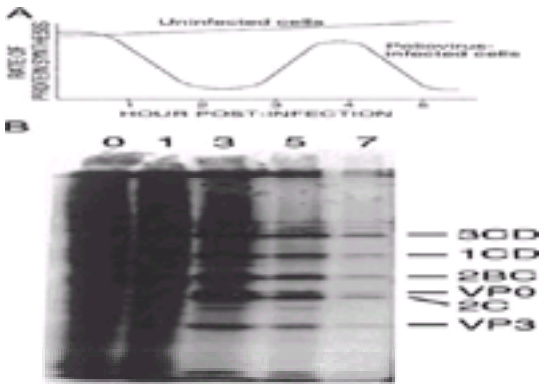

FIG. 18. Inhibition of cellular translation in cells infected with poliovirus. **A:** Protein synthesis in poliovirus-infected and uninfected cells at different times after infection. Poliovirus infection results in inhibition of host cell translation beginning about 1 hour after infection. The increase in translation beginning 3 hours after infection is due to the synthesis of viral proteins. **B:** Polyacrylamide gel showing inhibition of cellular translation. At different times after infection (indicated at the top of each lane), cells were incubated with ^{35}S-methionine for 15 minutes; the cell extracts were then fractionated on an SDS-polyacrylamide gel. By 5 hours after infection, host translation is markedly inhibited and replaced by the synthesis of viral proteins, identified at the right.

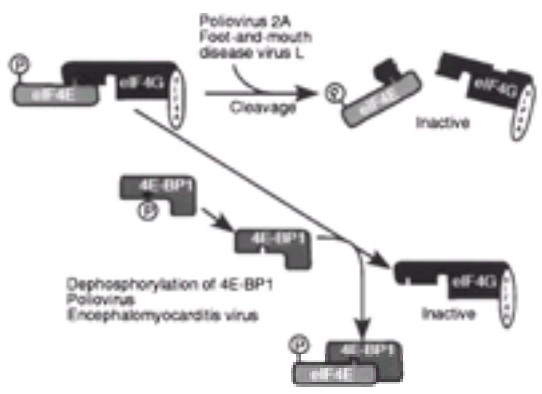

FIG. 19. Two mechanisms for regulating eIF4F activity in picornavirus-infected cells. The proteins 4E-BP1 and 4E-BP1 bind eIF4E and prevent it from interacting with eIF4G. 4E-BP1 binds eIF4E when it is dephosphorylated, an event that occurs in cells infected with poliovirus and encephalomyocarditis virus. Cleavage of eIF4G takes place in cells infected with poliovirus, rhinovirus, and foot-and-mouth disease virus, among others. Cleavage removes the binding site in eIF4G for eIF4E. As a result, eIF4F is unable to recruit ribosomes to the mRNA through the 5'-cap structure, and translation by 5' end–dependent initiation is inhibited.

Both forms of eIF4G are cleaved by protease 2A^{pro} of poliovirus and rhinovirus (119,298). *In vitro* cleavage of eIF4G by purified 2A^{pro} of rhinovirus is inefficient unless eIF4G is bound to eIF4E (128). This finding indicates that eIF4G is not cleaved as an individual polypeptide, but rather as part of the eIF4F complex. Binding of eIF4E to eIF4G may induce conformational changes in eIF4G that make it a more efficient substrate for the protease. Poliovirus 2A ^{pro} efficiently cleaves eIF4GI, but not eIF4GII, consistent with the differential cleavage of these proteins during virus infection (119). Cleavage of eIF4G in cells infected with foot-and-mouth disease virus is carried out by the L ^{pro} protein. The cleavage sites in eIF4G for the two proteinases are different: L ^{pro} cleaves between Gly-479 and Arg-480, whereas 2A^{pro} cleaves between Arg-486 and Gly-487 (171,181).

Modulation of eIF4E Activity

Two related low-molecular-weight cell proteins, 4E-BP1 and 4E-BP2, bind to eIF4E and inhibit translation by 5' end–dependent scanning, but not by internal ribosome entry (see Fig. 19) (243). 4E-BP1 is identical to a protein called PHAS-I (phosphorylated heat- and acid-stable protein regulated by insulin), which was previously known to be an important phosphorylation substrate in cells treated with insulin and growth factors (190). Phosphorylation of 4E-BP1 *in vitro* blocks its association with eIF4E. Binding of either 4E-BP1 or 4E-BP2 to eIF4E does not prevent it from interacting with the 5' cap but does inhibit binding to eIF4G. Consequently, active eIF4F is not formed. eIF4G and the 4E-BPs have a common sequence motif that binds eIF4E. Treatment of cells with hormones and growth factors leads to the phosphorylation of 4E-BP1 and its release from eIF4E. Those mRNAs with extensive secondary structure in the 5'-untranslated region, which are translated poorly, are preferentially sensitive to the phosphorylation state of 4E-BP1. As expected, translation by internal ribosome binding is not affected when 4E-BP1 is dephosphorylated. The nature of the signaling pathway through which binding of extracellular ligands leads to phosphorylation of 4E-BPs has not yet been elucidated (107).

Infection with several picornaviruses causes alteration of the phosphorylation state of 4E-BP1 and 4E-BP2 (see Fig. 19). Infection of cells with encephalomyocarditis virus causes inhibition of cellular translation, but in contrast to the shutoff that occurs in poliovirus-infected cells, shutoff cellular protein synthesis occurs late in infection and is not mediated by cleavage of eIF4G. Infection with encephalomyocarditis virus induces dephosphorylation of 4E-BP1, which then binds eIF4E to prevent it from forming eIF4F (108). Translation of cellular mRNAs is inhibited, but that of the viral RNA is not inhibited because it contains an IRES. Dephosphorylation of 4E-BP1 also occurs late in cells infected with poliovirus, but this event does not coincide with inhibition of cellular translation, which occurs earlier in infection (108).

Inhibition of Cellular RNA Synthesis

Infection of cells with picornaviruses leads to a rapid inhibition of host cell RNA synthesis catalyzed by all three classes of DNA-dependent RNA polymerase. RNA polymerases I, II, and III from poliovirus-infected cells are enzymatically active, suggesting that accessory proteins may be the target of transcriptional inhibition. Studies of *in vitro* systems have demonstrated the inhibition of specific transcription factors required by each of the three RNA polymerases. The RNA polymerase factor TFIID, which is a multiprotein complex, is inactivated in poliovirus-infected cells (176). This inactivation appears to be due, at least in part, to cleavage of a subunit of TFIID, the TATA-binding protein, by protease $3C^{pro}$ (63). A pol III DNA-binding transcription factor, TFIIC, is also cleaved and inactivated by $3C^{pro}$ (62). The target of $3C^{pro}$ is the a subunit of TFIIIC, which contacts the pol III promoter. An unidentified pol I transcription factor is cleaved by $3C^{pro}$, resulting in inhibition of pol I transcription in infected cells (273).

Cytopathic Effects

When cells are productively infected with poliovirus, they develop the characteristic morphologic changes known as *cytopathic effects.* These include condensation of chromatin, nuclear blebbing, proliferation of membranous vesicles, changes in membrane permeability, leakage of intracellular components, and shriveling of the entire cell. The cause of cytopathic effects is unknown. One hypothesis is that leakage of lysosomal contents is partly responsible (125). Although cellular RNA, protein, and DNA synthesis are inhibited during the first few hours of infection, they cannot account for cytopathic effects.

When poliovirus reproduction is hindered by certain drugs or other restrictive conditions, cell death occurs through induction of apoptosis (302). Although certain manifestations of cytopathic effects and apoptosis are similar, such as chromatin condensation and nuclear deformation, the pathways leading to their induction differ (3). During productive infections of cultured cells with poliovirus, apoptosis is blocked by a virus-encoded inhibitor (302). However, viral replication and central nervous system injury in mice infected with poliovirus are associated with apoptosis (110). Expression in cells of poliovirus protein 2A or 3C leads to induction of apoptosis (23,111). The viral inhibitor of apoptosis has not been identified. The ability of different strains of Theiler's murine encephalomyelitis virus to induce apoptosis may be a determinant of disease. The TO strain of Theiler's virus, which causes a persistent demyelinating disease in mice, encodes an additional protein, L* (57). This protein is produced by initiation from an AUG that is 13 nucleotides downstream from the initiator AUG of the polyprotein, in a different reading frame. In contrast, nondemyelinating strains of the virus, such as GDVII, do not encode L*. It was subsequently found that L* has antiapoptotic properties in macrophages and is critical for virus persistence (103). The ability of L* to inhibit apoptosis may be a key factor in determining whether infection of mice results in acute disease or persistence and demyelination.

Perspectives

Since the isolation of poliovirus in 1908, research on the virus has waxed and waned. With each lull in activity, questions were raised about whether it was productive to continue research on the virus. Each time, new technologies emerged that allowed the field to advance and become active once again. With global eradication of poliomyelitis looming on the horizon, research on poliovirus is as vibrant as ever. Many questions remain about nearly every stage of the replicative cycle, and an unprecedented array of experimental techniques and reagents are available to address them. We are on the verge of understanding the dynamics of the virion as it binds to the receptor and releases its nucleic acid. Why has poliovirus selected its particular receptor? Does the interaction lead to intracellular signaling that is beneficial for the virus? How is the genome extruded from the virus particle? Does the mechanism of RNA synthesis in infected cells resemble that which occurs *in vitro?* Why does RNA synthesis occur on membranes, and how is translation and replication regulated so that the processes do not collide? What other host proteins are involved in RNA synthesis, and what are their roles? How does the viral RNA enter the virion, and what causes the dramatic reorganization of the interior during the final stages of maturation? The study of poliovirus provides a unique opportunity to address fundamental questions in virology. However, we may not be able to answer these and many other interesting questions before the time comes to destroy all stocks of poliovirus, as part of the polio eradication effort (78). Fortunately, the same questions

apply to other members of the Picornaviridae, and it is anticipated that research activity on these viruses will rapidly intensify in the next few years. Although future versions of this chapter may not contain as much information about poliovirus, the lessons we have learned will not be forgotten.

CHAPTER 24 Enteroviruses: Polioviruses, Coxsackieviruses, Echoviruses, and Newer Enteroviruses

Mark A. Pallansch and Raymond P. Roos

Human enteroviruses are members of the Enterovirus genus of the family *Picornaviridae* (Table 1). Although most enterovirus infections are asymptomatic, there are estimates of as many as 5 to 10 million symptomatic enterovirus infections each year in the United States (308). The majority of enterovirus infections do not cause significant disease, but infection can lead to serious illness, especially in infants and the immunocompromised. In addition, this group of viruses is the most common cause of aseptic meningitis, the most frequent central nervous system (CNS) infection. Enteroviruses have been implicated in chronic as well as acute diseases. These chronic diseases include dermatomyositis, polymyositis, dilated cardiomyopathy, and diabetes mellitus.

Genus and species	Number of serotypes
Genus Enterovirus	
Poliovirus	3
Human enterovirus A	12
Human enterovirus B	36
Human enterovirus C	11
Human enterovirus D	2
Bovine enterovirus	2
Porcine sapelovirus A	1
Porcine enterovirus B	2
Genus Hepatovirus	1
Genus Rhinovirus	
Human rhinovirus A	18
Human rhinovirus B	3
Unassigned	82
Genus Cardiovirus	
Encephalomyocarditis virus	1
Theilovirus	2 or 3
Genus Kobuvirus[b]	1
Genus Teschovirus[b]	
Porcine teschovirus	10
Genus Erbovirus[b]	1
Genus Aphthovirus	
Foot-and-mouth disease virus	7
Equine rhinitis A virus	1
Genus Parechovirus	3
Recognized picornaviruses not yet placed in genera	At least 20

[a]The new classification scheme that is shown is from the International Committee for the Taxonomy of Viruses Picornavirus Study Group (323) and divides serotypes into different species, at least partly on the basis of genome organization and sequence similarity. The particular enteroviruses that make up the species are detailed in Tables 6–8.
[b]Proposed as a genus.

TABLE 1. *Picornavirus genera, species,[a] and serotype*

HISTORY

The history of enteroviruses is very much the history of poliovirus. In fact, many of the poliovirus milestones are landmarks not only in the study of enterovirus but for all of virology.

Poliomyelitis is believed to be an ancient disease. It has been suggested that the depiction of a young man with an atrophic limb on an Egyptian stele from the second millennium B.C. represents a sequela of poliomyelitis (153). The first

clinical descriptions of poliomyelitis were made in the 1800s, with reports of cases of paralysis with fever. In 1840, von Heine (119) published a monograph more specifically describing the affliction. His contributions and those published later by Medin from Sweden (202) led to paralytic poliomyelitis being referred to as Heine-Medin disease. Another early report, by Charcot and Joffroy (50), described the pathologic changes in the anterior horn motor neurons of the spinal cord in poliomyelitis.

The 1900s began a new era in poliomyelitis investigations, and the beginning of an understanding of the infectious nature of this disease. Wickman (331) and others recognized the communicable nature of poliomyelitis, the importance of asymptomatic infected individuals in transmission of poliovirus, and the role of enteric infection in disease pathogenesis. The role of the gastrointestinal tract in the initiation and spread of poliovirus infection was later confirmed by Trask and colleagues (320). In a classic study, Viennese investigators Landsteiner and Popper (178) proved the infectious nature of poliomyelitis by successfully transmitting the clinical disease and its pathology to monkeys following inoculation of CNS tissue homogenates from human cases.

Despite this progress, there were a number of unfortunate misconceptions about poliomyelitis that initially confused scientists and misdirected efforts for control. These misconceptions included a belief that the virus was exclusively neurotropic, that the nasopharynx was a major site for virus entry into the CNS, and that the virus spread to the nervous system prior to viremia and by way of the olfactory nerve. As a result of these misconceptions and the failure of several poorly conceived immunization attempts, some with rather disastrous results (250), there was an atmosphere of pessimism by the middle of the 20th century concerning the eventual control of poliomyelitis, even among scientists working in the field. In 1945, Burnet (44) wrote, “The practical problem of preventing infantile paralysis has not been solved. It is even doubtful whether it ever will be solved.” The eventual realization that virus entered via the oral/gastrointestinal route and that CNS disease followed a viremia did much to boost hopes for effective immunization (38).

Building on studies of others, Enders and colleagues (89) performed a landmark study showing that poliovirus could be propagated in nonneural tissue culture. These investigations had implications for all of virology because they indicated, first, that poliovirus grew in various tissue culture cells that did not correspond to the tissues infected during the human disease, and second, that poliovirus destroyed cells with a specific cytopathic effect. Neutralization tests showed that poliovirus has three serotypes (39), and serologic tests (22) confirmed the fact that most infected individuals do not manifest clinical disease. These investigations laid a critical framework for the preparation of a vaccine, and they clarified a host of confusing data, such as the apparent presence of second attacks of poliomyelitis.

A variety of vaccines were subsequently produced, with the most well-known being the Salk inactivated vaccine delivered via the intramuscular route (licensed in 1955 in the United States) and the Sabin live, attenuated vaccine delivered via the oral route (licensed in 1961–1962). The importance of these vaccines and the individuals who produced them can begin to be realized by noting that more Americans knew the name of Jonas Salk than the President of the United States. The real impact of these vaccines will ultimately be felt with the complete global eradication of poliomyelitis.

Poliovirus work has had a continuing significant impact on the field of molecular virology. Poliovirus was the first animal virus completely cloned and sequenced (169,262), the first RNA animal virus for which an infectious clone was constructed (261), and the first human virus that had its three-dimensional structure solved by x-ray crystallography (128). In 1989, Racaniello and colleagues (211) identified the poliovirus receptor (PVR), a finding that was followed by the generation of mice carrying PVR as a transgene (173,267).

Coxsackieviruses (group A) were first isolated during a poliomyelitis epidemic in 1948 from the feces of paralyzed children in Coxsackie, New York (70). These isolates were obtained by inoculation of suckling mice, the pathogenicity in mice clearly differentiating these viruses from poliovirus. In the following year, coxsackievirus group B was isolated from cases of aseptic meningitis (210). The original coxsackievirus group A isolates produced myositis with flaccid hind limb paralysis in newborn mice, whereas the group B coxsackieviruses produced a generalized infection in newborn mice, with myositis as well as involvement of the brain, pancreas, heart, and brown fat.

In 1951, echoviruses were first isolated from the stool of asymptomatic individuals (277). Echoviruses received their name because they were *e*nteric isolates, *c*ytopathogenic in tissue culture, isolated from *h*umans, and *o*rphans (i.e., unassociated with a known clinical disease). Subsequent studies have shown that echoviruses do, in fact, cause a variety of human diseases.

INFECTIOUS AGENTS

Physical and Chemical Properties

Enteroviruses are distinguished from other picornaviruses on the basis of physical properties, such as buoyant density in cesium chloride and stability in weak acid. Many aspects of enteroviral pathology, transmission, and general epidemiology are directly related to the biophysical properties and the cytolytic life cycle of these viruses. The infectious virus is relatively resistant to many common laboratory disinfectants, including 70% ethanol, isopropanol, dilute Lysol, and quaternary ammonium compounds. The virus is insensitive to lipid solvents, including ether and chloroform, and it is stable in many detergents at ambient temperature. Formaldehyde, gluteraldehyde, strong acid, sodium hypochlorite, and free residual chlorine inactivate enteroviruses. Concentration, pH, extraneous organic materials, and contact time affect the degree of inactivation by these compounds. Similar inactivation is achieved when virus is present on fomites, although conditions may not be exactly comparable (2). In general, most reagents that inactivate enteroviruses are dependent on active chemical modification of the virion, while most extractive solvents have no effect.

Enteroviruses are relatively thermostable but less so than hepatitis A virus. Most enteroviruses are readily inactivated at 42°C, although some sulfhydral reducing agents and magnesium cations can stabilize viruses so that they are relatively stable at 50°C (8,83). The process of thermal inactivation appears to involve several steps culminating in the irreversible

release of RNA from the altered virion particles. The relative sensitivity to modest elevations in temperature makes it possible to use pasteurization to inactivate enteroviruses in many biologically active preparations (124).

As with other infectious agents, ultraviolet light can be used to inactivate enteroviruses, particularly on surfaces. In addition, the process of drying on surfaces significantly reduces virus titers. The degree of virus loss by drying is related to porosity of the surfaces and the presence of organic material (1).

Many studies of enterovirus inactivation have been conducted using poliovirus as a model enterovirus. A report describing strain-specific differences for gluteraldehyde inactivation among echovirus 25 isolates, however, implies that the assumption that poliovirus is representative of all enteroviruses may not be valid (49). The inactivation of infectivity may not be directly related to the destruction of the viral genome, because the polymerase chain reaction can be used to amplify viral RNA even after inactivation of virus has occurred (193). This would suggest that reactivation of infectivity may be possible in some circumstances. In fact, some examples of recovered infectivity have been reported through increased multiplicity of infection in cell culture (301,345), but the practical significance of these observations is not clear.

Antigenic Characteristics

As described in Chapter 23, the picornaviruses are among the simplest RNA viruses, having a highly structured capsid with little place for elaboration. Yet, despite the limited genetic material and structural constraints, evolution within the picornaviruses has resulted in a very large number of readily distinguishable members. This variability has been categorized antigenically as serotype. Each of the serotypes correlates with the immunologic response of the human host, protection from disease, receptor usage, and, to a lesser extent, the spectrum of clinical disease. These correlations, however, have only a partial relationship with their naming scheme. This limitation is derived from the original classification of enteroviruses into polioviruses, coxsackie A or B viruses, and echoviruses, based on the specific human disease they cause (poliomyelitis), pathogenicity in suckling mice (coxsackieviruses), and growth in cell culture (echoviruses). Within each of these groups, isolates can be readily distinguished on the basis of antigenicity as measured with antisera raised in animals. Reference antisera are obtained through the World Health Organization, Geneva, or directly from the World Health Organization Collaborating Center Virus Reference and Research, Copenhagen, by prior arrangement.

These antigenic groupings, which define the serotypes, became more complicated as the number of different viruses increased. The distinction between serotypes also began to blur as isolates were discovered that were weakly antigenically related at a lower level to known serotypes. Despite these limitations, the serotype remains the single most important physical property that distinguishes the different enteroviruses. The prototype enterovirus strains are maintained in the American Type Culture collection, Rockville, Maryland, and in the World Health Organization Collaborating Reference Laboratories. A new classification scheme divides the members of the enterovirus genera into species, at least partly on the basis of genome organization and sequence similarity (see Table 1).

Although the classification system distinguishes enteroviruses on the basis of differences in antigenicity and mouse pathogenicity, the coxsackie B viruses and many of the echoviruses are genetically related to each other, as are the polioviruses and some of the coxsackie A viruses. In addition to the genetic relatedness, many enterovirus serotypes share some antigenicity. For example, polioviruses 1 and 2 share a common antigen, and antigenic relationships also exist between coxsackieviruses A3 and A8, A11 and A15, A13 and A18, A16 and enterovirus 71, and A24 and enterovirus 70, and between echoviruses 6 and 30, and 12 and 29. When virions are disrupted by heating, particularly in the presence of detergent, nonsurface antigens are exposed that are shared broadly among many enteroviruses (212).

In addition to the 64 prototype strains, antigenic variants exist for several enteroviruses. One type of antigenic variant is the prime strain, identified for many enteroviruses, including coxsackieviruses A17 and A24; echoviruses 1 to 6, 9, 11, 29, and 30; and enterovirus 70 (3,149,294). A prime strain is defined by the following properties relative to the prototype strain (294): reference antisera to the prototype strain neutralize the prime strain poorly, or not at all; antisera prepared to the prime strain neutralize the prime strain and the prototype strain equally well; the prototype and prime strains share complement-fixing antigens. A prime strain thus appears to elicit a broader spectrum of neutralizing antibodies, suggesting the presence of additional antigenic epitopes compared to its corresponding prototype strain.

A second type of antigenic variant, referred to as an intratypic variant, has also been identified for some of the enteroviruses, including coxsackieviruses A24, B1 to B4, B6; echoviruses 4, 9, and 33; and enterovirus 70 (4,198,293,309). Such variants generally have an antigenic spectrum that is different from (possibly narrower, and overlapping) their corresponding prototype strains, and thus cannot be classified as prime strains. The reference antisera and antisera prepared against the intratypic variant have a reciprocal, reduced neutralization activity with the heterologous strain compared to the homologous one.

The origin of prime and intratypic variant strains is speculative, but they may result from either antigenic drift or recombination. The specific epitope changes among these antigenic variants have not been described, and therefore the structural changes involved are not known. In addition, it is not understood why some serotypes have numerous prime strains, others have antigenic variants, and still others are antigenically homogeneous. It is possible that different serotypes have different degrees of structural constraint on their capsid and therefore have different capacities for antigenic variation.

Despite this lack of understanding of molecular variation in virus structure as measured by polyclonal antibodies, high-resolution studies of the virion surface have been particularly useful in identifying the targets of neutralization of enteroviruses by monoclonal antibodies (see later section Pathogenesis) (129,249). In addition, there are other antigenic sites that elicit immune responses that are not neutralizing. The observed structure of the antigenic sites explains why antigenicity of the virus is destroyed by disruption of the virion structure.

The poliovirus neutralizing antibody response is serotype specific, with the exception of some minor cross-reaction

between poliovirus 1 and 2. A monoclonal antibody has been described that reacts with this shared site that is not found on poliovirus type 3 (322). As noted, heat-disrupted virions, particularly those heated in the presence of detergent, induce antibodies that react with many enteroviruses. These broadly reacting antibodies are generally not neutralizing, and at least one of these epitopes has been mapped to the amino-terminal region of capsid protein VP1 (288). Antisera raised in animals to each of the enteroviruses are largely type specific and are used for the determination of serotype in a neutralization assay. The virus also contains more than one T-cell epitope, but the role of cell-mediated immunity in controlling infection is not well understood (see the section Pathogenesis).

Although there are measurable *in vitro* differences in antigenic properties among strains within a serotype, the biologic significance of these differences has not been determined. Several polioviruses isolated during outbreaks have demonstrated different antigenic properties when compared to the reference vaccine strains (113,146). In all cases, immunity derived from vaccination has been sufficient to provide protection and control of these strains (41). In addition, even in the face of massive immunization campaigns, no antigenic “escape mutants” resistant to neutralization have ever been observed, and successive genotypes of poliovirus have been eliminated. Natural antigenic variants have also been identified with panels of monoclonal antibodies for several nonpolio enteroviruses (116,251).

Propagation and Assay in Cell Culture

One of the prominent characteristics of enteroviruses is the cytolytic nature of growth in cell culture. For many years, poliovirus was the prototype of a lytic viral infection. At the microscopic level, infection is usually manifest within 1 to 7 days by the appearance of a characteristic cytopathic effect, which features visible rounding, shrinking, nuclear pyknosis, refractility, and cell degeneration (Fig. 1 and Fig. 2). The earliest effects may be seen in less than 24 hours if the inoculum contains a large number of infectious particles. With fewer numbers of virions, however, visible changes are not recognizable for several days, even though a sufficient number of cells are infected. In addition, some enteroviruses either do not cause cytopathic effect at all, or do so only after several passages. In general, once focal cytopathic effect is detected, there is rapid spread of infection throughout the cell sheet with total destruction of the monolayer, sometimes in a matter of hours (see Fig. 2). The nature of the cytopathic effect in various cell cultures is so characteristic that a cautious presumptive diagnosis of enterovirus infection can often be made at initial detection of cytopathic changes (see later section Diagnosis). However, some components of a sample inoculated onto cell cultures may produce cell toxicity in the first 24 hours, which may be confused with viral cytopathic effect. To distinguish toxicity from virus cytopathic effect, an additional passage can be performed so that toxic components of a specimen can be diluted; the passage will allow cells to maintain viability or, alternatively, for the virus to amplify and produce cytopathic effect.

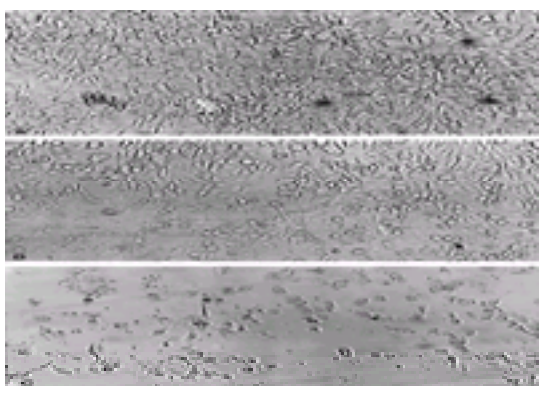

FIG. 1. Normal and poliovirus-infected monkey kidney cells in culture (cells neither fixed nor stained; ×150). **A:** Monolayer of normal unstained monkey kidney cells in culture. **B:** Unstained monkey kidney cell culture showing early stage of cytopathic effect typical of poliovirus infection. Approximately 25% of the cells in the culture show cytopathic effect (especially rounding) indicative of virus multiplication (1+ cytopathic effect score). **C:** Unstained monkey kidney culture illustrating more advanced cytopathic effect (3+ to 4+ cytopathic effect). Almost 100% of the cells are affected, and most of the cell sheet has come loose from the wall of the culture tube. (From ref. 207, with permission.)

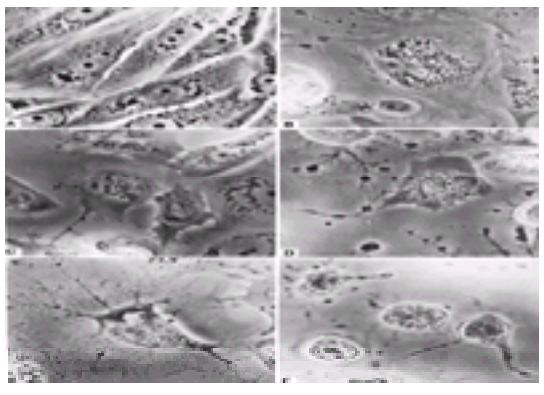

FIG. 2. Micrographs of living cells as seen in the phase microscope. Normal and poliovirus-infected monkey kidney epithelial cells in culture (×600). **A:** Normal monolayer, uninfected. **B:** Cell in early phase of infection with poliovirus type 1. In the cell in the center of the field, the nucleus is forced aside to the left edge of the cell by a clump of cytoplasmic material. **C:** Cells from the same culture at a slightly more advanced stage. The cells are beginning to pull away from each other. **D:** Another field of the culture at a more advanced stage. In the cell in the center of the field, the outlines of the nucleus are obscured by the paranuclear mass. Clear, filamentous areas are seen in the cytoplasm (*a*). They appear to arise in the central zone of the cytoplasm, and they constantly change their shape and location, moving toward the clear peripheral zone. The cell has lost contact with its neighbors and exhibits threadlike cytoplasmic extensions that contain dense swellings. **E:** Culture at a slightly more advanced stage. The cell has begun to round up, and large clear vacuoles (*V*) are seen in the upper left of the cytoplasm. The nucleus is masked by the cytoplasmic paranuclear mass

(*P*). **F:** Last stages of cytopathic degeneration induced by poliovirus. (From ref. 201, with permission.)

Viruses may be quantified and the cytopathic effect visualized by plaque formation on cell cultures under an agar overlay. Poliovirus plaques are very characteristic, with sharply defined, circular, clear-centered holes. Coxsackievirus B plaques may appear more slowly and do not have distinct edges. Coxsackievirus A plaques, when present, are variable in appearance. The speed at which plaques appear is often an intrinsic property of a specific serotype and cell culture type, and some viruses that form plaques readily on one cell culture line will not form recognizable plaques on another.

All known enteroviruses can be propagated in cell culture or in suckling mice. Most of the serotypes can be grown in at least one or more human or primate continuous cell cultures. No cell line, however, is able to support the growth of all cultivable enteroviruses. Even after many years of experimentation, a few serotypes (e.g., coxsackievirus A1) can be propagated only in suckling mice. The typical host range of human enteroviruses in cell cultures or animals is shown in a broad, generalized way in Table 2.

Virus	Antigenic types[a]	Cytopathic effect: Monkey kidney tissue culture	Cytopathic effect: Human tissue culture	Illness and pathology: Sucking mouse	Illness and pathology: Monkey
Polioviruses	1-3	+	+	−	+
Coxsackieviruses, group A	1-24[b]	±	±	+	−
Coxsackieviruses, group B	1-6	+	+	+	−
Echoviruses	1-34[c]	+	±	−	−
Enteroviruses	68-71	+	+	−	−

[a] Many enterovirus strains have been isolated that do not conform to these categories.
[b] New types, beginning with type 68, are now assigned enterovirus type numbers instead of coxsackievirus or echovirus numbers. Types 68–71 have been identified.
[c] Type 23 has been found to be the same as echovirus 9.
Echovirus 8 was determined to be the same serotype as echovirus 1; echovirus 10 has been reclassified as a reovirus type 1; echoviruses 22 and 23 as parechoviruses types 1 and 2; echovirus 28 as human rhinovirus 1A; and echovirus 34 as coxsackievirus A24.
Source: Adapted from refs. 51 and 227.

TABLE 2. *Usual host range of human enteroviruses: animal and tissue culture spectrum*[a]

Infection of target cells depends on viruses binding to specific receptors on the cell surface. Collectively, the enteroviruses use a large number of different receptors. These have been identified for numerous serotypes, and included PVR, decay accelerating factor, and intercellular adhesion molecule 1 (which is also used by some human rhinoviruses). At this time, however, there is no clearly recognizable pattern determining which serotypes use which receptors. In some cases, a single receptor seems to be used by a relatively well defined subset of the serotypes. For example, the three serotypes of poliovirus are the only enteroviruses that can use the PVR to infect cells. The coxsackie B viruses can use the coxsackievirus and adenovirus receptor (177). Some serotypes, however, are clearly able to use more than one receptor, whereas some individual isolates within a serotype may not be able to use the same receptor as the prototype strain for that serotype (31). Furthermore, even though an identified receptor is required for attachment to the target cell, another protein may be required for entry into the cell (299). Although a theoretical possibility, it has not been demonstrated that viruses are able to readily adapt receptor usage to that of a related virus. For example, even at high multiplicity, it is not possible to select mutants of coxsackie A viruses closely related to polioviruses that will use the PVR to infect cells. Nevertheless, the multiplicity of receptors within the enterovirus genus implies that on an evolutionary time scale viruses must be able to modify receptor usage. The structural correlates related to receptor binding are under active investigation.

A practical adaptation of the identification and genetic cloning of enterovirus receptors is the introduction of the receptor into animals and cells that do not normally permit virus infection. This approach has resulted both in advances in understanding the pathogenesis of poliovirus infection in a nonprimate animal model system, and in its practical application in the diagnostic laboratory. The L20B cells, which are murine cells that express PVR, are now used routinely to selectively isolate poliovirus (see the later section Diagnosis) as part of the global poliovirus laboratory network supporting the poliomyelitis eradication initiative (253).

Infection in Experimental Animals, Host Range

Man is the natural host for all human enteroviruses. Although serologically distinct picornaviruses with the same physical properties as enteroviruses have been found in many animals, human beings do not usually have recognizable infections with these animal enteroviruses. On the other hand, some animals are susceptible to experimental infection with human enteroviruses. These include nonhuman primates and PVR transgenic mice for polioviruses, mice and some monkeys for coxsackieviruses A and B, and monkeys for echoviruses. Human enterovirus infection of nonhuman primates appears to be largely subclinical, perhaps related to the homology that several simian enteroviruses share with human viruses (257). Among higher primates, chimpanzees and gorillas appear to be able to acquire poliovirus infection and develop disease from humans through natural exposure (84). At least one human enterovirus, coxsackievirus B5, is closely related antigenically to the porcine enterovirus causing swine vesicular disease, with about 50% genetic homology. Genetic studies of a number of strains of swine vesicular disease virus and epidemiologic information gleaned from outbreaks strongly suggest that a human coxsackievirus B5 was specifically introduced into swine several decades ago (349).

Even though most coxsackie A viruses have been successfully grown in various cell culture systems, isolation from clinical specimens is sometimes unsuccessful, necessitating the inoculation of suckling mice. Inoculation of suckling mice and subsequent virus identification is a process analogous to that of cell culture inoculation. The two groups of coxsackieviruses can be distinguished by the distinct pathology that they cause in mice (Fig. 3 and Fig. 4). With

coxsackievirus A infection, newborn mice develop flaccid paralysis and severe, extensive degeneration of skeletal muscle (sparing the tongue, heart, and CNS), and they may have renal lesions. Death usually occurs within a week. Coxsackievirus B infection proceeds more slowly and is characterized by spastic paralysis and tremors associated with encephalomyelitis, focal myositis, necrosis of brown fat pads, myocarditis, hepatitis, and acinar cell pancreatitis. Echoviruses, except for some isolates of echovirus type 9, do not generally cause disease in mice. A blind passage in mice may be necessary if the amount of coxsackievirus is very low, or possibly because passage of the virus is needed for it to adapt to growth in mice. Once a virus is growing in suckling mice, the specific enterovirus type can be identified by serum pool neutralizations in other litters of suckling mice, analogous to the process in cell culture (see section Diagnosis).

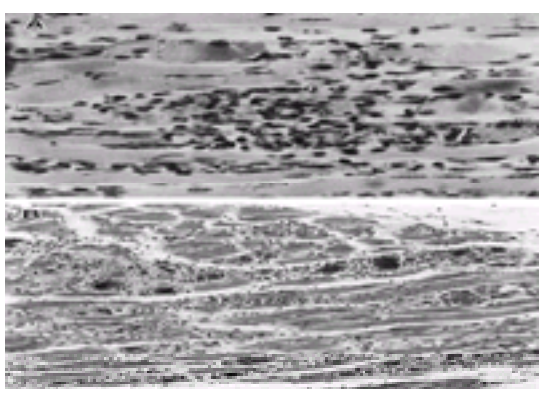

FIG. 3. Photomicrographs of lesions of striated muscle in suckling mice infected with coxsackieviruses. **A:** Two sarcolemmic tubes with numerous mononuclear phagocytes and remnants of hyaline material within the sarcolemmic sheaths. Acute stage of infection with Conn-5 strain, prototype of coxsackievirus B1 (×450). **B:** Partly mineralized residual masses surrounded by fibrous capsules, and sometimes by giant cells. The remainder of the muscle is completely restored. Texas-1 strain of coxsackievirus A4, 11 days after onset of paralysis (×180). (From ref. 207, with permission.)

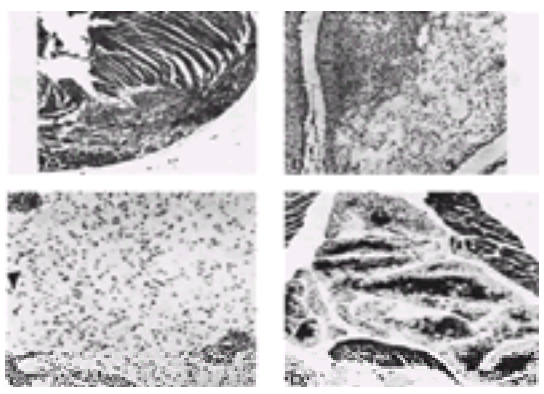

FIG. 4. Photomicrographs of lesions in heart, brain, and fat lobules of suckling mice in acute stage of infection with Conn-5 strain of coxsackievirus B1 (90). **A:** Heart. Large zone of myocardial necrosis at apex of left ventricle (×170). **B:** Brain. Rarefaction after necrosis in cerebrum (×140). **C:** Brain. Encephalitis showing marked perivascular cuffing and leptomeningitis (×190). **D:** Fat lobes. Interlobular edema and acute necrotizing steatitis, illustrating the selective destruction of the peripheral parts of the lobules [shown as pale margins, with preservation of the central parts (dark fuchsinophilic areas)] (×72). (From ref. 207, with permission.)

PATHOGENESIS

Entry, Site of Primary Replication, and Spread

It is appropriate to discuss the pathogenesis of poliovirus as a prototype for enteroviruses that enter the body via the oral route, as it is presumed that the general principals governing poliovirus pathogenesis will also be in effect with respect to nonpolio enteroviruses. However, some enteroviruses have other routes of infection, which may be associated with distinctive disease phenotypes. For example, coxsackievirus A21, a major enteroviral cause of respiratory infections, spreads via the intranasal or aerosol route through contaminated respiratory secretions, which can contain infectious virus. In addition, enterovirus 70, a cause of acute hemorrhagic conjunctivitis, spreads either directly through ocular and respiratory secretions or indirectly through contaminated items.

A discussion of the pathogenesis of poliomyelitis has benefited from study of the natural disease in humans, experimental disease in nonhuman primates, and experimental disease in mice that carry PVR as a transgene (77). Intracerebral inoculation of these transgenic mice with any of the three serotypes of poliovirus leads to a clinicopathologic syndrome similar to human paralytic poliomyelitis. The insensitivity of these mice to oral inoculation (see the section Animal Models, Poliovirus) may be one reason that many questions still remain about the pathogenesis of poliomyelitis.

The patterns of virus shedding and routes of transmission for polioviruses are similar to those seen for other enteroviruses. Poliovirus is resistant to the acidity of the stomach, making the small bowel a suitable milieu for viral replication following ingestion of the virus. Poliovirus is very efficient in establishing infection, and as few as 100 tissue

culture 50% infective doses ($TCID_{50}$) can infect an infant by the oral route (216). Fecal shedding of virus occurs for a prolonged period of time, sometimes for more than 6 weeks. Shedding may be intermittent and is affected by the immune status of the individual; the quantity and duration of virus shedding may be significantly reduced as a result of immunity from a prior natural infection with wild poliovirus, vaccination with oral poliovirus vaccine or the enhanced inactivated poliovirus vaccine, or because of competing enteric infections. Virus can be recovered from throat swabs and washings during the early acute phases of infection, but secretion of virus in saliva occurs for a much shorter time than fecal shedding. It is likely that person-to-person spread was the principal mode of transmission during an outbreak of poliomyelitis in Finland in 1984 involving an estimated 100,000 people during a 1-month period, because freezing during this winter month allowed little opportunity for significant fecal-oral transmission through exposure to contaminated surface or drinking water.

Poliovirus is thought to multiply initially in mucosal tissue, specifically Peyer's patches and the tonsils (Fig. 5); replication in these sites is usually detectable within 1 to 3 days. Virus then multiplies in deep cervical and mesenteric lymph nodes, leading to a “minor” viremia with subsequent invasion of systemic reticuloendothelial tissues, including lymph nodes, bone marrow, liver, and spleen. The CNS can be invaded at this stage, but CNS disease is more likely to occur after amplification in the systemic reticuloendothelial tissues followed by a subsequent “major” viremia. Most individuals infected with poliovirus or other enteroviruses control infection prior to the major viremia, resulting in an asymptomatic infection.

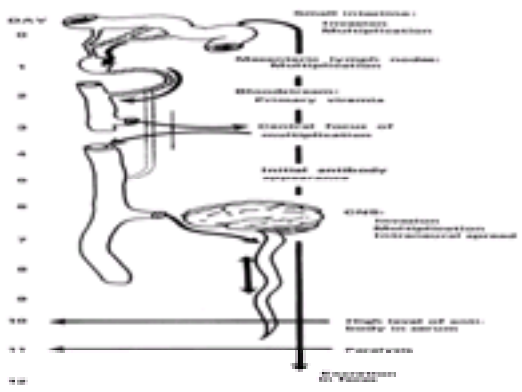

FIG. 5. This schematic illustration represents a longstanding view of the pathogenesis of poliovirus. Note that additional data emphasize the importance of retrograde axonal flow of virus into the central nervous system. Virus enters by way of the alimentary tract and multiplies locally at the initial sites of virus implantation (tonsils, Peyer's patch) or the lymph nodes that drain these tissues, and virus begins to appear in the throat and in the feces—leading to virus shedding into the environment. At this time, it is possible that virus may spread to the CNS by peripheral or cranial nerve axonal flow. Secondary virus spread occurs by way of the bloodstream to other susceptible tissues—namely, other lymph nodes, brown fat, muscle, and the CNS. Virus can then also spread into the CNS at this time by means of peripheral or cranial nerve retrograde axonal flow—for example, from muscle. If a high level of virus replication occurs within the CNS, motor neurons die and paralysis ensues. (Modified from Fenner by Melnick in ref. 207, and used with permission.)

There has been a longstanding controversy concerning the means by which poliomyelitis enters the CNS. The fact that paralytic poliomyelitis follows a viremia and that circulating neutralizing antibodies can prevent poliomyelitis clearly supports the importance of viremia in CNS spread (232). Although viremia appears critical for the delivery of virus into the CNS, a number of epidemiologic findings and experimental studies (see later) suggest that poliovirus is also capable of spreading into the CNS via peripheral or cranial nerves, presumably by retrograde axonal flow.

The importance of the peripheral nerve as a potential route for CNS invasion has been tragically demonstrated in the Cutter's vaccine incident, as well as by “provocation poliomyelitis” (307). In the Cutter's incident, intramuscular injections of incompletely inactivated poliovirus vaccine led to paralytic disease that tended to be initially localized to the extremity that had received the injection (233). Provocation poliomyelitis refers to an increased risk of paralytic disease in individuals who receive intramuscular injections during the incubation period of natural poliovirus infection. The term was more recently used for a situation in which intramuscular injections affected the outcome of vaccination with attenuated oral poliovirus vaccine (rather than affecting the outcome of natural poliovirus infection) (307). It is presumed that the intramuscular injection allowed the vaccine strain to gain entry into the peripheral nerve endings and then to spread to the spinal cord by retrograde axonal flow; however, it remains possible that the injection increased vascular permeability of the muscle to the virus, enhancing the viremia, with a subsequent blood-borne local spread into the spinal cord region that innervated the injected limb. It is likely that a situation resembling provocation poliomyelitis may underlie the finding that more severe paralytic disease and an increased incidence of bulbar poliomyelitis are associated with performance of a tonsillectomy during the incubation period of poliovirus infection; it may be that the tonsillectomy fosters entry of the virus into the brainstem via a cranial nerve (in contrast to entry into the spinal cord via a peripheral nerve in provocation poliomyelitis).

The possibility of virus spread by a peripheral nerve initially gained xperimental support from studies in nonhuman primates performed by Nathanson and Bodian (231) and others. More recent investigations of this issue have been carried out in PVR transgenic mice. In an attempt to reproduce the phenomenon of provocation poliomyelitis, PVR transgenic mice received an intramuscular injection at the same time as receiving poliovirus intravenously (111). These mice developed paralysis initially localized to the limb that received the intramuscular injections. This localization was not seen if there was an ipsilateral sciatic nerve block, demonstrating the critical role for retrograde axonal flow in this model system. The intramuscular injection caused an increase in poliovirus replication, presumably the result of an up-regulation of the human PVR or an increase in invading inflammatory cells susceptible to the infection.

Studies of Ren and Racaniello (268) and Ohka and colleague (242) have demonstrated that poliovirus can indeed spread into the CNS of PVR transgenic mice by retrograde axonal flow following virus inoculation of an extremity. Transection of the sciatic nerve before inoculation and within 4 hours after inoculation prevented paralysis (242). Poliovirus antigen as well as 160S intact viral particles were detected in the axons of the sciatic nerve, demonstrating that virions were being transported in the peripheral nerve following inoculation of the hindlimb.

The preceding data suggest that poliovirus is capable of entering the CNS following muscle infection via retrograde axonal flow. It is not unlikely that this occurs to some extent following the natural (oral) route of poliovirus infection, as studies have shown a low level of infectious virus in muscle following oral administration of virus to PVR transgenic mice (236) and chimpanzees (37). In addition, it is possible that following ingestion poliovirus also spreads from the intestines to the brainstem via the vagal nerve by means of retrograde axonal flow, as shown for reovirus (226). Axonal flow may also be important in association with the viremia. It is possible that viremia seeds muscle, which then leads to spread of the virus into the CNS via the axon. Recent data generated from PVR transgenic mice indicate that poliovirus is efficiently delivered across the blood–brain barrier (338), a further piece of evidence suggesting that the most common natural route of entry into the CNS is by the blood. In summary, viremia is important in the spread of poliovirus into the CNS, but it is likely that other means of virus spread, such as axonal flow, are also involved.

Cell and Tissue Tropism

An unexplained feature of poliovirus pathogenesis is the selective vulnerability of the motor neuron to poliovirus infection. Although the expression of PVR influences the distribution of poliovirus infection [e.g., glial cells do not express PVR and are not infected by poliovirus (77,236,338)], there appears to be a very imperfect correlation between PVR expression in a particular tissue and the distribution of virus in that tissue following intracerebral and intravenous inoculation. For example, there are higher levels of PVR expressed in human liver, lung, and heart than in the brain, despite the fact that these visceral tissues are not normally thought to be infected following poliovirus infection (236). Further cellular localization of specific spliced forms of PVR using appropriate probes or monoclonal antibodies may clarify these issues. The findings to date indicate that other factors besides PVR play an important role in determining the distribution of viral infectivity (77,338). Additional determinants of the tissue and cellular distribution of poliovirus (and of other enteroviruses) include the route of inoculation, host tissue- and cell-specific factors, and viral genomic elements. Regions of the poliovirus capsid proteins that interact with the cellular receptor can also affect tropism. In addition, elements in the viral genome that influence the efficiency of translation initiation or replication affect virus growth in specific cells. The internal ribosome entry site, a part of the viral 5' untranslated region that affects the efficiency of translation initiation, has a key role in neurovirulence (110): cell-specific factors bind to the internal ribosome entry site, affect the efficiency of translation initiation, and can therefore influence tropism and virulence (see the Virulence section later).

Immune Response

B-Cell Response

The efficacy of the immune response is key to the outcome of enteroviral infections. The humoral immune response in enteroviral infections is especially important for protection and life-long immunity. For example, a high level of poliovirus neutralizing antibody response following natural infection or vaccination protects against disease, although infection of the gut can occur—that is, there is no “sterilizing immunity.” The importance of the humoral immune response in enteroviral infections is demonstrated by the occurrence of persistent enterovirus infections in agammaglobulinemics (see the Meningitis and Encephalitis section), and in the increased susceptibility to enteroviral infection as well as the increased severity of enteroviral disease among neonates and infants (see Neonatal and Infant Disease in the section Clinical Features).

The neutralizing antibody response against poliovirus has been characterized by generating neutralizing monoclonal antibodies, then growing virus in the presence of the antibody to produce monoclonal antibody-resistant virus, and finally identifying the neutralizing epitope for the virus by sequencing the coding region for the capsid proteins of the virus. The neutralization sites are generally nonsequential conformational antigenic sites that correspond to exposed loops of the capsid proteins rising from the surface of the virions (128); some regions that are internally located in the native virion, however, can also function as neutralization sites (280). Using this approach, a limited number of major neutralizing antibody sites have generally been found in the case of poliovirus type 1: the BC loop of VP1; a complex site including residues 220 to 222 from VP1 (site 2a) and residues 169 and 170 and others of VP2 (site 2b); a complex site including residues 286 to 290 from VP1 (site 3a); and residues 58 and 59 and others on VP3 (site 3b) (214). Although only a limited number of studies have been performed to identify neutralization sites of nonpolio enteroviruses, the results have suggested similarities in the location of their antigenic sites to those found with poliovirus.

Results from investigations of enterovirus neutralizing monoclonal antibodies may not be easily extrapolated to answer questions related to neutralizing sites for polyclonal antibodies in human serum. Responses in humans may differ from those seen in inbred mice, and they may vary from one person to another. Another potential shortcoming of studies with poliovirus neutralizing monoclonal antibodies is that these antibodies have been raised against capsid proteins. Therefore, it has not been possible to identify neutralizing antibodies that are directed against nonstructural proteins, if they exist. Last, it is uncertain how well *in vitro* neutralization of poliovirus by monoclonal antibodies corresponds to protection from natural disease.

T-Cell Response

There are several ways in which T cells may lead to protection and immunity from enterovirus infection. T cells may have a role in providing help for the B-cell humoral immune response, which, as just noted, plays a critical role in the clearance of enteroviruses. In addition, cytolytic T cells may clear the virus directly by causing lysis of virus-infected cells or by means of cytokine release. Infecting mice that have varied mutations in their genetic background has further delineated

the importance of different arms of the immune response in clearance of enteroviruses and in enterovirus-induced disease.

Although the T-cell response is believed important in the clearance of many viruses, it has been investigated to only a limited extent in the case of human enterovirus infections. In one study of peripheral blood lymphocytes from humans vaccinated against poliovirus, T-cell epitopes were found in a region between VP1 amino acids 161 and 221, and another between VP1 244 and 264 (306). Other investigations have made use of mice immunized with inactivated poliovirus (180) or with Sabin vaccine strains (197).

To further clarify the correlates of immunity in the case of poliovirus, experiments were conducted in PVR transgenic mice (197). T cells were established from spleens of the transgenic mice infected with neurovirulent poliovirus type 3 Leon strain or from normal BALB/c mice immunized with attenuated Sabin type 3 vaccine strain. The primary cytokines secreted by the clones were typical of those found with helper T-cell subtype 1 (Th1). Adoptive transfer of the Th1 clone along with primed B cells was necessary for protection against poliovirus challenge, demonstrating the importance of antibody production by these B cells in virus protection. The findings of this study were surprising considering the generally held beliefs that secretory IgA is critical for gut immunity, and that Th2-type cells are responsible for providing help for IgA antibody production. A potential explanation for the findings may be that the transgenic mice were challenged by the intravenous rather than the more natural oral route. In other words, it may be that the more natural oral challenge would have generated Th2 rather than Th1-type cells.

In studies of coxsackievirus B3 infection of C3H/HeJ mice, Beck and colleagues (28) identified a shared T-cell epitope present in a number of enteroviruses as well as a comovirus. The results suggested that this epitope was present in a nonstructural protein, 2C. Infection of C3H/HeJ (H-2k) with coxsackievirus B3 showed that structural proteins, as expected, also contain T-cell epitopes (21).

Immunopathology

Although the B- and T-cell response in enterovirus infections has a role in virus clearance, there are indications that it may also lead to disease. There are several reasons for considering a role for immunopathology in some enterovirus-induced diseases: (a) the enterovirus-induced diseases have inflammatory pathology; (b) the experimental animal models for these enterovirus-induced diseases demonstrate the importance of genetic susceptibility in their causation, and the efficacy of treatment with immunosuppressive drugs; and (c) the enterovirus-induced diseases are related to human diseases that are considered to have an autoimmune contribution. An immune-mediated disease process has been most vigorously proposed in the case of enterovirus-induced chronic dilated cardiomyopathy lesions, chronic myositis, and diabetes.

A role for both molecular mimicry and bystander damage has been proposed in virus-induced autoimmune disease. In the former, an immune response directed against the virus cross-reacts with a cellular protein and causes disease. In the case of bystander damage, a virus up-regulates nonspecific immune responses that lead to pathology. Recent data regarding coxsackievirus-induced insulin-dependent diabetes mellitus and coxsackievirus-induced myocarditis suggest the importance of bystander damage rather than molecular mimicry (see later section Diabetes) (134,135). The activation of autoreactive resting T cells could be induced by cytokines or other factors, such as the release of self-antigen (134). The presence of proinflammatory cytokines would then activate Th1 cells or macrophages that foster immunopathology. Once damage occurs, new cellular epitopes that are not normally exposed and that are antigenic may trigger additional reactive epitopes, a process called epitope spreading.

Cardiac Disease

The evidence for enterovirus infection as an etiology for human acute and chronic cardiac disease is summarized in the section Clinical Features: Cardiac Disease . Most of the investigations related to a possible immune contribution to these cardiac diseases have been explored in experimental model systems, especially related to coxsackievirus B3 infection. Coxsackievirus B3 produces an experimental acute myocarditis that can progress to chronic dilated cardiomyopathy in particular susceptible mouse strains. As discussed later, the pathogenesis of experimental cardiac lesions induced by coxsackievirus B3 is complicated and controversial (140), with evidence that direct viral lysis as well as the immune system contribute to pathology.

Studies with mice that have severe combined immunodeficiency disease, which are susceptible to myocardiopathy, have emphasized the importance of direct viral lysis as a cause for cardiac tissue damage (55). It may be, however, that one cannot extrapolate the results obtained from immunocompromised mice to immunocompetent animals, and that disease pathogenesis varies depending on the intactness of the immune system (i.e., a direct viral lytic infection may be more important as a cause for cardiac lesions in immunocompromised than in normal mice).

In mouse strains that develop chronic myocarditis, coxsackievirus B3 RNA persists in the infected heart (and can be detected by *in situ* hybridization) in the absence of infectious virus (170). This persistent viral infection may trigger an immune response that can foster the disease (142). Some investigators have suggested that the immune system may be important because of antigenic mimicry, a situation in which the immune response against the virus cross-reacts with the heart. The possibility of a cross-reactive autoantigen is of interest because immunization with cardiac myosin induces an autoimmune myocarditis in mice (234). Studies have reported that monoclonal antibodies that neutralize coxsackievirus bind to heart muscle (63), and that adoptive transfer of similar antibodies leads to myocarditis (95). Similarly, T-cell hybridomas derived from the hearts of coxsackievirus B–infected mice respond to cardiac myosin as well as to the virus (296). On the other hand, a recent study failed to find support for a role for molecular mimicry in coxsackievirus B3–induced myocarditis (135). These investigators found that heart disease did not develop in transgenic mice that express interferon-g in their pancreatic cells (and therefore have a low level of virus replication in the heart), even though the animals generated a similar immune response to that seen in nontransgenic; they concluded that the immune system's involvement depends on damage to the heart by the virus. A role of T-cell inflammation in the development of

disease is supported by studies that demonstrate that knock-out of a chemokine, monocyte chemoattractant protein-1 (MIP-1a), interferes with the development of coxsackievirus-induced myocarditis (60).

Studies have suggested that there is a differing immunopathogenesis of disease depending on the genetics of the host (141). A recent study using A/J mice demonstrated a decrease in mortality and cardiac tissue inflammation in mice that lacked both CD4+ and CD8+ T cells, but not an absence of either CD4+ or CD8+ T cells alone (246). In other strains of mice, the CD8+ T-cell response rather than the CD4+ T-cell response appears to play a pathogenic role, whereas in still others, the CD8+ T-cell response has a protective role (122). DBA/2 mice infected with coxsackievirus B3 develop an anti-heart IgG antibody response associated with the myocarditis, whereas CD8+ T cells appear important in the pathogenesis of myocarditis in BALB/c mice; the differences seen following infection of BALB/c mice versus DBA/2 may have resulted from the fact that Th1 cells are preferentially activated in the case of BALB/c mice (providing helper activity for CD8+ cytolytic T cells), whereas Th2 cells are activated in the case of DBA/2 mice (inducing cytokines that lead to B-cell activation) (296). Another possible reason that humoral factors do not seem as pathogenic in BALB/c mice as in DBA/2 mice may be that BALB/c mice have significantly less myosin in their cardiac extracellular matrix—that is, there is a genetically determined decrease in target organ antigen (186).

As Schwimmbeck notes, “Despite the demonstration of autoimmune phenomena in patients with myocarditis and dilated cardiomyopathy, there is no proof of the autoimmune pathogenesis of these diseases” (296). It is clear that the role of the immune system in enterovirus-induced cardiac disease is complex and poorly understood, and that more studies are needed to clarify this subject. Disease is also influenced by host genetic (143) and cardiovirulent genetic determinants of the coxsackievirus strain and of the particular isolate (319) (see later section Coxsackievirus and Myocarditis). Recent studies have also suggested a role for apoptosis during enterovirus infection (123,339).

Inflammatory Muscle Disease

The immune system is believed to play a role in the inflammatory myopathies (see later section Clinical Features), and CD8+ T cells, CD4+ T cells, cytokines, and autoantibodies have been implicated in their pathogenesis (185). Some investigations have focused attention on experimental infections with the Tucson strain of Coxsackievirus B1, because it can produce a chronic form of muscle disease following intraperitoneal inoculation of certain mouse strains. Interestingly, the disease progresses despite the disappearance of infectious virus from muscle by 2 to 4 weeks after inoculation (312). In some cases, viral RNA persists for as long as a year after infection. A recent study reports evidence of viral double-stranded RNA, perhaps increasing stability and fostering persistence of the viral genome (313). A role for the immune system and especially T cells has been proposed but remains incompletely delineated.

Diabetes

Coxsackievirus B4 has been isolated from rare cases of fatal diabetes in humans (271). In addition, certain strains of this virus induce a pancreatitis and islitis in particular strains of mice (297). Viral RNA can persist for months in the pancreas in the absence of infectious virus or viral protein antigen. Islet cell inflammation and diabetes generally continue in these mice for over a year. These observations suggest that experimentally induced diabetes is caused by a persistent restricted viral infection with a contribution from the immune system to the disease process. The mechanisms involved in the pathogenesis of this experimental coxsackievirus-induced diabetes mellitus and its relationship to human insulin-dependent diabetes mellitus remain unclear.

An intriguing finding related to insulin-dependent diabetes mellitus is the sequence similarity between coxsackievirus B protein 2C and glutamic acid decarboxylase (GAD_{65}) (159), which is expressed in the pancreas and CNS. Antibody to GAD_{65} is associated with insulin-dependent diabetes mellitus (and with a rare neuromuscular disease called the stiff-man syndrome). The appearance of antibodies to GAD_{65}, as well as to islet cells and insulin, frequently precedes the onset of human diabetes. In addition, recent studies in transgenic mice suggest that there is a correlation between GAD_{65} expression and the development of diabetes in the nonobese diabetic (NOD) mouse, which is a genetically determined, immune-mediated mouse model of diabetes (344). These results raise the possibility that coxsackievirus infection leads to an immune response against 2C that cross-reacts with GAD_{65} and induces diabetes through a mechanism of molecular mimicry. A cross-reactivity between protein 2C and GAD_{65}, however, has not been consistently found (275), and some investigators have found that the immunodominant T-cell epitope is in a region of GAD_{65} that is distinct from the one with 2C sequence homology (191). In summary, although the proposal that antigenic mimicry between GAD_{65} and protein 2C is an intriguing one, its importance in the pathogenesis of insulin-dependent diabetes mellitus remains unproven.

A recent report demonstrating the complicated role of enteroviruses in diabetes mellitus favors a role for bystander damage rather than molecular mimicry. This study involves the use of BDC2.5 mice, which carry a transgene encoding a diabetogenic T-cell receptor specific to an islet granule antigen that is distinct from GAD_{65} and does not cross-react with coxsackievirus B4 (134). Inoculation of this mouse with coxsackievirus B4 led to the rapid development of diabetes mellitus. The infected BDC2.5 mice were found to have infiltration of the islet cells with lymphocytes carrying the transgenic T-cell receptor, even though the target cell for this virus is the exocrine pancreas and not the islet cells. It is presumed that this acceleration of diabetes is caused by bystander cells that respond to the release of proinflammatory cytokines, leading to activation of T cells that destroy the islet cells. Molecular mimicry did not seem involved in disease pathogenesis because coxsackievirus B4 virus failed to accelerate the development of insulin-dependent diabetes mellitus in the infected NOD mouse despite the known cross-reactivity of GAD_{65} with the coxsackieviral 2C protein; in addition, there was no increase in T-cell reactivity against GAD_{65} in splenocytes from these mice. The results suggest that enteroviral infections involving the pancreas (or other organs) may provide an environmental trigger that induces autoimmune disease in genetically susceptible animals. The implications of this study are that cytokines or islet cell antigens were released during the infection, causing activation of resting islet-specific memory lymphocytes through bystander mechanisms. These observations may have relevance to the human situation, where coxsackievirus infections of the pancreas could activate autoreactive T cells leading to insulitis and diabetes mellitus. Other transgenic mouse studies have also demonstrated complex and variable requirements during the development of experimental

insulin-dependent diabetes mellitus (324).

Animal Models

Poliovirus

Nonadapted poliovirus infects only primates, at least partly related to the presence of PVR in primates and not in other species. Studies of poliovirus neurovirulence that have made use of nonhuman primates have been limited by the relatively small number of animals that can be used as a result of ethical and financial concerns. The Lansing strain of poliovirus type 2 was adapted to mice to circumvent these difficulties; however, this mouse-adapted strain of poliovirus binds by a receptor that is not yet identified and is distinct from PVR. Of greater importance in the study of poliovirus disease pathogenesis is the PVR transgenic mice.

The use of PVR transgenic mice to study human poliovirus infection has been extraordinarily valuable. However, as in all animal models, infections in these mice are not a perfect model for the human disease. The mice are not as sensitive as humans to poliovirus infection by the oral route (173). Therefore, investigations of disease pathogenesis in PVR transgenic mice have generally involved routes of infection distinct from that seen with human poliomyelitis. This shortcoming is probably not secondary to the low expression of the PVR in intestinal epithelial cells, because transgenic mice that carry a promoter for rat intestine fatty acid binding protein to direct expression of PVR fail to have a more efficient gastrointestinal infection or an increase in the virus titer in feces after oral challenge (350). There are also differences between mice and humans in the organization of the CNS, including the motor pathways, which are likely to influence the character and development of the paralytic disease.

Nonpolio Enteroviruses

There are several examples of experimental models of nonpolio enterovirus infections. Although coxsackieviruses can cause a myocarditis in many species, including monkeys, the best-studied experimental enterovirus-induced acute and chronic heart disease is caused by coxsackievirus B3 infection in mice (see previous section Immunopathology: Cardiac Disease).

Strains of coxsackievirus A and B and echovirus cause myositis in mice (88). One of the best-studied experimental models of myositis is infection of mice with the Tucson strain of coxsackievirus B1 (see previous section Immunopathology: Diabetes).

A number of enteroviruses can infect the acinar cells of the pancreas in mice, but only a select group of enteroviruses infect the islet cells and produce diabetes. The latter group includes several members of coxsackievirus B group following passage in the pancreas of mice or in mouse beta cell cultures (317). Most experimental studies of enterovirus-induced diabetes have made use of the E2 strain of coxsackievirus B4. The latter virus produces an acute pancreatic infection with islet cell inflammation and necrosis in certain strains of mice (297). Some investigators have studied the NOD mouse following infection with coxsackievirus (see previous section Immunopathology: Diabetes) (324).

Both enteroviruses 70 and 71 can produce paralytic disease in monkeys (117). These experimental animals may be important in identifying virulence determinants and also in vaccine studies.

Virulence

Poliovirus and Neurovirulence

The molecular basis for viral determinants of neurovirulence is a topic of great interest, especially in the case of poliovirus. This subject has been best studied for poliovirus, at least partly because of the availability of well-characterized attenuated vaccine strains of poliovirus generated by Sabin.

Sabin developed attenuated vaccine strains for all three poliovirus serotypes through passage of virus in animals and in cell culture, with the concomitant assessment of the neurovirulence potential of the passed virus following inoculation of nonhuman primates. These vaccine strains grow well in tissue culture but poorly in the CNS of monkeys, which is presumably the reason that they are attenuated. The vaccines are inoculated into monkeys to assess their neurovirulence and ensure that they are sufficiently attenuated (Fig. 6).

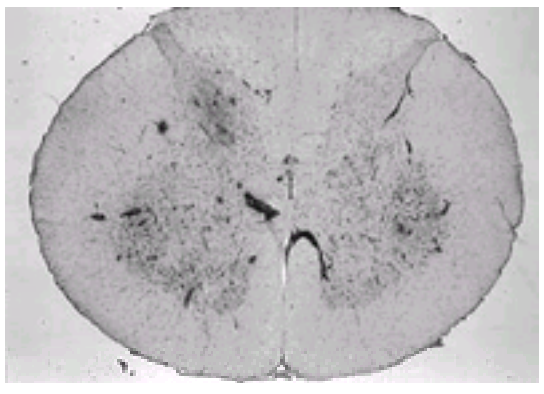

FIG. 6. Section of rhesus monkey spinal cord 17 days after inoculation with poliovirus type-3 in the anterior lumbar cord. There was evidence of hemorrhage and neuronal degeneration in the gray matter. (Courtesy of Dr. Philip J. Snoy, Center for Biologics Evaluation and Research, Food and Drug Administration.)

Despite the excellent safety record of Sabin oral poliovirus vaccine, vaccine-associated paralytic poliomyelitis occurs, albeit infrequently. Most of the cases have occurred after the first dose of the oral vaccine. The overall frequency of cases associated with the first dose of vaccine was reported as one case per 520,000. Of 105 cases of vaccine-associated poliomyelitis that occurred in the United States from 1973 through 1984, 14 occurred in immunocompromised individuals; 35 cases occurred in vaccinees, 50 in contacts of the vaccinees, and 6 in people with no apparent history of vaccination or exposure to vaccines (235).

Individuals with humoral immunodeficiencies have an increased risk of developing poliomyelitis, and therefore oral poliovirus vaccination of this group is contraindicated. These patients are unable to clear the vaccine virus from the intestinal tract and can excrete virus from the gut for prolonged periods of time, sometimes for over a decade. CNS disease and paralysis can occur in these individuals because virus persistence in the gut is associated with a low level of neutralizing antibody (295). At times, poliovirus can cause a slowly progressive neurodegenerative process (71). The use of immunoglobulin therapy in immunocompromised individuals is at least partly effective in preventing (and treating) these complications. Recent studies suggest that pleconaril may also have a place in this treatment (238). In addition, the use of inactivated poliovirus vaccine rather than the live poliovirus vaccine avoids the risk of vaccine-associated paralytic poliomyelitis.

Vaccine-associated paralytic poliomyelitis results from a reversion of the vaccine strain to a more neurovirulent form. Mutation is frequent, because poliovirus, like other positive-stranded RNA viruses, has an error-prone RNA-dependent RNA polymerase. For this reason, RNA viruses exist as a quasi-species, and mutations are even present in plaque-purified stocks of virus. Studies of normal immunocompetent individuals following vaccination have shown that there is rapid reversion of excreted virus to a genotype containing neurovirulent determinants (see later); in addition, intertypic recombinant viruses containing segments from the different poliovirus serotypes are generated in the gut and excreted in the feces (213). A recent reverse transcriptase–polymerase chain reaction analysis of isolates from the stool and the CNS of vaccine-associated paralytic poliomyelitis demonstrated that many varied poliovirus genotypes exist in a patient at the same time, including recombinants from the three poliovirus serotypes (98). Inoculation of these isolates into PVR transgenic mice failed to clarify the reasons why particular genotypes were present in the CNS or the gut. In other words, the CNS isolates were not more neurovirulent than isolates found in the gut, suggesting that random selection might determine whether an isolate spreads from the gut to the CNS. Not only do poliovirus serotypes recombine, but there is evidence of recombination between poliovirus and nonpolio enteroviruses, as demonstrated most recently in an outbreak in the Dominican Republic and Haiti (18).

Vaccine-associated paralytic poliomyelitis usually results from reversion of poliovirus type 3, less commonly from reversion of poliovirus type 2, and rarely with type 1 vaccine strains. The paucity of differences between the parental neurovirulent poliovirus type 3 and the vaccine strain (11 nucleotide and 3 amino acid changes) is presumed responsible for the frequent reversion of this serotype to a neurovirulent phenotype with the subsequent development of paralytic disease. The relatively small number of vaccine-associated paralytic poliomyelitis cases among vaccine recipients for types 1 and 2 may result from the many differences between the vaccine and parental neurovirulent strain (at least 56 nucleotide changes for type 1, and 23 nucleotide changes for type 2). In addition, the parental type 2 strain has a relatively decreased neurovirulence on its own.

A comparison of the sequences of neurovirulent parental poliovirus strains, the attenuated vaccine strains, and neurovirulent revertants from cases of vaccine-associated paralytic poliomyelitis, coupled with an investigation of engineered viruses generated from segments of infectious clones interchanged between the vaccine and neurovirulent parental strain, have identified changes critical for determining the phenotype of attenuated Sabin strains. All three Sabin poliovirus serotypes are thought to have a mutation in a major determinant for neurovirulence in a similar location in the internal ribosome entry site in the 5'-untranslated region: nucleotides 480 (type 1) (160), 481 (type 2) (195), and 472 (type 3) (90). It has been hypothesized that these mutations destabilize the secondary structure of the RNA (194). The destabilization is believed to perturb binding of neural cell-specific factors to the internal ribosome entry site in the viral RNA genome, so that there is inefficient translation initiation of the viral genome with a subsequent decrease in virus growth in neurons (leading to an attenuated phenotype). In other words, a factor in neurons binds the Sabin strain's mutated internal ribosomal entry site (IRES) far less effectively than the IRES of the virulent wild type, and therefore translation of the RNA from the vaccine strain is decreased in neurons, and subsequent virus growth in neurons is attenuated.

The importance of the 5'-untranslated region and cell-specific viral translational regulation in neurovirulence has also been shown in studies in which the rhinovirus type 2 IRES has been substituted for a similar region of poliovirus type 1 (110). The chimeric virus grew well in HeLa cells but was attenuated in both PVR transgenic mice and monkeys.

Recent data have modified our understanding of the relative importance of mutated nucleotides in the 5'-untranslated regions of the Sabin strains of type 1 and 2 (272). Studies of the Sabin strain of type 1 demonstrated that there is indeed frequent reversion of nucleotide 480 (and 525) following passage in cell culture and after vaccination into humans or monkeys; however, the presence of these mutations in as high as 17% of the vaccine lot did not consistently cause failure of the lot in a monkey neurovirulence test. On the other hand, the presence of the mutation in over 70% of the lot of virus did lead to an enhanced neurovirulence (272). These results suggest that nucleotide 480 in poliovirus type 1 has a less dramatic effect on neurovirulence in monkeys than previously suspected. Similar observations were made with Sabin strain type 2. In this case, inoculation of Sabin strain type 2 (with an additional single mutation at nucleotide 481 from A to a G) into a larger group of monkeys than was used in earlier studies (256), as well as into transgenic mice, showed no enhanced neurovirulence (273).

Additional determinants for attenuation besides those in the 5'-untranslated region have been identified (263). Transgenic mouse studies have shown that there are additional attenuating mutations in the case of Sabin poliovirus type 1 at amino acid 65 of VP4, 225 of VP3, 106 of VP1 (and also more weak determinants at 134 and 109 of VP1) (42).

In the case of Sabin poliovirus type 2, studies in monkeys and mice have demonstrated a determinant for attenuation at amino acid 143 of VP1 (270). Studies in monkeys have identified additional attenuating determinants in the case of Sabin poliovirus type 3, at amino acid 91 of capsid protein VP3 (330) and amino acid 6 of capsid protein VP1 (316). Other studies in monkeys found that there may be additional attenuating determinants in the polymerase 3D and 3'-noncoding regions (56,244) that were not found in studies with the transgenic mice (42). These results suggest that results obtained from one species may not be easily extrapolated to another species.

It remains unclear why so few vaccinated individuals develop paralytic poliomyelitis, given the relatively few changes in sequence between the parental and vaccine strains coupled with the frequency of reversion of the vaccine strain to more neurovirulent variants. The safety of the vaccine is even more remarkable given the fact that excreted virus from vaccinees contains revertants with wild-type neurovirulent determinants. The reason(s) may be as complicated and poorly understood as the reason that only 1% of the individuals exposed to wild-type poliovirus develop paralytic disease. Most likely, the outcome of the exposure depends on the dosage of the virus, the virus's neurovirulence determinants, genetic factors of the host and virus that influence virus growth, and the quality and rapidity of the immune response. It is also possible that differences in the inherent neurovirulence of wild and vaccine strains are not as important to the outcome of infection as differences in transmissibility and replication of particular isolates, for which there are no good models for study.

Coxsackievirus and Myocarditis

In an approach analogous to those used to clarify the neurovirulence determinants of poliovirus, studies have been performed to identify cardiovirulent determinants in coxsackievirus B3. Tu et al. (321) tested the effect of infection of mice with viruses generated from chimeric coxsackievirus B3 cDNAs in which segments of a myocarditic and amyocarditic strain (derived by tissue culture passage of the myocarditic strain) were recombined. The cardiovirulent phenotype was linked to nucleotide 234 (U in cardiovirulent and C in avirulent) in the 5'-untranslated region of coxsackievirus B3. However, sequencing studies of the 5'-untranslated region of coxsackievirus B3 isolates from humans found that this nucleotide was unlikely to be a major determinant in nature, because many coxsackievirus B3 isolates contain a U at nucleotide 234 despite marked differences in cardiovirulence (96). Other studies found that a single mutation at VP2 position 165 in the “puff” loop was critical for cardiovirulence (171), or that nucleotide 2916 was important for cardiovirulence (46). Some of these studies also involved somewhat artificially generated mutant viruses (96,171), and therefore they may have identified determinants of cardiovirulence that do not vary among natural isolates (87). A recent study involving recombinant viruses engineered from cDNA segments derived from two clinical coxsackievirus B3 isolates with marked differences in cardiovirulence identified the 5'-untranslated region as a major determinant of the cardiovirulence phenotype (87). It is clear that cardiovirulence may depend on multiple determinants throughout the genome. The identification of these sites and an understanding of their relative importance to the phenotype await continuing study.

A recent study of interest found that expression of coxsackieviral proteins in the heart as transgenes in mice, independent of any viral replication, induced dilated cardiomyopathy (329). Subsequent *in vitro* studies showed that purified coxsackievirus protease 2A cleaves dystrophin (25), a key protein component of heart muscle that is frequently mutated in inherited forms of dilated cardiomyopathy. In addition, the investigators found that coxsackievirus infection of cells in culture or mice leads to dystrophin cleavage, supporting a role for protease 2A in the disease process. If this model is correct, the similar specificity of the proteolytic activity of 2A in different enteroviruses would imply that multiple enterovirus serotypes have the potential to induce cardiomyopathies. Further studies are needed to validate the importance of coxsackievirus 2A in the pathogenesis of cardiomyopathy. For example, it will be important to verify that the presence of active 2A as a transgene, in the absence of other viral proteins, induces dilated cardiomyopathy; there may be difficulties, however, in ensuring 2A expression while avoiding host-cell translation shut-off with subsequent cell death.

Coxsackievirus and Infection of the Pancreas

Coxsackievirus A serotypes produce a widespread myositis in newborn mice, whereas group B viruses induce a focal myositis with infection of other tissues. Studies related to virulence associated with coxsackievirus B4 infection of the pancreas have been performed in mice with a virus strain that causes acinitis rather than islitis (264). Investigations using recombinant viruses demonstrated that a single amino acid in VP1 was critical for the virulent phenotype; however, these animals died of an acinitis in the pancreas, so there is no information at present regarding the identification of viral determinants critical in inducing diabetes.

Persistence

Enteroviruses are generally considered a cause of acute infections rather than persistent infections. It is clear, however, that persistent enterovirus infections occur in humans with humoral immunodeficiency because of a failure to clear virus. For example, agammaglobulinemic patients vaccinated with the Sabin strain of poliovirus may excrete virus for prolonged periods from the gut and develop paralytic disease after a long incubation period. These patients may also develop a chronic neurodegenerative-like disease with evidence of chronic brain and spinal cord inflammation (71). Other patients with immunodeficiency, especially X-linked agammaglobulinemia, can develop a chronic nonpolio enterovirus-induced aseptic meningitis or meningoencephalitis (see later section Meningitis and Encephalitis); these patients may have an associated dermatomyositis-like syndrome with inflammation of multiple organs (201). Echovirus strains are the predominant nonpolio enterovirus isolated from these cases for reasons that are not understood.

There have also been reports demonstrating persistence of enterovirus or the enterovirus genome in immunocompetent humans and animals with several diseases, including chronic dilated myocardiopathy, inflammatory muscle disease (myositis), and diabetes (see relevant sections of Clinical Features). In addition, enteroviruses, including poliovirus, have been implicated in the etiology of postpolio syndrome and amyotrophic lateral sclerosis (see later section Clinical Features: Poliomyelitis: Postpolio Syndrome and Amyotrophic Lateral Sclerosis). Additional studies will be important to

clarify how enterovirus infections may lead to chronic human diseases, and to determine whether the immune response or other factors are important in their pathogenesis.

EPIDEMIOLOGY

Demographics

Despite the nearly ubiquitous nature of enterovirus infections and the wide variety of clinical presentations, the demographics of the various infections and diseases have some consistent characteristics. In particular, several factors including age, sex, and socioeconomic status have largely predictable effects.

One of the most important determinants of enterovirus infection outcome is age. Different age groups have different susceptibilities to infection, severity of illness, clinical manifestations, and prognoses following enterovirus infection. Understanding these age effects on outcome of infection is complicated by the widely divergent prior history of infection and resulting immunity. Nevertheless, it is possible to make certain generalizations.

The largest amount and duration of virus shedding occurs on primary infection with a given enterovirus serotype. Because infection is so common, most primary infections occur during childhood. For these reasons, young children are probably the most important transmitters of enteroviruses, particularly within households. The greater exposure of children to virus during infection may make them more likely to have significant clinical symptoms. For example, in outbreaks of meningitis, children typically have higher rates of disease than adults (103,148). Unfortunately, most studies do not separately determine age-specific infection rates and disease rates, and the relative rates at which adults are infected are not generally known.

The incidence of poliomyelitis is relatively low for the first 4 to 6 months of life in developing nonindustrialized countries (in which control through vaccination has not yet been achieved) because of the frequent presence of protective maternal antibody. In these countries, there is an increased incidence of paralytic disease in children older than 6 months compared to children in wealthier industrialized countries, presumably related to an earlier exposure to virus as a result of poor sanitary conditions. Ironically, areas with improved hygiene may have a decrease in infant exposure, leaving an older (unexposed) population susceptible to epidemic disease, with high rates of paralytic disease during an outbreak (260). Adults are more likely to be severely affected in both nonindustrialized and wealthier industrialized countries, tending to acquire paralytic poliomyelitis rather than nonparalytic CNS disease (i.e., aseptic meningitis), abortive illness, or asymptomatic infection (132). The reason for the increase in severity later in life is unknown. A possible reason relates to the finding that fast axonal flow—which appears important in the spread of poliovirus within the CNS (155)—increases with age. In addition, it may be that PVR expression or host factors important in replication change with age.

Severity of a number of enteroviral diseases besides poliomyelitis may be strikingly age-related. There is an indirect indication that a delay in first infection with a number of enteroviruses increases risk of more severe disease. For example, exanthema associated with coxsackie A viruses and echoviruses are for the most part milder in children than in adults. On the other hand, some enteroviruses cause more severe disease in newborns than in older children and adults, possibly inducing a fulminant “viral sepsis” with myocarditis, encephalitis, and sometimes death (see later section Clinical Features: Neonate and Infant Disease) (52,150). In addition, recent outbreaks of hand-foot-and-mouth disease caused by enterovirus 71 have been associated with a significant CNS complication, fatal brainstem encephalitis, that was restricted largely to young children (Table 3) (see later section Meningitis and Encephalitis) (174,192).

Year	Location	Clinical findings
1969–1973	California	Aseptic meningitis, encephalitis
1972	New York	Aseptic meningitis, encephalitis, hand-foot-and-mouth disease
1972	Australia	Aseptic meningitis, rash, polyneuritis, acute respiratory infection
1973	Sweden	Aseptic meningitis, hand-foot-and-mouth disease
1973	Japan	Hand-foot-and-mouth disease, aseptic meningitis
1975	Bulgaria	Aseptic meningitis, encephalitis, acute myocarditis, acute flaccid paralysis
1978*	Hungary	Aseptic meningitis, encephalitis, acute flaccid paralysis
1985	Hong Kong	Micropiegia
1986	Australia	Central nervous system involvement
1987	USA	Acute flaccid paralysis, meningitis, encephalitis
1988	China	Hand-foot-and-mouth disease
1987	Malaysia	Fatal encephalitis, acute flaccid paralysis, hand-foot-and-mouth disease
1998	Taiwan	Fatal encephalitis, hand-foot-and-mouth disease

*A mixed epidemic of tick borne encephalitis (chiefly in adults) and enterovirus 71 disease (chiefly in children).

TABLE 3. *Some enterovirus 71 outbreaks, 1969 TO 1989*

In general, encephalitis and aseptic meningitis caused by enteroviruses appear to be most frequent among those 5 to 14 years old rather than those older or younger. In a 10-year surveillance summary from the United States (222), adults tended to be overrepresented among cases of severe disease (paralysis, encephalitis, meningitis, carditis) when compared with the age distribution of the enterovirus-infected population as a whole. In another study, the mean age among patients with coxsackievirus B meningitis (7.7 years) or pericarditis (9.9 years) was greater than the mean age of patients with coxsackievirus B gastroenteritis (1.3 years) (80).

Enterovirus diseases, and possibly also enterovirus infections, occur more frequently in males than in females (103,223), although some exceptions have been described (78). In numerous reports, the male-to-female ratio appears to generally range between about 1.2 and 2.5:1; that is, approximately 55% to 70% of such diseases occur in males. Male predominance tends to be greater for the more severe diseases, for example CNS disease or carditis, than for less severe disease, for example pleurodynia, hand-foot-and-mouth disease, respiratory disease, acute hemorrhagic

conjunctivitis, rash, or undifferentiated febrile illness.

The apparent predominance of enteroviral infections among males may have both sociologic and biologic explanations. Population-based measurements of infection such as serosurveys, which should be gender neutral, have not consistently demonstrated a higher infection rate for males. Several additional explanations for the male predominance have been proposed on the basis of studies of infections in healthy children (97): a longer duration of virus excretion occurs in males than in females (leading to increased chance of identifying infected males); a higher virus titer occurs in the feces of males (leading to a similar increase in diagnosis). Another possibility is that there may indeed be more frequent infections in males because of a greater exposure to the pathogen, perhaps because there are differences in the parental treatment and play habits of younger boys, and greater activity among older boys. An additional possibility is that males are more likely to develop a serious illness from a given enterovirus infection than females. For example, the reason that human myopericarditis is more common in adolescent and adult males than in females (except in pregnant and postpartum women) (333) could be caused by sex-related endocrine effects leading to differences in disease susceptibility.

Enterovirus infections are more prevalent among persons of lower socioeconomic status and those living in urban areas (115,152). In a study utilizing active surveillance of healthy children for enterovirus infections in West Virginia during 1951 to 1953, the rate of isolations among children in a lower socioeconomic setting was 2 to 7 times higher than among children in a higher socioeconomic setting (131). A similar study in Ghana during 1971 to 1973 further indicated that enterovirus isolations were significantly more frequent from children in areas with poorer sanitation and in urban areas during both rainy and dry seasons (247).

Paradoxically, poliomyelitis and possibly other enterovirus diseases tend to be “diseases of development.” In the case of poliomyelitis, improvement in a country's hygienic and socioeconomic conditions (before vaccination programs) successfully reduces the incidence of paralysis due to poliovirus and leads to a transitional period in which there is a delay in age of first infection with a subsequent temporary increase in the paralysis-to-infection ratio. Prior to the introduction of the poliovirus vaccine in the United States and other developed countries, paralytic poliomyelitis was disproportionately a disease of the middle and upper socioeconomic classes; this disease distribution was a result of infection at an older age, when paralysis was a more frequent complication. Ironically, the delay was a result of improved hygiene. The infant mortality rate, a general indicator of a country's level of health development, may be inversely correlated with the age-specific incidence of poliomyelitis (205).

Transmission

Enteroviruses can be isolated from both the lower and upper alimentary tract and can be transmitted by both fecal-oral and respiratory routes. Fecal-oral transmission may predominate in areas with poor sanitary conditions, whereas respiratory transmission may be important in more developed areas (133). The relative importance of the different modes of transmission probably varies with the particular enterovirus and the environmental setting. It is believed that almost all enteroviruses, except possibly enterovirus type 70, can be transmitted by the fecal-oral route; however, it is not known whether most can also be transmitted by the respiratory route. Enterovirus 70 and coxsackie A24 variant, the agents that cause acute hemorrhagic conjunctivitis, are seldom isolated from the respiratory tract or stool specimens, and are probably primarily spread by direct or indirect contact with eye secretions (175). Enteroviruses that cause a vesicular exanthem can presumably be spread by direct or indirect contact with vesicular fluid, which contains infectious virus.

It is likely that enteroviruses are transmitted in the same manner as are other viruses causing the common cold—that is, by hand contact with secretions (e.g., on the hand of another person) and autoinoculation to the mouth, nose, or eyes. Direct bloodstream inoculation, usually by laboratory accidents such as needle sticks and shattered glass vials, may result in enterovirus infection; however, neither blood transfusion nor mosquito or other insect bites appear to transmit infection. The isolation of enteroviruses from flies has led to a suspicion that houseflies (*Musca domestica*) and various filth flies may be vehicles of mechanical transmission. There is no evidence that venereal transmission is important.

Transmission within households has been well studied for both polioviruses and nonpolio enteroviruses. Small children generally introduce enteroviruses into the family, although young adults make up the majority of index cases in some outbreaks of acute hemorrhagic conjunctivitis (290). Intrafamily transmission may be rapid and relatively complete, depending on duration of virus excretion, household size, number of siblings, socioeconomic status, immune status of household members, and other risk factors (115). Transmission has been generally found to be greatest in large families of lower socioeconomic status with a greater number of 5- to 9-year-old children and with no evidence of serologic immunity to the virus type. Not surprisingly, infections in different family members may result in different clinical manifestations.

Observations of household transmission of various enteroviruses have documented that many infected contacts do not become ill and that the extent of secondary transmission varies with different enteroviruses. Household secondary attack rates in susceptible members may be greatest for the agents of acute hemorrhagic conjunctivitis (enterovirus type 70 and coxsackievirus A24 variant) and for the polioviruses, and of lesser magnitude for the coxsackieviruses and echoviruses. In some studies, secondary attack rates may be 90% or greater, although they are typically lower. New York Virus Watch data indicate that enterovirus infections were more frequent among 2- to 9-year-old children and that secondary coxsackievirus infections were more frequent in mothers (78%) than in fathers (47%) (172). In the same study, coxsackieviruses spread to 76% of exposed susceptibles versus 25% of exposed persons who had detectable antibody to the infecting type; echoviruses infected 43% of susceptibles and only one person with antibody. The greater spread of polioviruses and coxsackieviruses may derive from longer periods of virus excretion.

Transmission occurs within the neighborhood and community, particularly where people congregate. In addition, like many other viruses, enteroviruses can be rapidly transmitted within institutions when circumstances permit (e.g., crowding, poor hygiene, or contaminated water). School teams or activity groups and institutionalized ambulatory retarded children or adults may be at special risk (12). Despite crowding, enterovirus transmission is not usually

accelerated to a noticeable degree in institutions where good sanitation is found.

As a result of widespread but incomplete poliovirus immunization, rare poliovirus-susceptible enclaves have arisen. These usually consist of unvaccinated religious groups in countries with an otherwise high prevalence of poliovirus immunity. Despite the barrier of millions of immune persons, poliovirus outbreaks have occurred in some of these enclaves (245). The frequency and ease of international travel may result in the continuous introduction of wild poliovirus in all regions of the world, indicating that a large proportion of the population must be vaccinated if poliomyelitis epidemics are to be prevented. This suggests that herd immunity may be of only limited value in protecting groups of susceptible persons who have regular contact with outside populations, and it raises questions about the risks that such groups may pose to the community at large.

Nosocomial transmission of various coxsackieviruses of groups A and B and the echoviruses has also been well documented, typically in newborn nurseries. Hospital staff may have been involved in mediating transmission in some of these outbreaks. Enterovirus type 70, as well as coxsackievirus A24 variant, is highly transmissible and may cause outbreaks in ophthalmology clinics when instruments are inadequately cleaned between patients. An apparent outbreak of coxsackievirus A1, which included some fatal cases, has been reported in bone marrow transplant recipients (318).

Although human enteroviruses have been isolated from various environmental sources, man is thought to be the only important natural reservoir (85,91). There is not known to be any extrahuman reservoir. Survival beyond a few weeks does not generally occur, although enteroviruses can survive for months in favorable environmental conditions; these favorable conditions include neutral pH, moisture, and low temperatures, especially in the presence of organic matter, which protects against inactivation.

Although there is little evidence that enteroviruses found in the environment are of public health importance, concern has been expressed about possible dangers of contaminated sources of water (Fig. 7). Recreational swimming water has been investigated in several studies, and enteroviruses have been isolated from swimming and wading pools in the absence of fecal coliforms and in the presence of “recommended” levels of free residual chlorine. Coxsackievirus B5 was isolated from an unchlorinated lake swimming area during an outbreak at a boy's camp in Vermont, although the outbreak itself was explained by person-to-person transmission. In one study, the relative risk of enterovirus infection among children was found to be significantly higher for beach swimmers, especially for those under 4 years old (68). These reports suggest that swallowing of contaminated pool or lake water may theoretically account for transmission, but there is no proof that this type of transmission is significant in many typical recreational settings.

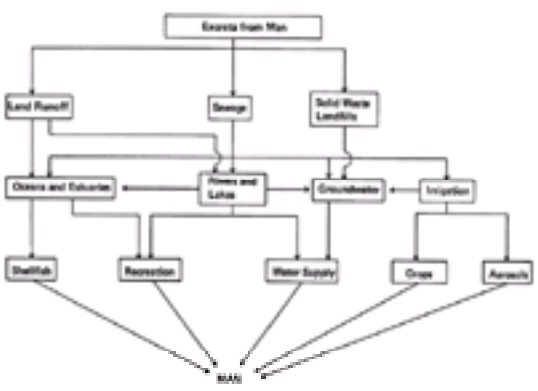

FIG. 7. Routes of potential enteric virus transmission in the environment. (From ref. 201, with permission.)

Enteroviruses have been found in surface and ground waters throughout the world. In the tropics, virus survival is more prolonged in ground water because it is cooler than surface water. As in the case with swimming pools, enteroviruses can be found in these waters even after chlorination and even in the absence of fecal coliforms. In industrialized countries, enterovirus transmission from potable water is apparently uncommon but is a constant source of concern for public health investigators, because the usual conditions under which city drinking water is chlorinated may be insufficient to completely inactivate enteroviruses.

Enteroviruses have been isolated from raw or partly cooked mollusks and crustacea, and their overlying waters (105). Shellfish rapidly concentrate many viruses, including enteroviruses. These viruses may survive in oysters for 3 weeks at temperatures of 1° to 21°C. To date, there has not been an outbreak of enterovirus disease attributed to consumption of shellfish. Other food-borne transmission has been documented but is thought to be uncommon. A 1976 outbreak of aseptic meningitis attributed to echovirus type 4 was apparently caused by consumption of contaminated coleslaw at a large picnic (Centers for Disease Control, unpublished data, 1976).

Enteroviruses, especially polioviruses, are regularly found in sewage. Enteroviruses are more prevalent in sewage from areas with low socioeconomic conditions or with large proportions of young children. In addition, sewage workers have been shown to have a higher prevalence of serum antibodies to enteroviruses than highway maintenance workers, consistent with an occupational risk (58).

Soil and crops also provide conditions favorable to enteroviruses. Enteroviruses survive well in sludge and remain on the surface of sludge-treated soil and even on crops. Air samples from aerosolized spray irrigants using contaminated effluents have also been found to contain enteroviruses (221). Survival of enteroviruses on vegetable food crops exposed to contaminated water or fertilizer has not been proven to be associated with virus transmission.

Prevalence and Disease Incidence

Incidence data about diseases caused by particular enterovirus types may be derived from prospective longitudinal surveillance of a defined population, or a sample of the population, in which the occurrence of disease and/or infection can be reliably determined. The Virus Watch program in the 1960s in United States cities exemplifies this type of surveillance study, in which specimens from subject children were obtained every 2 weeks for virologic evaluation (61,172,308). While difficult and extremely expensive, such prospective cohort studies avoid many of the pitfalls of passive surveillance, and they allow interpretations about both infection and disease incidence.

Less useful information is based on passive case finding. Ascertainment may be incomplete because the surveillance system is likely to identify a case only if it is easily recognizable and diagnosed by someone who decides to report it. Since such data indicate neither how many ill persons were not reported, nor how many ill persons had negative laboratory tests, the information is mostly of qualitative value; however, it may be useful in indicating trends. Despite these limitations, occasional reports do appear (29,308).

In the United States, enterovirus surveillance data are collected and analyzed by the Centers for Disease Control and Prevention. The data have been reported irregularly since the beginning of the program in 1961 (222,225). In the United States, the only notifiable enteroviral diseases are poliomyelitis and encephalitis. These are reportable by diagnosis only (e.g., encephalitis) and not by etiology (e.g., echovirus encephalitis). Such disease-based surveillance is the most accessible but the least representative of all surveillance data.

Enterovirus excretion does not necessarily imply association with disease, since most such excretion is asymptomatic. This word of caution applies particularly to developing countries where enteroviruses are ubiquitous and childhood infections commonplace and characteristically silent.

Enterovirus activity in populations may be either sporadic or epidemic, and certain enterovirus types are associated with both sporadic and epidemic disease occurrences. The reported incidence or prevalence of a given enterovirus disease may be actually and/or artifactually increased in an outbreak situation when there is a sudden focus of attention that improves diagnosis and reporting of cases, but this may also increase reporting of “noncases.” In addition, there may be a tendency for other strains to be excluded when a particular strain is predominant in a community; however, large communities with summer enteroviral disease typically support co-circulation of several different types simultaneously and in no particular pattern.

An important concept in understanding the epidemiology of the enteroviruses is variation: by serotype, by time, by geographic location, and by disease. This concept is illustrated in surveillance studies of nonpolio enterovirus infections. For example, Figure 8 summarizes the data for the years from 1970 to 1998 for coxsackievirus B3, echovirus 11, and echovirus 30 isolates in the United States collected and analyzed by the Centers for Disease Control and Prevention. These data illustrate endemic and epidemic patterns of enterovirus prevalence. The epidemic pattern, as typified by echovirus 11 and echovirus 30, is characterized by peaks in numbers of isolations followed by periods with few isolations. These peaks may be sharp (1- or 2-year) or broad (multiyear) periods of increased virus isolations. For example, during the study period there were several major epidemics of echovirus 30 in the United States: outbreaks from 1981 to 1982, 1990 to 1994, and 1997 to 1998. By contrast, endemic viruses such as coxsackievirus B3 are isolated nearly every year and in similar numbers each year. Even with endemic viruses, larger outbreaks do occasionally occur, as with coxsackievirus B3 in 1980. Similar endemic and epidemic patterns are seen for the other echoviruses and coxsackie A viruses.

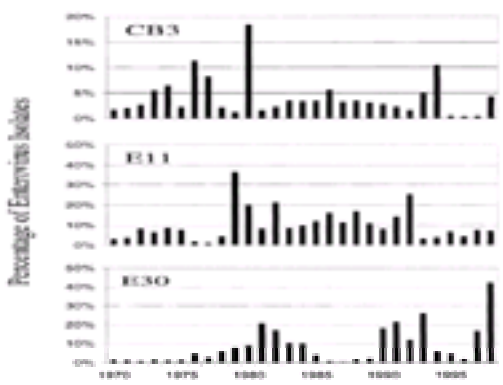

FIG. 8. Reported enterovirus isolations in the United States, 1970–1998. The graphs represent the percentage of total enterovirus isolations in a given year for each of three common serotypes, coxsackievirus B3 (CB3), echovirus 11 (E11), and echovirus 30 (E30). Note that full scale for the CB3 panel is 20%, whereas it is 50% for both of the echoviruses.

Variation by location is also a major characteristic of enteroviruses. Outbreaks can be restricted to small groups such as schools and day care centers or to selected communities, or they may become widespread at the regional, national, or even international level. Outbreaks in small groups can sometimes be linked epidemiologically to a breakdown in hygiene practices. Even during national outbreaks of a specific serotype, the location of virus activity may not be uniform. During the period of 1990 to 1993, echovirus 30 was the most commonly isolated enterovirus in the United States (Fig. 9). As can be seen in Figure 9, not all parts of the country had echovirus 30 isolates during the entire period. Some areas, such as the New England states, had extensive circulation in only one year, whereas other areas, such as the entire western United States, had extensive virus circulation for three or more of the four years. It is important to note, therefore, that

aggregate national data can obscure significant regional and local variation in viral prevalence.

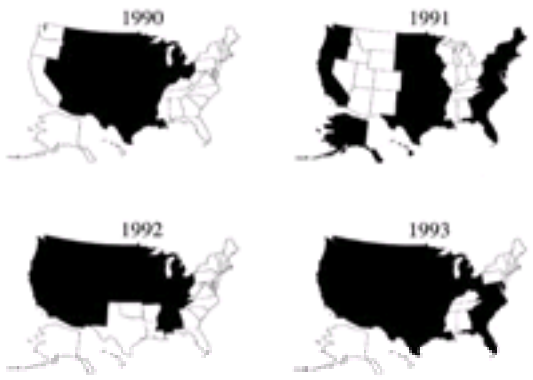

FIG. 9. Geographic distribution of echovirus 30 isolates in the United States, 1990–1993. Maps represent regions of the United States where echovirus 30 was one of the three most common enterovirus isolates for the given year. States are shaded on a regional basis, because not all states report enterovirus isolation data.

In temperate climates, enteroviruses are characteristically found during the summer and early autumn, although outbreaks may continue into the winter. In fact, naturally occurring enteroviruses have a distinct seasonal pattern of circulation that varies by geographic area; in contrast, live attenuated polioviruses (mostly vaccine strains) are isolated year round, reflecting the routine administration of poliomyelitis vaccine to children. In tropical and semitropical areas, circulation tends to be year-round or associated with the rainy season. In the United States, 10 years of surveillance indicated that 82% of enterovirus isolations were made during the five summer/fall months of June to October. In a 6-year study of viral CNS disease, 85% of enteroviral disease, compared with 12% to 26% of diseases caused by other viral agents, occurred between June and November (222).

Many studies have examined the prevalence of antibodies to the enteroviruses in specific populations (reviewed in refs. 206,220) (see later section Diagnosis), with several important conclusions. First, the number of persons who have neutralizing antibody to any given enterovirus is large, indicating a high incidence of past infection. A high incidence of recent infection is also suggested by surveys of IgM antibodies to enteroviruses, which typically show 4% to 6% positivity. Second, infections with one serotype of enterovirus can boost antibody titers to other enterovirus serotypes as measured by either IgM or neutralization. The pattern of the heterotypic response varies by serotype and among individuals. The nature of this heterotypic response has been recently explored through the identification of specific epitopes using monoclonal antibodies and peptide antisera (114,288,337). Third, the pattern of antibody prevalence by serotype varies by geographic location, by time, and by age. Thus, prevalence data from different years and locations are not directly comparable. These three points must be considered when interpreting the findings of serologic studies of associations between enterovirus infection and disease.

Enterovirus isolates are routinely characterized by serotype using polyclonal animal sera, and by this criterion, the serotypes appear to be quite stable and well defined. However, studies using monoclonal antibodies prepared against coxsackievirus B3 and coxsackievirus B4 suggest that there can be considerable antigenic variation within a serotype of coxsackievirus B (131,251). Monoclonal antibodies have been used to study coxsackievirus B strains, plaque variants of the prototypes, and clinical isolates (137,259,327). In all cases, multiple differences between strains were detected at many epitopes, although no correlation with clinical symptoms was made. This antigenic diversity among the multiple viral epitopes has so far yielded very little additional understanding about the biology of infection and pathogenesis.

Molecular Epidemiology

Study of the molecular variation of viral proteins or nucleic acid may contribute significant epidemiologic information on viral diseases (see later section Diagnosis). For the enteroviruses, and in particular poliovirus, three types of molecular studies have been used to generate epidemiologic information: analysis of antigenic variation of virion proteins using monoclonal antibodies, examination of changes in the viral genome using oligonucleotide fingerprinting, and direct analysis of genomic variation using nucleic acid sequencing.

All three approaches have been utilized in addressing the classic problem of differentiating wild from vaccine-derived poliovirus (62,92,113). The first successful test intended to differentiate between wild and vaccine viruses depended on cross-absorbed antibody. This approach was subsequently refined, and it is now possible to distinguish between wild and vaccine polioviruses using cross-absorbed rabbit IgG in an enzyme-linked immunoabsorbent assay (ELISA) (100,101).

The advent of monoclonal antibody technology provided the possibility of generating vaccine-specific antibodies. There now exists a collection of monoclonal antibodies that are capable of uniquely recognizing the Sabin vaccine strains (151). These antibodies have also been used to show changes in the antigenic properties of vaccine virus excreted by a primary vaccinee, demonstrating that the virus can become antigenically less vaccine-like (215). This antigenic drift to a less-vaccine-like virus helps explain some of the difficulties in using antigenic tests to differentiate wild from vaccine virus. It thus appears that enteroviruses may undergo continuous antigenic drift in natural host populations, although it is not known whether this occurs in response to the selection pressures of gut immunity. All studies looking at antigenic properties of enteroviruses emphasize the significant variation observable at individual epitopes despite consistent serotype stability.

At about the same time that monoclonal antibodies were first being produced, oligonucleotide mapping began to be applied to the study of poliovirus (118,237). These oligonucleotide maps appear to be characteristic for given strains of

virus and have been referred to as fingerprints. Studies of wild and vaccine polioviruses have revealed many aspects of poliovirus molecular epidemiology. First, fingerprints of poliovirus strains that are epidemiologically distinct (i.e., those that are isolated sporadically or from persons in different epidemics) are unequivocally different. Second, poliovirus genomes appear to spontaneously and randomly mutate during replication in humans, resulting in variation in fingerprint types isolated during epidemics, presumably reflecting single and multiple generations of person-to-person transmission.

Several studies using oligonucleotide fingerprinting have examined isolates of enterovirus 70. Fingerprints of isolates obtained from multiple sites worldwide during the 1981 to 1982 pandemic showed that all of the isolates were very closely related, supporting a single agent as the etiology of the global outbreak (165). Further studies demonstrated that the changes in the genome of enterovirus 70 were progressive, with increased numbers of changes with time over a 10-year period. Quantitative analysis of these fingerprint data suggested a common origin for all enterovirus 70 isolates, with an estimated date of origin of 1966 to 1967, most likely in West Africa, 2 or 3 years prior to the first known pandemic of this disease (218,311).

Both monoclonal antibodies and oligonucleotide fingerprinting are limited by their ability to show similarities and small differences only among relatively closely related viruses. However, neither technique is able to detect any patterns among seemingly unrelated virus isolates. The introduction of the technique of genomic nucleic acid sequencing and its application to the study of wild poliovirus isolates from different parts of the world has significantly extended the epidemiologic power of molecular studies (276). By analyzing the random mutations that occur in the genome of different polioviruses, closely related viruses were easily detected and, in addition, more distantly related viruses were clustered into distinct geographic groupings of endemic circulation. This approach allowed epidemiologic links to be extended beyond those identified with other techniques.

Nucleic acid sequencing technology has been most comprehensively applied to studies of poliovirus, where the information has proved valuable for supporting the global poliovirus eradication program (163,164). From these studies, it is possible to determine (a) if an isolated poliovirus is related to vaccine virus, (b) similarities among isolates in an epidemic, and (c) differences among isolates from different geographic areas. By comparing the changes that are observed between virus strains, the geographic and temporal origin of a virus can be determined. Building on a nucleic acid sequence database of poliovirus strains worldwide, it has been possible to develop rapid approaches to tracking wild poliovirus strains (9,190,230,276,351).

Studies on the molecular epidemiology of nonpolio enteroviruses have focused on the evolutionary inference derived from the comparison of virus isolates within a serotype over time, as well as the comparison of isolates from different serotypes and even between different genera within the *Picornaviridae*. Molecular epidemiologic studies using sequencing have been reported for coxsackievirus B1, coxsackievirus B5, echovirus 30, and enterovirus 71 (43,86,176,239,353). One of the studies of coxsackievirus B5 isolates examined the pattern of genetic changes over three separate outbreaks in the United States. The nucleotide sequence from multiple isolates from the epidemics showed that each of the epidemics was caused by a single genotype. The genotype of coxsackievirus B5 observed in the 1967 epidemic showed more similarity to the virus observed in the 1983 epidemic than to viruses isolated during the intervening years (176), suggesting discontinuous transmission of the epidemic coxsackievirus B5 in the United States during this time. In an analogous manner, echovirus 30 genotypes have demonstrated an overlapping succession among the isolates characterized in the United States (239). More than one genotype may be found in certain periods, and the displaced genotype can be found in other parts of the world after isolations have ceased in the United States for many years. In studies of enterovirus 71 isolates, three distinct genotypes have been characterized (43). Unlike the situation with echovirus 30 and more similar to the coxsackievirus B5 example, the transition from one genotype to another occurred during a single year, 1987, and the older genotype has not been isolated since in the United States despite isolation in other parts of the world.

CLINICAL FEATURES

Asymptomatic Infections

The great majority of enterovirus infections are asymptomatic. On the other hand, these viruses can cause a spectrum of clinically distinct syndromes when they lead to disease. Table 4,Table 5,Table 6,Table 7 and Table 8 list the prototype enterovirus strains and the illness if any in the person from whom the prototype virus was isolated. Individual serotypes generally lead to varied symptomatology and disease processes. Similarly, individual clinical disorders can generally be caused by a number of different enteroviruses (Table 9). On occasion, however, particular syndromes are associated with specific enteroviruses. For example, acute hemorrhagic conjunctivitis is usually caused by coxsackievirus A24 variant or enterovirus 70. Acute flaccid paralysis is usually caused by poliovirus or enterovirus 71. The occasional isolates from cases of diabetes are usually coxsackievirus B serotypes.

[a]Cross-reactivity has been observed between A2 and A8, A11 and A13, and A12 and A18; QN-19 antiserum partially neutralizes coxsackievirus A24. But A24 antiserum does not neutralize CN-19 virus, although it reacts with the virus in complement fixation and gel diffusion tests.

[b]All isolates were from stools, except for prototypes of A4 and A12, which were isolated from sewage and flies, as indicated. Numerous strains of each of these types were isolated from stools also.

[c]When coxsackieviruses have been isolated from patients with paralytic poliomyelitis, the patient has often been found to have a dual infection, the poliomyelitis presumably being responsible for the paralytic illness.

[d]The Colo virus was isolated from throat washings.

[a]Types 1 and 9 share antigens; type 1 having the broader spectrum. Type 10 was soon excluded from this group. It turned out to be a simple RNA virus and was reclassified as a prototype reovirus. Type 28 was reclassified as rhinovirus type 1. Type 22 and 23 have been reclassified as members of the genus Parechovirus and are named parechovirus 1 and 2. These viruses share only superficial virus replicative traits with members of this new genus. Type 24, Dn-19, is now considered a prime strain of coxsackievirus A24, rather than a distinct prototype.

TABLE 8. *High-numbered enterovirus types*

TABLE 9. *Clinical syndromes associated with infections by enteroviruses*

Poliomyelitis

As is true for nonpolio enteroviruses, infection of the vast majority of patients with poliovirus does not result in disease or lead to any symptomatology. The most common symptomatic disease caused by poliovirus, known as abortive poliomyelitis, is a mild febrile illness with gastrointestinal signs that occurs in 4% to 8% of individuals. The incubation period from infection to the onset of abortive poliomyelitis is usually 1 to 3 days, although symptoms may be seen as late as 5 days after infection. Less frequently, poliovirus infection results in aseptic meningitis. This nonparalytic illness has the typical features of viral meningitis, with fever, headache, and meningeal signs but an absence of signs of CNS parenchymal involvement. The meningitis has a self-limited course and lasts for a few days to 2 weeks. Only 1 in 200 poliovirus infections in a fully susceptible population results in the paralytic disease known as poliomyelitis. The incubation period from infection to the onset of paralysis is usually 4 to 10 days, although it can be as short as 3 days or longer than a month. The paralysis generally occurs 2 to 5 days after headaches and peaks within a few days. There is usually a prodrome with sensory complaints and shooting or aching pains in muscle. The muscle pains may reflect growth of the virus in this tissue, which is known to occur (269). In children, one can see a biphasic or “dromedary” course of neurologic involvement, and paralysis can occur as the initial symptom.

Paralysis is classified as either spinal or bulbar depending on whether the spinal cord or brainstem, respectively, is involved. Not infrequently, the spinal form becomes associated with the bulbar form during the course of the disease, resulting in so-called bulbospinal polio. Spinal polio is usually asymmetric, flaccid, and limited to the extremities and trunk, and it varies from a mild weakness to a complete quadriplegia. Only about 10% to 15% of poliomyelitis cases are bulbar, a term indicating involvement of the motor cranial nerves or medullary centers controlling respiration and the vasomotor system. The most frequent cranial nerves affected are IX and X, leading to paralysis of the pharyngeal and laryngeal muscles with resultant difficulty swallowing and talking. Involvement of other cranial nerves may lead to weakness of the face (VII) and tongue (XII). Most dreaded is involvement of the brainstem reticular formation, resulting in respiratory compromise, potentially requiring ventilatory support. One can see evidence of autonomic involvement, manifest as abnormalities of sweating, urination, defecation, and blood pressure control. Recovery can be very delayed. Not infrequently, one extremity is left severely weak and atrophic, with a relatively normal contralateral limb.

The pathology of poliomyelitis is one of inflammation and destruction of the gray matter of the CNS, especially of the spinal cord. Motor neurons up and down the neuraxis can be infected by poliovirus, including “upper” motor neurons located rostrally in the brainstem and cerebral hemispheres in addition to the anterior horn “lower” motor neurons in the spinal cord. The widespread nature of the gray matter infection demonstrates that the disease is frequently a polioencephalomyelitis (i.e., inflammation of the gray matter of the brain and spinal cord) rather than merely a poliomyelitis (inflammation of the gray matter of the spinal cord). Interestingly, the perivascular mononuclear inflammatory cells can persist for months, although virus is difficult to culture from the spinal cord after a week (36). Although the focus of pathology in the spinal cord is in the anterior horn, there are also abnormalities outside the motor system in the posterior horn and intermediolateral column. Similarly, the brainstem shows involvement of a number of sensory cranial nerve nuclei and of the reticular formation in addition to the motor cranial nerve nuclei. Neurons die with evidence of chromatolysis followed by neuronophagia. Recent investigations of PVR transgenic mice have demonstrated that spinal cord neurons die by apoptosis (99); studies in cell culture have also shown evidence of apoptosis of cells following poliovirus infection (10).

Poliomyelitis or acute flaccid paralysis may occur as a result of infection with other enteroviruses besides poliovirus. Enterovirus 71 is emerging as the most important virulent neurotropic enterovirus during the poliomyelitis eradication period. This virus causes epidemics of poliomyelitis-type disease, including bulbar disease (57). In an enterovirus 71 epidemic in Bulgaria in 1975, a paralytic disease occurred in as many as 21% of approximately 700 patients, with a case fatality rate approaching 30% (303). Enterovirus 71 is also associated with epidemic encephalitis and meningitis (see later section Meningitis and Encephalitis). Enterovirus 70, a cause of epidemics of acute hemorrhagic conjunctivitis, can lead to a severe and acute paralytic disease (325). The incidence of paralysis is probably 1 in 10,000 infections (153). These patients can also have cranial nerve palsies, autonomic abnormalities, and sensory signs. Sometimes, enterovirus 70 infections may cause isolated cranial nerve palsies, most commonly involving the facial nerve. The eye disease is usually spread by direct or indirect contamination of the eye rather than the fecal-oral route. Enteroviruses 71 and 70 can both produce paralytic disease in monkeys (153), although this is not a consistent finding for all isolates. Some echoviruses and coxsackieviruses have also been associated with acute flaccid paralysis. For example, coxsackievirus A7 virus has been reported to cause outbreaks of paralysis (108).

Postpolio Syndrome and Amyotrophic Lateral Sclerosis

Patients with postpolio syndrome complain of new weakness, fatigue, and pain decades after paralytic poliomyelitis. One

subgroup of this syndrome, called postpoliomyelitis progressive muscular atrophy, is an uncommon primary neurologic disorder manifested by slowly progressive atrophy of muscles with evidence of on-going motor nerve damage (47). Some investigators have reported a persistent poliovirus infection in the spinal fluid or CNS tissue from postpoliomyelitis progressive muscular atrophy patients (183,184,227,253,300), but others have failed to confirm these findings (156,203,287). One of the groups that originally reported enterovirus genome in postpolio syndrome patients later claimed that both patients and controls had evidence of enteroviral genome in the CNS (228). Although the poliovirus genome of a mouse-adapted mutant poliovirus has been reported to persist at low levels following experimental infection of mice (81), the only consistent evidence for persistent poliovirus infection in humans has been found in immunocompromised individuals (see previous section Pathogenesis, and the next section Meningitis and Encephalitis). We await more convincing data demonstrating that a persistent infection underlies the postpolio syndrome.

The issue of whether poliovirus can persist in postpoliomyelitis progressive muscular atrophy has raised questions about whether poliovirus or another enterovirus is involved in amyotrophic lateral sclerosis, a chronic progressive noninflammatory disease of unknown etiology associated with the death of motor neurons. A 1994 study reported evidence of enteroviral sequences in spinal cord tissue from patients with motor neuron disease (334). One later study was generally negative (274, but a recent investigation using reverse transcriptase polymerase chain reaction and reverse transcriptase *in situ* hybridization with primers from the 5'-untranslated region reported finding enterovirus sequences resembling echovirus 6 and 7 in CNS tissue from 13 of 17 amyotrophic lateral sclerosis patients (and a low percentage of controls) (32). Although a role for enteroviruses in amyotrophic lateral sclerosis seems unlikely given the immunocompetence of these patients and the noninflammatory pathology of the disease, it is clear that further studies are indicated using blinded samples and probes from throughout the enteroviral genome.

Meningitis and Encephalitis

Aseptic meningitis is a nonbacterial inflammation of the meninges associated with fever, headache, photophobia, and meningeal signs in the absence of signs of brain parenchymal involvement (284). The syndrome is the most common CNS infection, with 7,000 cases of aseptic meningitis reported per year in the United States and an actual incidence believed to be 10-fold higher (283). In one survey from Finland, aseptic meningitis occurred in 219 of 100,000 children under 1 year of age, and in 19 of 100,000 children aged 1 to 4 years, demonstrating a decreased incidence with increase in age (266).

Enteroviruses are the main recognized cause of aseptic meningitis in both children and adults in developed countries, and enteroviruses were identified in 85% to 95% of cases in which a specific pathogen was cultured (284). In one study (158), 62% of infants less than 3 months old with aseptic meningitis had coxsackievirus group B as the etiologic agent. In addition, aseptic meningitis is the most common clinical syndrome caused by enteroviruses that results in medical attention.

Enteroviruses should be suspected as the causative agent for aseptic meningitis occurring in the summer and fall in temperate zones. The seasonal increase in incidence of enteroviral aseptic meningitis may result because the fecal-oral route of transmission is facilitated in warm periods when less clothing is worn (153). Fever is common in patients with enterovirus-induced aseptic meningitis, as with most cases of aseptic meningitis. At times, the fever has a biphasic pattern, initially associated with constitutional symptoms and then returning with meningeal signs. One may see nonneurologic abnormalities associated with enteroviral meningitis, such as a rash, which may be helpful in the diagnosis and identification of the particular enteroviral serotype (153) (see later section Respiratory Infections, Herpangina, and Hand-foot-and-mouth Disease). For example, rashes have been associated with CNS disease caused by coxsackieviruses A5, A9, and A16, and echoviruses 4, 6, 9, and 16. The rash associated with echovirus 9 meningitis can be petechial, resembling meningococcemia.

Encephalitis signifies that the brain parenchyma is infected, with the possibility of a disturbed state of consciousness, focal neurologic signs, and seizures. The distinction between an aseptic meningitis and an encephalitis is an important one because the absence of parenchymal involvement in aseptic meningitis suggests a more benign condition and a more favorable prognosis. Encephalitis is usually associated with aseptic meningitis, so that one is usually dealing with a meningoencephalitis.

Patients with enterovirus encephalitis usually have a global neurologic depression in function, although one can occasionally see focal neurologic signs, resembling herpes simplex virus encephalitis (219). Cases associated with an acute cerebellar ataxia have been reported in children infected with various enteroviruses, including polioviruses, echoviruses 6 and 9, and coxsackieviruses A2 and A9 (153). Other uncommon clinical manifestations that have been reported include acute hemiplegia, opsoclonus-myoclonus, movement disorders, and Guillain-Barré syndrome (153). At times, the spinal cord rather than the brain is involved (i.e., there is a myelitis) (see preceding section Poliomyelitis).

The meningeal syndrome is usually a self-limited and benign one, with evidence of improvement in days to a week. Deaths have been reported, however, following infection with a number of enteroviruses, including coxsackievirus B1 and echoviruses 9, 17, and 21 (153). Morbidity and mortality are also increased in the neonate. The neonate's disease tends to be especially severe when the disease appears soon after birth, perhaps reflecting perinatal spread of virus to the fetus from the mother. Mortality is increased in the neonate partly because the aseptic meningitis can be associated with systemic disease, such as hepatitis and myocarditis, as well as encephalitis. The largest study of recovered patients failed to find any neurodevelopmental abnormalities above levels seen in controls (281).

Isolation of enteroviruses may be unsuccessful because a particular enterovirus may grow poorly in cell culture or because inhibitory factors, such as neutralizing antibody, may be present in the spinal fluid. With the use of reverse transcriptase polymerase chain reaction, enterovirus genome may be found in a significant number of culture-negative spinal fluid samples from cases of aseptic meningitis. Using reverse transcriptase–polymerase chain reaction, the New York State Department of Health found evidence of the enterovirus genome in the spinal fluid from 13 patients in a series of 33 cases of CNS infection occurring from July 1997 to November 1998 (138). In another series, 23 of 39 adult patients

diagnosed with aseptic meningitis between August 15 and October 31, 1998, had evidence of enteroviral genome by reverse transcriptase–polymerase chain reaction (284). The potential usefulness of reverse transcriptase–polymerase chain reaction can be seen in a recent report of a Swiss epidemic of aseptic meningitis caused by echovirus 30, when enterovirus genome was identified by using this technique in 42 of 50 spinal fluid cultures (84%) that were negative for virus by cell culture (104). On the other hand, the use of reverse transcriptase—polymerase chain reaction may be unsuccessful because some so-called generic reverse transcriptase–polymerase chain reaction primers may fail to hybridize well to particular enteroviruses because of a difference in target sequence.

Enteroviruses appear to vary in their neurotropism and neurovirulence, and some types are overrepresented as etiologic agents of aseptic meningitis. In the past, poliovirus was a major cause of meningitis, but this infection is now rare except in association with vaccine-associated paralytic poliomyelitis. In the United States, the 15 most common enterovirus isolates make up over 80% of all the United States isolates (308). Recent enteroviruses implicated in aseptic meningitis in the United States have included coxsackievirus B5 and echoviruses 4, 6, 9, 11, and 30 (283), although from time to time most enteroviruses have been the cause of occasional cases.

Although a specific virus is not usually identified in most cases of encephalitis, and although the number of cases in which an enterovirus has been identified as the cause of encephalitis is low, enteroviruses nevertheless rank second to herpes simplex virus and comparable to arboviruses as a recognized cause of encephalitis in the United States. The New York State Department of Health found evidence of enterovirus genome by polymerase chain reaction in the spinal fluid of 3 of 41 cases of encephalitis over the period from July 1997 to November 1998 (138); herpes simplex virus genome and arbovirus genome were each found in five cases.

In some areas of the world, epidemics of enterovirus 71 (57, 303) have been associated with a high incidence of aseptic meningitis as well as CNS parenchymal involvement; the CNS infection has caused acute flaccid paralysis as well as a more varied clinical symptomatology (204). As noted previously, enterovirus 71 is emerging as the most significant neurotropic enterovirus in some areas of the world. This virus circulates in the United States, and 26% of adults tested in a seroepidemiologic study in New York in 1972 had antibody (79). An epidemic of enterovirus 71 infection in 1998 in Taiwan involved frequent CNS disease and 129,106 reports of hand-foot-and-mouth disease or herpangina (see later section Respiratory Infections, Herpangina, and Hand-foot-and-mouth Disease), which may correspond to 1 million actual cases of enterovirus infection (126). The hand-foot-and-mouth disease patients had vesicular lesions on their hands, feet, mouth, and at times buttocks, whereas the patients with herpangina had vesicular lesions of the palate and pharynx. Of special concern was the finding of 405 severe cases with associated complications, 78 of which were fatal. Among the more severe cases, the case fatality rate in different areas ranged from 7.7% to 31.0%. Most of the hospitalized cases (80%) and the deaths (91%) were in children younger than 5 years of age. The most frequent complication was encephalitis. Other serious complications, which were associated at times with encephalitis, included aseptic meningitis, myocarditis, and pulmonary edema and hemorrhage. It is unclear whether the pulmonary signs were related to viral invasion of the lungs or to brain injury from the viral encephalitis.

A recent review (139) of 41 hospitalized children with neurologic complications and culture-confirmed enterovirus 71 infection during the Taiwan epidemic in 1998 demonstrated an unusual and rather distinctive neurologic manifestation, brainstem encephalitis or rhombencephalitis. The mean age of the 41 children was 2.5 years (with a range from 3 months to 8.2 years). There was frequently an associated condition: hand-foot-and-mouth disease in 68%, or herpangina in 15%. The neurologic disease usually followed the initial illness of fever and skin or mucosal lesions, and it was manifested as rhombencephalitis (37 patients), aseptic meningitis (3 patients), and acute flaccid paralysis (associated with the disease in 4 patients, and following rhombencephalitis in 3 of the 4). At times, breathing difficulties and coma were seen in the rhombencephalitis patients, progressing to death in five of them. The brainstem and spinal cord pathology was presumably related to direct viral injury, as virus was cultured from the spinal cord and brainstem of the one patient who underwent autopsy. Five of the patients who survived had neurologic sequelae. Enterovirus 71 brainstem involvement was also seen during an epidemic in Malaysia in 1997, but not in earlier epidemics. In contrast, hand-foot-and-mouth disease and herpangina did not occur during the previous epidemics in Bulgaria and Hungary. It is not clear whether the changes in enterovirus 71 disease phenotype represent the emergence (or reemergence) of a more virulent strain, or whether it is related to the serologic status of the at-risk populations.

There are likely to be epidemiologic, host genetic, and viral genetic factors that determine which enteroviruses are more neurotrophic than others. For example, some epidemics of aseptic meningitis may be caused by infection of a seronegative population with a particular rare enterovirus. Host factors in neural cells may also affect the replication or translation of some enteroviruses differently from other enteroviruses. There may be determinants in the viral genome that affect neurovirulence (see previous section Pathogenesis).

The presence of immunodeficiency predisposes to a syndrome of enterovirus-induced aseptic meningitis or meningoencephalitis, at times producing a persistent CNS infection. McKinney and colleagues (201) reviewed over 40 cases of chronic enteroviral meningoencephalitis in patients with congenital immunodeficiencies, most commonly X-linked agammaglobulinemia. Clinical features were remarkably varied and included headaches, seizures, ataxia, a disturbed state of consciousness, motor deficits, personality changes with cognitive decline, and sensory disturbances. At times, patients had other associated abnormalities, such as a dermatomyositis syndrome (in 21 of 41 patients; see later section Muscle Disease), rashes (16 of 35 cases), edema (20 of 40 cases), and hepatitis (15 of 32 patients). Although some cases started abruptly, most tended to be slowly progressive, at times lasting years, but with a not infrequent fatal outcome. Most patients had a spinal fluid mononuclear cell pleocytosis with an increase in protein. Some cases at autopsy had evidence of inflammatory infiltrates in the heart, lungs, kidneys, adrenals, thyroid, and pancreas, in addition to the CNS.

In the series of McKinney and colleagues (201), 37 of 41 immunocompromised patients with an associated CNS enterovirus infection had echovirus infection, with echovirus type 11 isolated in 11 cases. Other isolates besides echovirus included single cases with coxsackievirus A11, A15, B2, and B3. The reason for the preponderance of echoviruses, especially echovirus 11, remains unclear. Some patients had evidence of more than one sequential or simultaneous enterovirus infection. A more recent study reported that spinal fluid from 18 of 27 immunocompromised

patients with an associated CNS enterovirus infection had polymerase chain reaction evidence of enterovirus genome, although enteroviruses could be cultured from only two (328). The low incidence of enterovirus isolation in this series contrasts with the high frequency (93%) of culture-positive enteroviruses noted in a previous large review. Rotbart (283) questions whether this discrepancy may be a result of the more frequent and probably earlier use of intravenous immunoglobulin as treatment for patients in the more recent study. Intravenous immunoglobulin treatment may decrease the level of infectious virus but not clear it completely. The patients from the recent series had more frequent evidence of normal spinal fluid protein and cells, suggesting that the clinical spectrum of treated disease may have changed from previous descriptions. Last, it is likely that the more frequent and early institution of intravenous immunoglobulin treatment will alter the spectrum of enteroviruses that are seen—that is, strains that are less common in the population (and not neutralized by the pools of immunoglobulin used for therapy) may more likely be present.

Cardiac Disease

Myocarditis is an inflammation of the myocardium associated with damage that is unrelated to an ischemic injury. Myocarditis is frequently self-limited and subclinical, with few if any sequelae. On the other hand, the acute disease may lead to significant morbidity and even death. On the basis of well-established criteria, one study found evidence of myocarditis in approximately 1% of autopsies (107).

In some cases, the myocardial inflammation may persist, producing a chronic myocarditis that can progress to dilated cardiomyopathy (reviewed in refs. 48,157,200,282). In dilated cardiomyopathy, the heart is large, with impaired function and evidence of heart failure but with little or no inflammation. The incidence of dilated cardiomyopathy in the United States has been reported to be 6 cases per 100,000 (59), and approximately 100,000 new cases occur each year. Patients with dilated cardiomyopathy are frequent recipients of heart transplants, making up perhaps 50% of all cardiac transplant patients. Of note is the observation that nonpolio enteroviruses, especially coxsackievirus B3, cause acute and chronic myocarditis in animals, and that a contribution from the immune system to the chronic disease has been proposed (see earlier section Pathogenesis).

Acute Cardiac Disease

Enteroviruses have been implicated as an etiologic agent of viral myocarditis in humans. It is believed that 1.5% of enteroviral infections, including 3.2% of coxsackievirus B infections, result in overt cardiac signs or symptoms (108). Myocarditis is a very frequent autopsy finding in children who die of overwhelming coxsackievirus infection (158). Coxsackievirus B5 has been implicated in cardiac disease, although other coxsackieviruses of group B or group A or echoviruses have also been identified. The peak age group in which myocarditis caused by coxsackieviruses of the B group occurs is young adults, primarily between 20 and 39, with a higher prevalence among men (335).

A summary of data from varied sources showed that the prevalence of enteroviral infection in acute myocarditis on the basis of serologic studies is 34% (214 positives in 636 patients) compared to 4% (44 in 1,139) of controls (199). However, there are a number of potential shortcomings to these studies. The serologic studies demonstrating seroconversion with an enterovirus do not prove that enteroviruses are involved in the pathogenesis of cardiomyopathy, as they may result merely from an unrelated infection (see later section Differential and Presumptive Diagnosis). In addition, there is evidence that multiple enteroviruses can circulate at the time of an epidemic, so that isolation of an enterovirus does not prove its role in a disease; for example, more than 10 enteroviruses were recovered from the community during an echovirus 9 epidemic (153).

A metaanalysis of data obtained from molecular studies (slot blot hybridization, *in situ* hybridization, and reverse transcriptase–polymerase chain reaction) published in 12 reports found 23% of cases (68/289) and 6% of controls (14/216) had evidence of enterovirus genome in heart tissue, giving an odds ratio of 4.4 with a 95% confidence interval of 2.4 to 8.2 (24). These data, coupled to reports of positive virus isolations from the heart, indicate that enteroviruses may represent a common cause of acute myocarditis. The surprisingly large number of positive results in controls is presumed to result from difficulties in obtaining appropriately controlled heart tissue.

Chronic Cardiac Disease

Human dilated cardiomyopathy has multiple causes, both inherited and sporadic. A prior history of enteroviral infection of the heart, especially with coxsackievirus B, has been implicated in sporadic human dilated cardiomyopathy (23,308). A summary of serologic data from multiple sources found that the prevalence of enteroviruses in dilated cardiomyopathy was 24% (64/260) compared to 10% of controls (26/255) (199). These serologic data suffer from the same drawbacks that were just noted.

In contrast to acute myocarditis, there are no reports of isolation of enteroviruses from chronic dilated cardiomyopathy, suggesting that the virus may have a restricted expression or disappear following the acute infection. These possibilities led to studies probing affected tissues for persistent enteroviral genome. A metaanalysis of data from molecular studies described in 17 published reports found 23% of the patients and 7% of controls had evidence of enteroviral genome, giving an odds ratio of 3.8 with a 95% confidence interval of 2.1 to 4.6 (24). The metaanalysis data are suggestive of an association between enterovirus infection and chronic cardiac disease; however, it remains a possibility that RNA from other laboratory-based enteroviral studies contaminated test samples in the highly sensitive polymerase chain reaction studies. Most of the hybridization and polymerase chain reaction studies did not include sequencing of the viral genome, and therefore failed to more directly prove that an enterovirus was involved. In a few cases, however, there was partial sequencing of the RNA found in clinical samples; for example, Archard et al. (19) identified the amplified sequence as coxsackievirus B.

Not all the viral genomic studies have been positive. One recent investigation involving a nested polymerase chain reaction failed to find evidence of enterovirus RNA in 287 heart biopsy specimens from 38 patients with dilated cardiomyopathy and 39 patients with heart failure of unknown cause (74). There are at least two other studies that have

also been negative (187,298). The lack of consistent reproducible results regarding the presence of enteroviral genome in tissue from patients with cardiomyopathy indicates that further studies are needed under careful, blinded conditions.

Arrhythmogenic right ventricular dysplasia/cardiomyopathy is a variation of dilated cardiomyopathy in which there is fatty or fibrous tissue replacement of the right ventricular myocardium. About 65% of cases have evidence of inflammatory infiltrates (27). A recent reverse transcriptase–polymerase chain reaction investigation reported that heart tissue from three of eight patients had evidence of a slightly varying RNA sequence that was most similar to coxsackievirus B2 (112). At the same time, these investigators found a positive result by reverse transcriptase–polymerase chain reaction in 7 of 23 patients with myocarditis or dilated cardiomyopathy (and in none of five patients with noninfectious cardiomyopathy). Further studies of this disease process are indicated.

Muscle Disease Including Pleurodynia

The relationship of enteroviruses to inflammatory muscle diseases was initially recognized because of the myotropism of coxsackieviruses in suckling mice. This observation was fueled by the association of these viruses with epidemic pleurodynia on the Danish island of Bornholm. The latter disease, called Bornholm disease, has occurred as an epidemic and also sporadically in various locales. Bornholm disease is an acute febrile illness with myalgia, especially involving the chest and abdomen, but without muscle weakness. Relapses may occur. Coxsackievirus B3 and B5 are the most frequently recognized etiologic agents, although other enteroviruses have also been isolated (347). The limited information from muscle biopsy findings suggests that the inflammation in this disease may be confined to the endomysial part of the muscle and is therefore not a true myositis (67).

Inflammatory muscle diseases can be acute or chronic. Acute inflammatory muscle diseases are generally called acute polymyositis or acute myositis. These acute diseases are characterized by fever with myalgia, elevated muscle enzymes, and, at times, myoglobinuria. Chronic inflammatory muscle diseases are primary inflammatory diseases of the muscle that are generally classified as polymyositis, dermatomyositis, or inclusion body myositis. These diseases cause a subacute to chronic progressive weakness with a distinctive pathology on muscle biopsy. Dermatomyositis is distinguished from the other two inflammatory myopathies because it is associated with a characteristic rash.

The causes of chronic inflammatory myopathy are generally unknown. Hypotheses concerning the etiology of polymyositis and dermatomyositis include a direct virus infection, especially an enterovirus infection, or an autoimmune process in which the virus infection triggers a reaction against muscle (see earlier section Pathogenesis). The fact that coxsackieviruses cause acute and chronic inflammatory myopathy in experimental animals provides additional support for their involvement in human inflammatory muscle diseases. Investigations of this model system may help clarify the pathogenesis of these diseases in humans.

Enteroviruses have been implicated in polymyositis on the basis of serologic and electron microscopic studies (66). The findings from serologic studies have varied interpretations, however, and may simply reflect an intercurrent enterovirus infection that is unrelated to the acute myositis. Similarly, ribosomes or glycogen have an ultrastructural appearance that resembles an enterovirus, and therefore electron micrographs implicating enteroviruses may have been misinterpreted.

Enteroviruses have been isolated from cases of inflammatory myopathies, but these isolations have generally been rare and from single cases with acute (33) or atypical clinical pictures (315). The inability to isolate virus from cases of chronic inflammatory myopathy has suggested that there is a restricted expression of the virus with little infectious virus present. For this reason, investigators have probed muscle tissue from patients with inflammatory myopathy for picornaviral genome. Some reports involving slot blot or *in situ* hybridization studies of muscle tissues from patients with inflammatory myopathies have shown positive results using enterovirus-specific probes (346). In some cases, the product amplified in a reverse transcriptase–polymerase chain reaction has been identified as coxsackievirus group B sequence (20). In contrast, other studies using reverse transcriptase–polymerase chain reaction and nucleic acid hybridization have been negative (125,181,182,248). It remains a possibility that an enterovirus could trigger an autoimmune inflammatory muscle disease and then disappear. Additional studies firmly indicating enteroviral involvement in the pathogenesis of inflammatory muscle disease are needed. Studies regarding the possible role of enteroviruses in chronic fatigue syndrome have similarly failed to find reproducible evidence of enterovirus involvement (reviewed in ref. 67).

Of special interest in the issue of enterovirus involvement in inflammatory muscle disease is the observation that patients with immunodeficient states can manifest a dermatomyositis-like disease with an accompanying persistent echovirus infection (326,332). It should be noted, however, that questions have been raised as to whether these patients had a true myositis (i.e., inflammation of the muscle) or a fasciitis with interstitial inflammation in the endomysium (67). The inflammatory muscle disease is associated with a chronic encephalomyelitis as well as a more disseminated disease in which enteroviruses, especially echoviruses, can be cultured from the spinal fluid (see previous section Meningitis and Encephalitis) (352). Although virus has been isolated on occasions from affected muscle, it remains unclear whether the dermatomyositis syndrome in immunodeficient patients is a result of direct invasion of the muscle by the virus or an immune-mediated disease associated with virus persistence. The existence of this dermatomyositis-like syndrome demonstrates that echoviruses, and perhaps other enteroviruses, may be able to produce a chronic myositis in humans that is associated with a persistent infection and chronic inflammation.

Diabetes

Both genetic and environmental factors, including enterovirus infection, have been implicated in the etiology of insulin-dependent diabetes mellitus. A number of epidemiologic and serologic studies have demonstrated a relationship between enterovirus infection and the development of diabetes. D'Allessio (69) found that 15 of 84 cases (17.8%) of newly diagnosed insulin-dependent diabetes mellitus had evidence of IgM antibody against coxsackievirus B, compared to 5 of 71 controls (7.0%). The individuals with IgM antibody were especially common in association with HLA-DR3 positivity. A recent prospective study in Finland found a greater incidence of serologic conversion of enterovirus antibodies among children who developed insulin-dependent diabetes mellitus than among those who did not (147). The

antibody present in the prediabetic period was directed against a number of different enterovirus serotypes, including coxsackievirus A9, B1, B2, B3, and B5 (279).

There have been rare but well-documented isolations of coxsackievirus B4 from the pancreas of patients with acute-onset as well as from fatal cases of insulin-dependent diabetes mellitus (265,271). Some of the isolates have been demonstrated to be diabetogenic when inoculated into certain mouse strains (342) and nonhuman primates (343). In addition, patients dying from coxsackieviral myocarditis can have an associated pancreatitis including islitis. More recent investigations have involved probing tissues from patients for evidence of enterovirus genome. Andreoletti et al. (13) reported that peripheral blood mononuclear cells from 42% of newly diagnosed patients with insulin-dependent diabetes mellitus, and from no controls, had evidence of enteroviral genome with a sequence similar to that of coxsackievirus B3 and 4; this study clearly needs to be reproduced. Although it is likely that enteroviruses are capable of causing diabetes mellitus in animals and humans, it remains unclear how often this occurs in humans, and what if any immune mechanisms are involved.

Eye Infections

Acute hemorrhagic conjunctivitis is characterized by a short incubation period of 24 to 48 hours preceding a rapid onset of uniocular or binocular symptoms and signs. Patients manifest excessive lacrimation, pain, periorbital swelling, and redness of the conjunctiva (from subconjunctival petechiae to frank hemorrhages) (340). Keratitis with accompanying pain and possible visual impairment as well as anterior uveitis may be seen. The epidemic disease can also be associated with nonophthalmic symptoms and signs, such as neurologic dysfunction (see previous section Poliomyelitis) and respiratory and gastrointestinal disturbances. The disease usually resolves without sequelae in 1 to 2 weeks.

The first pandemic of acute hemorrhagic conjunctivitis was recognized in 1969 in Africa. Within 2 years, two enteroviruses, a new antigenic variant of coxsackievirus A24 and a previously unknown enterovirus serotype designated enterovirus 70, were implicated as etiologic agents responsible for the epidemics of this disease (189). During the first pandemic from 1969 to 1971, millions of people were likely to have been infected. Subsequent epidemics of acute hemorrhagic conjunctivitis have continued in various locations throughout the world. Other enteroviruses have also been recognized as causes of acute hemorrhagic conjunctivitis (e.g., echovirus type 7) (289) and as causes of sporadic conjunctivitis and keratoconjunctivitis (161). The ocular disease caused by enteroviruses is often indistinguishable from acute hemorrhagic conjunctivitis caused by various adenovirus serotypes.

Respiratory Infections, Herpangina, and Hand-Foot-and-Mouth Disease

Enteroviruses are a common cause of respiratory illnesses. A recent review notes that enteroviruses were isolated in 1.7% of 3,119 respiratory specimens submitted for viral culture from 1983 to 1994 (54), and in 6.4% of all the viruses that were isolated from these specimens (54/838). Respiratory illness occurred in 15% of enterovirus infections collected by the World Health Organization from 1967 to 1974 (108) and 21% of cases from the Centers for Disease Control obtained from 1970 to 1979 (16). The enteroviruses implicated in these respiratory infections included coxsackie type A viruses (12.4%), coxsackievirus type B (20.3%), and echoviruses (12.6%) (108).

Enteroviral respiratory infections are more frequently associated with upper respiratory infections, such as the common cold, croup, and epiglottitis, than lower respiratory infections, such as pneumonia. The infections are frequently subclinical, but if they cause clinical disease it tends to be self-limited and mild, with a short incubation period of 1 to 3 days. More severe lower respiratory infections may be related to a higher dose of virus in the inoculum. In a series of infants with coxsackievirus B infections, 30 of 77 patients had marked abnormalities (e.g., interstitial inflammation and hemorrhage), and 12 had virus isolated from the lung (158).

Herpangina is a febrile illness of relatively sudden onset with complaints of fever and sore throat. There are characteristic lesions on the anterior tonsillar pillars, soft palate, uvula, tonsils, and posterior pharynx. The illness, which has a predilection for the young, is usually self-limited and disappears within a few days. At times, the disease is associated with more significant clinical abnormalities such as meningitis. Hand-foot-and-mouth disease is an illness associated with vesicular lesions of the hands, feet, mouth, and, at times, buttocks.

A number of enteroviruses have been identified as causes for herpangina, including coxsackievirus A and B serotypes, echovirus types 6, 9, 11, 16, 17, 22, and 25 (54), and enterovirus 71. The main causes of hand-foot-and-mouth disease are coxsackieviruses A10 and A16 and enterovirus 71 (108,222). The pathogenesis of the lesions seen in herpangina is not clear; however, experimental infection of rhesus monkeys with coxsackievirus A4 may provide a model system for the study of the pathogenesis of herpangina. In this system, ingestion of the virus by the oral route leads to multiplication in the lower gastrointestinal tract, followed by viremia and then multiplication in the oropharynx (305).

Neonate and Infant Disease

Neonates are at increased risk from enteroviral infections. This increased susceptibility is present in humans as well as experimental animals infected with varied enteroviruses (55).

The increased risk of neonates to enterovirus infection was apparent in the prevaccine era with respect to poliovirus. Although the incidence of paralytic disease among neonates approached 40% born to mothers with poliomyelitis at the time of delivery, the overall incidence of neonatal poliomyelitis was an infrequent occurrence, perhaps related to the protective effect of maternal antibody (336). Neonatal poliomyelitis generally had a shorter incubation period and a higher case fatality rate than found with disease later in life, demonstrating the increased susceptibility of immature hosts to enterovirus infection. Infection of the mother early in gestation was associated with an increased risk of abortion, stillbirth, and prematurity (55).

Nonpolio enteroviruses are a not infrequent cause of infection in neonates and infants. In a series from the Centers for

Disease Control, enterovirus isolates from patients less than 2 months old included echoviruses (51%), coxsackievirus B (45%), and coxsackievirus A (4%) (224). Echovirus serotypes included 4, 9, 11, 17 to 20, 22, and 31 (201).

The most frequent presentation in the neonate infected with nonpolio enteroviruses is asymptomatic disease (152). Symptomatic cases most commonly manifest a self-contained febrile illness, at times associated with irritability and nonspecific signs of infection, making enterovirus infection a leading cause of fever in the infant. A rash of variable character is seen in over 30% of cases (5). More serious infections can be seen, with the peak of symptoms correlating with viremia (65). Nonpolio enteroviruses are the most frequently identified cause of aseptic meningitis in infants less than a month old, and are believed responsible for more than a third of these cases (302). In a small series of patients with pneumonia in the first month of life, enteroviruses were implicated in 15% of cases (6/40) (6). There is usually a history of fever or respiratory symptoms in the mother a week prior to the delivery, although mothers can be asymptomatic or have a more severe disease.

One of the serious infections caused by enteroviruses is a sepsis-like disease. In one series, enteroviruses were implicated in 65% of infants less than 3 months old admitted for suspected sepsis (64). In another, more recent series, there was evidence of enteroviral genome in 80 of 345 infants less than 90 days old admitted to a medical center with suspected sepsis (45). A number of other studies have yielded similar results, emphasizing the importance of enteroviruses as a cause for a sepsis-like syndrome among neonates and infants (65)—in fact, enteroviruses tend to be a more common cause of this syndrome than bacteria in the summer and fall (45). There may be extensive multiorgan involvement in severely affected cases, especially ones that go on to a fatal outcome; the organs affected include liver, lung, heart, pancreas, and brain.

The incidence and severity of enterovirus infections among infants can be better appreciated by reviewing a study conducted in Nassau County, New York, from 1970 to 1979 (158). Out of 153,250 live births, 77 infants younger than 3 months required hospitalization for group B coxsackievirus infection. These 77 cases were from a pool of 602 infants who tested positive for group B coxsackievirus, demonstrating the high frequency of group B coxsackievirus infection in infants. The attack rate might have been even higher than was found, because the positive samples from this study were from only a limited number of infants hospitalized in the community. Twenty-four mothers had evidence of a viral-like infection occurring within a period from 10 days prior to delivery to 5 days after delivery. The most common syndrome that was seen was aseptic meningitis. Some of the infections in the infants were very serious, as evidenced by the finding that eight children died from overwhelming group B coxsackievirus infection. All but one of these eight had evidence of myocarditis.

Severe enterovirus disease in the young is associated with an early age of illness, prematurity, a more severe illness in the mother, multiorgan disease, low socioeconomic status, bottle-feeding, specific enterovirus types, and an absence of neutralizing antibody to the pathogen (5). The level of maternal neutralizing antibody appears to be important both for determining the risk of developing infection and for modulating the severity of disease (7). The importance of antibody in determining the outcome of disease suggested a role for administration of intravenous immunoglobulin in the treatment of neonatal infections, especially with a pool of immunoglobulin that contains a high level of neutralizing antibody to the particular virus involved (7). Long-term sequelae following neonatal myocarditis or CNS infection appear infrequent (5,283).

Nonpolio enteroviral infection may affect the fetus, inducing clinical abnormalities and causing overt disease in the neonate. There are reports of abortion and stillbirth associated with maternal enteroviral infections, although these are infrequent (5). The relationship between maternal enterovirus infection and congenital anomalies in the newborn remains unclear.

There are a number of routes by which enteroviruses can cause neonatal disease. Studies have found evidence of placentitis and viral infection in fetal tissues (5). Virus may enter the placenta or fetus from contaminated maternal blood, feces, or vaginal secretions; this may occur during pregnancy, with virus penetrating the fetal membranes, or at the time of the delivery. In addition, infection of the neonate may result from a viremia, because enteroviruses have been cultured from cord blood (154), but it is unclear how often this route of transmission occurs. Infection can also occur from virus shed by other neonates or hospital staff in the nursery. In cases involving nursery outbreaks, implementation of infection controls, such as strict hand washing and the isolation of affected patients, has a role in prevention of new cases.

DIAGNOSIS

Differential and Presumptive Diagnosis

The process of diagnosing an enterovirus infection or establishing that an enterovirus infection produced a particular clinical syndrome can be complicated and challenging. This problem results from the biology and epidemiology of enterovirus infections, as well as from limitations in current diagnostic methodologies. Although it is possible to demonstrate that a person is infected with an enterovirus, this association does not necessarily prove likely disease causation. On the other hand, a presumptive diagnosis in certain epidemiologic and clinical situations can be possible with a high degree of certainty on clinical grounds alone.

There are several related biologic properties that complicate the diagnosis of enterovirus-induced disease. The first is that most virus replication and infection typically occurs in the respiratory and gastrointestinal tract. These infections are often asymptomatic, with few if any systemic clinical signs. Since these infections are extremely common, even random sampling of healthy individuals can demonstrate enterovirus infections at substantial rates. For this reason, the simple recovery or detection of virus from certain nonsterile sites does not establish a firm linkage to disease, and it may be merely coincidental.

A second difficulty is that even when illness results from the enterovirus infection, most of the signs and symptoms are relatively generic and usually lack specificity. This is often the reason that a diagnosis of enterovirus-induced disease is

not considered until other etiologies are excluded, after which optimal specimens are often unfortunately depleted or no longer available. The collection of appropriate clinical specimens for virus isolation or detection is critical to laboratory confirmation of enterovirus infection. At times, the appropriate specimens are not obtained, even in the case of serious disease processes where enteroviruses are clearly a potential etiologic agent, such as meningitis, encephalitis, or myocarditis. The exclusive use of CNS or cardiac specimens to diagnose these conditions limits the sensitivity for detection of infection. For example, even though it is possible to detect enteroviruses in the cerebrospinal fluid from meningitis cases, it is uncommon to find virus in the cerebrospinal fluid from cases of encephalitis where there is a reasonable suspicion of enterovirus as the cause. There are some exceptions: sometimes the virus has readily been recovered from cerebrospinal fluid, such as during the recent outbreaks of fatal encephalitis associated with enterovirus 71 (14). In general, however, the specimen with the highest sensitivity for establishing an acute infection is a stool specimen, regardless of clinical presentation (217). The difficulty with virus isolation is further compounded because virus shedding from the gastrointestinal tract may stop prior to the onset of symptoms, and therefore sensitivity for virus isolation may be lower.

There are circumstances, however, where a presumptive diagnosis can be made on the basis of limited information. This is because of the pronounced seasonality of enterovirus infection in temperate latitudes and the tendency for enteroviruses to cause community outbreaks. For example, cases of aseptic meningitis occurring during the late summer and early autumn have a high probability of enterovirus etiology. In this situation, a presumptive diagnosis of an enterovirus infection could be made on the basis of signs and symptoms, exclusion of other nonviral pathogens, and evidence of characteristic cytopathology of inoculated cell cultures. Another example pertains to epidemic acute hemorrhagic conjunctivitis; in this case, the identification of an enterovirus (either coxsackievirus A24 variant or enterovirus 70) precludes further testing of specimens from other patients with similar symptoms.

Laboratory Diagnosis

Virus Isolation

Many of the detailed procedures for the established laboratory diagnosis of enterovirus infections have been described previously (106). The traditional techniques for detecting and characterizing enteroviruses rely on the time-consuming and labor-intensive procedures of viral isolation in cell culture and neutralization by reference antisera. Isolation of enteroviruses from specimens using appropriate cultured cell lines is often possible within 2 or 3 days and remains a very sensitive method for detecting these viruses. The best specimens for isolation of virus are, in order of preference, stool specimens or rectal swabs, throat swabs or washings, and cerebrospinal fluid. Throat swabs or washings and cerebrospinal fluid are most likely to yield virus isolates if they are obtained early in the acute phase of the illness. For cases of acute hemorrhagic conjunctivitis, the best specimens are conjunctival swabs (340), although occasionally virus can be isolated from tears (341). Since the major pandemic in 1981, however, isolation of enterovirus 70 from patients with acute hemorrhagic conjunctivitis has been very difficult, and molecular methods provide the only sensitive method of detection for this agent (304).

With the accelerating efforts to eradicate poliovirus, virologic surveillance has become a critical part of the program (144,254). For this reason, specimens of good quality are important for confirmation of the diagnosis of suspected poliomyelitis. Isolation of the virus also makes it possible to determine whether the virus is wild type or vaccine related. This information is important to public health officials in areas considered to be free of wild poliovirus, because decisions must be made as to whether control programs are needed to prevent further cases of poliomyelitis. Laboratory studies of isolates can also be used to support the diagnosis of poliovirus infection when the patient has no knowledge of any exposure or has an atypical disease presentation. In the case of suspect cases of poliomyelitis, fecal specimens for viral isolation should always be obtained, because the virus is shed the longest and in highest titer from the intestinal tract. Early in the acute phase of the illness, virus is frequently isolated from the throat. Isolation of virus from cerebrospinal fluid provides the most direct link to disease but is usually less successful. The earlier in the course of illness that cerebrospinal fluid specimens are collected, the more likely virus will be isolated.

The procedure for virus isolation involves inoculation of appropriate specimens onto susceptible cultured cells. Unfortunately, there is no single cell line capable of growing all human enteroviruses. It is common practice to use several types of human and primate cells to increase the spectrum of viruses that can be detected (53). Even with a variety of cells, however, there remain several coxsackievirus A serotypes that fail to propagate in culture. The coxsackieviruses, including those that do not grow in cell culture, can be isolated and propagated in suckling mice.

As a consequence of current poliovirus eradication activities and the importance of poliovirus as a public health problem, specific diagnostic procedures have been developed to detect this virus. In general, poliovirus grows quite well on a variety of primate and human cell culture lines, but it cannot be distinguished from other enteroviruses solely on the basis of cytopathic effect. Polioviruses are unique in the use of a specific receptor to infect cells, PVR, which is distinct from receptors used by all other enteroviruses to infect cells. This receptor has been transfected and expressed in a murine cell line that normally cannot be infected by most enteroviruses but is permissive to viral replication when the viral genome is present within the cell. One of these transfected murine cells, L20B, can grow poliovirus, and it has been exploited to selectively isolate poliovirus, even in the presence of other enteroviruses (136). When a specimen is inoculated onto these cells and a characteristic enterovirus cytopathic effect is seen, the virus can be presumptively identified as a poliovirus. However, there are a few strains of certain nonpolio enterovirus serotypes that are able to grow on the parent murine cells, and therefore growth on L20B cells is not a definitive identification of poliovirus, and confirmatory testing is required.

In routine diagnostic testing, all enterovirus growth in cell culture is detected by its cytopathic effect, and the isolate is typically confirmed as a specific enterovirus by neutralization with type-specific antisera. The most widely used reagent antiserum was prepared in horses and can be obtained from the World Health Organization (208); however, supplies are now becoming limited. As there are at least 66 different known enteroviruses, it would be impractical to attempt neutralization using all possible reference antisera individually. Type-specific antisera are therefore combined in intersecting pools in such a way that antibody to any one type is present in only a limited number of pools. In the Lim,

Benyesh-Melnick (LBM) pool scheme (209), antibodies to 42 different enteroviruses are sorted into eight pools (labeled A through H) (Table 10 and Fig. 10). The typical neutralization test consists of mixing approximately 100 $TCID_{50}$ of an unknown virus with an antiserum pool and incubating at 37°C for 2 hours. Next, the virus–antiserum mixture is inoculated onto a susceptible cell culture system, which is then observed for several days. A separate virus–antiserum mixture is made for each of the available antiserum pools. The pool that neutralizes the unknown isolate identifies the virus. For example, if only LBM pools E and F neutralize the unknown virus, it is presumptively identified as echovirus 18, because only antisera to this virus are found in both of these pools and not in the others. If only pool A neutralizes the isolate, the identity is echovirus 15. Other pool schemes have been devised and used successfully, but they are less widely used due to limited reagent availability. If the virus cannot be identified by use of the A to H pools, other pools and single antisera can be tested. Despite these efforts, the neutralization assay may still fail. Additional procedures may need to be performed, including filtration, treatment with chloroform, and resolution of mixtures by terminal dilution or plaque purification. Even with all of these procedures, “untypable” enteroviruses may still be encountered. They may represent mixed infections, aggregates of viruses, extreme antigenic drift, or undiscovered types. In theory, it should be possible to identify or characterize all of these, but such laborious and time-consuming processes are rarely justified. For clinical management of routine cases, it is seldom critical to identify the specific nonpolio enterovirus type. A high index of suspicion for an enterovirus infection can be developed by reflecting on the clinical picture, the virus isolate's cytopathic effect and cell culture systems utilized, and knowledge of basic enterovirus epidemiology.

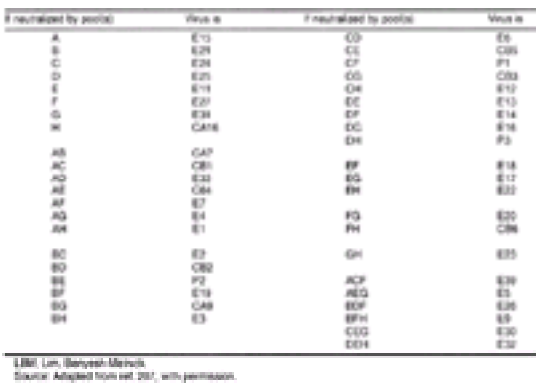

TABLE 10. *Code for reading results of neutralization tests using LBM antiserum pools A–H*

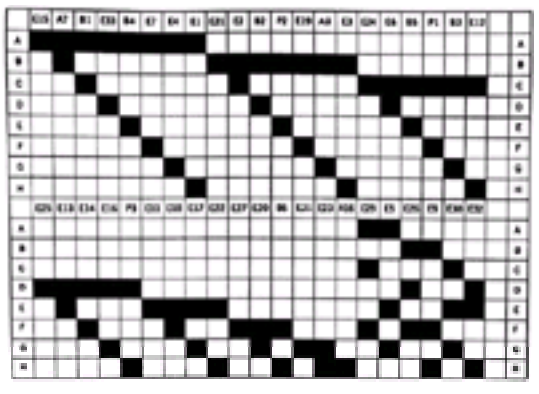

FIG. 10. Schema of antiserum pools. Multiple antisera are incorporated into different pools; a virus isolate can be specifically typed by its pattern of neutralization in tests against the pools. With the antiserum combinations shown, new isolates of 42 enteroviruses can be identified in tests against only eight pools (188,209).

Antibody Tests

Serologic diagnosis of enterovirus infection is made by comparing titers in acute and convalescent phase (“paired”) serum specimens. If an enterovirus isolation and identification have been made, paired serum can be tested against the patient's own isolate. If not, it still may be possible to establish a likely enterovirus infection if a particular serotype is suspected. In this case, a reference strain maintained in the laboratory may be used in a neutralization test. In general, however, enterovirus serodiagnosis is more relevant to epidemiologic studies than to clinical diagnosis (see earlier section Epidemiology). The most basic serologic test is that of neutralization in cell culture. The mechanics of the assay are similar to the test used for identification of isolates, except that a known virus is mixed with serial dilutions of antisera from a patient. There are other, less widely accepted serologic methods, all with particular strengths and weaknesses, including plaque reduction neutralization, complement fixation, passive hemagglutination, hemagglutination–inhibition, and immunofluorescence. A fourfold or greater rise in type-specific neutralizing antibody titer is considered diagnostic of infection. Unfortunately, antibody may already be present at the time the original specimen is obtained because of the extended incubation period and prodromal period of many enteroviral illnesses, complicating interpretation of results.

Many serologic studies rely on the detection of IgM antibody as evidence for recent enterovirus infection, and this is now widely used as an alternative to the neutralization and complement-fixation test. In the last decade, several groups have developed an ELISA for enterovirus-specific IgM (30,196). These tests have been found positive for nearly 90% of culture-confirmed coxsackievirus B infections, and can be performed rapidly. The ELISA has been successfully applied for epidemiologic investigations of outbreaks (102), as well as for specific diagnostic use (72).

In most cases, the IgM ELISA test is not completely serotype specific. Depending on the configuration and sensitivity of

the test, from 10% to nearly 70% of serum samples show a heterotypic response caused by other enterovirus infections. This heterotypic response has been exploited to measure broadly reactive antibody, and the assay used to detect enterovirus infection generically (40,310). In attempting to characterize the exact nature of the response using different antigens, it is clear that the human immune response to enterovirus infection includes antibodies that react with both serotype-specific epitopes and shared epitopes (93). Despite this problem, which is inherently biologic, there remains a fairly high concordance of results between assays of different configurations (127). In summary, the IgM assays that are generally used in epidemiologic studies have very good sensitivity and appear to be very specific for enterovirus infection; however, these assays detect heterotypic antibodies resulting from other enterovirus infections, and therefore cannot be considered strictly serotype specific. Attempts to improve the serotype specificity of these assays have, as expected, either reduced the sensitivity of the assay or decreased the convenience. A positive result with either the neutralization test or IgM ELISA indicates a recent viral infection; however, the infecting serotype found with the IgM assay may not be the same one determined by the neutralization test.

Molecular Detection

The application of molecular biology techniques to clinical virology has begun to significantly change approaches to enterovirus diagnostics (see also the earlier section Epidemiology). Because of distinct advantages in speed, many of these procedures have already supplanted traditional methods of detection and characterization. Continued development and refinement of these procedures will undoubtedly lead to even further application of the methodologies to a broader spectrum of enterovirus diagnostic problems and ultimately into routine primary usage.

As with virus isolation and serotyping, the molecular methods attempt to detect the presence of enteroviruses in a specimen and, in some procedures, to further characterize the detected virus. The techniques can be grouped on the basis of their infrastructure and technical requirements and the types of specimens to which they are applicable. Additionally, the tests can be grouped on the basis of the type of answer the test provides and the predictive value of a positive and a negative result. The first broad group of tests is based on the polymerase chain reaction, which is used primarily to detect enterovirus genome in cell cultures, clinical specimens, and biopsy or autopsy tissues. The second group of tests is based on nucleic acid probe hybridization and is used for both detection and characterization, although usually with less sensitivity than polymerase chain reaction. The third and newest procedure utilizes genomic sequencing for characterization of enteroviruses at the highest levels of specificity.

By far the most common use of polymerase chain reaction for enterovirus diagnosis is the direct detection of virus in clinical specimens (162,243,286). There are numerous variations on the details of the procedures, but all methods that are able to generically detect enteroviruses have several common features. The most important property of these tests is that the primers are targeted to amplify the 5'-untranslated region of the virus genome. Many different primers targeted to this region have been published, and they target different sequences and provide different product sizes. Unfortunately, many of these primers have not been completely evaluated on a large number of clinical isolates to confirm reactivity with all enterovirus serotypes and strains within serotypes, and therefore they have not been validated sufficiently for diagnostic use (229). The major advantage of the pan-enterovirus polymerase chain reaction is that rapid detection of an enterovirus is possible, even with very small amounts of clinical specimens such as spinal fluid. It is also possible to detect enteroviruses that do not readily grow in cell culture. As with all polymerase chain reactions, the sensitivity of amplification of RNA from biologic specimens is extremely variable, depending on the nature of the specimen. Although the polymerase chain reaction procedure can be shown to give a positive result even from only one or a few copies of viral RNA, it is not unusual for the sensitivity to be many orders of magnitude lower in certain specimens (e.g., stool). For this reason, despite the theoretical advantage of the polymerase chain reaction to greatly improve enterovirus detection from clinical specimens, the gains in practice are much more modest (e.g., with spinal fluid) or nonexistent (e.g., with stool) (11,314).

By changing the target for amplification, it is possible to characterize a particular enterovirus using the polymerase chain reaction. Because the antigenic property of viruses that defines serotype is a property of the viral capsid proteins, there are sequences that correspond to this conserved antigenic property within the capsid-coding region of the virus. Extensive studies of the capsid region of poliovirus isolates have led to the design of primers that can selectively amplify isolates from a single serotype but not from other isolates of heterologous serotypes (168). This is accomplished, despite the high rate of synonymous nucleotide substitutions, through the use of inosine in the primer synthesis. In an analogous manner, the ability of poliovirus to uniquely bind to the PVR is also an intrinsic property of the capsid proteins. The amino acids that are involved in receptor binding have been well characterized from studies of the three-dimensional structure of the virion. When primers are designed that correspond to these presumably poliovirus-specific sequences, amplification is observed with all poliovirus isolates but not with other enteroviruses (167). It should be possible to extend these principles to other enterovirus receptor groups and serotypes, and to provide tools for rapid serotype characterization of enteroviruses without the requirement for cell culture procedures.

Nucleic acid probes, the first application of molecular techniques developed for detecting enterovirus genomes, are largely being replaced by the polymerase chain reaction. These early probes were made by synthesizing cDNA from coxsackievirus B viral RNA. The cDNA was cloned into bacteria, amplified, and radiochemically labeled to provide a reagent for detecting enterovirus genomes by nucleic acid hybridization. Further refinement of this technique included the use of RNA probes to improve sensitivity, introduction of nonradiochemical labeling of probes, and the application of these techniques to *in situ* hybridization in myocardial tissue (130). This technique has been particularly useful for understanding the cytopathology of enterovirus infection, especially in studies of myocarditis. The technique, however, cannot be used to identify the serotype of the enterovirus in a specimen because of probe binding to related serotypes.

Nucleic acid probe hybridization has also been extensively used in the poliovirus eradication program as a basic technique to determine whether an isolate is a vaccine-derived or a wild poliovirus. For wild polioviruses, probes can identify the specific strain and therefore its probable geographic origin (73).

A goal in virus identification is knowledge of the sequence of the viral genome. Encoded within this sequence are determinants for all the biologic properties that are attributable to a given virus. Therefore, the nucleic acid sequence

information of a virus represents its ultimate characterization. All important information about a virus could potentially be obtained directly by polymerase chain reaction in conjunction with nucleic acid sequencing if all the molecular correlates of viral phenotypic determinants were understood. At present, however, the genetic location for many properties of the virus remains uncertain. Nevertheless, it is possible at present to use sequence information to assign an enterovirus isolate to a particular serotype (240). The molecular typing system is based on reverse transcriptase–polymerase chain reaction and nucleotide sequencing of the 3' half of the genomic region encoding VP1. The serotype of an unknown isolate is inferred by comparison of the partial VP1 sequence to a database containing VP1 sequences for the prototype and variant strains of all 66 human enterovirus serotypes. Strains of homologous serotypes are easily discriminated from heterologous serotypes (Fig. 11). This method can greatly reduce the time required to type an enterovirus isolate, and it can be used to type isolates that are difficult or impossible to type using standard immunologic reagents. The technique is also useful to rapidly determine whether viruses isolated during an outbreak are epidemiologically related.

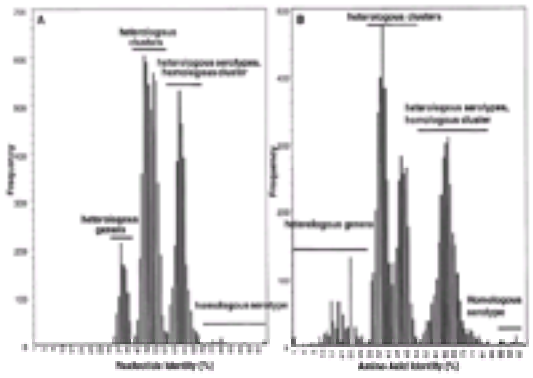

FIG. 11. Serotype identification using sequence data. Frequency distribution of pairwise identity scores for comparison of VP1 nucleotide and deduced amino acid sequences. **A:** Nucleotide sequence distribution. **B:** Amino acid sequence distribution (240). Serotype identification of an isolate can be achieved by comparing the sequence of the isolate with known sequences in VP1 for all serotypes and looking for identities of greater than 75% in nucleotide sequence or greater than 88% in amino acid sequence.

PREVENTION AND CONTROL

Treatment

There is no currently available drug treatment for enteroviral infections in clinical use. However, the effectiveness of a variety of drugs *in vitro*, as well as in animal models, has been documented, and a variety of clinical trials are in progress. In addition, pooled immunoglobulin has been used as a therapy for prevention and treatment of enteroviral disease in immunocompromised individuals.

There are several therapies (e.g., interferon and anti-viral antibody) that target early stages in the virus life cycle, such as spread. Interferon alpha and beta have been found to be effective in coxsackievirus A24 *in vitro* infections (179). Pooled immunoglobulin has been effectively used in enterovirus-induced CNS infections in immunocompromised patients, both by the intravenous route as well as via a shunt into the spinal fluid. Intravenous immunoglobulin appears to stabilize and improve some of these infections, although the disease can progress even in the face of intrathecal immunoglobulin. In some cases, efficacy may be limited by inadequate amounts of the relevant antibody in the immunoglobulin pool (e.g., if the infection involves an unusual and rare enterovirus serotype), as well as problems in the delivery of adequate levels of antibody to the appropriate infected cells. Pilot studies have been conducted administering intravenous immunoglobulin in neonates suspected of having enteroviral infection (7).

Other antiviral drugs have been developed to target specific enteroviral proteins. The WIN compounds, which were originally shown to be effective against rhinovirus, have attracted the most attention. These drugs bind a hydrophobic site near the surface of the virion called the pocket (348), which lies in the floor of the “canyon ”—the region believed to bind the virion to the cellular receptor. By binding to the pocket, these compounds are believed to interfere with viral uncoating and/or adsorption. Variations in activity of WIN compounds against different picornaviruses are presumably related to the particular fit of the drug into the pocket of a specific enterovirus strain. Oral administration of WIN 54954 significantly decreased the number of upper respiratory infections following challenge with coxsackievirus A21 (i.e., 3 of 27 patients in the treated group had an upper respiratory infection versus 15 of 23 in the placebo group) with decreased associated symptoms and viral titers (292); adverse reactions, however, curtailed further investigations with this drug. Pleconaril or VP 63843 is a more recently developed WIN-type compound with a broad *in vitro* inhibitory activity against 95% of the 215 nonpolio enteroviruses that were tested (252). Pleconaril integrates within the hydrophobic pockets of the virus capsid, interfering with capsid functions such as attachment. Significant activity was noted against some serotypes, such as echovirus 11. A randomized, double-blind study involving the administration of pleconaril following a challenge with coxsackievirus A21 showed statistically significant decreases in viral shedding in nasal secretions, nasal mucus production, and total respiratory illness symptom scores in pleconaril-treated patients compared to placebo-treated subjects (291). Another phase II trial of the same drug against enteroviral meningitis showed a statistically significant decrease in disease duration (9.5 days in the placebo group versus 4.0 days in the treatment group), headache duration, and use and amount of analgesia (285). A recent report found that pleconaril treatment cleared an enteroviral gastrointestinal infection in two infants with subacute combined immunodeficiency (238). Trials involving the use of pleconaril in other enteroviral infections including neonatal sepsis are in progress.

Mutant viruses resistant to the WIN compounds can arise. In the case of resistance to rhinovirus, the mutant viruses tend to have bulky amino acid substitutions that sterically block entry of the drug into the pocket (120). These mutant viruses

may not be as significant a problem as expected, as drug-resistant coxsackievirus B3 mutants that appeared in tissue culture following exposure to the WIN compounds tended to be attenuated when inoculated into mice (109).

Enviroxime is an antiviral drug that targets nonstructural protein 3A, leading to a block in the synthesis of plus-strand viral RNA. Although this compound inhibits enterovirus and rhinovirus *in vitro* infections, it is toxic and not effective in humans (82). Resistance to enviroxime is determined by changes in the amino acid at position 30 in protein 3A (121).

Other possible targets for antiviral agents include the viral receptor, the viral proteases (2A or 3C), and the viral replicase (3D).

Poliovirus Vaccine and Eradication

The poliovirus field was fortunate to have more than one excellent vaccine, since both the killed intramuscular vaccine of Salk and the oral attenuated vaccine of Sabin were available. Both of these vaccines led to the production of antipoliovirus antibody (Fig. 12) (234) with subsequent protection from disease. Although there has been a continuing advocacy for one or the other vaccine over the years, it is clear that each has advantages and disadvantages (Table 11 and Table 12)— and that there are appropriate circumstances for the use of each. Now, with the incidence of poliovirus declining dramatically, new guidelines from the Centers for Disease Control and the Advisory Committee of Immunization Practices for vaccine use have been developed in the United States, with a switch from live vaccine to the exclusive use of killed vaccine (at 2 months, 4 months, 6 to 18 months, and 4 to 6 years of age). The main expected benefit for this change is the elimination of vaccine-associated paralytic poliomyelitis.

Advantages
Safe because inactivation ensures that there is no infectious virus
Can be used in immunodeficient and immunosuppressed individuals
Provides excellent systemic immunity
Disadvantages
Requires intramuscular injection with repeated doses
More expensive than live vaccine
Potential hazards because of the use of wild seed virus in production
Reduced intestinal immunity compared to natural infection

TABLE 11. *Killed polio vaccine: advantages and disadvantages*

Advantages
Confers both systemic and intestinal immunity
Relatively inexpensive
Provides herd immunity because the virus is excreted into the environment
Oral delivery
Relatively safe
Disadvantages
May mutate to neurovirulent form causing vaccine-associated paralytic poliomyelitis
Contraindicated in immunodeficient and immunosuppressed individuals
Requires monkeys for safety testing

TABLE 12. *Live polio vaccine: advantages and disadvantages*

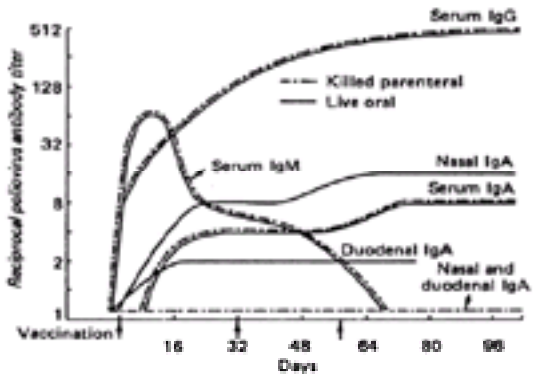

FIG. 12. Serum and secretory antibody responses to oral administration of live attenuated polio vaccine and to intramuscular inoculation of killed polio vaccine (241).

The poliovirus vaccination program has been remarkably successful. As a result of the universal use of Sabin oral poliovirus vaccine, no case of paralytic poliomyelitis from indigenous wild-type poliomyelitis has occurred in the United States since 1980 or in the entire region of the Americas since 1991, laying a framework for the global eradication of

poliovirus. The ultimate eradication of poliovirus seems likely, given the biologic properties of poliovirus and the availability of effective vaccines. Of note, poliovirus is dependent on nearly continuous person-to-person transmission for its survival, because there are no nonhuman reservoirs and because the virus persists for a relatively short time in the environment. Routine immunization in most developed countries was successful in eliminating the indigenous circulation of virus, but many developing countries remained endemic decades after the introduction of poliovirus vaccines. Then, in little more than two decades after the widespread availability of the oral poliovirus vaccine, disease eradication was undertaken, beginning in the Americas (76).

A progress report on the global efforts to eradicate poliovirus is provided on a Web site, http://www.polioeradication.org/. There are four fundamental components of the strategy to eradicate poliovirus (145). First is the achievement and maintenance of high levels of routine immunization. With the accelerated activities resulting from the Expanded Program on Immunization of the World Health Organization, routine coverage with three doses of oral poliovirus vaccine in children under 1 year of age reached nearly 90% of the world's children by 1990.

The second element of the strategy is the use of National Immunization Days for the delivery of vaccine to all children under 5 years of age in a very short period of time, usually from one to a few days (34). The mass immunization interferes with the spread of wild poliovirus. This strategy was used in many early immunization efforts in the 1960s, and it was applied successfully in Cuba to achieve and maintain the elimination of poliovirus from that country following three successive years of annual campaigns (278). The current National Immunization Days are carried out in two rounds about 1 month apart, and they are targeted for the “low season” of poliovirus circulation, when poliovirus transmission is presumably least efficient and therefore most easily disrupted. The National Immunization Days have grown in an extraordinary way as more countries adopt this strategy. Some campaigns now represent the largest public health activities on record. For example, in India in 1999, more than 125 million children were vaccinated in a single day in two rounds 1 month apart. During the same year, more than 450 million children were vaccinated in these mass campaigns worldwide.

The third basic element is the use of surveillance based on cases of acute flaccid paralysis (35). One of the major differences between the smallpox eradication program and the efforts to eradicate poliovirus is the low rate of clinical disease with poliovirus. Because less than 1% of infected susceptible individuals will develop paralytic illness, most infections are not clinically recognized. Therefore, unlike smallpox, where almost all infections were symptomatic, poliovirus is quite difficult to detect; this is certainly a challenge to eradication efforts. To improve the sensitivity of detecting poliovirus infection and yet achieve a practical system, surveillance was developed around the unique clinical presentation of paralytic poliomyelitis. To avoid the requirement of extensive neurologic examinations, which are not feasible in many developing countries, the surveillance was simplified to include any case of acute-onset flaccid paralysis. This system reports many other diseases in addition to poliomyelitis, such as Guillain-Barré syndrome, transverse myelitis, and traumatic neuropathy. However, this loss of specificity is compensated for by a gain in sensitivity, because most cases of true poliomyelitis are reported. It remains unclear how stable the incidence of nonpoliovirus-induced flaccid paralysis will be.

The remaining part of the surveillance is focused on detection of the virus. Two stool specimens are collected from all cases of acute flaccid paralysis and tested in a global network of laboratories to attempt isolation of poliovirus if it is present (144). The major advantages of this surveillance system are simplicity, practicality, and reasonable sensitivity for detection of poliovirus. The major disadvantages are the requirement to rapidly collect, transport, and test a large number of specimens from all areas of the world, and the requirement of high-quality laboratory testing.

The last element of the eradication strategy is the use of “mopping-up” activities (75). This strategy focuses on an area or country where the previous three parts of the program have successfully reduced the number of poliovirus cases to a small number, and where surveillance has localized the remaining reservoirs of transmission. It is then possible to intensify immunization activities in those targeted communities that contain the remaining circulating virus, or the last “chains of transmission.” These intensified activities usually involve active searches in communities for children, including house-to-house or boat-to-boat immunization (15). Teams visit all residences in the area and ensure that children are not missed.

These elements of poliovirus eradication strategy have proven successful in large parts of the world. Since the program began, many countries are now free of indigenous poliovirus circulation. This can be seen in Figure 13, where in 1988 poliovirus was found on all the continents (except Australia), with estimates of more than 350,000 cases of poliovirus each year. In 1999, the number of countries with proven or suspected poliovirus was only 50, and all of the Americas, Europe, and the Far East are believed to be free of poliovirus (17). The remaining countries with large numbers of poliomyelitis cases include countries in south Asia (India, Bangladesh, Pakistan, and Afghanistan) and sub-Saharan Africa (Nigeria, Ethiopia, Democratic Republic of Congo, Angola, Ivory Coast, and other countries in central and western Africa).

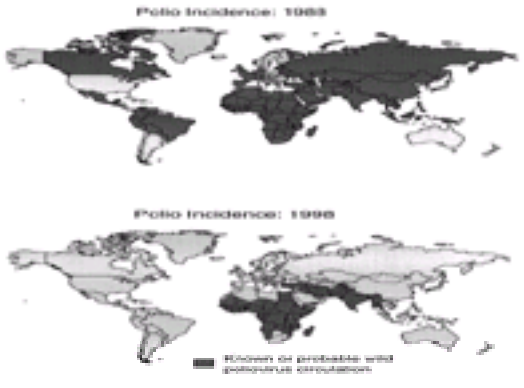

FIG. 13. World map depicting the circulation of wild poliovirus for 1988 and 1998 as reported to the WHO. (Adapted from

Centers for Disease Control, unpublished data.)

In 1988, in part based on the rapid progress of eradication activities in the Americas, the World Health Assembly unanimously adopted a resolution calling for the global eradication of poliovirus before the end of the 20th century. This resolution was reaffirmed in May of 1999, and an acceleration of activities was urged. These accelerated activities include additional rounds of National Immunization Days in large endemic countries, intensified surveillance in high-risk communities, and mopping-up in focal reservoirs.

The achievement of eradication is only the first step in a process that, like smallpox, will lead to the cessation of vaccination and realization of savings that will exceed $1.5 billion per year (26). After wild virus circulation is interrupted, the only remaining viruses will be in the laboratories of the world. Therefore, it will be necessary to institute proper containment of poliovirus, and shift studies to other viruses where possible. A plan for these steps of containment has been drafted and will be implemented in phases as eradication proceeds. In the first pre-eradication phase, preparation for later phases is to be undertaken by conducting an inventory of all institutions and laboratories that have wild polioviruses or potentially infectious materials. Wherever possible, use of vaccine strains of poliovirus should be substituted for wild strains. In the second phase, which begins 1 year after the last wild virus has been isolated anywhere in the world, all work with wild polioviruses will be done at the higher Biosafety Level 3/polio level of containment. At this point, the main risk of reintroduction is from the laboratory. Other possible concerns involve the excretion of virus from immunodeficient individuals. It is sometime during this phase, once all countries have been certified as being free of circulating poliovirus and all laboratories have properly contained, referred, or destroyed their poliovirus stocks and potentially infectious materials, that the Global Certification Commission will declare poliovirus eradicated. The last phase of containment will occur sometime in the future when the decision is made to stop vaccination with oral poliovirus vaccine. At this point, all infectious polioviruses will need to be in maximum containment.

There are numerous unknowns and potential obstacles that remain to be faced in the eradication efforts. Because of the inherent insensitivity of detecting poliovirus infection, it is important that surveillance quality be achieved and maintained for a period of time. Although the exact length of time required to be assured of success is not known in all circumstances, the minimum requirement is 3 years. Previous experience indicates that if excellent surveillance is achieved and maintained, poliovirus genotypes that have not been detected for a period of 1 year are not detected ever again. This has been true for more than a dozen genotypes that have been eliminated from circulation (Fig. 14).

FIG. 14. World map depicting type 1 poliovirus genotypes in different regions from 1992 to 1999 and the years in which the eradication occurred. (Adapted from Centers for Disease Control, unpublished data.)

One potential problem with poliovirus eradication pertains to individuals with immune deficiencies, who may continue to excrete poliovirus for periods of over a decade. Prolonged excretion of vaccine-related poliovirus has been observed in several patients with humoral immune deficiencies, such as agammaglobulinemia, but not with wild polioviruses (166). It is not clear whether this lack of persistent wild virus infection is caused by the greater neurovirulence of wild polioviruses—leading to a uniformly, fatal outcome—or by the lack of exposure to wild virus by patients with severe immune deficiencies who are largely residents of poliovirus-free countries. There is currently no evidence that patients with cell-mediated deficiencies are at increased risk for chronic poliovirus infections; however, studies are being undertaken to specifically look at prolonged infection in human immunodeficiency virus–infected children and adults.

The last potential obstacle will be the final cessation of vaccination with oral poliovirus vaccine. Since oral poliovirus vaccine strains retain the demonstrable ability to revert to neurovirulence and the potential to regain the increased transmissibility of wild viruses, they pose a continual threat for reintroduction of a new wild poliovirus strain into circulation. The analysis of the risks of different strategies for stopping vaccination are complicated by the lack of information about reversion of vaccine strains. For example, it is not known exactly which genetic determinants are responsible for the property of transmissibility, although it is fairly clear that these are different determinants from the ones controlling neurovirulence.

A recent outbreak of poliomyelitis in the Dominican Republic and Haiti in the summer of 2000 underscores the importance of maintaining excellent surveillance, the need to maintain high vaccine coverage, and the critical importance of developing strategies for the cessation of vaccination with the oral poliovirus vaccine (18). The outbreak affected at least 19 children and was confirmed by virus isolation from 6 of the cases. A type 1 poliovirus that was isolated was clearly related by nucleic acid sequencing to the vaccine strain and was distinct from all wild type and reference strains of poliovirus. Preliminary characterization of the isolates showed reversion of the type 1 attenuation markers and apparent

recombination with an unknown nonpolio enterovirus. The extent of change from the parental vaccine strain was compatible with circulation of this strain for approximately two years prior to the first recognized cases. The intermediate isolates were likely missed because of inadequate surveillance in the affected regions.

The world has endured the crippling effects of poliovirus for millennia, yet the end of these particular viruses is approaching. It is possible that the next edition of this chapter will treat poliovirus as a historic footnote, rather than a major focus of public health activities.

PERSPECTIVES

For 25 to 50 year prior to the identification of acquired immunodeficiency syndrome, much of virology was focused on poliovirus. With the eradication of poliovirus imminent, the picornavirology field is about to change and will never be the same again. It is somewhat ironic to realize that despite the incredible advances in our understanding of the molecular aspects of poliovirus and the relatively recent availability of extraordinarily powerful molecular tools for studying poliovirus, the eradication has been made possible through the use of vaccines that were developed prior to the molecular virologic revolution and without any of the new knowledge or technology. The eradication of poliovirus will become a reality as a result of the use of the Salk and Sabin vaccines, vaccines that were generated empirically prior to the breakthroughs in our understanding of the molecular biology of poliovirus.

But perhaps it is a bit unfair to belittle the achievements of modern techniques in the eradication of poliovirus. Certainly, the tools of molecular biology were and will continue to be important in monitoring and tracking poliovirus and identifying strains. In fact, it is likely that the need for continuing poliovirus surveillance will foster the development of novel diagnostic methods that will not only assist in surveillance of poliomyelitis but also can be used to identify new enteroviruses—for example, the efficient detection of viruses that may not grow in cell culture. Additionally, these tools will provide better and more accurate descriptions of the epidemiology of enterovirus infections.

What new directions will drive the field of picornavirology? One enterovirus that is likely to be targeted from a medical perspective is enterovirus 71. The ability of this virus to mount huge epidemics and to be a major cause of neurologic disease, especially acute flaccid paralysis, is likely to have already generated special interest with respect to vaccine development.

It is clear that the coxsackieviruses will also be a subject for increased study among picornavirologists. The large number of diseases that the coxsackieviruses cause also makes this group of viruses of great interest from the point of view of vaccine development. In addition, investigations of coxsackieviral diseases may clarify the pathogenesis of virus-induced autoimmune diseases.

The next decade is likely to see the development of a number of antiviral drugs that are effective in enteroviral infections. Some of these new drugs will probably take advantage of the receptors used by different viruses as well as our increased understanding of nonstructural enteroviral proteins. Enteroviruses will still be very much with us, even after the eradication of poliovirus.
