FOOD SCIENCE AND TECHNOLOGY

A Series of Monographs, Textbooks, and Reference Books

Editorial Advisory Board

76. Food Chemistry: Third Edition, *edited by Owen R. Fennema*
77. Handbook of Food Analysis: Volumes 1 and 2, *edited by Leo M. L. Nollet*
78. Computerized Control Systems in the Food Industry, *edited by Gauri S. Mittal*
79. Techniques for Analyzing Food Aroma, *edited by Ray Marsili*
80. Food Proteins and Their Applications, *edited by Srinivasan Damodaran and Alain Paraf*
81. Food Emulsions: Third Edition, Revised and Expanded, *edited by Stig E. Friberg and Kåre Larsson*
82. Nonthermal Preservation of Foods, *Gustavo V. Barbosa-Cánovas, Usha R. Pothakamury, Enrique Palou, and Barry G. Swanson*
83. Milk and Dairy Product Technology, *Edgar Spreer*
84. Applied Dairy Microbiology, *edited by Elmer H. Marth and James L. Steele*
85. Lactic Acid Bacteria: Microbiology and Functional Aspects, Second Edition, Revised and Expanded, *edited by Seppo Salminen and Atte von Wright*
86. Handbook of Vegetable Science and Technology: Production, Composition, Storage, and Processing, *edited by D. K. Salunkhe and S. S. Kadam*
87. Polysaccharide Association Structures in Food, *edited by Reginald H. Walter*
88. Food Lipids: Chemistry, Nutrition, and Biotechnology, *edited by Casimir C. Akoh and David B. Min*
89. Spice Science and Technology, *Kenji Hirasa and Mitsuo Takemasa*
90. Dairy Technology: Principles of Milk Properties and Processes, *P. Walstra, T. J. Geurts, A. Noomen, A. Jellema, and M. A. J. S. van Boekel*
91. Coloring of Food, Drugs, and Cosmetics, *Gisbert Otterstätter*
92. *Listeria*, Listeriosis, and Food Safety: Second Edition, Revised and Expanded, *edited by Elliot T. Ryser and Elmer H. Marth*
93. Complex Carbohydrates in Foods, *edited by Susan Sungsoo Cho, Leon Prosky, and Mark Dreher*

94. Handbook of Food Preservation, *edited by M. Shafiur Rahman*
95. International Food Safety Handbook: Science, International Regulation, and Control, *edited by Kees van der Heijden, Maged Younes, Lawrence Fishbein, and Sanford Miller*
96. Fatty Acids in Foods and Their Health Implications: Second Edition, Revised and Expanded, *edited by Ching Kuang Chow*
97. Seafood Enzymes: Utilization and Influence on Postharvest Seafood Quality, *edited by Norman F. Haard and Benjamin K. Simpson*
98. Safe Handling of Foods, *edited by Jeffrey M. Farber and Ewen C. D. Todd*
99. Handbook of Cereal Science and Technology: Second Edition, Revised and Expanded, *edited by Karel Kulp and Joseph G. Ponte, Jr.*
100. Food Analysis by HPLC: Second Edition, Revised and Expanded, *edited by Leo M. L. Nollet*
101. Surimi and Surimi Seafood, *edited by Jae W. Park*
102. Drug Residues in Foods: Pharmacology, Food Safety, and Analysis, *Nickos A. Botsoglou and Dimitrios J. Fletouris*
103. Seafood and Freshwater Toxins: Pharmacology, Physiology, and Detection, *edited by Luis M. Botana*
104. Handbook of Nutrition and Diet, *Babasaheb B. Desai*
105. Nondestructive Food Evaluation: Techniques to Analyze Properties and Quality, *edited by Sundaram Gunasekaran*
106. Green Tea: Health Benefits and Applications, *Yukihiko Hara*
107. Food Processing Operations Modeling: Design and Analysis, *edited by Joseph Irudayaraj*
108. Wine Microbiology: Science and Technology, *Claudio Delfini and Joseph V. Formica*
109. Handbook of Microwave Technology for Food Applications, *edited by Ashim K. Datta and Ramaswamy C. Anantheswaran*
110. Applied Dairy Microbiology: Second Edition, Revised and Expanded, *edited by Elmer H. Marth and James L. Steele*
111. Transport Properties of Foods, *George D. Saravacos and Zacharias B. Maroulis*
112. Alternative Sweeteners: Third Edition, Revised and Expanded, *edited by Lyn O'Brien Nabors*
113. Handbook of Dietary Fiber, *edited by Susan Sungsoo Cho and Mark L. Dreher*
114. Control of Foodborne Microorganisms, *edited by Vijay K. Juneja and John N. Sofos*
115. Flavor, Fragrance, and Odor Analysis, *edited by Ray Marsili*
116. Food Additives: Second Edition, Revised and Expanded, *edited by A. Larry Branen, P. Michael Davidson, Seppo Salminen, and John H. Thorngate, III*
117. Food Lipids: Chemistry, Nutrition, and Biotechnology: Second Edition, Revised and Expanded, *edited by Casimir C. Akoh and David B. Min*
118. Food Protein Analysis: Quantitative Effects on Processing, *R. K. Owusu-Apenten*
119. Handbook of Food Toxicology, *S. S. Deshpande*
120. Food Plant Sanitation, *edited by Y. H. Hui, Bernard L. Bruinsma, J. Richard Gorham, Wai-Kit Nip, Phillip S. Tong, and Phil Ventresca*
121. Physical Chemistry of Foods, *Pieter Walstra*
122. Handbook of Food Enzymology, *edited by John R. Whitaker, Alphons G. J. Voragen, and Dominic W. S. Wong*
123. Postharvest Physiology and Pathology of Vegetables: Second Edition, Revised and Expanded, *edited by Jerry A. Bartz and Jeffrey K. Brecht*
124. Characterization of Cereals and Flours: Properties, Analysis, and Applications, *edited by Gönül Kaletunç and Kenneth J. Breslauer*
125. International Handbook of Foodborne Pathogens, *edited by Marianne D. Miliotis and Jeffrey W. Bier*
126. Food Process Design, *Zacharias B. Maroulis and George D. Saravacos*
127. Handbook of Dough Fermentations, *edited by Karel Kulp and Klaus Lorenz*

128. Extraction Optimization in Food Engineering, *edited by Constantina Tzia and George Liadakis*
129. Physical Properties of Food Preservation: Second Edition, Revised and Expanded, *Marcus Karel and Daryl B. Lund*
130. Handbook of Vegetable Preservation and Processing, *edited by Y. H. Hui, Sue Ghazala, Dee M. Graham, K. D. Murrell, and Wai-Kit Nip*
131. Handbook of Flavor Characterization: Sensory Analysis, Chemistry, and Physiology, *edited by Kathryn Deibler and Jeannine Delwiche*
132. Food Emulsions: Fourth Edition, Revised and Expanded, *edited by Stig E. Friberg, Kare Larsson, and Johan Sjoblom*
133. Handbook of Frozen Foods, *edited by Y. H. Hui, Paul Cornillon, Isabel Guerrero Legarret, Miang H. Lim, K. D. Murrell, and Wai-Kit Nip*
134. Handbook of Food and Beverage Fermentation Technology, *edited by Y. H. Hui, Lisbeth Meunier-Goddik, Ase Solvejg Hansen, Jytte Josephsen, Wai-Kit Nip, Peggy S. Stanfield, and Fidel Toldrá*
135. Genetic Variation in Taste Sensitivity, *edited by John Prescott and Beverly J. Tepper*
136. Industrialization of Indigenous Fermented Foods: Second Edition, Revised and Expanded, *edited by Keith H. Steinkraus*
137. Vitamin E: Food Chemistry, Composition, and Analysis, *Ronald Eitenmiller and Junsoo Lee*
138. Handbook of Food Analysis: Second Edition, Revised and Expanded, Volumes 1, 2, and 3, *edited by Leo M. L. Nollet*
139. Lactic Acid Bacteria: Microbiological and Functional Aspects: Third Edition, Revised and Expanded, *edited by Seppo Salminen, Atte von Wright, and Arthur Ouwehand*
140. Fat Crystal Networks, *Alejandro G. Marangoni*
141. Novel Food Processing Technologies, *edited by Gustavo V. Barbosa-Cánovas, M. Soledad Tapia, and M. Pilar Cano*
142. Surimi and Surimi Seafood: Second Edition, *edited by Jae W. Park*
143. Food Plant Design, *Antonio Lopez-Gomez; Gustavo V. Barbosa-Cánovas*
144. Engineering Properties of Foods: Third Edition, *edited by M. A. Rao, Syed S.H. Rizvi, and Ashim K. Datta*
145. Antimicrobials in Food: Third Edition, *edited by P. Michael Davidson, John N. Sofos, and A. L. Branen*
146. Encapsulated and Powdered Foods, *edited by Charles Onwulata*
147. Dairy Science and Technology: Second Edition, *Pieter Walstra, Jan T. M. Wouters and Tom J. Geurts*
148. Food Biotechnology, Second Edition, *edited by Kalidas Shetty, Gopinadhan Paliyath, Anthony Pometto and Robert E. Levin*
149. Handbook of Food Science, Technology, and Engineering - 4 Volume Set, *edited by Y. H. Hui*
150. Thermal Food Processing: New Technologies and Quality Issues, *edited by Da-Wen Sun*
151. Aflatoxin and Food Safety, *edited by Hamed K. Abbas*
152. Food Packaging: Principles and Practice, Second Edition, *Gordon L. Robertson*

Preface

Major challenges facing the world today are not just those of food production and food quality for meeting protein and calorie needs (basic nutritional needs), but also those related to better health. A significant challenge is the outbreak of oxidation-linked disease epidemics caused by calorie sufficiency and excess calories. This nutritional epidemic is occurring not only in the developed world, but also in newly industrialized countries such as China, Brazil, Mexico, and India, which have the most rapidly growing type 2 diabetes problem in the world. Because diabetes is tied to other oxidation-linked diseases such as cardiovascular disease (CVD) and cancer, it will inevitably place a tremendous burden on the emerging health-care systems of these countries. This situation will place further strain and pressure on existing health-care challenges such as treatment of infectious diseases like AIDS, tuberculosis, and foodborne illnesses among lower income populations. In the more developed countries, the continuous and steady advancement of obesity and its subsequent consequences of increases in diabetes, CVD, and cancer are posing additional challenges. All major health challenges, be they of calorie sufficiency- or calorie insufficiency-linked infectious diseases, are directly or indirectly related to diet and environmentally linked disease. Therefore, technologies for disease chemoprevention through dietary modification (reduced calorie intake with more fruits and vegetables and novel ingredients from other food-grade biological and microbial systems) will be very important to help manage these emerging health-care challenges. In addition, advances in food biotechnology must be more nutritionally relevant and must consider the environmental impacts and consequences of food production and consumption.

Thus, with these critical issues in mind, *Food Biotechnology*, 2nd Edition, has been assembled with the hope of being an authoritative, comprehensive, conceptually sound, and highly informative compilation of recent advances in various important areas of food biotechnology. The topics herein deal with bioconversion of food raw materials to processed products, improvement of food quality, food safety, designing of ingredients for functional foods, biochemical advances in traditional fermentation, and, most importantly, they provide an international perspective to the whole field. Biotechnology has become an important tool in recent years, and several scientists across the world are investigating advanced and novel biological, cellular, molecular, and biochemical strategies for improving food production and processing, for enhancing food safety and quality, and for improving from organoleptic to functional aspects of food and food ingredients for better human health. Thus, this volume has amassed diverse topics from appropriate experts in specific areas from across the globe. The book is divided into three sections. The first section deals with food microbiology, the second with plant and animal food applications and functional foods, and the third section deals with food safety, novel bioprocessing, traditional fermentations, and regulatory and patent issues at an international level. In all, there are 70 chapters covering key areas of food biotechnology within the three sections. The first 20

chapters in Section 1, dealing with food microbiology, provide in-depth accounts of basic principles of microbiology, fermentation technologies, aspects of genetic engineering for production of various food ingredients, and several other specialized topics involving microbial systems. Section 2, comprising 27 chapters, is quite diverse and deals with plant tissue culture techniques, genetic engineering of plants and animals, functional food ingredients and their health benefits, probiotics, antibody production for oral vaccines, and several topics on enzyme technologies. Section 3, with 23 chapters, is quite diverse and examines several aspects of food safety issues, bioprocessing, and fermentation biotechnologies used across the globe. In essence, this book has brought together diverse areas of food biotechnology with a strong focus on biochemistry and molecular biology, and it is unique in that respect. This strong molecular- and biochemically based conceptual viewpoint provided by many chapters will form the basis for development of food biotechnology over the next few decades, particularly in the context of designing food ingredients for better health and microbial food safety.

The editors wish to thank all the authors for their outstanding efforts to document and present their research and their conceptual information about their current understanding of this field. Their efforts have particularly advanced our conceptual knowledge with regard to food safety, novel microbial processing, novel applications of plant foods and ingredients, and functional food ingredients.

The editors also would like to thank the staff of Marcel Dekker, CRC, and Taylor and Francis for their help and support in the timely publication of this 2nd edition, and particularly for coordinating the work of the authors of 70 chapters across several countries. All these efforts have advanced the frontiers of food biotechnology and have given it a stronger molecular, metabolic, biochemical, and nutritionally relevant emphasis that is conceptually applicable in any part of the world.

The Editorial Board

Editors

Dr. Kalidas Shetty is a professor of food biotechnology in the Department of Food Science at the University of Massachusetts-Amherst. He received his BS degree from the University of Agricultural Sciences, Bangalore, India, majoring in applied microbiology, and MS and PhD from the University of Idaho, Moscow in microbiology. He then pursued postdoctoral studies in plant biotechnology in Japan (National Institute of Agro-Biological Sciences, Tsukuba Science City) and Canada (University of Guelph) prior to joining the University of Massachusetts in 1993.

Dr. Shetty's research interests focus on redox pathway-linked biochemical regulation of phenolic phytochemicals in food botanicals using novel tissue culture, seed sprout, and fermentation systems. This focus is contributing to innovative advances in the areas of nutraceuticals, functional foods, and food antimicrobial strategies. In particular, the susceptibility of bacterial food pathogens to phenolic phytochemicals at low pH through redox-linked pathways is his major interest in developing new food safety strategies. He has published over 100 manuscripts in peer-reviewed journals and over 25 as invited reviews and in conference proceedings. He holds four United States patents.

Dr. Shetty was appointed as the editor of the journal *Food Biotechnology*, published by Marcel Dekker (now Taylor and Francis). He is also on the editorial board of three additional journals in the areas of food and environmental sciences.

In 2004, Professor Shetty was selected by the U.S. State Department as a Jefferson Science Fellow to advise the Bureau of Economic and Business Affairs on scientific issues as they relate to international diplomacy and international development. This program, administered by the U.S. National Academies, allowed Dr. Shetty to serve as science advisor at the U.S. State Department for 1 year in 2004–2005, and he will continue to serve as science advisor for 5 more years following his return to the University of Massachusetts. Dr. Shetty has widely traveled and has been invited to present lectures and seminars in the areas of food biotechnology, functional foods and dietary phytochemicals, and food safety in over 20 countries in Asia, Europe, and the Americas. In 1998 he was awarded the Asia-Pacific Clinical Nutrition Society Award for his contributions to the area of phytochemicals, functional foods, and human health based on his understanding of Asian food traditions. At the University of Massachusetts he has won the College of Food and Natural Resources Outstanding Teaching Award and a Certificate of Achievement for Outstanding Outreach Contributions.

Dr. Anthony L. Pometto is a professor of industrial microbiology in the Department of Food Science and Human Nutrition at Iowa State University. He received his BS degree in biology from George Mason University, Fairfax, Virginia, and his MS and PhD in bacteriology from the University of Idaho, Moscow, Idaho. Dr. Pometto worked as a full-time

scientific aide in the Department of Bacteriology and Biochemistry at the University of Idaho for twelve years. He joined the faculty at Iowa State University in 1988.

Dr. Pometto's research interests focus on microbial degradation of degradable plastics, bioconversion of agricultural commodities into value-added products via fermentation, development of novel bioreactors, production of enzymes for the food industry, and the utilization of food industrial wastes. He has co-authored over 60 peer-reviewed journal articles and over 25 articles as invited reviews, book chapters, and conference proceedings. He is a co-inventor on three United States patents. He is also a member of editorial board of the journal *Food Biotechnology*, published by Marcel Dekker (now Taylor and Francis).

Dr. Pometto became director of the NASA Food Technology Commercial Space Center at Iowa State University in 2000. The Center is associated with the NASA Johnson Space Center, Houston, Texas, which manages all the food systems for the shuttle, International Space Center, and planetary exploration missions. The NASA Food Technology Commercial Space Center at Iowa State University was founded in August 1999 and has the mission to engage industry and academia to develop food products and processes that will benefit NASA and the public. The specific objectives are as follows: (1) to develop food products that meet the shelf life requirements for the shuttle, ISS and the planetary outpost, which are nine months, one year, and five years, respectively; (2) to develop equipment and process technologies to convert the proposed over 15 crops grown on the planetary outpost, Moon or Mars, into safe, edible foods; and (3) to build partnerships with food companies to develop these new food products and processes to make them available for NASA utilization. The space food challenges being addressed by the Center's commercial partners and affiliate faculty are development of new food products, development of new food processing equipment, extending the shelf life of foods, improving and monitoring food safety, packaging of foods, development of food waste management systems, and development of disinfection systems for space travel. For more information, please see the web site http://www.ag.iastate.edu/centers/ftcsc/.

Dr. Pometto has recently been named associate director of the Iowa State University Institute for Food Safety and Security, which was created in 2002 as one of six presidential academic initiatives. Dr. Pometto works with the Institute's director, Dr. Manjit Misra, to bring together the research, education, and outreach components of food safety and security at Iowa State University into one umbrella institute for the purposes of efficient teamwork that is well-positioned among government, industry, and producers.

Dr. Gopinadhan Paliyath is an associate professor at the Department of Plant Agriculture, University of Guelph, Ontario, Canada. Dr. Paliyath has a very broad background in plant science, with a specialization in biochemistry. He obtained his BS. Ed. degree (botany and chemistry) in science education from the University of Mysore, MS degree (botany) from the University of Calicut, and PhD degree (biochemistry) from the Indian Institute of Science, Bangalore. He did postdoctoral work at Washington State University, the University of Waterloo, and the University of Guelph.

The focus of Dr. Paliyath's current research is in the areas of post-harvest biology and technology, functional foods, and nutraceuticals. He is investigating the signal transduction events in response to ethylene and the role of phospholipase D in such events. Various aspects dealing with improvement in fruit and vegetable shelf life and quality, and the efficacy of functional food ingredients are also being investigated. Technologies and products have been developed for enhancing the shelf life and quality of fruits, vegetables, and flowers based on phospholipase D inhibition (US Patent #6,514,914). As well, he is

developing novel technologies for the isolation of active nutraceutical fractions and the use of nutraceuticals to enhance the functional food value of processed fruits and vegetables. Phospholipase D inhibition technology for fruit and vegetable preservation has been licensed for commercialization. His current research also includes investigations into the mechanism of action of nutraceuticals (grape and wine polyphenols) as cancer chemopreventive agents.

Dr. Paliyath has authored over 150 research contributions that include peer-reviewed publications (60), patents at various stages (one issued, one on file, one in process), chapters in books (10), and several conference presentations and reports.

SECTION 3 FOOD SAFETY, NOVEL BIOPROCESSING, TRADITIONAL FERMENTATIONS, AND REGULATORY ISSUES

Section 1

Food Microbiology

1.01

Food Microbiology

Robert E. Levin

CONTENTS

1.1 INTRODUCTION

Food biotechnology integrates biochemistry, chemistry, microbiology, and chemical engineering for the enhanced production of food products. The application of microbiology to food systems encompasses methods involved in the assessment of microbial food safety and the use of microorganisms for the production of foods and beverages, food products, food additives. Microorganisms involved either directly or indirectly with food systems include bacteria, molds, yeasts, and algae. Each of these microbial groups has unique metabolic aspects that are either utilized or circumvented to achieve optimization of various microbial processes.

1.2 GENERAL ASPECTS

1.2.1 Applications of Microbiology to Foods

Ancient Egyptians used fermentation to produce beer and convert grape juice to wine. They also practiced the aerobic conversion of the alcohol in wine to the acetic acid of vinegar, and the leavening of bread. The present practices of using, for example, pectinases for enhanced release of fruit juices from tissue and amylases for the enzymatic modification of starches, are examples involving the indirect application of microorganisms to foods and food components. The production of xanthan gum by the plant pathogenic bacterium *Xanthomonas campestris* for use as a viscosity agent in beverages and semisolid food products is an example of the use of an originally undesirable organism for the production of a desirable food and beverage additive. The use of the mold *Aspergillus niger* to produce high yields of citric acid as a food and beverage acidulant was established in the 1920s and is a classic example of an initial surface culture process that was eventually converted to a submerged aerated process with the use of mutants.

1.2.2 The Nature of Microorganisms

Microscopic organisms are presently divided into three major groups: (1) Eubacteria (bacteria), which lack a discernible nucleus and mitochondria; (2) Archaebacteria (bacteria), which also lack a discernible nucleus and mitochondria; and (3) Eukaryotes (yeasts, molds, algae, and protozoa), which possess both a clearly discernible nucleus and mitochondria, plus filamentous structures known as endothelial reticulum. Mitochondria are self-replicating organelles and contain their own deoxyribonucleic acid (DNA), referred to as mitochondrial DNA. In Eukaryotes, the cytochrome and tricarboxylic acid (TCA) enzymes required for aerobic synthesis of ATP are located in the mitochondrial membrane, while with prokaryotes and Archaebacteria the cytochromes are in the cytoplasmic membrane and the TCA enzymes are in the cytoplasm.

All microorganisms are allocated to a specific group with respect to growth temperature. Obligate psychrophiles are defined as those organisms capable of growth at or near 0°C but not at 20°C. Such organisms usually have a maximum growth temperature of 15–17°C. Psychrotrophic organisms are capable of growth at or near 0°C but exhibit optimum growth at approximately 25°C and are frequently unable to grow at 30°C. Mesophiles exhibit growth from 20–45°C with an optimum growth temperature usually in the range of 30–35°C. Thermophiles exhibit growth in the range of 45–65°C. Hyperthermophiles are organisms from oceanic thermal vents and hot springs that are restricted to growth temperatures from 70–120°C. Hyperthermophiles have not yet been isolated from foods.

1.3 FUNGI

1.3.1 Fungal Cell Walls

The fungal cell wall is composed mainly of carbohydrates together with some protein and lipids. The cytoplasmic membrane, unlike the membrane of bacteria, contains sterols. The most important carbohydrates are mannan, glucan, chitin, and cellulose. The wall of some molds is primarily a chitin–glucan structure, whereas mannan is more predominant in yeasts, resulting in mannan–chitin or mannan–glucan cell wall structures. The digestive juice of the garden snail *Helix pomatia,* available commercially as glusulase, is high in β-1, 3- and β-1, 6-glucanase activity and is frequently used to digest the cell wall of molds and some yeasts. Novozyme 234 (Novo Industries) will yield protoplasts of *Aspergillus* and *Penicillium* (1). Novozyme 234 is notably effective for digesting the cell wall of *Schizosaccharomyces pombe*, while glusulase Nee-154 (DuPont; Endo Laboratories) is used with *Saccharomyces cerevisiae*. Both Novozyme 234 and the yeast lytic enzyme from *Arthrobacter luteus* (ICN Biomedicals), otherwise known as lyticase or zymolase (Sigma), are effective for yielding spheroplasts of *Yarrowia lipolytica* (formerly *Candida lipolytica*) (2). Yeasts and molds harvested from the exponential phase of growth are more sensitive to the activity of these cell wall digesting enzyme preparations than are late exponential or stationary phase cells.

1.3.2 Yeasts

Yeasts can be divided into two metabolic groups: facultative anaerobes and obligate aerobes. The facultative anaerobes are capable of anaerobic growth and fermentative conversion of sugars to ethyl alcohol, CO_2, and cell mass, in addition to the aerobic conversion of sugars to CO_2 and H_2O, and much higher yields of cell mass. Fermentative yeasts such as *S. cerevisiae* (Figure 1.1), when grown in the presence of 3 ppm of the DNA intercollating agent acriflavine, can have their mitochondrial DNA selectively mutated so that mitochondria are eliminated, resulting in obligately fermentative strains unable to utilize oxygen (3). Such strains produce smaller cells than wild-type strains and result in "petite" colonies that are notably reduced in size.

Baker's yeast was originally obtained from the brewing industry; the top yeast *S. cerevisiae* was conveniently skimmed from the top surface of fermentation tanks. During the mid-1800s the brewing industry converted to strains of the bottom-settling yeast *Saccharomyces carlesburgensis,* which precipitated the establishment of the baker's yeast industry. Producing baker's yeast using sucrose derived from molasses requires vigorous aeration of the culture medium so that a maximum amount of carbon flows to cell mass production and not to ethyl alcohol formation. Vigorous aeration of *S. cerevisiae* strains in the presence of an abundant level of carbohydrate (about 3%) results in the metabolic dominance of fermentation and is known as the crabtree effect (4). This in turn results in a significant level of ethyl alcohol and a notably reduced level of cell mass. The baker's yeast industry is able to overcome the crabtree effect using incremental feeding which involves the pulsed addition of molasses to aerated culture tanks, so that at no time does the residual level of sucrose rise above 0.0001%. Thus there is no feedback repression of mitochondria formation caused by elevated levels of sucrose. In this case, derepressed mutants that do not exhibit feedback repression are not used. The yeast *Candida utilis* is facultatively anaerobic; however, under conditions of vigorous aeration and elevated sugar levels the crabtree effect is not observed. Thus, the organism can be conveniently used to convert the lactose in whey and the sugars in sulfite waste liquor to cell mass for use as food and fodder yeast.

All yeasts are capable of utilizing glucose. The utilization of other sugars depends on the species; the spectrum of sugars used constitutes a major criterion for the identity of

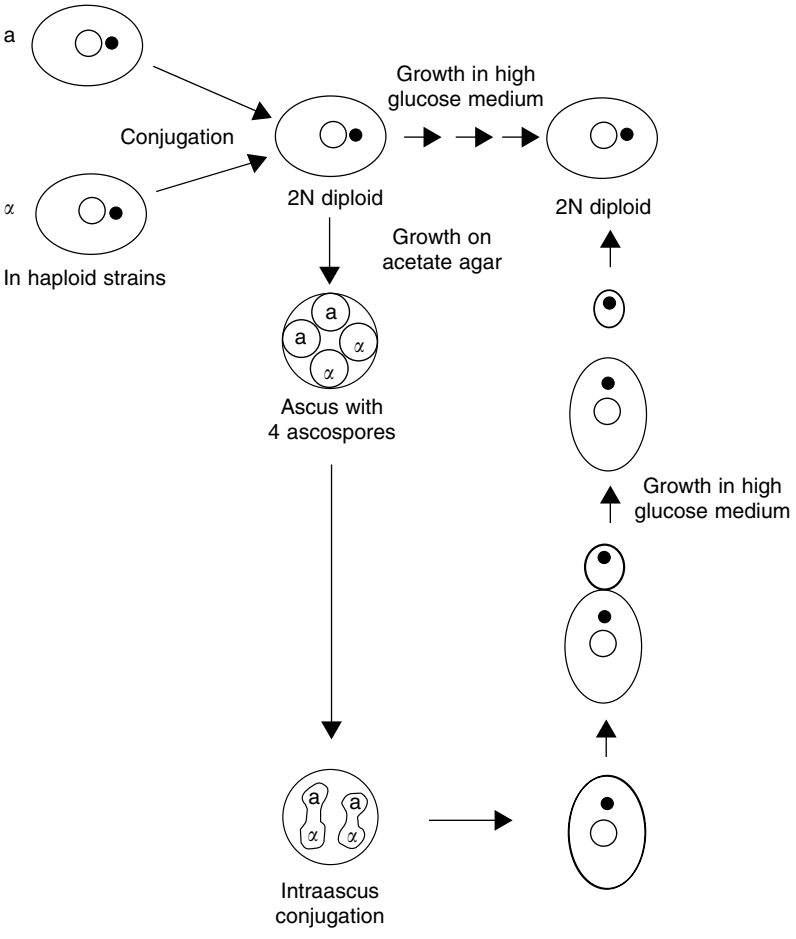

Figure 1.1 Life cycle of *Saccharomyces cerevisiae.*

yeasts. All yeasts are capable of utilizing ammonium sulfate as a sole source of nitrogen. Very few yeasts are capable of utilizing nitrate as a sole nitrogen source. Among ascospore-producing yeasts, the number (1, 4, or 8) and shape of ascospores (spherical, oval, kidney, hat, saturn, needle) in asci constitutes an additional major criterion for genus and species identity. Most yeasts divide by budding; however, members of the strongly fermentative yeast genus *Schizosaccharomyces* divide solely by transverse fission (Figure 1.2).

1.3.3 Molds

In developing mold cultures for the production of food additives, it is important to keep in mind that all molds are obligate aerobes. The maximum production of primary metabolites (e.g., amino acids) and secondary metabolites (e.g., extraceullular enzymes) invariably occurs with wild-type cultures under the condition of static surface growth. This contrasts with submerged cultivation which invariably involves the use of selected mutants. Molds are classified into four classes. The Phycomycetes do not have complete cross walls in their hyphae and therefore exhibit unidirectional protoplasmic streaming (coenocytic movement) or flow throughout their hyphae. Phycomycetes also possess the unifying characteristic of producing aerially borne asexual fruiting structures known as sporangia, with internal sporangiospores borne on a bulblike structure referred to as the

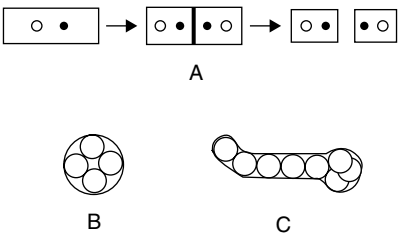

Figure 1.2 Cellular structures and asci of the strongly fermentative yeast genus *Schizosaccharomyces*. (A) Transverse fission of vegetative cells exhibited by all members of the non-budding genus *Schizosaccharomyces*. (B) Ascus containing four ascospores representative of *Schiz. pombe* and *Schiz. versatilis.* (C) Swollen and distended ascus of *Schiz. octosporus* containing eight ascospores.

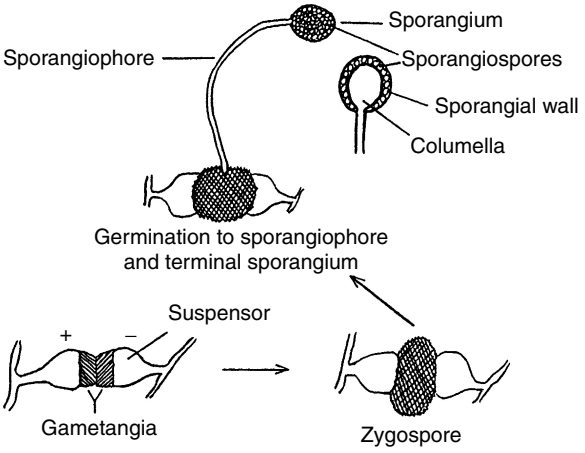

Figure 1.3 Asexual and sexual structures of a typical terrestrial member of the class Phycomycetes.

columella (Figure 1.3). Some, but not all, Phycomycetes produce a sexual spore, known as a zygospore, derived from the fusion of opposite mating types which occurs freely in culture media (Figure 1.3). Color and the microscopic orientation and appearance of these structures are used to establish genera and species. The class Ascomycetes houses fungi (both yeasts and molds) that produce the sexual ascospore. Molds in this class have complete cross walls in their hyphae and therefore do not exhibit protoplasmic streaming. All ascomycete molds produce characteristic conidiospores, which occur in chains or clusters. The characteristic blue-green coloration of members of the genus *Penicillium* (Figure 1.4) is due to the coloration of the long chains of conidiospores borne by all members of this genus. The characteristic coloration (yellow, brown, green) of various species of the genus *Aspergillus* (Figure 1.4) is also due to the coloration of the conidiospores. The major criteria for the establishment of genus and species of this class are the visual coloration of the mass of growth in conjunction with the microscopic appearance and three dimensional orientation of the hyphae and conidiospores. A major distinction between ascomycete yeasts and molds is derived from the fact that yeasts produce "naked" asci and frequently contain four and sometimes eight ascospores, depending on the species. The asci of yeasts occur free in the medium, whereas most ascomycete molds produce asci

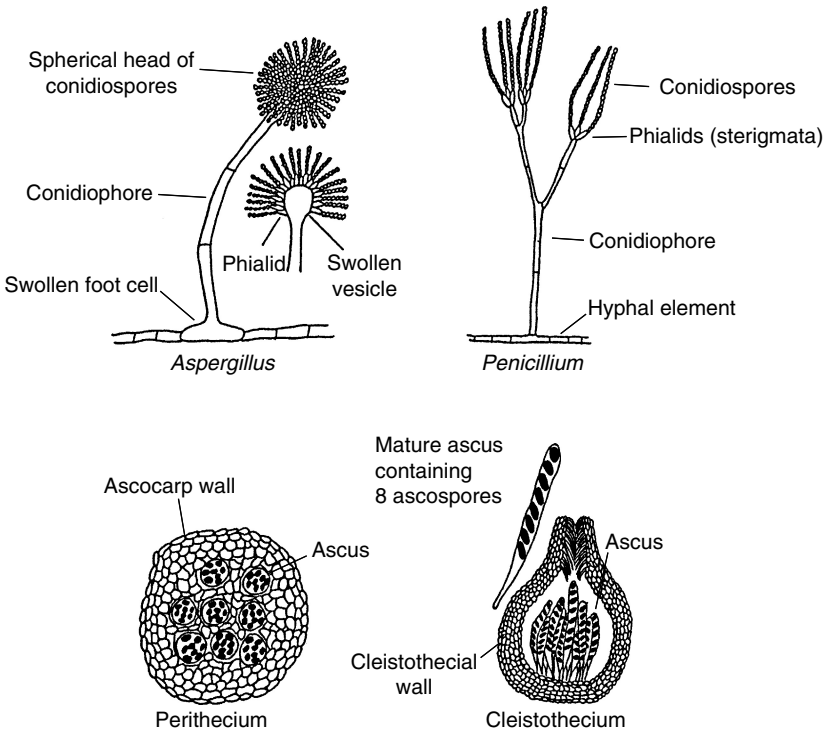

Figure 1.4 Asexual and sexual structures of fungal members of the class Ascomycetes.

with internal ascospores inside a fruiting structure known as a cleistothecium (completely closed) or as a perithecium (open at one end) (Figure 1.4). The class Fungi imperfecti (Figure 1.5), otherwise known as Deuteromycetes, is essentially identical to the Ascomycetes (hyphal crosswalls are present and conidiospores are produced) except that the sexual ascospore is not produced. The class Basidiomycetes houses molds and yeast-like organisms that produce the sexual basidiospore; many also produce conidiospores. Other basidiomycetes produce budding yeastlike cells, which can result in confusing such isolates with true yeasts. The commercial use of molds in various food systems usually involves the harvesting of the asexual sporangiospores or conidiospores for use as inoculum. This allows the density of the inoculum to be based on the precise density or number of spores per unit of volume, which can be readily determined by microscopic count. The use of mycelial mass as an inoculum is more difficult with respect to directly determining the quantity of the cell mass in the inoculum volume, for obvious physical reasons.

1.4 MICROBIAL TAXONOMY

1.4.1 General

After Anton van Leeuwenhoek developed the microscope (circa 1700), Carle Linnaeus developed the binomial system of nomenclature in which each biological entity is allocated to a genus and species. The first letter of the genus designation is always capitalized, the species is entirely lower cased, and both are in italics, e.g., *Penicillium roquefortii, Schizosaccharomyces octosporus, Saccharomyces cerevisiae, Xanthomonas campestris,*

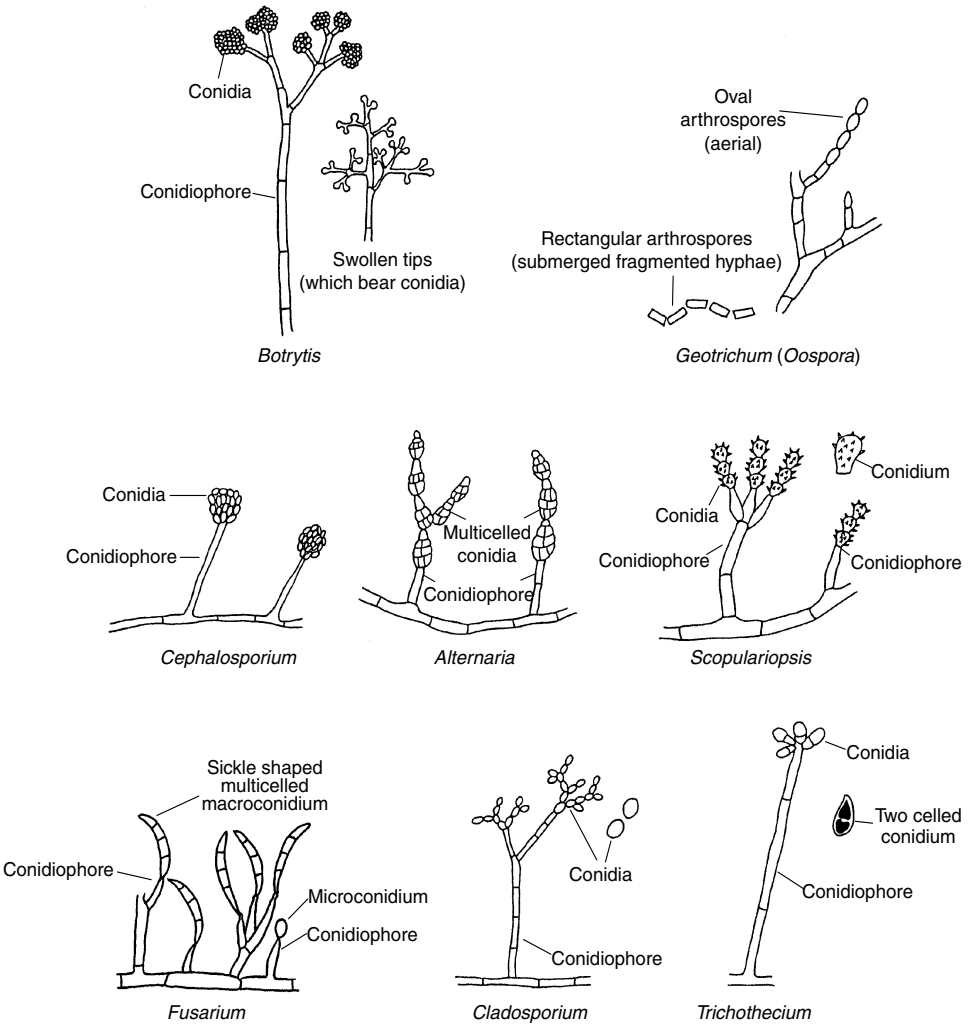

Figure 1.5 Shape and configuration of conidiospores and associated structures of representative members of the class *Fungi imperfecti*.

Lactobacillus acidophilus. The concept of a bacterial genus usually encompasses a well-defined group that is clearly separated from other genera. Interestingly, there is no general agreement on the definition of a genus in bacterial taxonomy (5). The composition of numerous bacterial genera are presently considered to involve a significant level of subjectivity (5).

Species are frequently divided into subspecies, called varieties, serotypes, or biotypes, using the abbreviations "var." or "subsp.", e.g., *Saccharomyces italicus* var. melibiase, *Escherichia coli* subsp. communior. An organism is occasionally found in the literature under several names; e.g., *Candida utilis, Torula utilis, Torulopsis utili*s. Only one of the names is usually correct, the others being synonyms. In this case *Candida utilis* is correct (6). However, when two organisms can be confused in the text resulting from such contractions, e.g., the bacterium *Escherichia coli (E. coli)* vs. the protozoan *Entamoeba coli (E. coli*), alternate contractions, solely for the purpose of clarity, are then used, e.g., *Esch. coli* vs. *Ent. coli.*

1.4.2 Classification of Bacteria

Bacteria are now classified into two major groups, the Eubacteria and the Archaebacteria (which were formerly grouped under the Protista). The majority of bacteria involved with food systems are Eubacteria. The Archaebacteria presently house the unique halobacteria, which are obligate halophiles and can cause the red tainting of salted fish. All bacteria fall into two convenient groups, those that stain purple with the Gram stain (Gram-positive) and those that stain red with the Gram stain (Gram-negative). In Gram-positive bacteria, there is a bi-lipid membrane between the cell wall and cytoplasm, with the cell wall consisting mainly of peptidoglycan linked with teichoic acids. The cell envelope of Gram-negative bacteria is more complex, consisting of three layers, often referred to collectively as the sacculus. The innermost layer (i.e., the inner cytoplasmic membrane) is adhered to the peptidoglycan layer (otherwise referred to as the murein sacculus (7)), which is covalently linked to elongated lipoprotein molecules. This peptidoglycan–lipoprotein complex partly occupies the periplasmic space between the two (inner and outer) hydrophobic membranes. The outermost layer is an outer membrane consisting of phospholipids, lipopolysaccharides (LPS), and proteins. The LPS content of the sacculus of Gram-negative bacteria constitutes an impermeable barrier to many polar and nonpolar molecules, including dyes and surface-active agents such as bile salts. This difference in permeability to dyes and surface-active agents is used in the selective isolation of Gram-negative organisms with the complete exclusion of Gram-positive organisms, as with the use of MacConkey agar.

There are three general metabolic groups of bacteria: (1) obligate aerobes, (2) facultative anaerobes, and (3) obligate anaerobes. Representative members of each of these groups are found among both the Gram-positive and Gram-negative bacteria.

1.4.3 Serotypes

Serotyping involves the production of antibodies following the injection of a suitable mammal with the microorganism or a specific extract of the organism. If an organism is nonflagellated then serotyping will be based on the somatic antigens. If the organism is flagellated then serotyping may also be based on the flagella antigens. Three antigenic sites are recognized: somatic (O) (German "Ohne") or body, flagella (H) (German "Hauch") or motility, and K (German "Kapsel"), e.g., *Escherichia coli* O157:H7. The O antigens are comprised of the O polysaccharides that are on the surface and are heat stabile. The K and H antigens are heat labile. With whole bacterial cells, agglutination methods are used. With soluble antigens such as toxins, precipitin or gel diffusion assays are used.

1.4.4 Molecular Taxonomy

Each microbial species is presently characterized as having a specific percent molar content of guanosine (G) + cytosine (C) in its DNA. The applicable equation is: 100 mols % = mols % G + mols % C + mols % T + mols % A. Because each guanine nucleotide on one strand of DNA is hydrogen bonded to a cytosine nucleotide on the opposite strand, and because each thymidine nucleotide is hydrogen bonded to a cytosine nucleotide on the opposite strand, the mols % guanine is always equal to the mols % C and the mols % thymine is always equal to the mols % cytosine. By convention, each organism is then defined on the basis its mols % G + C content or GC ratio; 100 mols % = (mols% G + C) + (mols% A + T) or mols % GC = 100 mols % − (mols % A + T). All strains of *S. cerevisiae* are defined as having a molar GC content of 39%. Any yeast strain that deviates significantly from this value cannot be considered *S. cerevisiae*. With unknown isolates, the value of the molar GC content is primarily exclusionary. An unknown organism with a molar GC content of 50% is clearly not *S. cerevisiae.* An unknown isolate with a

molar GC content of 39% may be *S. cerevisiae,* but a molar GC content of 39% is not conclusive evidence of identity. Because all biological species fall within the range of about 10% to 90% GC, numerous unrelated species have the same numerical value for their molar GC DNA content. For example, micrococci and all mammals and fish have a molar GC content of 45%.

The practical definition of a species is that it consists of a collection of strains that share many features in common and that differ considerably from other strains (5). A species is presently defined as encompassing strains with approximately 70% or greater DNA–DNA similarity based on DNA strand hybridization, and with 5% or less Tm (Thermal denaturation temperature) for the hybridized strands (8). Phenotypic characteristics should agree with this definition. This corresponds to a 16S ribosomal ribonucleic acid (rRNA) similarity of 98% or higher (9). The nucleotide sequences of rRNA are far more conserved than DNA among various taxonomic groups. rRNA is capable of hybridizing with DNA; however, RNA–DNA hybridization is far less discriminating in terms of recognizing differences between strains of the same species. It is, however, of utility in discerning the difference between two different species of the same genus. Stated more succinctly, DNA–DNA hybridization experiments are used to detect similarities between closely related organisms, whereas RNA–DNA hybridization experiments are used to detect similarities between more distantly related organisms (10). rRNA sequence data is considered more appropriate for determining inter- and intrageneric relationships than for confirming the species identity of an isolate (11). Several groups of organisms have been found to share almost identical 16S rRNA sequences but a DNA–DNA hybridization significantly lower than 70%, indicating that they represent different species (12).

The early classification of microorganisms was based on the utility of their recognition and identification. What emerged with bacteria, however, was a dual system of classification, one based on metabolism and the other on morphology, which are still with us. In 1910, Orla-Jensen proposed that all lactic-acid-producing bacteria (cocci and rods) be housed in the family Lactobacteriacea. In contrast, the family Micrococcaceae houses the various genera of spherical cells or cocci. The bacterial phylogeny that has emerged from molecular sequence data has little in common with these early concepts regarding the morphological relationships of microbial groups (13). Morphology is no longer the guiding principle regarding phylogenetic relationships, in that most characteristics of bacterial morphology are presently regarded as too simple not to have evolved independently in unrelated organisms (13). However, the concept of morphology as a utilitarian character of an organism can be of great value, if, for example, one suspects that a pure culture of a coccus is contaminated and finds rods present.

1.5 METABOLIC CONTROL FOR ENHANCED METABOLITE PRODUCTION

A number of microbial processes in the production of various food additives involve limiting one or more critical nutrients. The submerged production of citric acid by *A. niger* involves limiting both iron and phosphate to achieve maximum yields (14). The production and excretion of maximum amounts of glutamic acid by *Corynebacterium glutamicum* is dependent on cell permeability. Increased permeability can be achieved through biotin deficiency, through oleic acid deficiency in oleic acid auxotrophs, through the addition of saturated fatty acids or penicillin, or by glycerol deficiency in glycerol auxotrophs (15).

1.6 MUTAGENESIS FOR OVERPRODUCTION OF METABOLITES

Increased yields of microbially produced food additives can often be achieved by the selection of overproducing mutants. Such desirable mutants will frequently be produced spontaneously or by a mutagenic agent. There are three fundamental types of mutational events: (1) nucleotide deletions, (2) base-pair substitutions, and (3) gene duplications. Mutants that result from large deletions have the greatest stability. Mutants exhibiting high levels of reversion to wild-type cells are usually derived from base-pair substitution mutations. Alkylating agents are among the most potent direct-acting mutagenic agents.

A variety of methods has been developed for the production of mutants. The frequently used mutagen N-methyl N-nitrosoguanidine (nitrosoguanidine or NTG) functions by forming a methyl group adduct to guanine, and results in multiple mutations. Ethyl methane sulfonate is less lethal and usually results in single mutations. Although yielding large numbers of mutants, such agents usually result in mutations with significant rates of reversion to wild type. Exposure of cells to ultraviolet (UV) irradiation results in approximately equal numbers of both deletions and base-pair substitutions (16). UV irradiation will therefore yield a higher percent of more stable mutants (derived from frame shift mutations) and is the preferred method for mutagenesis. The usual procedure is to expose a cell suspension to UV irradiation to achieve a 50% reduction in viable cells and then to plate out the survivors to isolate mutants. This implies preliminary knowledge of the UV destruction rate. NTG, however, usually produces higher levels of mutagenesis than UV.

Overproducing riboflavin mutants of the mold *Ashbya gossypii* can initially be detected by visually observing the increased intensity of orange coloration of the colonies (17,18). Wild-type isolates of *Pfaffia rhodozyma* produce the red carotenoid pigment astaxanthan which imparts the characteristic pink coloration of salmon tissue, and they are initially a light pink. Sequential mutagenesis has been found to result in a seven- to ten-fold increase in pigment production, which is readily detected by visually observing the colonies (19,20). The detection of amino acid overproducing colonies is greatly facilitated by plating overproducing cells (approximately 100 per plate) in the presence of large numbers of cells (approximately 10^8) of an appropriate auxotrophic indicator organism incapable of growth in the agar medium, used because of the absence of the amino acid to be overproduced. Overproduction by a colony is then visually observed and can be semiquantitatively assessed on the basis of the diameter of the zone of growth of the indicator organism surrounding the amino acid overproducing colony.

To use *Brevibacterium ammoniagenes* to overproduce 5′-inosine monophosphate (5′-IMP) by direct fermentation, it is necessary to overcome feedback inhibition due to the synthesis of 5′-adenosine monophosphate (5′-AMP). This can be accomplished by mutationally blocking adenine synthesis while maintaining a low Mn^{++} level, which allows the membrane transit of 5′-IMP into the culture medium (21). The isolation of permeability mutants that allow secretion of 5′-IMP irrespective of Mn concentration has been a significant advance (22). The addition of low levels of adenine to the culture medium for growth is required.

1.7 SELECTIVE CULTIVATION

1.7.1 Selective Enrichment

Microorganisms of public health significance associated with foods are usually present as a small minority of the total microbial population. For both detection and quantitation of

such microorganisms, selective enrichment cultivation is usually undertaken. Selective enrichment involves conditions of cultivation that favor the development of the target organism over that of the usual majority of extraneous microorganisms. Selective agents are often derived from the environment in which such organisms of public health significance are found. Most culture media for selective enrichment of *E. coli* make use of the fact that the organism is a common inhabitant of the intestinal tract of mammals and hence is normally in contact with surface-active agents such as bile salts, which are frequently used as selective agents for the organism. Bile salts are notably inhibitory to many Gram-positive organisms. Gram-negative bacteria, in general, are significantly more tolerant of various dyes compared to Gram-positive bacteria, resulting in the incorporation of a variety of dyes for the enrichment cultivation of numerous Gram-negative organisms. This difference in sensitivity to bile salts and dyes is due to the presence of lipopolysaccharide in the external membrane of Gram-negative bacteria that is absent in Gram-positives.

Incubation temperature has also been used successfully with selective chemical agents for the selective cultivation and enumeration of certain bacteria. The use of 45.5°C for the most probable number (MPN) enumeration of *E. coli* using the culture broth known as EC functions selectively in conjunction with the content of 0.15% bile salts no. 3. Selective enrichment of pathogenic vibrios such as *Vibrio vulnificus* and *Vibrio parahaemolyticus* makes use of the fact that they are marine organisms and hence are quite tolerant of the somewhat alkaline pH of seawater, which is usually about 7.8. This tolerance toward an alkaline growth environment extends to a pH of 8.5 to 8.7, which is the usual initial pH range used for enrichment cultivation of these organisms. The natural habitat for *Staphylococcus aureus* is the human skin. The level of sodium chloride on the skin surface during physical exertion under warm weather conditions is often at or near saturation, when one considers the process of evaporation. *S. aureus,* as would be expected, exhibits a significant level of salt tolerance, resulting in the use of enrichment and isolation media for the organism containing 7.5–10% NaCl. NaCl at a level of 7.5% is notably inhibitory to most Gram-positive and Gram-negative bacteria.

A wide variety of antibiotics is now added to media for selective isolation of bacterial pathogens from foods. Yeasts and molds are closely associated with acid fruits. The use of acidified culture media (pH 3.5–5.5) is a long established and highly effective method of inhibiting most bacteria, while allowing unrestricted growth of yeasts and molds.

The successful use of selective enrichment media is predicated on cultivation and enumeration of undamaged cells. Cells of a target organism that have undergone membrane damage through freezing and thawing or heating will often not survive the stress imposed by a selective culture medium originally developed using undamaged cells. The enumeration of damaged cells therefore usually requires initial growth in a nonselective repair medium prior to transfer to a selective medium.

1.7.2 Use of Incubation Temperature for Selective Isolation

Temperature alone can be a highly selective mechanism for the selective isolation of specific groups of organisms. Incubation at 55–65°C will ensure the sole development of obligately thermophilic organisms such as *Bacillus stearothermophilus*. Determination of the number of bacteria on fish generally involves incubation of culture plates at 20°C and resulting development of psychrotrophic organisms that grow optimally at about 25°C and which are also capable of growth at 2°C. By incubating the plates at 10°C, and then replica-plating the resulting colonies to sets of plates incubated at 10 and 20°C, one can readily identify and isolate obligately psychrophilic fishery bacteria, capable of growth from 0–17°C but unable to grow at 20°C (23).

1.7.3 The Use of Mineral Salts Media for the Isolation of Unique Carbon Sources Utilizing Microorganisms

The isolation of microorganisms capable of utilizing unique carbon sources is greatly facilitated if the organism being sought is capable of growth in a strictly glucose–mineral salts medium. Unique carbon and energy sources such as methanol, cholesterol, and naphthalene, can then be added as sole carbon sources with the assurance that only organisms capable of attacking these unique substrates will grow.

1.7.4 Selective Isolation as a Result of Sequential Biochemical Activity

The production of vinegar represents a unique sequence of environmental and biochemical events. The sugars in a fruit juice are first fermented anaerobically by yeasts to ethanol, which is then subjected to vigorous aeration, resulting in the oxidative conversion of ethyl alcohol to acetic acid (usually 4–5%) by resident acetic acid bacteria. Ethanol as an intermediate product will sustain the growth of fewer microorganisms than will glucose because it contains less energy than glucose and is therefore more restrictive with respect to microorganisms capable of attacking it. Acetic acid contains even less energy than ethanol, and, at a level of 4%, results in complete microbial preservation or stability in the absence of oxygen.

The methane fermentation, which is frequently used to digest solid waste materials, involves the initial anaerobic formation of intermediate metabolic products such as ethanol, and lower fatty acids such as acetic acid and butyric acid, by members of the genus *Clostridium* and various facultative anaerobes. These metabolic intermediates are then converted anaerobically to gaseous methane by methane bacteria with the result that the initial solid matter is converted to a gaseous product.

The selective isolation of notably acid tolerant lactic acid bacteria in contrast to moderately acid tolerant lactics can be achieved using the dynamics of the sauerkraut fermentation. Here, 2.5% NaCl is uniformly applied to sliced cabbage in a suitable container. The first brine formed from osmotic expression of water from the tissue by the salt is nearly at a saturation level with respect to NaCl and will not allow microbial growth. As more and more water is drawn from the tissue, along with sugar and other nutrients, the NaCl concentration in the brine becomes progressively less inhibitory. At about 6.5% NaCl coliforms will begin to develop at the initial pH of about 6.5 and will reduce the pH to about 5.5. As these organisms undergo autolysis following their growth, the brine becomes nutritionally enhanced so as to allow a mixture of moderately and notably acid tolerant lactic acid bacteria, that are far more nutritionally fastidious, to initiate growth under anaerobic conditions. The organisms of highest acid tolerance, such as *Lactobacillus plantarum* and *Pediococcus lactis,* will be the last remaining viable organisms by the time a final pH of 3.7 has been reached at an NaCl concentration of about 3.0%.

1.8 ELECTROSTIMULATION OF METABOLITE PRODUCTION

A notably innovative approach toward increasing the microbial production of an end product is electrostimulation. Electrical stimulation of microbial metabolite production is based on the use of an artificial electron carrier such as neutral red, allowing an electric current to indirectly supply the electron-driving force needed to generate a proton-motive force for energy conservation and the electrons needed for growth and end product production (24).

The system involves the use of an electrochemical bioreactor utilizing an anodic chamber and a cathodic chamber divided by a cation selective membrane (24). The cathodic chamber is used as the fermentation vessel. The neutral red serves as a reduced electron carrier and migrates from the anode to the cathode where it enters the cells and couples to a suitable redox enzyme system which accepts the electrons. Electrostimulation has been used to increase L-glutamic acid production by *Brevibacterium flavum* (25), and shows promise with other fermentation processes (26).

1.9 ASPECTS OF MICROBIAL EVOLUTION

One of the foremost examples of microbial evolution and its impact on society involves *E. coli* O157:H7. *E.* is a member of the family Enterobacteriaceae. Molecular phylogeny studies indicate that it is closely related to other mammalian pathogens such as *Vibrio, Shigella, Salmonella,* and *Haemophilus* (27). The enterobacteria are facultative anaerobes, allowing them to live anaereobically as commensulate organisms inside the mammalian intestine and aerobically in various terrestrial environments. Horizontal or lateral gene transfer via sexual recombination, transduction (phage infection), and transformation (direct uptake of naked DNA) is known to occur with strains of *E. coli. Escherichia coli* O157:H7 is an exceptionally lethal example of a harmless commensulate organism (nonpathogenic *E. coli*) that has sequentially acquired a number of discreet genes, each of which enhances human pathogenicity.

O157:H7 strains of *E. coli* are usually described as enterohemolytic, frequently causing hemolytic-uremic syndrome (HUS) with an unusually low infectious dose estimated to be below 100 CFU (28) and a notably high fatality of 10% for those developing HUS (29). Prior to 1982, outbreaks of hemorrhagic colitis and HUS were not reported as attributable to the O157:H7 serotype, this implies that it is a newly emerged pathogen and serotype.

There are presently four recognized phenotypic properties that characterize O157:H7 strains of *E. coli:* (1) inability to ferment sorbitol within 24 hrs, (2) inability to produce β-glucuronidase, (3) poor growth above 44°C, and (4) significantly greater acid tolerance than commensurate strains of *E. coli*. In addition, most strains of *E. coli* O157:H7 produce the shiga-like toxins SLT1 and SLT2, which are encoded for by two independent temperate phages that have presumably previously passed through a strain of *Shigella shiga* with incorporation of the toxin DNA sequences into their genomic DNA, and also harbor a large enterocyte attachment factor (EAF) 60-Mdalt plasmid, designated pO157, that encodes several genes involved in pilus formation and attachment to enterocytes and hemolysin production. The remaining known genes (at least 7) involved in pathogenicity are located in a 35.6 kb chromosomal pathogenicity island termed the locus of enterocyte effacement (30,31,32). The presence of plasmids is known to be associated with the acquisition of virulence factors and antibiotic resistance. In addition, the hypermutable state of O157:H7 strains presumably confers even greater genetic diversity than is present with commensurate strains (33). Inferential conclusions from experimental data indicate that strains of *E. coli* derived from humans are subject to significant levels of gene transfer and genetic recombination (27). Clonal analysis suggests that the immediate ancestor of O157:H7 was a pathogenic clone with a propensity to acquire new virulence factors in nature (34,35). The evolutionary sequence presumably involved has been elegantly presented in detail by Whittam (34). It is quite possible that the selective pressure for the acquisition of such an array of genes enhancing pathogenicity has come about from the development of antibiotic resistant strains.

Principles of Biochemistry and Molecular Biology

Patrick P. McCue and Kalidas Shetty

CONTENTS

2.1 PREFACE

Literally, biochemistry is the study of the chemistry of "life," or, rather, of living organisms. As biochemists, we investigate through experimentation the processes that occur in living organisms. Ever since the first description of cells by the English scientist Robert Hooke in 1663, man has been interested in understanding how cells operate, both alone and in cooperation (as tissues). Desire to investigate objects invisible to the naked eye led to the necessity for scientists to become creative in their design of experiments. Over the years, such ingenuity resulted in the development of technologies that as a whole became the core of a scientific discipline that would soon become known as "biochemistry" by the turn of the nineteenth century.

With the advent of molecular biological technologies adding to the core classical approaches, modern-day biochemistry is comprised of essentially two general areas of experimentation: (1) purification and characterization of macro-scale cellular components via classical approaches, and (2) purification and characterization of micro-scale cellular components via molecular biological approaches. It is difficult to generalize the study of biochemistry into two separate groups of approaches, as researchers typically blend any number of techniques from both approaches into their experimental milieu, but as the aim of this section is to introduce the scientific discipline of biochemistry — its essence, its mode of thinking — it will be easier for the unfamiliar reader if we separate the classical from the modern molecular approaches, if only for the sake of clarity. In so doing, we will review significant aspects of the history of biochemistry, so that the reader may gain an insight into the thinking of the time and better understand how these techniques arose. The scientific range of biochemistry is both vast and complex. In writing this chapter we assume that the reader has studied the general subject in lecture. It is not our aim for this chapter to be all-encompassing, but, rather, for it to give a basic to intermediate understanding of the areas relevant to food biotechnology so that the reader may gain a solid foundation upon which to more fully explore and understand the ideas that will be presented in the succeeding chapters.

2.2 A BRIEF HISTORY OF CLASSICAL BIOCHEMISTRY

The beginnings of biochemistry have their roots in chemists' attempts to define the molecular principles of the world in which we live. In 1803, Englishman John Dalton, a school teacher who studied chemistry in his spare time, postulated the modern atomic theory, in which he stated (1) that all matter must be composed of submicroscopic units named atoms, (2) that each element has its own kind of atom, and (3) that atoms of different elements come together in defined numbers to make the numerous diverse molecules that make up the millions of known substances. In investigating Dalton's theory, chemists found that atoms must obey certain rules in forming molecules and that they are only able to interact with other atoms in certain fixed numbers (i.e., only certain bonds can be formed by certain atoms and in certain numbers).

At that time, it was known that the world that we know and live in was composed of living material (organic) and non-living material (inorganic). Biochemistry as a discipline did not exist yet, but rather was getting its beginnings in an off-shoot of chemistry, known as "chemical physiology." Significant physiological questions remained unanswered, such as what caused the difference between inorganic and organic material and how the processes of living tissue were controlled. With no distinct branch of science to cover this emerging area, investigations were left to adventurous chemists willing or compelled to

investigate these intriguing questions. We say "adventurous" in that many of the pioneering scientists were not funded to conduct research in this new field.

In this period of the early nineteenth century, it was believed that only living tissues could perform the reactions of living cells. Beliefs such as this were soon to change. In 1828, Friedrich Wöhler accomplished the synthesis of urea from inorganic matter, proving that reactions of living tissues were not restricted to living tissues, but could be recreated *in vitro* (1). In 1830, proteins were discovered, and chemists found that the formation of proteins from amino acids also obeyed certain rules, similar to as well as dependent upon those of molecule formation by atoms. Discoveries such as these compelled interested scientists to further characterize the cellular machinery.

The idea that reactions of living cells did not need living hosts to occur was advanced further almost 70 years later in 1897, when Edvard and Hans Buchner showed that dead cell extracts can perform reactions of living cells (2). The molecules responsible for performing these reactions were called enzymes. In the late 1800s, Emil Fischer suggested a model mechanism for the action of enzymes that resembled the interaction of a lock and key, in which an enzyme (the lock) interacted with or bound to its substrate (the key), facilitating the subsequent reaction. The model suggested that the enzyme itself would remain intact and unchanged by the reaction. At the turn of the nineteenth century, the field of biochemistry emerged from the area of chemical physiology. The focus of biochemistry was the characterization of the structure and function of enzymes, as well as the elucidation of enzymatic pathways.

As it turns out, food science played a prominent role in the beginnings of biochemistry, as many of the first biochemists investigated various aspects of nutrition. One of the main figures in the establishment of biochemistry as a field of both teaching and research was a British scientist by the name of Frederick Gowland Hopkins, who was interested in understanding the metabolism of living cells. In 1912, Hopkins published a paper in the *Journal of Physiology* in which he demonstrated the importance (discovery) of vitamins and essential amino acids as growth-stimulating agents in the normal diet (3). In 1914, Hopkins was appointed as Cambridge University's first Professor of Biochemistry. Hopkins was knighted in 1925 and received the Nobel Prize in Medicine and Physiology in 1929.

In the early 1900s, biochemistry made another significant advancement when enzymes were proven to be proteins. In 1926, James Sumner and colleagues at Cornell University Medical College demonstrated that urease could be crystallized (4) and, in 1932, that proteolysis of purified urease enzyme results in loss of enzyme activity (5). Though his work was initially met with skepticism, Sumner work was finally accepted, and he received the Nobel Prize in 1946.

The period between the 1940s and 1960s gave witness to arguably some of the most significant achievements in biochemistry, which gave birth to biochemical genetics and led to the emergence of molecular biology. In 1941, studying the metabolism of the orange bread mold *Neurospora crassa* irradiated with X-rays to cause mutations, researchers George Beadle and Edward Tatum demonstrated a 1:1 relationship between a mutation and the absence of a specific enzyme, by identifying mutants defective in specific steps of a metabolic pathway. Assuming that each mutant was defective in a single gene, Beadle and Tatum hypothesized that one gene may contain the genetic information responsible for one enzyme, and that mutants with a defective enzyme carried a defective gene for that enzyme (6). In 1944, building on research from 1928 performed by Frederick Griffith, which demonstrated that heat-killed virulent bacteria contained a "transforming principle (agent)," which could transform live, nonvirulent bacteria into the virulent type, researchers Avery, MacLeod, and McCarty (1944) demonstrated that deoxyribonucleic acid (DNA) was the information-carrying "transforming

principle" (7). In 1952, Alfred Hershey and Martha Chase demonstrated that DNA is the material of heredity in experiments that followed the cell fates of radio-labeled DNA and protein (8). In 1953, Watson and Crick reported that the structure of DNA was a double-helix (9). In 1958, Meselon and Stahl demonstrated that DNA replication is semi-conservative (10). In 1961, the existence of messenger ribonucleic acid (mRNA) was postulated by Jacob and Monod (11). Finally, in 1964, the genetic code was elucidated by Nirenberg and Leder using specific trinucleotides (12,13).

2.3 EXPERIMENTAL TECHNIQUES OF CLASSICAL BIOCHEMISTRY

The brief history of classical biochemistry (i.e., pre-molecular biology) related above highlights the progression of the science towards the elucidation of mechanisms (and their constituents) of increasingly smaller sizes from the micro-scale to the molecular. As a number of the "classical" techniques employed in the aforementioned experiments continue to find use alongside the largely molecular techniques in the experimental approaches of modern biochemistry, we will now shift to a brief explanation of the techniques most relevant to the application of biochemistry for food biotechnology. Since the period of time from the 1970s to the present has seen largely the development of experimental techniques relevant to molecular biology, these advances will be covered in the subsequent subsection of this chapter which will discuss relevant molecular biology techniques.

A main preoccupation of biochemistry is the study of enzyme activity (enzymology). For the better part of a century, the primary ways to determine the activity of an enzyme have been (1) to detect the presence or change in concentration of a predicted (or known) reaction product, (2) to follow the incorporation of a radioactively-labeled molecule (such as ^{14}C) in products of a metabolic pathway, or (3) to measure the change in concentration of a required co-factor (such as $NADP^+$) by detecting its absorbance at a certain wavelength of light using a spectrophotometer.

Key to the study of enzyme activity is the isolation of the reaction components (i.e., the enzyme, its substrate(s), and any required co-factors). A quick review of the history of biochemistry will reveal that our understanding of biological processes has increased concomitant to our ability to purify compounds related to or involved in such processes. Once the required reaction components have been isolated, the reaction can be reconstituted *in vitro* and the reaction kinetics investigated. We will introduce and describe two major biochemical approaches that have been (and continue to be) used to purify enzymes (proteins) and other compounds or molecules from crude solutions: chromatography and isoelectric focusing. Both approaches are typically employed subsequent to a salt precipitation procedure to concentrate the protein in a crude sample (with the most common salt used for this procedure being ammonium sulfate). Afterwards, we will discuss spectrophotometry, its history, and its relevance to enzymology.

2.3.1 Principles of Chromatography

2.3.1.1 Column Chromatography

Chromatography is a purification technique by which sample components are separated according to their ability (or inability) to interact with a mobile phase or a stationary phase through which the sample is passed. Although there are many types of chromatography available today, the underlying core separation principle is essentially the same for all of them. One of the most basic and most common chromatographic techniques is column

chromatography, in which a glass or plastic tube is filled with a mixture or slurry of a liquid mobile phase (typically a buffer) and a solid stationary phase. The sample, or solute, is applied to the top of the mixture (called the bed) in the vertically-supported tube and is allowed to pass through the two phases either by gravity flow or with pressure applied from an attached pump. The components of the sample distribute themselves between the mobile and stationary phases depending on their affinity for either (which is determined by the inherent chemical properties of each component). Molecules that have little or no affinity for the stationary phase spend more time in the mobile phase, pass quickly through the chromatography system, and are removed, or eluted. Molecules that have affinity for the stationary phase spend more time in the stationary, move more slowly through the system, and are eluted more slowly. The mobile phase that is collected after passing through the chromatography system is called the effluent and is or contains the sample molecules. Usually, the effluent is collected at different times or in fractions (such as for 2 Min periods or in 1–2 mL portions). Typically, fractions which are found to contain the desired components will be combined, or pooled, for further analysis.

In column chromatography, the solid phase is an adsorbing material which contains openings of various sizes (known as mesh sizes) through which the solute may pass. Low mesh sizes (20–50) have a lower number of openings per square inch of packed material and, thus, have a faster flow rate. Higher mesh sizes (200–400) have a higher number of openings per square inch and, thus, have a slower flow rate and are used mainly during high-resolution separations of nearly pure solutes.

2.3.1.2 Other Types of Chromatography

2.3.1.2.1 Ion-Exchange Chromatography Ion-exchange is a form of adsorption chromatography set up similarly to column chromatography in which solute molecules are separated on the basis of their affinity for a charged stationary phase. The column is packed with a stationary phase consisting of a synthetic resin that is tagged with ionic functional groups which electrostatically interact (reversibly) with ionic solutes. Depending on the experimental conditions, the solutes may have a negative or positive charge, or none at all (neutral). Solutes that are neutral, or that have a charge similar to that of the stationary phase, will elute with the buffer. Bound solutes can be released by increasing the ionic strength of the buffer (displacement) or increasing the pH of the buffer (weakening the interaction by charge reduction of the solute or resin).

2.3.1.2.2 Gel Exclusion Chromatography Gel exclusion chromatography is a form of column chromatography in which solute molecules are separated based on their molecular size. The column is packed with a stationary phase consisting of synthetic beads that contain small pores of a controlled size. Solute molecules that are too large to enter the pores will flow quickly through the column. Solute molecules that are small enough in size to enter the pores will remain in the column longer and thus are retarded in their travel through the column. The exclusion limit of the stationary phase defines the molecular mass of the smallest molecule that cannot enter the bead pore. Solute molecules with a molecular size greater than the exclusion limit will pass directly through the column. Gel matrices with an exclusion limit of approximately 6000 Daltons are routinely used for desalting of a protein sample following a salt precipitation procedure.

2.3.1.2.3 Thin-Layer Chromatography (TLC) TLC is performed by (1) coating a glass plate (similar in size to a microscope slide) with a thin layer of silica gel, alumina, or cellulose; (2) spotting a small drop of sample onto the coating and allowing it to dry; (3) and then standing the plate vertically in a shallow dish containing an appropriate solvent. As the solvent front moves vertically through the gel coating by capillary action,

the solute components are separated. Samples that are not colored are sometimes detected by radioactive or fluorescent methods, or through treatment with chemicals that develop colors. Unknown sample components are identified by comparing their distances traveled to those of known standards.

2.3.1.2.4 High-Performance Liquid Chromatography (HPLC) HPLC, one of the most common chromatographic techniques performed by food scientists, is an analytical technique well suited to the separation and identification of biological molecules such as proteins, nucleic acids, phenolic compounds, carbohydrates, and lipids. With the development of stationary phases with very small particles sizes and large surface areas, HPLC improves elution rates by applying high pressure to the solvent flow. The result is high resolution of a solute into its individual components in a relatively short period of time (typically between 10–60 Min). Unknown compounds are identified by comparing their retention times (that is, the amount of time required for the compound to elute from the column under specific experimental conditions) to those of known standards, either alone or in combination. The computerized systems in use today are relatively simple to use as they are largely automated and can be controlled by accompanying software.

2.3.2 Principles of Spectrophotometry

Another very common analytical laboratory technique is the measurement of the concentration of a compound, reaction component, or reaction product (or its rate of appearance or disappearance) by measuring its absorbance of a specific wavelength of light. A spectrophotometer is an instrument that can produce light at a selected wavelength, direct it through a sample (typically held in a cuvette), and measure the intensity of light transmitted by the sample. Many types of spectrophotometers exist. A UV/vis spectrophotometer, a type found in most laboratories, can produce light in both the ultraviolet (UV) spectrum (~190–340 nm) and the visible (vis) spectrum (340–800 nm).

The absorbance of a particular compound in a solution can be detected using a spectrophotometer. For example, $NADPH_2$, a co-factor produced by activity of the enzyme glucose-6-phosphate dehydrogenase, absorbs light at the wavelength of 340 nm. Thus, an increase in $NADPH_2$ of a solution can be detected as an increase in the absorbance of the solution at 340 nm. The peak absorbance wavelength has been determined for many substances.

The actual concentration of a chemical can be determined by its absorbance at a given wavelength, such as 340 nm for $NADPH_2$, using the Beer-Lambert Law represented by the mathematical equation $A = \varepsilon\, l\, c$. In this equation, A is the absorbance of a solution at a given wavelength of light. The term ε is a proportionality constant that defines the extent of absorption. It is called the molar extinction coefficient or the molar absorption coefficient, and is typically given in the units cm^{-1} and M^{-1}. The term l is the path length of light through the sample (usually 1 cm), and the term c is the concentration of absorbing material in the sample (usually in moles/liter, or M). Molar extinction coefficients have been determined for a great many compounds at specific wavelengths and environmental temperatures. The chromatographic technique HPLC combines high-pressure column chromatography with a spectrophotometer so as to detect specific chemicals by their characteristic absorption at given light wavelengths as they are eluted from the column and pass through the light beam.

2.4 A BRIEF HISTORY OF MODERN BIOCHEMISTRY – MOLECULAR BIOLOGY

Just as macromolecular entities such as proteins can be detected, purified, and characterized based on their inherent biological properties (i.e., molecular size, ionic charge at certain

pHs), so, too, can micro-molecular entities such as nucleic acids (DNA and RNA). In fact, since the core biological properties of DNA and RNA were reported in the 1950s and 1960s, a number of molecular purification and characterization techniques have been developed which take advantage of these properties. The advent of these molecular techniques, first viewed as tools of biochemistry, has led to the emergence of a new and related field of study known as molecular biology. Noting the recent advent of genomics and proteomics, advancements in this field continue to occur at a pace which rivals that of the electronics industry.

Currently, there is much support hailing the discovery of the double helix by Watson and Crick as the beginning of modern biochemistry and molecular biology (9). Others stress that it was the later-proven speculation by Watson and Crick that the pairing arrangement of bases in the double helix implied the existence of an information-carrying genetic code (or "copying mechanism," as they called it). One could just as easily argue that modern biochemistry arose from the work of Hershey and Chase, that demonstrated that DNA was the material of heredity, and shifted much focus away from protein. It would seem to most, though, that the works of Hershey and Chase, Watson and Crick, Messelson and Stahl, Jacob and Monod, and Nirenberg and Leder, as a whole, during 1953–1964, set the foundation for modern biochemistry and molecular biology.

Following the elucidation of the genetic code, the 1970s were witness to a number of important advances in relation to the study of DNA. Right away, the first restriction enzyme was isolated from *Hemophilus influenzae* by Smith and Wilcox (1970) (14). Three years later, Cohen and Boyer utilized restriction enzyme technology in developing DNA cloning and recombinant DNA (15). Ed Southern (1975) developed a DNA detection technique (later named after him) that employed blotting DNA to a membrane and hybridizing radio-labeled DNA probes that were complementary to specific sequences (16). In 1977, Sanger developed a rapid technique for manually sequencing DNA *in vitro* (17).

Similarly, the rapid pace of scientific advancement in microbiology continued during the 1980s and 1990s, and continues right up to the present time. In 1980, the U.S. Supreme Court decreed that life forms, such as genetically-modified organisms, could be patented. This decision facilitated the emergence of numerous biotechnology companies, such as Amgen. The 1980s also saw the invention of the polymerase chain reaction (PCR) technique for amplification of DNA sequences by Kary Mullis (18) and the development of the first genetically-modified crop, a tobacco (19). Soon after, during the late 1980s and early 1990s, Leroy Hood and colleagues developed the first automated DNA sequencer and protocols utilizing fluorescent dyes that could be read automatically (20). In the mid-1990s, J. Craig Venter developed a rapid technique for genomic sequencing known as "shotgun" sequencing, in which genomic DNA is broken into smaller fragments for sequencing and afterwards the resulting sequences are put back in order for further genetic analyses (21). Meanwhile, at Stanford University, Patrick Brown and colleagues were busy developing an automated method for quantitative gene expression, later to be known as the DNA microarray (22). In 1997, the first successfully cloned animal was born in Scotland, a sheep named Dolly (23). And finally, in 2001, after nearly 10 years of tense competition, two research groups, one privately funded and one publicly funded, published the first drafts of the human genome sequence (24,25).

2.5 KEY PRINCIPLES OF BIOCHEMISTRY AND MOLECULAR BIOLOGY

Now that we have an idea as to where biochemistry started and how far our knowledge has come, let us recap the main points that have been learned from the process.

2.5.1 Basic Cellular Biology

Living organisms are complicated, albeit organized, systems. Organization manifests itself as a molecular hierarchy of systems and pathways, occurring as organs (in larger creatures) made up of tissues, which themselves are made up of cells. The chemistry of living cells resembles the chemistry of organic reactions. The constituents of living cells are called biomolecules. Cells contain structures called organelles, which are complex assemblies of large molecules (macromolecules). Both of these components serve functional purposes. Also, living organisms can self-replicate.

Some reactions in the cell require energy to occur. Living systems harness energy from the environments in which they occur. Organisms acquire energy either through photosynthesis (like plants) or through the metabolism of food (like animals), by forming special biomolecules, such as adenosine triphosphate (ATP) or $NADPH_2$, that can serve as chemical sources of stored energy for thermodynamically unfavorable reactions.

All biomolecules contain carbon. The major precursors of biomolecules are water, carbon dioxide, ammonium, nitrate, and nitrogen. Precursors form metabolites. Metabolites are simple, organic compounds that are intermediates in cellular reactions, such as the biosynthesis of amino acids, sugars, nucleotides, and fatty acids. Metabolites are converted into larger macromolecules, such as proteins, polysaccharides, polynucleotides, and lipids. Macromolecules interact to form supramolecular complexes, such as enzyme complexes, ribosomes, chromosomes, and cytoskeletal elements. Organelles are membrane-bound sites of supramolecular complexes, such as the nucleus, mitochondria, and chloroplasts. Prokaryotic cells do not contain organelles. Eukaryotic cells are believed to have originally formed organelles from engulfed bacteria (symbiotic theory).

2.5.2 Macromolecules and Basic Cellular Chemistry

Macromolecules are composed of units that have structural polarity. As such, these molecules are not symmetrical, but rather have ends that are structurally different (a "head" and a "tail"). Some molecules may have a positively-charged end and a negatively-charged end. Structural polarity gives a macromolecule a sense of direction or orientation. Because of this directional nature of their structure, biological macromolecule subunits have the capacity to specify information in their arrangement. Biomolecular interactions, recognition, and environmental conditions are determined by numerous weak forces, such as hydrogen bonds or hydrophobic interactions, as well as structural complementarity.

Enzymes are macromolecules that accelerate (or catalyze) chemical reaction rates by several orders of magnitude, and add a measure of specificity to the reaction (i.e., only select substances may interact with the enzyme). Controlling enzyme activity allows control of metabolic reactions.

2.5.3 Importance of Water, Ionization, and Buffers

As organisms typically contain 70–90% water, water is an indirect participant in biological reactions. The "bent" structure of the water molecule is well-suited to hydrogen-bond formation (with a natural induced dipole charge) and in that formation, water can serve as either a proton (H^+) donor or a proton acceptor. Also, the natural ability of water to form hydration shells around ionic and hydrophobic solutes, as well as ice, influences how various reactions will occur (or not occur). The formation of membranes by fatty acids is influenced by the formation of micelles by amphipathic molecules (both partially hydrophobic and partially hydrophilic) in aqueous solutions.

Water shows a slight tendency to form ions, a property that allows it to conduct electricity. The ions formed from one water molecule are one proton (H^+) and one hydroxyl (OH^-), with the former being immediately hydrated to form a hydronium ion (H_3O^+),

although by convention we still refer to the proton concentration in solution and not the hydronium ion concentration.

At equilibrium, the concentration of free protons in water is equal to the concentration of free hydroxyl ions. The product of the two ion concentrations is called the ion product of water (K_w). When a solution is acidic, it contains a higher concentration of free protons and a lower concentration of free hydroxyl ions. Likewise, a basic solution contains more free hydroxyl ions than free protons. To simplify the expression of proton concentrations, the negative logarithm of the free proton concentration ($-\log [H^+]$) has been defined as the "power of hydrogen," or pH, where pH + pOH = 14. For example, the pH of bleach, a strong basic solution, is 12.6, whereas the pH of vinegar, a weak acid, is 2.9. The pH of blood is 7.4. Solutions with a pH of 7 are said to be neutral; that is, neither acid nor base.

Other substances that are able to dissociate into ions in water are called electrolytes, because the addition of their ions to those already present in water increases the ability of the solution to conduct electricity. Substances that dissociate almost completely into ions in water are called strong electrolytes. So-called "strong" acids and bases are examples of strong electrolytes. Similarly, substances that only slightly dissociate into ions in water are called weak electrolytes. Again, so-called weak acids and bases are examples of weak electrolytes. The extent to which a particular substance forms ions in water is called the ionization constant (K_a).

Solutions that resist changes in their pH when acids or bases are added are called buffers. A buffer is most effective when the pH of the solution is within one unit of the pK_a of the buffer solute (i.e., potassium phosphate). Since enzyme activity is very sensitive to changes in pH, maintenance of cellular pH is critical to the survival of living organisms. Intracellular pH is maintained by phosphate and histidine buffer systems. The bicarbonate buffer system controls the pH of blood and extracellular fluids.

2.5.4 Nucleic Acids

Although biochemistry arose as a scientific discipline from a concerted interest in the investigation of proteins and enzymes, modern biochemistry and molecular biology focus arguably more attention on nucleic acids and their role in directing cellular activities. Because nucleic acids encode the blueprints for protein design, thus controlling their activity, we will discuss nucleic acids first, and then proteins.

In the mid 1800s, a monk named Gregor Mendel postulated that each trait of a living organism (in his case, the pea plant) was regulated by tiny physical factors in the cells of the organism (later named "genes") that could be passed on to the next generation (6). As illustrated by the experiments of Hershey and Chase in 1952, nucleic acids contain the material of heredity (8). Later, it was found that, in fact, it is the nucleotide sequences which make up the nucleic acids that contain the genes. Thus, genes composed of specific nucleotide sequences are the material of heredity.

There are two basic types of nucleic acids, deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). Nucleic acids are composed of a five-carbon sugar, a phosphate group, and a nitrogenous base. The sugar in DNA is 2-deoxyribose. The sugar in RNA is ribose. The nitrogenous bases of nucleic acids are derived from either a purine (for adenine and guanine) or a pyrimidine (for cytosine, uracil, and thymine). Adenine, guanine, and cytosine are found in both DNA and RNA. Uracil is found only in RNA, and thymine is found only in DNA. In the DNA double helix, the base adenine (A) in one strand pairs with (i.e., hydrogen bonds to) a thymine base (T) in the opposite strand, while the base guanine (G) pairs with a cytosine (C) base. In DNA, the strands are anti-parallel, which means they run in opposite directions. In a DNA–RNA hybrid complex, the adenine bases in the DNA strand pair with cytosine bases in the RNA strand.

Nucleic acids are linear sequences of nucleotides. Nucleotides are nucleosides bound to a phosphate group through an ester linkage. The term "nucleoside" refers to a nitrogenous base linked to a five-carbon sugar. When bound to a sugar, the base becomes more water-soluble that it normally would be. To create nucleic acids, nucleotides join together to form ordered linear sequences in which the 5′-nucleoside monophosphate of one nucleotide is attached to the free 3′-OH group of the preceding nucleotide. Since the sequence originates at the 5′-end and extends to the 3′-end, base sequences are therefore represented in base shorthand (A, G, C, T, or U) written in a 5′-3′ orientation. The key importance of nucleic acids is in their ability to form ordered linear sequences which allows for nucleic acid sequences to hold [chemical] information, similar to the way words contain information because of the correct orientation of letters in the words.

For most living organisms, genetic information is stored in the form of DNA, although some viruses are known to use RNA. While there are two main types of nucleic acids, there are several main types of RNA, such as messenger RNA (mRNA), ribosomal RNA (rRNA), transfer RNA (tRNA), and, in eukaryotes, small nuclear RNA (snRNA). mRNA is produced during transcription, and acts as a physical messenger to carry the genetic information stored in DNA from the nucleus to the cytosol, where translation activities take place. rRNA molecules are involved in translation activities, along with ribosomes. tRNAs shuttle specific amino acids to the ribosome for protein synthesis. snRNAs join to form ribonucleoproteins that can edit (cut) mRNA sequences before they leave the nucleus.

DNA can be cut, or "cleaved," enzymatically at specific points, by restriction endonucleases. These restriction endonucleases recognize and cut at specific DNA sequences, usually between 4–6 bases in length. One of the first uses of these endonucleases was in restriction mapping of DNA. By this technique, specific sites on DNA molecules can be mapped. The technique involves creating fragments of various lengths, using restriction endonucleases. Then the orientation of the sites is deduced from the patterns formed after separating the fragments by electrophoresis through an agarose gel (explained later).

2.5.5 Proteins

Proteins are composed of one or more peptide chains, folded into specific arrangements. Peptide chains are linear sequences of amino acids. The specific arrangements into which peptide chains join together or fold are largely determined by the amino acid sequences of the peptide chains. There are only 20 naturally occurring amino acids. There are nonpolar, polar uncharged, acidic, and basic amino acids. Consistent with other biomolecules, amino acids are asymmetric. They have a carboxyl group (COO^-) on one end and an amino group (NH_3^+) on the other.

Amino acids can link together through peptide bonds to form linear sequences (polypeptide chains). In a peptide bond, the amino group of one amino acid links to the carboxyl group of another amino acid. One or more polypeptide chains can fold together to form proteins. When notating the sequences of polypeptide chains, amino acid names are typically abbreviated by using three-letter codes.

Proteins generally fold to form the most stable structures possible. In addition to the primary amino acid sequence, other forces influence protein folding and structure, such as hydrogen bonds, hydrophobic interactions, electrostatic interactions, and attractive or repulsive (van der Waals) forces. Sometimes proteins are "helped" into their appropriate conformations by helper proteins called molecular chaperones. A peptide chain folded into its natural conformation is said to be in its native structure. Non-native structures can result when proteins are broken down, or denatured, by cooking, or by treatment with a strong base, such as urea.

The amino acid sequence is the primary (1°) structure of a protein. The secondary structure (2°) of a protein consists of the α-helix or β-pleated sheet conformations formed by the polypeptide chains. Secondary structure largely depends on the amino acid sequences. The tertiary structure (3°) of a protein is the three-dimensional interactions of the secondary structure elements. Quaternary (4°) protein structure refers to the arrangement or interaction of two or more monomer subunits.

2.6 EXPERIMENTAL TECHNIQUES OF MODERN BIOCHEMISTRY AND MOLECULAR BIOLOGY

2.6.1 Detection of Proteins and Nucleic Acids

A great many techniques have been developed for the detection of proteins and nucleic acids. Previously, we discussed chromatography and spectrophotometry. Both of these techniques can be used to detect proteins and nucleic acids. For instance, both can be detected by their absorption of a specific wavelength of UV light. The peak absorption of proteins occurs at 280 nm, whereas the peak absorption of nucleic acids occurs at 260 nm.

2.6.1.1 Principles of Electrophoresis

Probably the most common technique employed in the laboratory to detect proteins or nucleic acids is electrophoresis. Electrophoresis is a technique by which the movement of charged molecules in an electric field can be studied. Most people have likely heard of the term "gel electrophoresis," which employs a buffer-saturated gel matrix as a support medium to which the sample to be analyzed is applied. The migration of the sample through the matrix of the gel is influenced by an applied electric field. Typical forms of gel used are agarose and polyacrylamide. The decision to use one over the other typically depends upon the specific need for a certain resolution power (which is greater for polyacrylamide) or the lack thereof. An agarose gel matrix is usually used in routine electrophoresis of DNA, such as to resolve PCR reaction products. Protein electrophoresis typically uses polyacrylamide.

The electric field is applied such that the positive electrode occurs on the opposite end of the gel to where the sample is applied (usually the top). For DNA electrophoresis, the nucleic acid samples migrate through the gel matrix towards the positive electrode because DNA has an inherent negative charge, due to the accumulation of phosphate groups in the DNA backbone. The charge of proteins, however, largely depends upon the pH of their environment. To resolve this problem, proteins are usually denatured in the presence of sodium dodecyl sulfate or SDS (a type of soap), which coats the denatured protein molecule and gives it an overall negative charge. This type of protein electrophoresis is referred to as SDS-PAGE.

For SDS-PAGE and normal DNA electrophoresis, after the electric field is applied, the molecules migrate through the gel matrix at rates which depend on their molecular size. Thus, larger proteins and oligonucleotides take longer to weave their way through the maze-like matrix, and thus remain "higher" on the gel, or closer to the sample application point. Smaller proteins and oligonucleotides are better able to pass through the matrix and thus are found "lower" or farther down the gel, closer to the positive electrode. Proteins and DNA molecules separated by electrophoresis are typically detected after separation by staining with fluorescent or colorimetric dyes, such as coomassie brilliant blue (for proteins) and ethidium bromide (for DNA).

2.6.2 Southern, Western, and Northern Blotting

Once proteins and DNAs have been separated by their molecular weight, specific molecules can then be detected. However, the gel matrix that is so useful in separating these molecules by their molecular size unfortunately interferes with detection methods that are used to identify specific molecules from a group sample. Further, only a minute amount of protein or DNA is typically present in a band on a gel. In 1975, Ed Southern developed a method known as Southern blotting, in which DNA can be transferred to a nitrocellulose filter (by placing the filter on the gel and allowing the buffer flow from the gel into the filter to carry with it DNA) (16). After DNA is transferred to the filter, the filter can be incubated with radioactively labeled DNA fragments known as probes. The probes will hybridize with complementary DNA sequences, if they are present. The filter then is exposed to x-ray film and any bound probes are detected on the film, in a process called an autoradiogram. This procedure is known as Western blotting when protein is transferred to a filter and Northern blotting when RNA is transferred.

2.6.3 Mass Spectrometry

Mass spectrometry is a powerful tool for accurately detecting and identifying specific proteins separated by 2-dimensional (2D) electrophoresis. First evolving in the early 1990s, the core technique has essentially three steps. In the first step of mass spectrometry, a complex protein sample is separated by 2D electrophoresis. By this method, the protein sample (not treated with SDS) is loaded into one well of a polyacrylamide gel that possesses a pH gradient, usually from 3–10, within the gel matrix. When the proteins in the complex sample travel through the gel during electrophoresis, they stop migrating at the pH at which the net electric charge of the molecule is zero. This pH value is called the isoelectric point or "pI" (1st dimension). After the proteins in the sample are separated according to their pI value, the entire lane of the gel is removed and laid across the top of a new, normal polyacrylamide gel (e.g., without a pH gradient), and the proteins are then further separated by their molecular weight (i.e., size; 2nd dimension) during a second electrophoresis step. During the second step of mass spectrometry, protein bands of interest are then excised from the second gel. Then the gel plug containing the protein-of-interest is digested using the enzyme trypsin. In the third step of the procedure, the peptides that result from the trypsin digest of the protein-of-interest are analyzed by mass spectrometry and the spectra produced by the collision-induced dissociation is searched against mass spectra of peptide sequences contained in a database.

2.6.4 Other Important Molecular Techniques

2.6.4.1 The Polymerase Chain Reaction (PCR)

Probably no other technique developed since the mid-1980s has revolutionized molecular genetics like the polymerase chain reaction (PCR). Developed by Kary Mullis, PCR solved the major problem of analyzing genes that are rare targets in a genome that could contain hundreds of thousands of genes (18). The core premise of PCR exploits certain features of DNA replication by DNA polymerase. First, because DNA polymerase requires a small section of DNA to initiate DNA synthesis, DNA polymerase can be directed to synthesize a specific region of DNA by supplying an oligonucleotide primer that anneals to the template DNA at that point. Second, the specific region of DNA can be amplified by supplying primers that flank the ends of the sequence, heating the reaction mixture to separate the original and newly synthesized strands, and allowing the reaction to occur over and over. In the original protocol, fresh DNA polymerase had to be supplied after each heating step. The method has since been facilitated by the discovery of thermal-stable DNA polymerases,

which eliminates the need to add fresh DNA. Because each round or cycle of new DNA synthesis doubles the amount of the target DNA molecule, a typical reaction consisting of 30 cycles can amplify the target sequence to well over 260,000,000 copies.

2.6.4.2 Real-Time PCR

An extension of the basic PCR methodology has been developed to help quantify transcript concentrations without resorting to the more time-consuming Northern blotting analysis. In real-time PCR, mRNA is isolated from a total RNA sample and used as a template for PCR. Using primers conjugated to fluorescent dyes, the efficiency of the PCR reaction can be followed by a computer-assisted instrument that can detect the fluorescent dyes. Since the amount of DNA that is synthesized during the linear portion of the reaction will largely be dependent upon the initial concentration of the template, the initial concentration of specific mRNA templates can be back-calculated using software that accompanies the instrument. Being able to accurately determine mRNA concentrations can help to identify the effect of chemicals or even environmental conditions on the expression of certain genes.

2.6.4.3 Microarrays

With the advent of genomic sequencing came the detection of numerous (hundreds, even thousands) of previously unknown genes in the genomes of various organisms. Now the area of functional genomics, which is the study of gene function through parallel expression measurements of a genome, has emerged. Functional genomics studies have the promising potential of identifying functions for these previously unknown genes. The most common tool to carry out these measurements is the cDNA microarray. The basic technique involves the isolation of mRNA from a biological sample in a normal or conditional state, the conversion of the mRNA into cDNA molecules which contain a fluorescent tag, and the hybridization of these tagged-cDNAs to a microarray which contains tagged-probes for specific genes. The result is something between a few thousand and tens of thousands of measurements of gene expression. The current disadvantage of microarrays is their high cost, but, as the price continues to decrease, the use of microarrays will likely become more and more prevalent, especially in drug discovery research.

Fermentation Technology and Bioreactor Design

A. Eugene Raj and N.Ganesh Karanth

CONTENTS

3.1 HISTORICAL PERSPECTIVE

Fermentation dates back to prehistoric times when cheese was made in Iraq from cow's and goat's milk (6000 BC). Egyptians first discovered the use of yeast to make leavened bread and wine (4000 BC); Sumerians fermented barley to beer (1750 BC); and Chinese used moldy soybean curds as antibiotics (500 BC) (1). A summary of the fermentation events, reported chronologically, is given in Table 3.1. The first half of the twentieth century saw the development of fermentation processes for the industrial production of alcohol, acetic acid, lactic acid, citric acid, gluconic acid, acetone, butanol, and glycerol. It was during this period that anaerobic fermentations were carried out in submerged culture and

Table 3.1
Historic fermentation events (2)

Application/ Event of Fermentation	Period (AD)
Wine preparation promoted by Roman Emperor	Third century
Fermentation of yeast by Erxleben	1818
Lactic acid fermentation by Pasteur	1860
Fermentation enzymes in yeast by Buchner	1897
Discovery of penicillin by Alexander Fleming	1929
Discovery of other antibiotics	1945–present

aerobic fermentation in surface culture. Continuous demands for increased productivity of aerobic industrial fermentations for baker's yeast and organic acid production led to the use of deep tank vessels sparged with large quantities of sterile air. Development of the penicillin process during the Second World War reaffirmed the development of industrial fermentation. However, the postwar period resulted in a temporary setback due to the growth of the petrochemical industry, and the availability of inexpensive chemicals for cheaper production of organic acids and solvents by chemical synthesis. Toward the end of the twentieth century, a better understanding of molecular biology led to the development of efficient fermentation systems for production of biochemicals. Presently, fermentation technology has gained increased credence due to the power of microbe design biotechnology, perceived hazards to people and the environment of chemical synthesis, and better economics from use of renewable raw materials.

3.2 FERMENTATION IN FOOD BIOTECHNOLOGY

Fermentation is an important part of our lives. The relevance of fermentation to day to day life is evident from the fact that food can be both spoiled and made by fermentation. Many of the foods used for human consumption are fermented foods. Fermentation is one of the oldest techniques used for food preservation. Muscle cells use fermentation to provide energy for a quick response. The oldest food biotechnological processes include the baking of yeast leavened breads, brewing of beer, sake and wine, and production of yogurt and cheese. Biotechnology can improve the baking process with improvements in cereal grains and starter culture through recombinant DNA technology, use of enzymes as processing aids, and application of advanced batch and continuous fermentation technologies (3). Brewing is regarded as a typical example of traditional or old biotechnology, because of its long history (4). Preservation of food remains one of the major objectives of fermentation. In addition, there are other aspects such as wholesomeness, acceptability, and overall quality, which have to be maintained in food fermentations (5).

3.3 TYPES OF FERMENTATION

The fermentation process is mainly divided into two broad categories: submerged fermentation and solid-state fermentation. The former has been readily employed in industries for large scale production of alcohol, organic acids, enzymes, antibiotics, vitamins, and amino acids. Solid-state fermentation has been used for the production of microbial metabolites from fungi, but suffers from limitations of operation at large scales due to operational difficulties.

3.3.1 Submerged Fermentation

Submerged fermentation is the most popularly used technique for the production of a large number of products using a wide range of microorganisms. The medium used for submerged fermentation contains relatively highly processed ingredients. The water activity of the medium is high, making it prone to contamination if asepsis is not maintained. Rheological problems can be encountered at high substrate concentrations. Mass transfer from gas to liquid phase is usually a limiting factor, but due to better mixing, diffusional limitation of nutrients is not encountered in submerged fermentation. Better bioprocess control of fermentation process is possible with the help of online sensors.

3.3.2 Solid-State Fermentation

Solid-state fermentation (SSF) is used for the production of bioproducts from microorganisms under conditions of low moisture content for growth. The medium used for SSF is usually a solid substrate (e.g., rice bran, wheat bran, or grain), which requires no processing. In order to optimize water activity requirements, which are of major importance for growth, it is necessary to take into account the water sorption properties of the solid substrate during the fermentation (6). In view of the low water content, fewer problems due to contamination are observed. The power requirements are lower than submerged fermentation. Inadequate mixing, limitations of nutrient diffusion, metabolic heat accumulation, and ineffective process control renders SSF generally applicable for low value products with less monitoring and control. There exists a potential for conducting SSF on inert substrate supports impregnated with defined media for the production of high value products (7).

3.4 BIOREACTOR CONFIGURATIONS

3.4.1 Submerged Fermentor Systems

The fermentor is the heart of any biochemical process in which microbial, mammalian, or plant cell systems are employed for the economic production of fermentation products. A properly designed fermentor should be used to provide an aseptic, controlled environment to facilitate optimal growth and product formation of a particular cell system. In view of the broad scope of the fermentor for cultivation of microbial, mammalian, or plant cells, it is more commonly referred to as a bioreactor; this term will be used because of its global application.

The efficiency of performance of a bioreactor is dependent on concentration of biomass, maintenance of aseptic conditions, efficient mass and heat transfer, and operation at optimum process conditions. Bioreactors can be classified into three groups based on the type of biochemical process employed (8):

1. Bioreactor with no agitation and aeration (anaerobic processes, e.g., production of wine and beer)
2. Bioreactor with agitation and aeration (aerobic submerged fermentation processes, e.g., production of citric acid and penicillin)
3. Bioreactor with aeration, but no agitation (aerobic solid state fermentation processes, e.g., production of food enzymes)

However, in industrial practice, bioreactors are distinguished by their configuration and design. The common modes of bioreactor configurations are discussed below.

3.4.1.1 Stirred Tank Bioreactor

The most commonly used bioreactor for industrial applications is the conventional stirred tank reactor (STR). The STR offers the advantages of high oxygen transfer rates required for high biomass productivity coupled with low investment and operating costs, which form the basis for any successful aerobic fermentation process. A schematic of a stirred tank bioreactor is shown in Figure 3.1. STRs typically have height to diameter ratios of 1:3 to 1:6. The agitator may be top driven or bottom driven depending on the scale of operation and other operational aspects. The choice of impeller depends on the physical and biological characteristics of the fermentation broth. Usually, a ring-type sparger with perforations is used to supply air to the fermentor. Baffles are provided to avoid vortex formation and improve mixing.

Most fermentation processes use complex medium ingredients like corn steep liquor, molasses, and soybean flour as inexpensive nutritional sources (for carbon and nitrogen), supplemented with vital growth factors (amino acids, proteins, and vitamins) (9). The high turbulence imparted by the impellers in an STR can result in foaming due to the presence of proteinaceous substrates. Although chemical antifoaming agents (silicone or polypropylene glycol) can be added to control the foam, these can have detrimental effects on microbial growth and product recovery. In order to overcome this, mechanical methods of foam suppression such as rakes on the stirrer shaft mounted above the critical

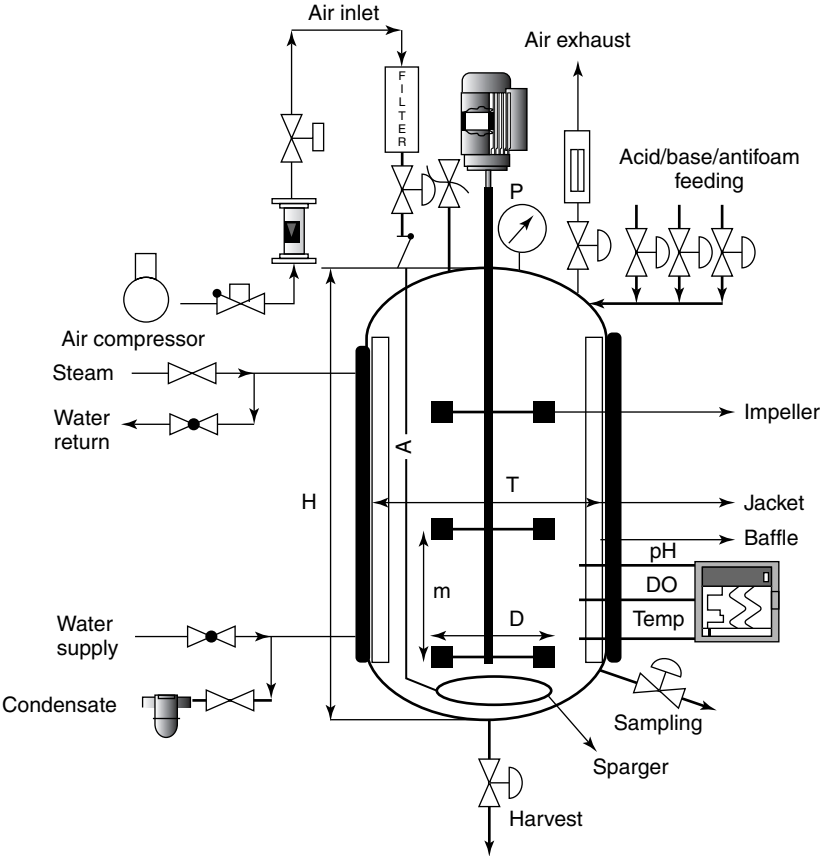

Figure 3.1 Stirred tank bioreactor

level have also been adopted. The emphasis on asepsis of the bioreactor, right from the end of the sterilization cycle to the end of the fermentation, has led to the maintenance of a minimum positive pressure in the fermentor to ensure sterility. A most important aspect of sterility is the point of contact between agitator shaft and vessel, which can be effectively sealed with a lubricated double mechanical seal. The sampling devices and injection ports must be contained in steam sterilizable closures.

3.4.1.2 Air Lift Bioreactor

For fermentations that have low shear and energy requirements, an air lift reactor can be useful. The amount of air required for the fermentation process is usually sufficient to act as the sole source of liquid mixing. In this process, air pumped from the bottom of the reactor creates buoyant, bubbles, which exert a drag on the surrounding fluid. A riser and a "down comer" inside the bioreactor impose a circulating fluid pattern of movement, which provides for oxygenation and mixing of the fermentation broth. The bottlenecks associated with large scale air lift bioreactors are inadequate sterilization, higher capital investment, and aeration requirements. Since mixing in an air lift is solely caused by aeration, the power required for fluid circulation and dispersion can be higher than that needed by an agitator in a stirred tank bioreactor. Air lift bioreactors have also been used for highly viscous fermentations, but the volumetric mass transfer coefficients are predictably low (10). An air lift bioreactor equipped with a draft tube results in better liquid circulation and larger gas to liquid interfacial areas, and gives higher mixing efficiency and oxygen transfer capability (11). A significant example of an air lift bioreactor that has been successfully scaled up to very large commercial levels is the ICI pressure cycle fermentor (12). In this process, methanol is used as substrate to produce single cell protein (SCP) using *Methylophilus methylotrophus* at a production capacity of 60,000 tons per year.

A three phase internal loop gas lift bioreactor was used for experimental studies on beer fermentation (13). This reactor has the advantages of high solid loading and better mass transfer properties than fluidized beds. Low density carriers of yeast cells, such as alginate and carrageenan gel particles, are typically used in three phase gas lift reactors for beer fermentations. The positive attributes of gas lift bioreactors are simple construction, low risk of contamination, easy adjustment and control of the operational parameters, and simple capacity enlargement (14,15). Research studies on air lift bioreactors have been carried out for the production of itaconic acid (16) and ξ-polylysine (17).

3.4.1.3 Fluidized Bed Bioreactor

In the last few decades, there has been a significant increase reported in the application of fluidized bed reactor systems. These have been mainly used for cells that have been immobilized onto particulate matter. This has the advantage that a high density of particles can be used, and that the flow velocity required for the fluidization can be achieved independently of the reactor throughput.

The main advantages of a fluidized bioreactor system as observed in ethanol production from *S.cerevisiae* (18) are superior mass and heat transfer characteristics, very good mixing between the three phases, relatively low energy requirements, and low shear rates (which makes a fluidized bed reactor suitable also for shear sensitive cells such as mammalian and plant cells).

Fluidized bed reactors have been used with cells adsorbed inside the carrier, made either of glass or of ceramics (19–21). The upward feed flow rate in a fluidized bed bioreactor is high enough to provide fluidization of carriers, resulting in improved mixing properties and medium distribution; but this can also induce carrier abrasion and damage.

In addition, fluidization of glass and ceramic carriers may require high medium flow rates that could result in higher pumping costs and eventually cell leakage. Gas liquid solid fluidized bed bioreactors have been employed for production of ligninolytic enzymes (22), treatment of wastewater from refineries (23), and raw wastewater (24).

3.4.1.4 Microcarrier Bioreactor

The majority of mammalian cells need a solid surface such as a microcarrier or a packed bed upon which to grow. The initial idea of culturing anchorage dependent mammalian cells in microcarriers was developed by van Wezel (25). The growth of cells on microcarrier beads depends directly on the surface available for growth up to the point where the microcarrier particles reach sufficient concentration to inhibit the cells and thus reduce cell yield. The microcarriers should have a density between 1.02 and 1.10 kg/m^3 to enable easy suspension in stirred reactors. The toxicity of the support can cause long lag phases, death of the cells in the early stages of development, and limited cell yields. Microcarrier bioreactor systems have been used for cultivation of human fibroblast cells to produce cell mass (26) and in the production of interferon (27). A great advantage of microcarriers is the high surface area for cell growth provided under low shear conditions, while still allowing conventional fermentor equipment to be used. However, bead to bead and bead to impeller collisions, and hydrodynamic shear forces, may cause reduced viability.

3.4.1.5 Membrane Bioreactor

Membrane bioreactors comprising hollow fiber systems have been developed and tested for the growth of mammalian and plant cells, and for the immobilization of bacteria, yeast and enzymes. Hollow fiber reactors have been used in the enzymatic hydrolysis of cellulose (28), penicillin (29), starch (30), hemoglobin (31), protein synthesis (32), and the culture of plant cells (33) and mammalian cells (34).

Hollow fibers can be made from cellulose acetate with a uniform wall matrix, or from acrylic copolymers or polysulphone fibers with asymmetric wall configurations. These hollow fibers have a highly porous surface wall about 70μm thick upon which the cells grow, and a cylindrical lumen of about 200μm in diameter. The surface of the lumen is covered with a thin ultrafiltration layer, which separates the immobilized cells and the lumen. Free diffusion of ions and molecules take place through the ultrafiltration layer, which may have nominal molecular weight cut offs (NMWCO) in the range of 10 kDa to 100 kDa. A hollow fiber bioreactor consists of a cylindrical bundle of a large number of individual fibers, which are held together in a shell and tube-type heat exchanger arrangement. Commercial hollow fiber bioreactor units are available with a luminal surface capacity between $0.01m^2$ and $1.0m^2$.

The advantages of using a hollow fiber reactor for microbial systems include high density of cell growth, using a perfusion system for simultaneous separation of product and biomass, and biocatalyst regeneration. However, a major disadvantage is the difficulty in monitoring and controlling the growth and metabolism of the culture. Other process constraints associated with microbial hollow fiber reactors are low oxygen transfer rates at high cell density and blockage, and rupture of the membranes due to excessive growth. The accumulation of toxic products in the hollow fiber might also inhibit the metabolic activity of the cell system. Further, the effect of microbial containment on physiology, long term viability, and productivity remains unclear. The technique has been used in the production of lactic acid (35), conversion of L-histidine and biosynthesis of β-galactosidase.

Membrane bioreactors have been used extensively for microbial, plant, and animal cell cultivations (36). A high performance membrane bioreactor has been studied for use

in ethanol (37) and organic acid fermentation (38). Continuous fermentation in a membrane bioreactor performed at a very high dilution rate enhanced productivity (39). A double vessel membrane bioreactor was reportedly employed for the production of wine from grape juice (40), wherein the low residual sugar level maintained favored higher wine production compared to a single vessel in continuous fermentation. The production of tissue plasminogen activator (tPA) in microfiltration hollow fiber (MFHF) bioreactors for mammalian cell culture has been reported (41).

3.4.1.6 Photobioreactor

Microalgae have been used successfully, with high productivity compared to higher plants. The high productivity in these systems is due to the high biomass produced in the bioreactor. Microalgae have been used for preparation of vitamins, pigments, antioxidants, and fatty acids, and as feed for aquaculture. The cultivation techniques employed are open systems and closed or semiclosed outdoor photobioreactors. The common photobioreactors used are tubular-type and plate-type reactors (42). The cyanobacterium *Spirulina platensis* has been studied in batch and continuous photobioreactors under varying conditions of incident light energy and nutrient limitations (43).

3.4.1.7 Innovative and Special Bioreactors

3.4.1.7.1 Space Bioreactor The transfer of knowledge from conventional bioreactor technology to microscale space bioreactors for cultivation of cells required in space is an emerging field of space life science research and applications. The first space bioreactors were developed and flown at the end of the last century (44). With the development of an international space station, special attention has been focused on the development of life support systems that allow recycling of expendable materials (i.e., water, air), the treatment of waste byproducts (45), and cultivation of microorganisms, mammalian cells, and tissues for food production. The bioreactors normally used on Earth may not be suitable in space for several reasons:

1. Materials presently utilized for the fabrication of a bioreactor are not acceptable in space for safety and environmental reasons.
2. The space bioreactor equipment has to comply with size, weight, and power requirements.
3. The microgravity conditions in space create a significant hindrance for the operation of a bioreactor due to alteration in the physical factors governing cell sedimentation, nutrient mixing, and byproduct dispersion.
4. Nutrients and oxygen and waste products should be efficiently transported by means of medium exchange, perfusion, or slow mixing, as convection currents are also reduced to near zero.

For these reasons, new types of bioreactors specifically adapted to space investigations had to be developed. Space based bioreactors provide an opportunity to understand how fermentation processes could occur in the absence of gravity in a cell and its surrounding environment. This unique research environment opens new horizons for exploring unconventional bioprocessing techniques (46). Several types of cultivation systems have been designed or are currently under development as given in Table 3.2.

3.4.1.7.2 Tissue Bioreactor Tissue bioreactors are expected to play a dominant role in the production of tissues for healthcare applications. In the twenty-first century,

Table 3.2
Characteristics of the different space cultivation systems reported (47).

Bioreactor	Space Flight	Specifications
Dynamic Cell culture System	Biokosmos 9 (1989), Shuttle (1992)	Cultivation chamber with medium exchange (osmotic pump), no regulation
Swiss Bioreactor (SBR 1)	2 Shuttle flights (1994,1996)	Zero headspace bioreactor for yeast cells, flexible continuous medium exchange (piezo-electric pump), sampling port, flow rate and pressure sensor. pH regulation, online data transfer.

tissue engineering and regenerative medicine are expected to be powerful tools for repairing damaged or diseased tissues and organs, because human donor tissue cannot meet the demand (48). Tissue engineering is the development of biological substitutes to restore, maintain, or improve tissue function (49). A clinically useful bioreactor system will need to be compact and capable of maintaining a large number of cells at relatively high densities over a prolonged period. The cultivation of hepatoma cells used for the production of bioartificial livers has been attempted in tissue bioreactors utilizing fluidized bed and hollow fiber setup (50). With the focus on automation and standardization of tissue manufacture in controlled systems, bioreactors have the potential to reduce production costs, facilitating global use of engineered tissues. The role of bioreactors in processes that are key for the *ex vivo* engineering of three dimensional tissues based on cells and scaffolds include cell seeding of porous scaffolds, nutrition of cells in resulting constructs, and mechanical stimulation of the developing tissues (51). A new challenge for bioprocess engineering in cell culture involves the development of highly sophisticated cultivation techniques for hematopoietic stem cells in novel bioreactors (52,53). The interdisciplinary research associated with tissue engineering will provide a basis for identifying process conditions required for generation of a specific tissue.

3.4.1.7.3 Nuclear Magnetic Resonance Bioreactor Nuclear Magnetic Resonance (NMR) spectroscopy has been used as a tool for noninvasive, real time studies of metabolic processes of cell suspensions in bioreactors (54). The NMR bioreactor is used for online NMR analysis of metabolic reactions in fermentation processes. One of the critical parameters in the evaluation of bioreactors for product formation is the oxygenation state of the cells, which can be determined using NMR (55). An NMR reactor (manufactured by M/s Bioengineering AG, Switzerland) is an autoclavable, miniaturized stirred vessel with ports to measure pH, pO_2, temperature, speed, and aeration, and for the addition of medium. The fully equipped NMR reactor can be inserted into an NMR unit.

3.4.1.7.4 Mass Spectrometer Coupled Bioreactor A minibioreactor with membrane inlet mass spectrometer probe is reported for biological processes with online analysis of volatile compounds such as H_2, CH_4, O_2, N_2, CO_2, ethanol, and methanol (56). The reactor comprises a small, stirred reaction vessel with a thermocouple, a pH probe, agitation, temperature control, and an option for aeration. The reactor is coupled to the mass spectrometer with the help of silicon rubber or fluorohydrocarbon membranes separating the bioreactor from the high vacuum in the mass spectrometer. Volatile compounds are selectively introduced into the mass spectrometer, where they are quantified according to their mass to charge ratio. Typical measurement ranges are from percent to parts per trillion levels in a few seconds to minutes. This bioreactor offers continuous, sensitive detection of small changes in the concentrations of dissolved gases, permitting fast kinetic measurements and in depth metabolic studies.

3.4.1.7.5 Integrated Bioreactor An integrated bioreactor is aimed at improving the productivity of the fermentation process by integration of fermentation and product recovery, for the continuous removal of a potentially inhibitory product. Two phase partitioning bioreactors have a great scope for increasing the productivity of a bioprocess (57). The concept of the two phase partitioning bioreactor can be applied to controlled delivery of a toxic substrate like phenol or benzene dissolved in an organic phase to a cell containing aqueous phase (58). A laboratory scale bioreactor coupling conventional electrodialysis and bipolar membrane electrodialysis was developed for *in situ* product removal and pH control in lactic acid fermentation (59). This electrokinetic process enabled removal of concentrated lactic acid directly from the bioreactor system, enabling good pH control and reduced end product inhibition of glucose catabolism. A membrane distillation integrated bioreactor for ethanol production using *S.cerevisiae* resulted in a higher productivity of 5.3 gm ethanol/dm^3/h, compared to 2.6 gm ethanol/dm^3/h without membrane distillation (60). The morphological and biochemical characteristics of transformed *Nicotiana glauca* roots demand integrated bioreactors for root growth and product extraction. A novel root tube bioreactor separator was used for the increased alkaloid productivity (61).

3.4.2 Solid-State Fermentor Systems

The main difference between submerged and solid-state fermentations is the amount of free liquid in the substrate. Solid-state fermentations (SSF) exhibit a poor conductive gas phase between the particles as compared to submerged fermentation (62,63). The presence of a wide variety of SSF matrices in terms of composition, size of solid substrate, mechanical resistance to air flow, porosity, and water holding capacity renders bioreactor design and control more difficult for the regulation of two important parameters, namely temperature and water content of the solid medium (64). Other factors that influence the bioreactor design are fungal morphological characteristics, resistance to mechanical agitation, and degree of asepsis required for the fermentation process. Solid-state bioreactor systems commonly used are shown in Figure 3.2.

3.4.2.1 Laboratory Scale SSF bioreactor

Small scale SSF equipment can be classified as those without forced aeration and agitation to include Petri dishes, jars, widemouth Erlenmeyer flasks, Roux bottles and roller bottles

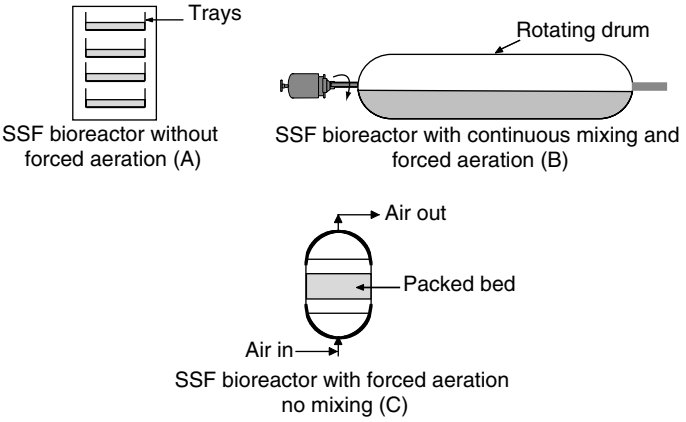

Figure 3.2 Solid state bioreactor systems

(65), and those incorporating continuous agitation of the solid medium such as a rotating drum bioreactor (66), a perforated drum bioreactor (67) and a horizontal paddle mixer. The former are easy to operate in large numbers and commonly used for the screening of substrates or microorganisms for research purposes, while the latter offer the advantage of temperature control due to continuous agitation.

3.4.2.2 Industrial Scale SSF Bioreactor

Industrial scale SSF bioreactors can be built with or without aeration. Those without forced aeration can exhibit limitation of heat and mass transfer as the fermentation progresses, changing the properties of the microorganism involved, particularly in light of associated complexities like heat build up and inadequate oxygen transfer. However, with aeration strategies like circulation of air around the substrate layer or passing air through the substrate layer,, these limitations are reduced to a certain extent.

3.4.2.2.1 SSF Bioreactor Without Forced Aeration On an industrial scale, this bioreactor is generally a tray fermentor; more commonly termed a Koji reactor. The trays containing the solid medium are stacked in tiers and placed in a humidity and temperature controlled chamber (68). This technology has the limitations of not conforming to asepsis conditions, and of high labor requirements. However, it is easily scaled up by the incorporation of additional trays.

3.4.2.2.2 SSF Bioreactor With Forced Aeration and No Mixing In this type of bioreactor, no mechanical agitation is provided, but the medium can be manually agitated *in situ* or it can be transferred into a kneading machine and reloaded into the basket. However, this type of device without agitation is limited by the metabolic heat produced. Considerable temperature gradients can exist within the substrate bed. As the majority of the heat is removed and water is evaporated by forced aeration, the bed dries out, reducing fermentation efficiency. Periodic water addition is required to maintain the moisture content at desired levels (69,70).

Suryanarayan (71) reported an industrial patented bioreactor, Plafractor™, with a capacity to hold 20 kg of wheat bran, constructed by stacking and interconnecting individual modules. The metabolic heat produced during fermentation is removed by conduction. There exist two channels in this bioreactor for ease of operation. The noncommunicating channels deliver cooling and heating fluids sandwiched between two sheets, while the communicating channels deliver fluids for sterilizing (steam or ethylene oxide), for adjusting the moisture and oxygen content, and for extracting the compound of interest after the cultivation. The interior of each module has a mixing arm that revolves about the central axis of the module while rotating.

3.4.2.2.3 SSF Bioreactor With Continuous Mixing and Forced Aeration A rotating drum bioreactor with continuous mixing maximizes the exposure of each substrate particle to a thermostatic air circulating unit in the headspace (72,73). A large reactor, capable of handling 10 kg of steamed wheat bran as substrate, has been reported (74). Large scale use of unagitated SSF is limited by the difficulty in maintaining temperature during the fermentation. However, in a rotating drum bioreactor, efficient heat transfer is possible by convective and evaporative cooling. As the scale of fermentation increases, evaporative cooling becomes significant, because the ratio of the heat produced to the surface area available for convection decreases (75).

The inherent difficulties encountered in the operation of solid-state fermentation systems on a large scale has led to new developments aimed at improving the efficiency of the fermentation process (76,77).

3.5 STAGES IN A FERMENTATION PROCESS

3.5.1 Upstream Processing

The upstream processing in a fermentation process includes preparation of the fermentation medium, sterilization of air and fermentation medium and inoculation of the fermentor.

3.5.1.1 Fermentation Medium

Metabolic activity can only be maintained if the necessary nutrients are available to the cell. A medium is defined as the substance surrounding the cells, which enables the microorganisms to grow and form products. While the single components of a medium are defined as substrates, generally, only the carbon source is called the substrate. Formulation of proper medium is an essential requirement for the success of a fermentation process.

Medium used for industrial fermentations should have the following criteria (78):

1. Maximum yield and concentration of product or biomass per unit mass of substrate
2. Minimum production of undesirable metabolites
3. Consistent quality of product
4. Minimal problems during sterilization and fermentation

The medium used for fermentation may be classified as defined, complex or technical medium. Defined medium consists only of precisely chemically defined substrates. At laboratory and pilot plant level where physical, chemical, and physiological parameters need to be standardized first, only defined media should be used for studies.

Complex medium is composed of substrates with undefined composition, such as extracts or hydrolysates from waste products, which are cheap substrates commonly used in industrial production. Relatively expensive substrates, such as yeast extract, brain heart infusion, peptone, casamio acids, and tryptone are often used for complex medium. In order to maximize the yield and selectivity of serine alkaline protease production by recombinant *Bacillus subtilis,* based on the amino acid compositions of the enzyme, the fermentation medium was designed with complex nutrients to supply the most needed amino acids to increase the yield (79).

Technical media are used on an industrial scale and are cheaper. Normally, but not necessarily, complex substrates are the main components. Culture medium formulated for the extracellular production of a hybrid ß-1,3-glucanase from *Bacillus* using a recombinant *Escherichia coli* contained lactose, yeast extract, and sodium chloride, and fermentation was carried out in shake flasks and a stirred tank bioreactor (80). The substrate sources can also be derived from industrial waste, and are often highly impure mixtures, requiring pretreatment before they could be used for a fermentation process. Examples are soy meal, whey, fishmeal, malt extract, and sulfite waste liquor. Wastewater from monosodium glutamate production, which contains high levels of chemical oxygen demand (COD), sulphate, and ammoniacal nitrogen at a low pH, has been used as the nitrogen and water source, with sugar beet pulp as the carbon source, for the production of pectinase by solid-state fermentation using *Aspergillus niger* (81).

3.5.1.2 Optimization of Fermentation Medium

Optimization of fermentation medium is done by using an experimental design considering the variables, mostly medium ingredients, that may have a significant influence on the

fermentation process. Experimental design for the fermentation process involves the determination of the optimum medium composition, while simultaneously figuring out the best process parameters. Design of experiments (DOE) is a systematic approach to problem solving which is applied to data collection and analysis to obtain information rich data (82). DOE is concerned with carrying out experiments under the constraints of minimum expense of time, costs, and number of runs. A properly designed experiment is more important than detailed statistical analysis. The primary goal of designing an experiment is to obtain valid results using a minimum of effort, time, and resources (83). The limitation of single factor at a time optimization is overcome by taking into account all the significant variables collectively by statistical experimental design using Response Surface Methodology (RSM) (84), which is used to evaluate the relative significance of variables in the presence of complex interactions (85,86).

3.5.1.3 Components of Industrial Fermentation Medium

In industrial processes, the cheapest substrates are used to keep the production costs low. Some of the cheap substrates available include barley, barley malt, blood meal, cane molasses, corn gluten meal, corn meal, corn steep liquor, cotton seed meal, dried distillers' solubles, fish solubles, fishmeal, linseed meal, meat meal, bone meal, oat flour, peanut meal, rice bran, rice flour, soybean meal, wheat flour, whey powder, and yeast hydrolysate (87). The composition of the medium has to reflect the demands necessary for the growth and synthesis of products other than cells. The carbon to nitrogen ratio has been found to be a good indicator for studying the optimum requirements for growth and product formation (88). Generally, media consist of an aqueous solution containing dissolved nutrient salts and a gaseous component (O_2). The different nutrient sources commonly used in fermentation media are shown in Table 3.3.

With the economics of fermentation playing an important role in a successful fermentation process, the efficient conversion of substrate to product is most crucial. In the present stage of advanced biotechnological development, this involves genetic engineering of the strain as well as a practical, focused approach in optimal use of the substrates with the aid of metabolic engineering (89). Metabolic engineering of *S.cerevisiae* for efficient xylose fermentation to ethanol has been reported (90).

Table 3.3
Nutritional sources used in fermentation media (91)

Carbon Source	Nitrogen Source		Inorganic Elements	Vitamins	Medium Additives
	Organic	Inorganic			
Carbohydrates, Alcohols, Carboxylic acids, Fats, Hydrocarbons, Gaseous substrates.	Urea, Aminoacids, Purines, Pyrimidines, Complex sources such as CSL, dried yeast, protein hydrolysates.	Nitrates, Nitrites, Ammonia, Molecular Nitrogen.	Phosphorus, Sulphur, Magnesium, Potassium, Calcium, Chlorine, Cobalt, Copper, Iron, Manganese, Molybdenum, Zinc.	Thiamine, Riboflavin, Pyridoxin, Biotin, Pantothenic acid, Niacin, Inositol, Choline.	Growth factors, Precursors, Detergents, Antifoaming agents, Anti-microbial agents.

3.5.1.4 Sterilization

Sterilization is a process by which microorganisms are either killed or removed from the material or equipment. Sterilization is necessary to ensure that only the desired microorganism is present to carry out the fermentation, that products are made of predicted quality, that the environment is protected from undesirable contamination, and that deterioration (microbial spoilage) of products is prevented.

3.5.1.4.1 Medium Sterilization Techniques The sterilization techniques applicable for fermentation media sterilization include:

1. Sterilization by high temperature achieved by direct or indirect steam or electric heating, which is the most popular and efficient method.
2. Sterilization of the medium for animal cell culture by membrane filtration with absolute rating of 0.1–0.04 μm.
3. Microwave irradiation, which is used commonly in food industries and has been reported to cause cell death (92).
4 Newer techniques, like high voltage pulses and photosemiconductor powders (93), which involve the rupture of the cell membrane by increasing the transmembrane electric field strength beyond a certain threshold.

3.5.1.4.2 Sterilization by Heat When a medium containing microorganisms is heated above a certain temperature limit, the microorganisms are unable to survive. However, because endospores have higher heat tolerance, inactivation of spores is a good indication of the sterilization process efficiency. In the testing of a heat sterilization process, *Bacillus stearothermophilus* spores, which are the most temperature resistant, are widely used as test organisms (94).

Batch sterilization: Sterilization of medium in the fermentor can be carried out in batch mode by passing steam through the available heat transfer area (jacket or limpet coil) or through direct steam sparging or with electrical heaters. The highest temperature to be operated for batch sterilization of medium is 121°C. The batch heat sterilization is described by a first order kinetics resulting in the equation:

$$N_t / N_o = e^{-kt} \tag{3.1}$$

where N_t is the number of surviving microorganisms at t, N_o is the initial number of microorganisms, k is the specific death rate, and t is time.

Equation 3.1 can be rearranged as:

$$\ln (N_o / N_t) = kt \tag{3.2}$$

The reaction or sterilization rate increases with increase in temperature due to an increase in the reaction rate constant or specific death rate (k). The relationship between temperature (T) and specific death rate (k) can be expressed as:

$$k = A\, e^{-E/RT} \tag{3.3}$$

where A is the Arrhenius constant, E is the activation energy, R is the gas constant and T is the absolute temperature.

Substituting k from Equation 3.3 into Equation 3.2:

$$\ln (N_o/N_t) = A\, e^{-E/RT}.t \tag{3.4}$$

The term "ln (N_o/N_t)" has been used as a design criterion for sterilization (95) and is represented as the Del factor (∇), which is a measure of the fractional reduction in viable cell count produced in a certain temperature and time regime. Thus, we have:

$$\nabla = A\, e^{-E/RT}.t \tag{3.5}$$

where t is the time required to achieve a certain ∇ value.

Rearranging Equation 3.5:

$$\ln (t) = E/RT + \ln (\nabla/A) \tag{3.6}$$

From a plot of ln (t) vs 1/T, the thermal death characteristics, namely activation energy (E) and Arrhenius constant (A), can be determined.

The batch sterilization cycle consists of heating, holding, and cooling cycles. The overall Del factor for destruction of cells during the sterilization period is represented as:

$$\nabla_{overall} = \nabla_{heating} + \nabla_{holding} + \nabla_{cooling} \tag{3.7}$$

By taking into account the Del factor during heating and cooling cycles in the design of a sterilization process, a minimum holding time is determined.

The advantages of batch sterilization are low capital equipment costs, low risk of contamination, easier manual control, and suitablity for media containing a high proportion of solids.

Continuous sterilization: Continuous sterilization has the advantages of relatively straightforward energy recovery, and lower nutrient degradation of heat labile substances due to shorter holding time. However, a disadvantage is that the presence of solids may give rise to inefficient sterilization, requiring a proper design.

Continuous heat sterilization essentially consists of a heating section using heat exchangers (typically spiral-type plates on an industrial scale), and a holding section where the temperature of the medium is maintained constant at the sterilization temperature. The inlet medium to the continuous sterilizer is preheated using hot fluid from the holding section in the heat exchanger. This process of energy transfer in the heat exchanger between the inlet raw medium and outlet sterilized medium not only cools the sterilized medium effectively, but also results in considerable energy savings. It is important to note that in the presence of solids, the rate at which medium can be heated is limited by the heat transfer rate from the liquid to the solid particles (96).

A continuous sterilizer has the advantage of being more economical in building area. It also offers greater possibility of automatic control, and reduction of sterilization process cycle time, resulting in minimum oversterilization and ease of scale up. Moreover, service requirements for steam and water are constant, compared with the fluctuating demand of batch sterilization. However, it may not be economical for small capacity batch fermentations.

3.5.1.4.3 Sterilization of Air Aerobic fermentation processes require significant quantities of sterile air. The sterilization of air in the strict bacteriological sense means the complete elimination of all viable microorganisms. The removal of bacteria by means of depth filters consisting of granular carbon or fibrous media has been almost universally adopted. In most fermentation systems, a prefilter usually made of cellulose, viscose, or glass wool is installed prior to the absolute filter to remove dust, oil droplets, and moisture from the process air. The most common material of construction of an absolute filter cartridge is pleated PTFE (Poly tetra fluoro ethylene, or Teflon™) membrane, which is hydrophobic and resists wetting. The membrane is intimately supported by pleated material, which prevents from distortion under high hydraulic or gas pressure. The absolute

filters have a rating of 0.2–0.01 μm (for total removal of bacteria, viruses, bacteriophage, or spherical particles of that size) and can be sterilized using steam. After air filter sterilization, the filters are held under positive pressure until the end of fermentation. Pharmaceutical grade cartridges are processed with deionized, pyrogen free water and evaluated by bacterial challenge in accordance with international recommendations using standard test organisms (e.g., *Pseudomonas diminuta*, *Acholeplasma laidlawii*).

3.5.1.5 Inoculation

The process of inoculation is the transfer of seed material or inoculum into the fermentor. Inoculation of a laboratory fermentor is generally done using presterilized tubing and a peristaltic pump. However, on a larger scale, inoculum transfer is done by applying a positive pressure on the inoculum fermentor and connecting it aseptically to the production fermentor. The connecting lines are sterilized before being used for transfer of inoculum. Heat susceptible substances such as amino acids and some vitamins must be dissolved in small volumes of water, sterilized by filtration and added separately to the final medium aseptically.

The performance of a fermentation process is dependent largely upon the physiological status of the inoculum (97). It is necessary that the inoculum transfer time be determined experimentally at a laboratory scale and that a standard is set for cultural conditions needed for development of the inoculum. Inoculum transfer is commonly done with vegetatively growing biomass determined by parameters such as turbidity, packed cell volume, dry weight, wet weight, or morphological characteristics (98). Online parameters which are considered for inoculum transfer include pH, dissolved oxygen, and oxygen and carbon dioxide concentration in the exit gas. The effect of inoculum age on the productivity of a secondary metabolite from *Streptomyces* species has been studied (99). The inoculum age at three time intervals, namely early log, log, and declining phases of growth determined online by the carbon dioxide production rates were carried out to determine the best inoculum for fermentation. It was observed that although there was a marginal influence on the biomass formation from the different inoculums, the log phase inoculum gave a significantly higher product concentration compared to the other two in the fermentor.

3.5.2 Fermentation Process

The fermentation process involves actual growth of the microorganism and formation of the product under agitation and aeration, to provide uniform environment and adequate oxygen to the cell for growth, survival, and product formation.

3.5.2.1 Modes of Operation

A fermentation system is usually operated in one of the following modes: batch, fed batch, or continuous fermentation. The choice of the fermentation mode is dependent on the relation of consumption of substrate to biomass and products.

3.5.2.1.1 Batch Fermentation Fermentation processes performed on a batch basis involve a sequence of operations, from development of inoculum from a stock culture, to seed for a production fermentor. The seed and production fermentors are the main concern in fermentation process development. A number of seed stages may be involved, but the production stage is usually performed in a single fermentor (100). The multistage system has the advantages of increased productivity resulting in lower total fermentor volume and the possibility for variation of the environmental conditions from stage to stage. The time required for batch fermentation varies from hours to weeks depending on the conversion attempted and conditions used. Growth rate in batch fermentation is normally uncontrolled and is highest at the start (101).

Productivity of batch fermentation: The productivity of batch fermentation is calculated by the final concentration of biomass or product being produced divided by the complete time of batch, which includes fermentation time and turnaround time (time for emptying, cleaning, sterilizing, and refilling). The batch fermentation setup and productivity for biomass production is shown in Figure 3.3 and Figure 3.4, respectively.

3.5.2.1.2 Continuous Fermentation Continuous fermentation is an open system to maintain cells in a state of balanced growth by continuously adding fresh medium and removing the culture medium at the same rate. Essentially, the two modes of operation for continuous fermentation are chemostats and auxostats. The commonly used auxostats include turbidostats (102), the pHauxostat (103), and the nutristat (104). The above modes of operation have specific control configurations and applications as discussed below.

Chemostat: Presently, the chemostat is the most widely used apparatus for studying microorganisms under constant environmental conditions. It is a continuous fermentation process performed in a Continuous Stirred Tank Reactor (CSTR). A CSTR operates by

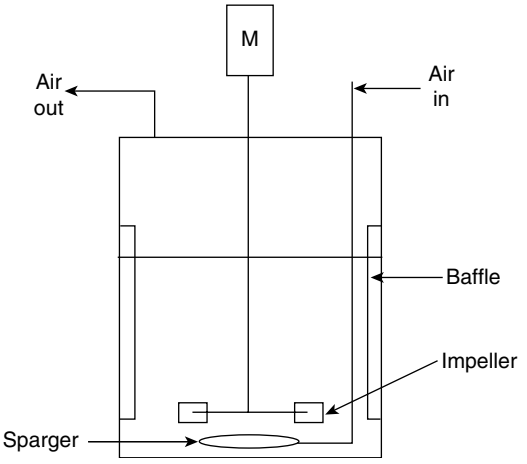

Figure 3.3 Batch fermentation system

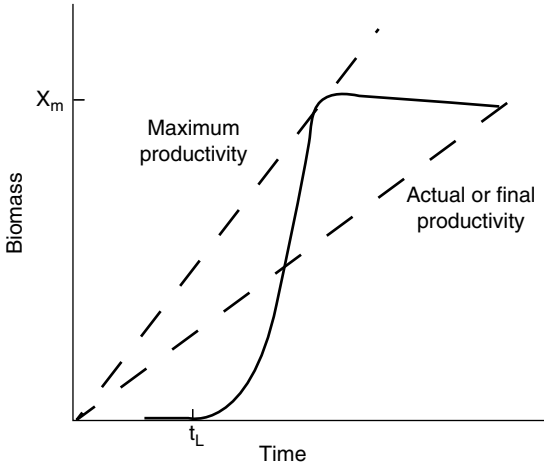

Figure 3.4 Productivity in batch fermentation

maintaining a growth rate through continuously feeding a growth limiting nutrient and withdrawing part of medium at the same rate, thereby achieving steady state growth. The growth limiting nutrient may be carbon, nitrogen, phosphorus, or any other essential nutrient, which influences the specific growth rate. A significant advantage of chemostat mode over batch mode is that by changing the feed rate of growth limiting nutrient, the growth rate can be varied. A schematic of chemostat (single stage) cultivation with and without cell recycle is shown in Figure 3.5 and Figure 3.6 respectively.

Auxostat: An auxostat is a continuous culture technique wherein the dilution rate is regulated based on an indication of the metabolic activity of the culture. A chemostat is essentially used for operation at moderate to low dilution rates, but an auxostat is used at high dilution rates. Population selection pressures in an auxostat lead to cultures that grow rapidly. Practical applications include high rate propagation, destruction of wastes with control at a concentration for maximum rate, open culturing because potential contaminating organisms cannot adapt before washing out, and operation of processes that benefit from careful balance of the ratios of nutrient concentrations. In a pHauxostat, the feed rate is regulated by measurement and control of the pH of the fermentation medium. This can be applied only if there is a change in pH consequent to the growth of microorganism. The pHauxostat has been used for continuous mass cultivation of bacteria for isolation of intracellular products (105,106).

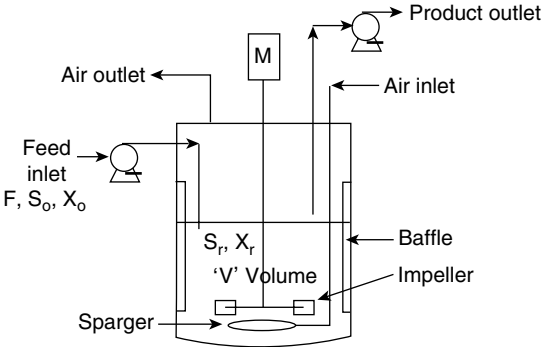

Figure 3.5 Continuous fermentation system

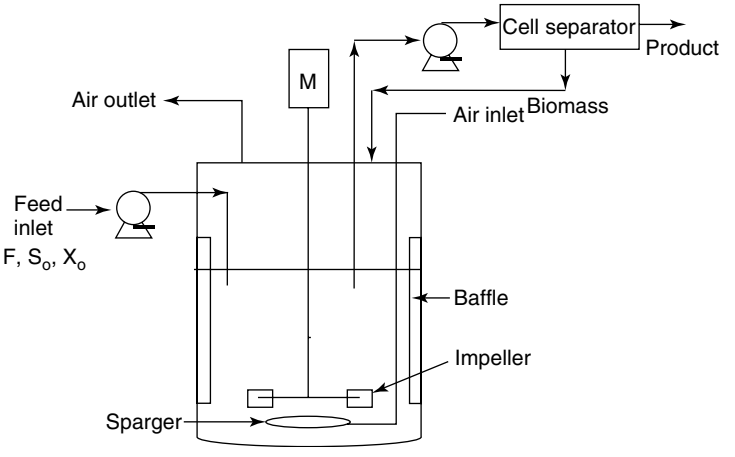

Figure 3.6 Continuous fermentation system with cell recycle

Turbidostat: The turbidostat controls the feed rate depending on the optical density (turbidity) of the fermentation broth, which is proportional to the biomass concentration. In this mode of operation, the culture cannot washout as in a chemostat. This mode of operation is ideal only when operated near maximum growth. The isolation of acid tolerant baker's yeast variants was developed in a turbidostat (107).

Nutristat: The nutristat involves regulation of the feed rate to maintain the residual substrate concentration during fermentation. The use of specific sensors for monitoring the residual substrate level during fermentation is employed. Ion selective electrodes (NH_4^+) have been used for control in the nutristat. However, the lack of reliable and accurate sensors for common substrates is a bottleneck to nutristat operation (108).

Productivity of continuous fermentation: For a continuous fermentation, there is no emptying, cleaning, sterilizing, and refilling component. The productivity of a continuous fermenter is calculated by multiplying the dilution rate (D) by the concentration of product in the outlet stream:

$$\text{Cell productivity} = \text{D.X (kg cells/m}^3\text{/h)} \tag{3.8}$$

$$\text{Product productivity} = \text{D.P (kg product/m}^3\text{/h)} \tag{3.9}$$

The productivity in continuous fermentation for biomass formation is represented in Figure 3.7. The commonly employed commercial applications of continuous culture include baker's yeast, vinegar, gluconic acid, acetone, butanol, and ethanol fermentation systems.

3.5.2.1.3 Fed Batch Fermentation Fed batch fermentation, which is a technique in between batch and continuous fermentation, is a more recent development in industrial fermentation systems. Neither batch nor continuous fermentation is suitable for non growth associated products. In order to produce such products, it is first necessary to build up a high concentration of cells in the growth or batch phase, and then switch the metabolism of the cell to arrest cell growth by feeding product precursors, carbon, and oxygen at a rate sufficient to meet the maintenance and product synthesis requirements. Essentially, fed batch fermentation involves two phases: growth phase and production phase. After the initial growth phase, one or more of the nutrients are supplied to the fermentor while cells and product remain in the fermentor.

The rationale for fed batch fermentation is to match the organism's demand for nutrients by feeding an appropriate amount of that nutrient. To determine the fed batch approach, nutrient demand has to be ascertained. This demand is a function of cell mass and cell yield on the nutrient. Though batch fermentation may be considered simple, fed batch fermentation

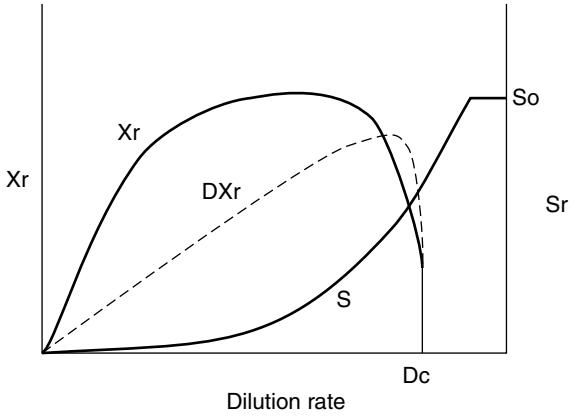

Figure 3.7 Cell productivity in continuous fermanation system

offers the convenience of better control over substrate concentration variations and differentiation of growth, leading to improved overall productivity with essentially the same equipment used for batch fermentation. Fed batch systems can be superior to continuous systems due to problems involving contamination during fermentation.

Fed batch fermentation is well suited for production of compounds during very slow growth where there is no possibility of cell washout. Fed batch fermentation is well suited for producing product or cells when: 1) Substrate is inhibitory and there is a need to maintain low substrate concentration to avoid the cells being inhibited (e.g., citric acid, amylase), and 2) Product or biomass yields at low substrate concentrations are high (e.g., baker's yeast, antibiotic production).

There are two methodologies in the fed batch approach, namely fixed volume fed batch and variable volume fed batch (109). In fixed volume fed batch fermentation, a very concentrated feed nutrient is fed to the fermentor so that there is no appreciable increase in volume. The specific growth rate decreases with time and the biomass increases directly with time. In variable volume fed batch fermentation, there is an increase in volume due to nutrient inflow and no outflow. The specific growth rate is solely dependent on the concentration of the limiting nutrient.

Productivity of fed batch fermentation: The productivity of a fermentation process is better in the fed batch mode compared to a batch mode of operation (110). In batch fermentation of *S. cerevisiae*, a dry cell weight of 10 g/L was obtained, whereas in fed batch mode, with respiratory quotient (RQ) as the control parameter for glucose feed, a final dry cell weight of 31–56 g/L was obtained (111).

3.5.2.2 Agitation

In stirred tank bioreactors, mixing and dispersion of air in the fermentation broth is achieved by mechanical agitation. The presence of impellers on the agitator shaft brings about uniform mixing of microorganisms and nutrients, and dispersion of air in the nutrient solution, resulting in efficient mass and heat transfer. Mixing by aeration or gas movement alone cannot be used in highly viscous systems due to coalescence of the gas bubbles. The heavy mycelial growth produced in antibiotic fermentations is typical of such a condition and hence mechanical agitation is essential for optimum production (112).

A turbine or a propeller, when rotated in a vessel without baffles, imparts circular flow due to swirling of the liquid around the vortex, which renders the motion unconducive for top to bottom mixing. In a baffled tank, on the other hand, the flow pattern may be radial or axial, promoting lateral flow and vertical flow currents, with the application of large amounts of power. Baffles reduce the unproductive tangential velocity component of all impellers to produce a more efficient radial or axial flow. Positioning and design of baffles, along with the placement, type, and design of heating coils has a significant impact on the flow patterns (113).

The types of impellers used in bioreactors are broadly classified based on flow pattern as radial flow (e.g., turbine) and axial flow (e.g., high efficiency impeller).

The Rushton turbine is the most common type of radial flow impeller. It consists of a number of short blades attached to a central shaft. The diameter of a turbine is normally between 30 and 50% of the tank diameter and there are usually between four to six blades. Turbines with flat blades are good for gas dispersion, where the gas is introduced just below the impeller on the axis and is drawn up to the blades and broken up into fine bubbles (114).

An axial flow impeller generates an axial flow pattern with the fluid flowing down the central axis and up on the sides of the tank. This flow pattern is also called down pumping because the impellers circulate the fermentation broth downward against the flow of the

rising air, thereby holding the gas in the system longer. In multiphase fermentation systems involving solids, the axial component of the flow due to agitation is useful to keep the solids in suspension (115).

Recent developments in impeller design have led to the emergence of high efficiency impellers like MIG and INTERMIG, which require 25% and 40% less power input to get the same degree of mixing as a turbine impeller. Recently, high solidity hydrofoil impellers with an up pumping mode of operation were reported to increase mass and heat transfer, to and improve blending. Blending, which is less complicated than mass transfer, is not efficient on a large scale compared to small lab scale fermenters due to the formation of dead zones between impellers. Hence, optimal blending is essential for maximum yield and productivity in large scale fermentations (116).

Multiple impeller bioreactors (with impellers fixed at various heights on the central shaft) are becoming increasingly popular due to efficient gas distribution, higher gas phase residence time, increased gas hold up, superior liquid flow (plug flow) characteristics, and lower power consumption per impeller as compared to single impeller systems (117,118). Using both Rushton turbines and high efficiency axial flow impellers on the same shaft is reported to improve fermenter performance with a decrease in the total power consumption (119).

3.5.2.3 Aeration

The cheapest mode of supplying oxygen to the fermentation media is air. The aeration system essentially comprises an air compressor, an air filter (prefilter and sterile filter) and a sparger. The air compressor used for fermentation may be a positive displacement or a nonpositive displacement unit, with the former being a reciprocating or rotary compressor and the latter a centrifugal compressor. The choice of compressor depends upon such factors as the discharge pressure, type of drive, capacity, and cost (120). Equipment sizing of the compressor is usually dependent on the maximum airflow requirement of a full production scale for all the fermentors. Careful scheduling of fermentations can frequently reduce the gap between peak and average demands and result in more economical use of the equipment.

The discharge pressure of the air from the compressor is subjected to pressure drop along the route at predictable locations, such as valves and pipefittings along the supply lines, air filters, the sparger, hydrostatic head, and static pressure, before it reaches the fermentor. The diameter of the supply line is so chosen that the maximum airflow may be enabled without undue pressure loss. A pressure drop of 1–2 p.s.i. per 100 ft of pipe may be used as a first approximation. The first three pressure drops discussed above increase with increasing flow rate, but the hydrostatic head and static pressure are independent of airflow. The hydrostatic head is the depth of nonaerated liquid above the sparger, corrected for density, and usually represents quite a large fraction of the total pressure loss. Air, filtered using sterile air filters, is passed into the fermentor from immediately after sterilization during the cooling cycle until the end of fermentation to maintain a positive pressure and circumvent contamination.

In most aerobic fermentations, peak oxygen consumption occurs over very short periods near the end of fermentation. It is possible to increase the oxygen uptake rate by providing high levels of oxygen transfer rate (OTR). OTR is the rate at which oxygen can be transferred from the air to the fermentation broth. It can be expressed as:

$$\mathrm{OTR} = k_L a\,(c^* - c_L) \tag{3.10}$$

where $k_L a$ is the volumetric mass transfer coefficient, c* is the dissolved oxygen concentration in equilibrium with the gas phase, and c_L is the dissolved oxygen concentration in the liquid.

The oxygen mass transfer coefficient, k_La, is directly related to power input by aeration and aeration rate by (121):

$$k_La = K\,(P_g/V)^a\,(v_s)^b \tag{3.11}$$

where P_g/V is the gas power input by aeration per unit volume and v_s is the superficial gas velocity.

A high k_La (volumetric mass transfer coefficient) indicates a high oxygen transfer rate (OTR) in the fermentation process. Since oxygen uptake rate is the key for a successful aerobic fermentation, a high k_La is required. However, providing higher levels of oxygen transfer usually requires very powerful drives, which add to mechanical problems and costs, as well as additional heat loads. OTR varies with the nature and the scale of the fermentation. For a $1m^3$ vessel, at an OTR between 250 and 300 mmol/L/h, heat transfer is not a major problem. However, for a $10m^3$ vessel, OTR at the above rates pose significant problems in terms of heat removal from the fermentor, indicationd the need for the use of internal cooling coils and low temperature coolants, which adds considerable operational costs.

3.5.2.4 Process Monitoring and Control

The complexity of metabolic biosynthesis involved in fermentation necessitates the use of process control parameters for monitoring and control to ensure optimum process performance. The process control variables in a fermentation process may be broadly classified as physical, chemical, and biological. The physical variables include temperature, impeller speed, aeration rate, and pressure. The chemical variables include pH, dissolved oxygen, dissolved carbon dioxide, and redox potential. The biological variables include biomass, oxygen uptake rate, carbon dioxide production rate, and respiration quotient. While the physical variables are usually measured by inline sensors forming an integral part of the fermentation equipment, the chemical or process variables are measured by online sensors crucial for the successful operation of a fermentation process. The biological variables are process indicators depending on proper monitoring and control of process variables in a fermentation process. A modern technique for bioprocess monitoring and control uses biosensors. A biosensor is a device that detects, transmits, and records information regarding a physiological or biochemical change resulting in the generation of electronic signals. The main function of a biosensor is integration of a biological component with an electronic transducer to convert the biochemical changes into a quantifiable electrical response. Biosensors make use of a variety of transducers such as electrochemical, optical, acoustic and electronic (122).

The development of miniaturized *in situ* sensors for online monitoring and control of pH and dissolved oxygen has been driven by fermentation processes and is shown in Figure 3.8 (123).

pH: Fermentation at the optimum pH is essential for cell growth and product formation. A sterilizable pH probe which functions based on a potentiometric principle consists of a glass electrode and a reference electrode. The reference electrode system consists of an Ag/AgCl electrode and a KCl electrolyte. A constant voltage of the reference electrode system is provided by the electrolyte. A ceramic diaphragm maintains the electrolytic contact between the reference electrode and fermentation broth. Based on the response from the pH probe to the pH controller, the acid or base pump is triggered for correction of pH. Steam sterilizable glass electrodes have the limitation of low mechanical stability over a period of repeated sterilizations. They can be replaced with optical sensors based on absorbance or fluorescence from pH-sensitive dyes (124).

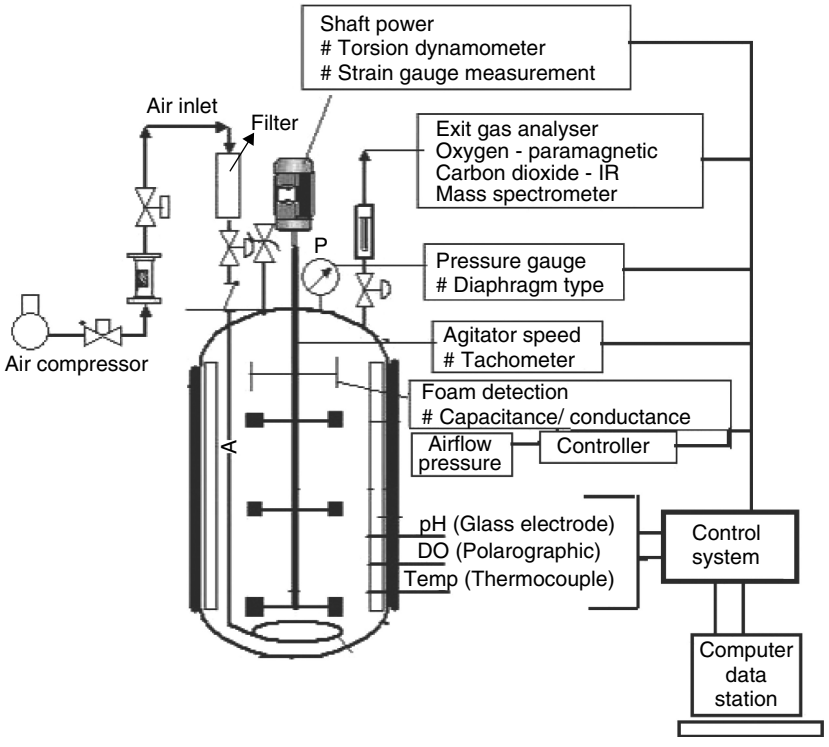

Figure 3.8 Bioprocess control of fermentation process

Dissolved oxygen: Monitoring of the dissolved oxygen (DO) concentration is essential, because sparingly soluble oxygen is one of the limiting substrates for fermentation. Two types of DO electrodes used in fermentation: polarographic and galvanic, with the former more commonly used as it is reliable and resistant to sterilization, while the latter is not widely used due to poor stability. The polarographic or amperometric electrode (-0.7V) needs an external voltage between a Pt cathode and an Ag/AgCl anode. The Pt cathode is in contact with KCl solution encapsulated by an oxygen permeable Teflon membrane. The DO from the broth diffuses across the membrane to be reduced at the Pt electrode surface. The DO concentration in a fermentor can be manipulated by two physical variables: impeller speed and aeration rate. The DO saturation (% pO_2) for a particular fermentation can be controlled individually, sequentially, or simultaneously manipulating the variables based on a feedback from the DO controller. The controller compares the deviation of the signal from the DO electrode with the set point and adjusts the impeller speed controller or the airflow controller for maintenance of DO saturation. Another possibility of DO control in fermentation exists by variation of the oxygen concentration in the gas by application of three proportional valves for controlling the flows of air, oxygen, and nitrogen (125). The steam sterilizable DO electrode (126) is widely used for online bioprocess monitoring of the dissolved oxygen concentration during fermentation. An alternative based on quenching of fluorescence has recently been introduced (127).

Dissolved carbon dioxide: Dissolved carbon dioxide (DCD) is another indicator of the metabolic status of the respiring cell. It is commonly used for animal cell cultivation where DCD concentration helps to maintain the carbon dioxide saturation during the bioprocess. DCD electrode operates on the principle of change in pH of an electrolyte buffer.

DCD sensors with bicarbonate buffers are not sterilizable, and have the limitations of drift and interference from changes in the medium composition. An *in situ* sterilizable DCD sensor with radiometric fluorescent dye HPTS (8-hydroxypyrene-1,3,6-trisulfonic acid) has been introduced (128).

Gas analysis: The exit gas composition from the fermentor, particularly oxygen and carbon dioxide, can be analyzed by a gas analyzer using paramagnetic and infrared detectors respectively. Mass spectrometry can also be used to analyze all gaseous components, including organic volatiles and lower alcohols, of the exhaust gas stream (129). From an oxygen to carbon dioxide gas balance across the fermentor, the oxygen uptake rate (OUR) or carbon dioxide production rate (CPR) can be determined. From a knowledge of the OUR and CPR during the fermentation process, the respiratory quotient (RQ = CPR/OUR) can be determined.

Redox potential: The redox potential of fermentation broth is related to the overall availability of free electrons in the solution. Redox potential operates on the principle that when a noble metal electrode (Pt, Au or Ag) is immersed into a redox system, a potential is developed the magnitude of which depends on the oxidation–reduction concentration ratio. The potential formed at the noble metal electrode is tapped off by a reference electrode, which is also immersed in the solution. The value of the potential is a measure of the concentration of oxidizing or reducing agents. Redox values are found to vary significantly with changing pH and are expressed in mV. The redox potential decreases with increasing pH value of the measured solution. The metabolic activity of microorganisms is strongly influenced by the redox potential of the culture environment. Monitoring and control of the redox potential before inoculation facilitates controlled addition of reducing agents to ensure the proper range for initiation of growth. Control of the redox potential is a vital tool in determining its influence on the metabolic pathways of microorganisms, substrate utilization, or production of specific metabolites (130).

Biomass concentration: Biomass concentration is an important biological variable, which indicates the progress of the fermentation. The common offline cell mass determination methods are based on dry cell weight and packed cell volume. Direct online characterization of cell populations in bioreactors in terms of morphological changes can be determined by *in situ* microscopy equipped with an image analyser (131). Indirect online methods for determination of cell concentration may be based on electrical or optical approach. Electrically, capacitance of the medium measures the fraction of fluid held by polarizable membranes (132). Optically, cell mass is often measured by light absorbance (turbidity) or scattering (nephelometry) continuously in the visible and near infrared ranges (133). The advantages of optical sensors for bioprocess monitoring are that they are very sensitive, give specific and reversible measurements, have a rapid response and versatility, and involve easy maintenance. The disadvantage of the optical method is that scattering and absorption are not linearly dependent on the cell density and are vulnerable to interference from particulates and gas bubbles. A biological receptor, namely an enzyme, microorganism, or antibody that produces an optical signal such as NADH fluorescence (NADH upon UV radiation at 366 nm emits fluoroscence at about 460 nm) in an optical biosensor (134). The signal is converted by an electronic transducer into an electrical signal. Bioluminescent sensors have also been developed, which consist of a bioluminescent enzyme and an optical transducer. Cell mass in animal cell cultivations can also be predicted by software sensors (135). Direct online biomass determination in fermentation processes is limited by the presence of suspended solids. The productivity of a fermentation process depends specifically on the biomass concentration achieved. Maximization of biomass concentration to high cell densities (136) is dependent on operating the fermentor at the optimum controlled process conditions.

Substrate and product concentration: The determination of the exact concentration of substrate and product during fermentation is critical for the maintenance of the optimum feed concentrations required for maximum productivity and efficient substrate utilization.

Flow Injection Analysis (FIA) is a method for online detection of concentration with a suitable detector, which may use amperometry, potentiometry, NADH-fluorescence, chemiluminescence, or UV/Vis spectrophotometry, and involves an analysis time lasting only a few minutes (137). FIA coupled with an immobilized ß-galactosidase biosensor has been reported for monitoring of lactose in a fermentation process (138). Biosensors used for FIA do not need sterile conditions for analysis. FIA systems inject low amounts of samples into the carrier stream and the probability of cell growth and protein precipitation is low because of the high dilution (139). Enzyme based biosensors have been used for monitoring and control of substrates and products involved in glutamate and penicillin fermentation processes (140). Chromatographic techniques like gas chromatography, high performance liquid chromatography, fast protein liquid chromatography, and membrane chromatography have been employed for process monitoring of fermentation processes (141). Recombinant protein product can be determined spectroscopically by attaching the gene for green fluorescent protein (GFP) to the product gene. The product concentration can then be determined by analyzing the fluorescence intensity of the GFP in the culture (142).

Mass spectrometric analysis of gases such as oxygen and carbon dioxide in the exit gas paved the way for determination of dissolved gases such as oxygen, carbon dioxide, methanol, ethanol, butanol, and acetone by the use of appropriate sampling systems (143). The accuracy of analysis is higher than observed with online probes. Sampling for offline analysis is crucial from the point of view of sterility and proper representation of the medium. Many sampling devices based on microfiltration, ultrafiltration, and dialysis have been used in the fermentation industry (144). A powerful analytical tool for noninvasive analyisis of intracellular metabolites is nuclear magnetic resonance (NMR) spectroscopy. *In vivo* determination of metabolites and metabolic processes by NMR spectroscopy serves as a vital tool for metabolic flux analysis and metabolic engineering (145). Fourier-Transform-Near-Infrared (FTNIR) spectroscopy, a standard technique used in the food industry, is now used in biotechnology for online process monitoring (146). Artificial or electronic noses, with their broadband sensing capabilities, prove useful for the online monitoring of both airborne and liquid borne compounds. With the aid of artificial nose technology it may be possible to devise two array sensors to monitor the concentrations of various important components in both the gas and liquid phases in the fermentor, eliminating the need to use a large number of sensors to monitor complex mixtures (147).

3.5.3 Downstream Processing

The products of fermentation are usually found in complex mixtures of dilute solutions and must be concentrated and purified. The separation of the product of interest from the fermentation broth depends on the accumulation of the product, which may be intracellular or extracellular. The typical downstream operations and the unit operations involved in the processing of fermentation broth (148) are:

1. Cell separation (settling, centrifugation, dead end filtration, and cross flow filtration)
2. Cell disruption (high pressure homogenization, wet milling, and lysis)
3. Clarification of extract (centrifugation, extraction, dead end filtration, and cross flow filtration)
4. Enrichment (precipitation, batch adsorption, ultrafiltration, and partition)

5. High resolution techniques (ion exchange, affinity, hydrophobic, gelfiltration, adsorption chromatography, and electrophoresis)
6. Concentration (sterile filtration, diafiltration, ultrafiltration, freeze drying, spray drying, and precipitation).

While downstream processing is an important part of fermentation process development, a detailed discussion on the subject is outside the scope of the chapter and hence not dealt with.

3.6 FERMENTATION SYSTEMS IN PRACTICE

3.6.1 Microbial Cultivation

Traditional microbial biotechnology began during the first World War when the development of acetone, butanol, and glycerol fermentations took place (149). Microbial primary metabolites used in the food and feed industries include: alcohols (ethanol), amino acids (monosodium glutamate, lysine, threonine, phenylalanine, and tryptophan), flavor nucleotides (5′-guanylic acid, 5′-inosinic acid), organic acids (acetic, propionic, succinic, fumaric, and lactic), polyols (glycerol, mannitol, erythritol, and xylitol), polysaccharides (xanthan and gelan), sugars (fructose, ribose, and sorbose), and vitamins (riboflavin, cyanocobalamin, and biotin). The group of microbially produced secondary metabolites important for health and nutrition includes antibiotics, other medicinals, toxins, biopesticides, and animal and plant growth factors (150). The targets uses of antibiotics (the best known group of secondary fermentation metabolites) include DNA replication (actinomycin, bleomycin, and griseofulvin), transcription (rifamycin), translation of 70-S ribosomes (chloramphenicol, tetracycline, lincomycin, erythromycin, and streptomycin), transcription by 80-S ribosomes (cyclohexamide), transcription by 70-S and 80-S ribosomes (puromycin and fusidic acid), and cell wall synthesis (cycloserine, bacitracin, penicillin, cephalosporin and vancomycin) (151).

Over the last three decades, traditional industrial microbiology, using the tools of molecular biology, has led to the development of recombinant organisms aimed at production of high value biopharmaceutical products such as erythropoietin, human growth hormones, and interferons (152). The major microbial hosts for the production of recombinant proteins are *E. coli* (153), *B. subtilis*, *S. cerevisiae*, *Pichia pastoris*, *Hansenula polymorpha* and *Aspergillus niger*. The major thrust of recombinant DNA technology has been in the area of rare mammalian peptides, such as hormones, growth factors, enzymes, antibodies and biological response modifiers (154).

3.6.2 Mammalian Cell Cultivation

Bioreactors developed for mammalian cell culture use a smooth surfaced ceramic for the growth of adherent cells or a porous ceramic for the immobilization of suspension cells. Mammalian cell culture technology has been used for the production of viral vaccines, monoclonal antibodies for diagnostic and therapeutic use, interferons, interleukins, growth factors, and blood regulation proteins. The design of novel bioreactors for mammalian cell culture must take into consideration process constraints such as cell line distribution, product formation, oxygen transfer, nutrient supply, and shear. A viable alternative to scalable mass cell culture is the use of bioreactors with ceramic matrices. Immobilization of adherent and suspension cells on these surfaces has resulted in the favorable production of both cells and cell derived proteins. Cell culture densities ranging

from 2×10^6 cells per mL (spinner flask culture) to 1×10^8 cells per mL (high density perfusion reactors) have been obtained (155).

For the cultivation of anchorage dependent animal cells, packed bed bioreactors have been used. Such reactors up to 100 L in size have been successfully operated with BHK 21 C13 monolayer cells for the production of foot-and-mouth disease virus vaccine antigen (156). In a commonly used packed bed bioreactor, glass beads ensure adherence and subsequent colonization *in situ* (157). The use of polyester or polyurethane foam matrices (158) for the culture of hybridomas ensures passive entrapment of the cells in the inert matrix with the added advantages of perfusion of cells with fresh medium, increased process intensity, and improved downstream processing. The first airlift fermentor (1000 L scale) to produce monoclonal antibodies from hybridoma cells in suspension was developed by Celltech (159).

3.6.3 Plant Cell Cultivation

Stirred tank fermentors have also been used for the growth of plant cells for the production of valuable products in single or multiple stages of cultivation. Plant cell culture is carried out by propagation of a callus, which is a mass of undifferentiated cells. To develop a new plant with shoot and root, cells from the callus must be cultured in different media. Desirable metabolites can be extracted from a callus without progression to a shoot and root. Plant cell culture may serve as a good medium for synthesis of metabolites useful in foods, biopesticides, and cosmetics. Plant cell culture has been proposed as an alternative technique for the supply of phytochemical to the normal plantation system (160). The benefits of such a system include a final product of required quality and consistency independent of the variations in plantation due to season, weather, disease, and pest destruction. Cultivation of plant cell suspensions in bioreactors has led to higher productivity of the final product. For instance, *Coleus* cells have been induced to produce rosmarinic acid at a rate of 0.91 g/L/day, which almost compares with microbial fermentation products like penicillin with 1.4-2.1 g/L/day (161). The potential of plant cell cultures for the production of valuable plant secondary metabolites like fragrances, food colors and flavors, and medicinal compounds has long been recognized. A cell suspension culture for the production of an antiinflamatory drug, shikonin, from cells of *Lithospermum erythrorhizon* has been developed on a commercial scale (162).

The main disadvantage of plant cell cultures and immobilized plant cells is the high degree of genetic and biochemical heterogeneity, resulting in process instability and low productivity of metabolites (163). It is possible to grow cultures of plant roots or shoots in the *de novo* synthesis of secondary products.

The industrial application of plant cell suspension cultures has, to date, been limited. Commercialization has essentially been impeded by economic feasibility factors, arising from both biological and engineering considerations. Sensitivity to hydrodynamic shear in bioreactors has generally been attributed to the physical characteristics of the suspended cells. However, shear sensitivity may not be very important (164). Hairy roots formed by plant transformation using *Agrobacterium rhizogenes* could be exploited to produce secondary metabolites (165). The difference between hairy root and cell suspension cultures is shown in Table 3.4 (166).

Due to the extremely slow growth rates and use of rich growth media in plant cell cultures, there is a high risk of microbial contamination, which can be avoided by immobilization of plant cells *in situ* in the reactor. In order to immobilize the plant cell aggregates in the reticulated polyurethane foam matrix, a suspension culture of cells is introduced aseptically into a sterile liquid medium containing the empty foam matrix. The plant cell aggregates are carried from the bulk liquid into the porous foam matrix by the

Table 3.4
Fermentation features of hairy root and plant cell suspension cultures

Fermentation Features	Hairy Root	Plant Cell Suspension
Medium	Simple, no vitamins or hormones	Complex, requires specific vitamins or hormones
Inoculum size	Largely independent, minimal lag	Size dependent , conditioning of medium needed
Genetic stability	Stable	Unstable
Metabolite production	Depends on level and charcateristc of parent plant	Unpredictable
Rheology	Newtonian broth	NonNewtonian broth
Operation	Easy with self immobilization	Requires support, mixing problems
Biomass density and stability	High, easily maintained oxygen transfer	Low, instability due to inefficient
Growth rate	Doubles in 2–7 days	Doubles in 14 days

liquid elements flowing through the open pore structure of the initially empty foam matrices. Once physically entrapped, the cell aggregates grow or adhere to each other to fill the rest of the available space with foam. Some of plant cell culture processes producing valuable products in bioreactor are shown in Table 3.5 (167).

With minor alterations to the conventional stirred tank bioreactor, it is possible to obtain practicable bioreactor systems suitable for use with immobilized plant cell cultures, such as the circulating bed bioreactor and the sheet bioreactor (168). In the former, the bioreactor is initially operated as a packed bed with foam particles held stationary between two retractable stainless steel grids. Once the cell aggregates are fully immobilized, the grids are retracted and the bioreactor is operated as a circulating bed. To achieve efficient immobilization, it is necessary to hold the foam particles stationary in the bioreactor. A modification of the STR with foam matrices in the form of sheets held stationary as vertical baffles around the central impeller is referred to as a sheet bioreactor. Microbial, mammalian, and plant cell cultivation is compared in Table 3.6 (169).

3.7 SCALE UP OF FERMENTATION PROCESSES

Scale up is crucial to the successful development of a fermentation process. Many large scale fermentation processes produced lower yield when compared to laboratory results (170,171). The traditional method for scaling up a fermentation system is based on empirical criteria such as constant power per unit volume, a constant mass transfer coefficient, constant mixing time, or constant impeller tip speed (172). The empirical criteria are subject to lacunae when there is a change in the controlling regime of the process. Another approach aimed at scale up is to scale down with the objective to determine the significant process parameters on a varying production scale in the laboratory (173,174). Due to the numerous pitfalls associated with the scale up of bioreactors and the lack of industrial scale up data available in literature, scale up may still be considered an art rather than science (175).

Scaling up of bioreactors by increasing the number of reactors rather than the size is also one approach, wherein both capital and labor costs increase linearly with increase in scale. The operation of multiple, smaller bioreactors rather than a single, larger bioreactor could be advantageous due to flexibility of operation, ease of start up, inoculum preparation,

Table 3.5
Plant cell cultures producing valuable products in a bioreactor

Plant Cell Line	Product	Mode	Bioreactor
Lithospermum erythrorhizon	Shikonin	Batch	Stirred tank
Coleus blumei	Rosmarinic acid	Fed batch	Stirred tank (Spiral)
Nicotiana tabacum	Geranoil	Batch	Stirred tank

Table 3.6
Fermentation characteristics for microbial, mammalian, and plant cell culture

Fermentation Parameter/Feature	Microbial Cell Culture	Mammalian Cell Culture	Plant Cell Culture
Operating pH range	2–10 depending on the fermentation	Usually between 6.8 and 7.2	Usually between 5.5 and 6.0
Operating temperature	25–50°C depending on the fermentation	Usually between 37 and 42°C	Usually between 25 and 30°C
Aeration rate	Higher rates of 1–2 vvm	Lower rates of up to 0.5 vvm	Lower rates of up to 0.5 vvm
Impeller	High shear impellers (disc turbine)	Low shear impellers (marine/pitched blade)	Low shear impellers (propeller)
Agitation	High speed (up to 1000 rpm) required for viscous broth	Low speed (up to 200 rpm)	Very low speed
Fermentor	Depends on fermentation broth	Membrane bioreactor also used	Air lift fermentor also used
pH control	Acid/alkali addition with peristaltic pump using pH controller	Sparged CO_2/N_2 gas to maintain pH using a four gas controller	Sparged CO_2/N_2 gas to maintain pH using a four gas controller
D.O control	Cascade control with agitation and aeration	Control of air/O_2 using a four gas controller	Control of air/O_2 using a four gas controller
Foam control	Antifoam agents added to reduce foam	Minimize foam using foam elimination chamber	Minimize foam using foam elimination chamber
Shear sensitivity	Insensitive	Sensitive	Sensitive
Specific growth rate	High (doubling time few hours)	Low (doubling time in days)	Low (doubling time in days)

cleaning, and sterilization (176). However, the final justification relies on the benefits from the economies of scale (177,178).

3.8 ASEPSIS IN FERMENTATION PROCESS

Asepsis in biotechnology means freedom from unwanted microorganisms, just as in clinical medicine it means freedom from pathogenic microorganisms (179). However, there do

exist many fermentation industries e.g., ethanol, baker's yeast, and vinegar, where asepsis is not a matter of concern. Economic considerations suggest that a contamination probability of 1 in 100 is acceptable for batch fermentations, considering a contamination probability of 1 in 1000 taken into design calculations for a sterilization process (180). Recombinant microorganisms are at a greater risk of being overwhelmed by wild organisms. Cell culture fermentations are susceptible to microbial contamination due to a longer fermentation process and a slow growth rate. However, with use of aseptic procedures large scale animal cell cultures are operated with a contamination rate of about 2% (181).

The sources of contamination in a fermentation process could be attributed to inoculum, nutrient medium, bioreactor system, air or liquid transfer, and mutation. The aseptic procedures necessary to achieve a sterile fermentation process include:

1. A sensitive sterility assessment protocol: The results of conventional sterility checks in nutrient media incubated at optimum conditions may not be possible before sufficient damage is done to the production fermentor. There is a need for accelerated detection of contaminants like use of thioglycolate agar and oxidoreductive indicators (e.g., methylene blue or resazurin) for rapid detection of aerobes and anaerobes in the medium (182).
2. Development of a certified laboratory inoculum: The preparation and propagation of inoculum required for fermentation should be carried out in designated clean rooms. The procedures and equipment used for sterilization of the media and glassware for inoculum preparation should be strictly followed.
3. Efficient sterilization of bioreactor, medium, and air: Proper sterilization of bioreactor, medium, and air is crucial for a successful fermentation batch. Continuous sterilizers have been employed for sterilization of medium required for large scale bioreactors (183). After sterilization of the bioreactor, the system should be held under positive pressure with sterile air to avoid the possibility of external air being drawn due to vacuum formation (184).
4. Asepsis during fermentation: The most common cause of loss of asepsis during fermentation is the depressurization of bioreactor which could be averted by providing the air compressor with automatic change over to a captive power generator and automatic closure of inlet and outlet valves at a fall in the preset pressure or air flow. Foaming is a characteristic feature of gas and liquid operation in presence of surface active agents.
5. Containment of foam: Foaming is perceived as the most probable cause of contamination in fermentation processes, leading to overflows and consequently loss of broth and products. The addition of silicon based antifoaming agents leads to a change in the hydrodynamic and mass transfer characteristics of the bioreactor (185). However, the use of foam breakers has been applied to avoid the need for addition of antifoaming agents, and the necessity of antifoaming agent addition depends on the nature of fermentation (186).
6. Routine and preventive maintenance of bioreactor: The inspection of a bioreactor should cover the shell, dome, agitator seal, air exhaust line, nozzles, sight glasses, O rings, air filters, probes, shaft, impellers, coils, sparger, inoculum, feed, and sampling lines (187).

Asepsis of a bioreactor ultimately rests on the integration of adequate bioreactor design, efficient validation and operating protocols, routine maintenance, and operation by skilled personnel.

3.9 BIOREACTOR DESIGN

The purpose of the fermentor is to provide an aseptic environment in which fermentation can be performed efficiently to achieve process targets. The reliable operation of a fermentation system to achieve process objectives depends on two factors: the fermentor design and the fermentation process. Therefore, rational design of a fermentor requires careful consideration of how it is integrated into the process design. The design should consider from the outset such factors as plant scheduling, space constraints, relationships between fermentor productivity and throughput rates of downstream equipment, containment and validation requirements, utilities requirements, potential interruptions in normal plant operation, overall labor requirements and operating versus capital costs. Consistency, safety, cost, and compliance with statutory requirements usually are of prime concern for production equipment.

3.9.1 Design Criteria

The objective of fermentor design is to produce fermentation systems necessary to build economical production facilities that satisfy well considered performance criteria. Reactor design and scale up considerations are driven by the need to provide the organism optimal conditions for producing the desired product uniformly in the reactor (188).

3.9.1.1 Mechanical Aspects

Mechanical design aspects are important for the successful operation of any fermentation plant. A few design ratios, which have gained significance irrespective of the fermentation system employed, include: vessel diameter to height ratio (should be in the range of 1:3–1:4), and impeller diameter to vessel diameter ratio (should be in the range of 0.3–0.5).

The mechanical design aspects with reference to the geometrical requirements of a fermentor are discussed in Standard Dimensions (Section 3.9.2).

Some practical aspects before getting on to the technical details of vessel design are:

1. Space requirements: The vessel dimensions must be chosen to meet plant space limitations. Poor choice of equipment sizes can cause inordinately high building costs.
2. Transportation: Shopbuilt vessels are usually less expensive and of higher quality than fieldbuilt vessels.
3. Special heads: A hemispherical bottom gives better mixing and less shear in tissue culture vessels than does a standard dished head.

3.9.1.2 Process Aspects

With the lack of adequate information on fermentor design for a particular fermentation process, design has been an applied art rather than a science. It requires a careful consideration of a host of interrelated factors, many of which are risk assessments and value judgments. Therefore, it is imperative that the design engineer applies experience and judgment in reaching reasonable compromises.

The fermentation process guidelines commonly employed without proper consideration of the process aspects do very little to promote good design. These include:

1. Aeration rate: The airflow rate to the fermentor must be generally one volume of air per liquid volume per minute (1 vvm). However, in practice, the aeration

rates depend on oxygen solubility in media, and 1 vvm may be too high for a particular fermentation process when operated at a larger scale.

2. Impeller tip speed: The tip speed of a fermentor impeller must not exceed 7.6 m/s.
3. Arrest of fermentative metabolism: At the end of fermentation, the fermentor broth must be cooled immediately and stored at 4°C, to arrest the fermentative metabolism.
4. The maximum production rate cell mass theory: Process optimization is achieved by obtaining very high cell mass concentrations at very high growth rates.
5. Oxygen transfer rate: The consequences of increasing OTR by increasing air flow rate and agitation could lead to foaming, increased gas holdup (189), higher gas velocities, higher vessel pressure, and oxygen enrichment.
6. Heat transfer rate: Heat transfer usually is the limiting constraint for highly aerobic large scale fermentors. Oxygen and heat transfer rates are coupled closely in aerobic fermentations. The total heat generated during growth (Q_{total}) is given by:

$$Q_{total} = Q_{metabolic} + Q_{mechanical} \tag{3.12}$$

where $Q_{metabolic}$ is the metabolic heat generated and $Q_{mechanical}$ is the heat generated by the agitation required to provide adequate oxygen transfer and mixing.

3.9.2 Standard Dimensions

The standard dimensions of a fermentor are shown in Figure 3.10. The standard geometric configurations in practice are:

1. H/T ratio: The geometric configuration of the fermentor is more commonly denoted by the H/T ratio. The height (H) and diameter (T) actually refers to the height and diameter of the fermentor. The H/T ratios of most stirred tank fermentors range from 3:1 to 4:1 while the ratio can be as high as 10:1 in the case of an air lift fermentor.
2. D/T ratio: The geometric configuration of the impeller is more commonly represented by D/T ratio, i.e., the impeller diameter (D) to tank diameter (T). Impellers with small D/T ratio must be operated at a higher speed in comparison with impellers of large D/T ratio to provide the same power requirement. D/T ratios of 0.3 to 0.5 are commonly used in fermentors. It should be noted that operation at higher impeller speed could result in increased shear rates and consequently may be detrimental for the microorganisms in the fermented broth.
3. Baffle ratio: Baffles play a vital role in improving the aeration efficiency and prevent vortex formation. Baffles should be installed so that there is a gap between the baffle and the vessel wall to minimize the microbial growth on the baffles and walls. The baffle ratio (BR) is given by (190)

$$BR = n_B.w_B / T \tag{3.13}$$

where n_B is the number of baffles installed, w_B is the width of the baffles and T is the diameter of the fermentor.

3.9.3 Jackets and Coils

Jackets are used for the circulation of steam and cooling water during the heating and cooling cycles of sterilization of the fermentor (191). Since microbial reactions are exothermic,

the heat produced during fermentations leads to a rise in the temperature of the broth, necessitating the need to maintain the temperature at the optimal value. The heat transfer is dependent on the area of contact surface of the cooling or heating fluid with the fermentor and the temperature gradient of the medium. Normally, steam is used as the heating fluid; and water, chilled water, or chilled brine are used as cooling fluids. The contact surface area of the jacket with the fermentor should be maximal and the pressure drop of the circulating fluids in the jacket should be minimal for better process performance. The layout of the external jackets could be a double jacket, a full pipe, or a half pipe (limpet coil), depending on the required area for heat transfer, the heating or cooling medium, and the circulation velocity (192).

The choice of jacket material usually is not critical, and it usually is best to leave the vessel fabricator some degree of flexibility to allow for his usual shop practices. Some guidelines are:

1. Stainless steel jacket cover made of SS304 to extend vessel life
2. Jacket is appropriately designed to increase vessel strength
3. For vessels less than 5 m^3 providing jacketing at the bottom, dished end may not contribute significantly to heat transfer
4. Jacket cover to the height equivalent to the operating volume of the fermentor
5. Jacket inlet and outlet lines should have end connections (flanged or sanitary coupling) between the external pipes and the jacket
6. Jacket design should favor minimum accumulation of solids to avoid ionic concentrations, which cause corrosion

If internal cooling coils are used, they can not only remove the excess heat from fermentation, but also act as baffles for better mixing. A minimum spacing of 150 mm between coils ensures that they withstand the thermal and mechanical stresses generated during fermentations. Joints between pipes should be butt welded, covered with a welded concentric tube, and lead tested (193).

3.9.4 Safety Codes

The safety of the vessel should be the foremost consideration in vessel design. The vessel must be fabricated in accordance with the Standard Code for unfired pressure vessels (194) and tested at design conditions to insure that the vessel can withstand all forces generated under the specified operating conditions. If operation is required at high operating pressures, one should consider ways to minimize the metal thickness to allow the use of cold rolled sheet rather than plate. This results in better heat transfer, a better interior finish, and a lower price.

3.9.5 Material of Construction

Stainless steel is the more commonly employed material for the fabrication of biotechnology equipment. The selection of the right steel quality in biotechnology is based on a compromise between material costs, availability, and the physical and chemical requirements of the process. Based on the crystal structure, standard chrome steels at room temperature are ferrite based (*alpha* or α iron). When ferric steels are heated to 910°C, the crystal structure is changed to the nonmagnetic austenite (*gamma* or γ iron). The stabilization of the austenite structure at room temperature is enhanced by the addition of austenite formers such as nickel, molybdenum, or carbon. Austenitic steels are the material of choice used as shell plate for fabrication of fermentors. Compared to the nonaustenites,

these steels show improved corrosion and heat resistance, and are nonmagnetic, apart from having good tenacity and workability (195).

Iron is the most abundant element in steel and very much prone to corrosion attack. Corrosion in the form of rust can be prevented by the addition of up to 12.5% chromium, which reacts with ambient oxygen to form a passive surface layer of chromium oxide. This chromium oxide layer protects the steel from corrosion. Stainless steels are defined with a maximum corrosion loss of 0.1 mm per year. Carbon in the stainless steel is required for stabilization of the austenite structure. The low carbon steels, SS 304L and SS 316L, are known worldwide as standard steels. Generally, vessels used in biological processes are fabricated with 316 or 316L steel. The vessels widely used in food technology or harvest storage tanks are fabricated with a cheaper and less corrosion resistant steel of grade 304 or 304L. For all other vessel parts not in contact with the product broth, such as jackets, cheaper, nonstainless steel grades are used (196). The commonly used steels in fermentation industry are shown in Table 3.7 (197).

The selection of a vessel material for fabrication should take into consideration:

1. Sensitivity of the organism, particularly eukaryotic cells
2. Extent of vessel corrosion on exposure to fermentation media and utilities (mostly acidic pH)
3. Aseptic operation requires use of SS316, SS316L, SS304, or SS304L, with specification of "L" contributing to an additional 15% vessel cost

Although the above factors govern the choice of material, testing of materials with actual fermentation broth or a growing culture is seldom reported.

3.9.6 Baffles

Baffles are usually welded to the interior of the vessel. Baffles usually take the form of metal strips, roughly one tenth of the vessel diameter in width, extending vertically down the height of the vessel and attached radially to the wall. Removable baffles mean unsealed joints. Baffles should be set off from the wall, to minimize solids build up and to simplify cleaning. Slots between the baffle and the vessel wall prevent the formation of dead spots. The provision of baffles increases the turbulence in the liquid and results in a more efficient utilization of power.

3.9.7 Sparger

A device for introducing air below the liquid level in the fermentor vessel is called a sparger. The use of spargers with very small orifices is more efficient than a single orifice delivering the same volume of air. However, aerobic fermentations, e.g., penicillin, produce large quantities of mycelium and mechanical agitation must be used in order to

Table 3.7
Commonly used steels in fermentation industry

Steel	Carbon (%)	Chromium (%)	Nickel (%)	Molybdenum (%)
SS 304	0.07	18.0	9.5	—
SS 304L	0.03	18.5	11.0	—
SS 316	0.05	17.5	11.0	2.7
SS 316L	0.03	17.5	11.5	2.7

ensure adequate dispersion of air and other nutrients in large scale fermentations. As the degree of agitation is increased, the relative efficiencies of the various types of spargers tend to converge, and at high agitation levels, all spargers give approximately the same performance. The types of spargers in general use may be classified as nozzle spargers, orifice spargers, and porous spargers.

Nozzle spargers consists of either a single nozzle or a cluster of nozzles radiating from a central delivery pipe. Orifice or ring spargers are the type in most common use; essentially a perforated pipe formed in the shape of a ring. The tendency of smaller orifices to block and the high pressure drop are the limiting factors. Porous spargers are of more academic than industrial interest and are used primarily in small scale aeration studies.

The factors relevant for good performance of the sparger include correct placement of the sparger holes in line with the impeller blades, choice of hole diameters to ensure critical orifice at maximum gas flow, and free draining back of the fermentation broth into the vessel. The consideration of gas distribution into the fermentor supports use of a ring sparger over other spargers.

3.9.8 Nozzles and Manways

Nozzle design must take into consideration the following:

1. To ensure aseptic connections to external piping for sizes up to 4 in (10 cm), the best choices are sanitary clamps (3-A), Ingold nozzles, and vacuum seals (Ultraseal or VCO). Above 4 in, welded flanges with flat gaskets are used.
2. In order to facilitate free draining, the nozzle is mounted at an angle of about 5°–15° off the horizontal.
3. For proper and safe cleaning of the nozzles, protrusions inside the vessel should be as minimal as possible.
4. Addition of feed through nozzles to the fermentor to take care that the added liquids do not dribble down the interior surfaces.
5. The use of manways obviates the need for full opening heads on larger vessels. Standard manway diameters range from 12 in to 28 in, usually in 2 in increments. A 16 in manway is the minimum practical size, but 18 in is usually better. The maximum size is determined by the vessel diameter. The manway collar should be kept as short as possible to make it easy to clean.

3.9.9 Piping and Valves

Piping materials: The most commonly used piping materials for biotechnology plants, in order of usage, are stainless steel, thermoplastics (polypropylene, polyethylene, polyvinyldine fluoride), carbon steel, copper, iron, glass, and lined pipe (glass and plastic liners).

The guiding document for engineering, design and installation of Water for Injection (WFI) and other sterile systems is CGMP-LVP (Current Good Manufacturing Practice–Large Volume Parenterals, Part 212.49 of Subpart C, Water and Other Liquid Handling Systems), which was issued by the Food and Drug Administration (FDA) in 1976 as a performance specification, in the absence of a code (198). This document specifically mentions stainless steel as the material of construction for WFI and by inference, sterile services.

In sterile fermentation processes, a great deal of attention is necessary for the layout of lines and the construction of joints. Lines for sterile air and lines for transferring sterile mash are the subject of special care during installation to prevent the formation of pockets where liquid can collect. Adequate slopes, continuous in one direction, have to be given in what would be normally horizontal lines. Loops in lines are best excluded,

but if unavoidable have to be provided with drain points so that residual mash and steam condensate can be removed. For purposes of sterilization, steam is introduced wherever possible at the highest point or points in the system, with the steam condensate removed from the lowest points.

Valves used on sterile lines have given cause for thought for a considerable time. For robust industrial processes such as alcohol fermentation, or even for yeast cultivation, the use of the standard type of gate valve is normally acceptable. However, for fermentation systems more prone to contamination, the use of a standard valve has obvious shortcomings. The introduction of a diaphragm capable of standing up to steam for longer periods into the valve has encouraged a gradual changeover to the use of the diaphragm type of valve. Presently, with a diaphragm life of 3–4 months, the use of this type of valve for aseptic applications is justified.

Drain valve: The best drain valve available is a flush mounted diaphragm valve. Designs that include a coupling connected directly to the tank should not be used for any aseptic application. There is no way to keep such a valve clean or free of solids buildup.

Sight Glass: Circular-type sight glasses with sanitary clamp mountings are generally used. These are easy to clean and to replace. The long, rectangular types are much more expensive, and require special modifications to make them self draining.

3.9.10 Steam Locks

A good steam lock assembly should have the following features:

1. Elimination of the chances of dead spots with inefficient sterilization
2. Thorough steaming of sterile lines to be done during non usage to avoid contamination
3. Lines from feed addition tanks should be able to be steamed through their entire lengths at any time after they are connected to the assembly
4. Steam locks to be checked for leakage of steam during steaming
5. Self draining of condensate through steam traps
6. Easy cleaning and maintenance of the steam lock assembly

3.9.11 Welds and Joints

Vessel welds of high quality are required to adhere to code purposes, ensure maximum smoothness and cleanability, and to minimize corrosion problems. Welding for aseptic fermentors should be carried out under an inert gas shield to minimize oxidation and flux residue, and create smoother, pit free welds. The TIG (tungsten inert gas) method is the most acceptable vessel welding technique giving a better finish and not subject to splattering problems compared to the MIG method. It is preferred to use 316L or 304L for multipass welds, to reduce carbide precipitation and consequent pitting near the welds. For single pass welds, one should use 316 or 304 to minimize ferrites in the metal.

A flanged joint for sterile fermentation processes should be constructed with smooth bore continuity throughout the joint. Smooth bore continuity is important, and can be compromised by such factors as tolerances in bore and circularity of commercial tubing, coupled with the tolerances in the bore of such things as slip on welding flanges, and the standard clearance holes for flange bolts. If in addition, the joint is badly cut or badly placed, focal points for lack of sterility with subsequent contamination can easily be produced. In important lines, the use of neck welding flanges is considered justified in spite of their additional cost. The use of welded fittings for branches and reducers, among other

fittings, will permit the construction of lines better suited to sterile operations than those normally obtained if the branch is made up by cutting and fitting the tubes.

3.9.12 Surface Treatment and Finish

The surface treatment of a vessel is required for any surface that comes in contact with the product. It is imperative that all stainless steel surfaces are treated and cleaned in a way that prevents corrosion under the operating conditions. Stainless steels are corrosion resistant due to the formation of a microscopically thin, invisible chromium oxide layer, which occurs on clean metal and polished surfaces only. The three main surface treatment methods used are mechanical, chemical, and electrochemical.

Mechanical Surface Treatment: It is possible to improve the surface quality of steel parts in contact with the product by means of mechanical treatment. The surface finish qualities of the vessel exterior are governed more by aesthetic rather than functional attributes. The quality and smoothness of the mechanically treated surfaces are defined by values in terms of arithmetic mean roughness, R_a. Minimal surface qualities of R_a ~0.6 µm (220 grit) are generally accepted and approved in biotechnology. The finest polish or abrasive belt (400 grit) can be used to achieve smoothness values of R_a 0.28–0.34 µm. The best possible smoothness values are achieved with steel grades, SS 304L and SS 316L.

Chemical surface treatment: The two main types of chemical surface treatment are cauterization and passivation. Cauterization is the dissolution of the flaws on the vessel surface with acid mixtures, such as 15–25% (v/v) HNO_3, and 1–8% (v/v) HF, for steel with chromium content above 15.5%. Surface imperfections in the interior of vessel prevent the formation a perfect passive layer. The impurities that require cauterization may be interior surfaces with oxidation tints, welding slag residues, and fine scales or overlaps generated during the working process.

Passivation is used either after cauterization or as a final treatment of ground, brushed, or polished steels with special surface structures. A natural passive layer is invariably formed when stainless steel is exposed to air. Artificial passivation with dilute nitric acid is frequently used for corrosion resistance at critical condition. The oxidizing effect of nitric acid accelerates the formation of a dense passive layer. Reports on passivation show that organic acid chelating agents can produce a more long lasting passive layer (199).

Electrochemical surface treatment: Electropolishing, or mirror polishing, is an electrochemical treatment which smoothes and polishes rough, dull surfaces. The vessel is immersed in an electrolyte and serves as an anode. The quality of the mirror polishing depends mainly on the source material and its mechanical pretreatment. Vessels with good R_a values may sometimes have microscopic surface roughness, which can be smoothed electrolytically. However, there is likelihood that existing imperfections on the material surface may be accentuated after mirror polishing. An electropolished (EP) vessel requires polishing to 320 grit. Finishes commonly used are shown in Table 3.8.

Inspection of Surface Treatment: The quality of the surface and welds after surface treatments are checked with following methods:

1. Visual inspection
2. Detection of ferric contaminations with the ferroxly test
3. Palladium testing to check the surface passivation
4. Detection detergent residues
5. Detection of chloride or sulfur contamination
6. Detection of pickling damage
7. Scanning needle electronic surface measurement

Table 3.8
Finish represented in Grit and Microns

Grit Designation	Microns (μm)
60	6.3
120	3.2
180	1.6
220	0.8
320	0.4
320 EP	< 0.4

3.9.13 Cleanability

The cleaning in place (CIP) system for the fermentor must be designed to ensure that all interior surfaces can be cleaned thoroughly. There should not be any accumulation of solids after CIP treatment. The inside of the fermentor should be smooth, free draining, and allow easy access for maintenance or repair. There should be no nooks and crannies, and all interior joints should be welded (not bolted) if possible. A dished head drains more freely than a flat head, but flat heads may still be used. The size and placement of the manway significantly affects the positioning of spray balls or hose nozzles, and the ease of access for manual cleaning (200).

3.9.14 Sterility Aspects

The design of a fermentor vessel has to meet aseptic conditions before it can be used for fermentation batches. An improper fermentor design may result in a nonsterile batch due to ineffective sterilization of dead volume or leakage.

Dead Volume: Organisms or media that are deposited in dead spaces may lead to subsequent contamination. In air filled cavities, sterilization temperature may not be reached. The installation of temperature probes into the fermentor at critical positions enables the monitoring of the actual temperature to ensure that efficient sterilization occurs.

Leakage: Most fermentation vessels are not hermetically sealed, and have a number of ports into and out of the fermentor. The common points of leakage from the fermentor include improper sealing of the manhole, sight and light glass, probes, inlet and outlet feed streams, mechanical seals and harvest or sampling valves. Leakage from the fermentor vessel may be identified by two methods, namely pressure test and sealing test.

Pressure test: The fermentor is filled to 70% of the total volume and mixed at the operating speed. Air or nitrogen is sparged into the fermentor to achieve a vessel pressure of 1.5 bars. All the ports are tightly secured and fermentor is examined for pressure loss. Care should be taken to maintain the mechanical seal at a positive pressure relative to the fermentor. If there is a drop in pressure, then there is a leakage from the fermentor.

Sealing test: The fermentor is filled with water up to the mechanical seal and a vessel overpressure of 1.5 bars is achieved. The temperature (T_o) and pressure (P_o) are recorded after ten minutes and again after about fifteen hours. If the specific leakage rate (L) in terms of grams of air per hour per meter of sealing length is less than 0.05 gm/h m, the vessel is considered tight; if higher, then the vessel has to be sealed effectively at the leakage points.

3.10 AGITATION SYSTEM DESIGN

Typical agitation equipment consists of the prime mover (usually an electric motor) coupled to the shaft through a reduction gear. Impellers and baffles are fitted to the shaft and

vessel, respectively, to give the desired liquid motion. The shaft may enter from the top, side or bottom, and is usually fitted with a mechanical seal at the vessel wall. The number and location of impeller units depends on the vessel. The general practice is to use one impeller for each diameter of depth. The type of impeller is more critical and different designs produce different fluid motions.

In a smooth walled tank, the liquid swirls round in the same general direction as the agitator. As the impeller speed is increased, a vortex is formed and the liquid level at the wall is raised above the average liquid level. This is normally undesirable for the following reasons:

1. Power is wasted in holding up the liquid at the wall
2. The relative speed of the impeller to the liquid is reduced
3. Slight radial movements of the vortex cause the liquid to swirl unevenly, and undesirable side thrusts are set up

3.10.1 Impeller Design

The common impeller designs used for stirred tank reactors are shown in Figure 3.9.

The optimum impeller to tank size ratio for gas or liquid mass transfer depends on the mixing power delivered relative to the gas velocity of the system. At relatively low levels of mixer horsepower, it is seen that relatively large D/T ratios are needed in order to have sufficient impeller pumping capacity to handle the volume of gas passing by the impeller. As the amount of power to the mixer is increased, the optimum D/T is reduced to a relatively small value, approximately 0.15 to 0.2. As the mixer power is increased far beyond that needed to disperse the gas, D/T becomes unimportant because it makes very little difference how the power is distributed. As the impeller diameter is increased, , the maximum shear rate at the same impeller speed is also increased. Thus on scale up, lower average shear rates will be encountered in the stream from the impeller due to lower impeller speeds, but higher maximum shear rates will be encountered due to the higher peripheral velocity of the impeller. The impellers operate at a viscosity range of the fermentation medium as shown in Table 3.9. The impeller spectrum depicting the proportion of flow and shear developed by different impellers is shown in Figure 3.10 (201).

3.10.2 Drive Location

The choice between bottom and top entering drives depends on convenience.

Top drive: Top drive continues to be the most common, because there is no threat of a major spillage as might occur through a bottom seal when subjected to grinding by broth particulates. The risk of a major spill is remote because the leak rate would be quite small, and corrective maintenance could be applied well before any catastrophic event could occur.

Bottom drive: Bottom drives do have some very positive advantages. They have shorter shafts, which means that steady bearings are not necessary in most cases; they have less expensive support structures; they are easier to access and simpler to maintain; and they result in lower overall height. From the point of view of asepsis and of the fermentation per se, there is no real difference between top and bottom entry, assuming proper seal design and maintenance.

3.10.3 Seals

Static Seals: Silicone is the best choice for the head plate and ethylene propylene diene monomer (EPDM) for all other static seals. Teflon has better temperature resistance, but it cold

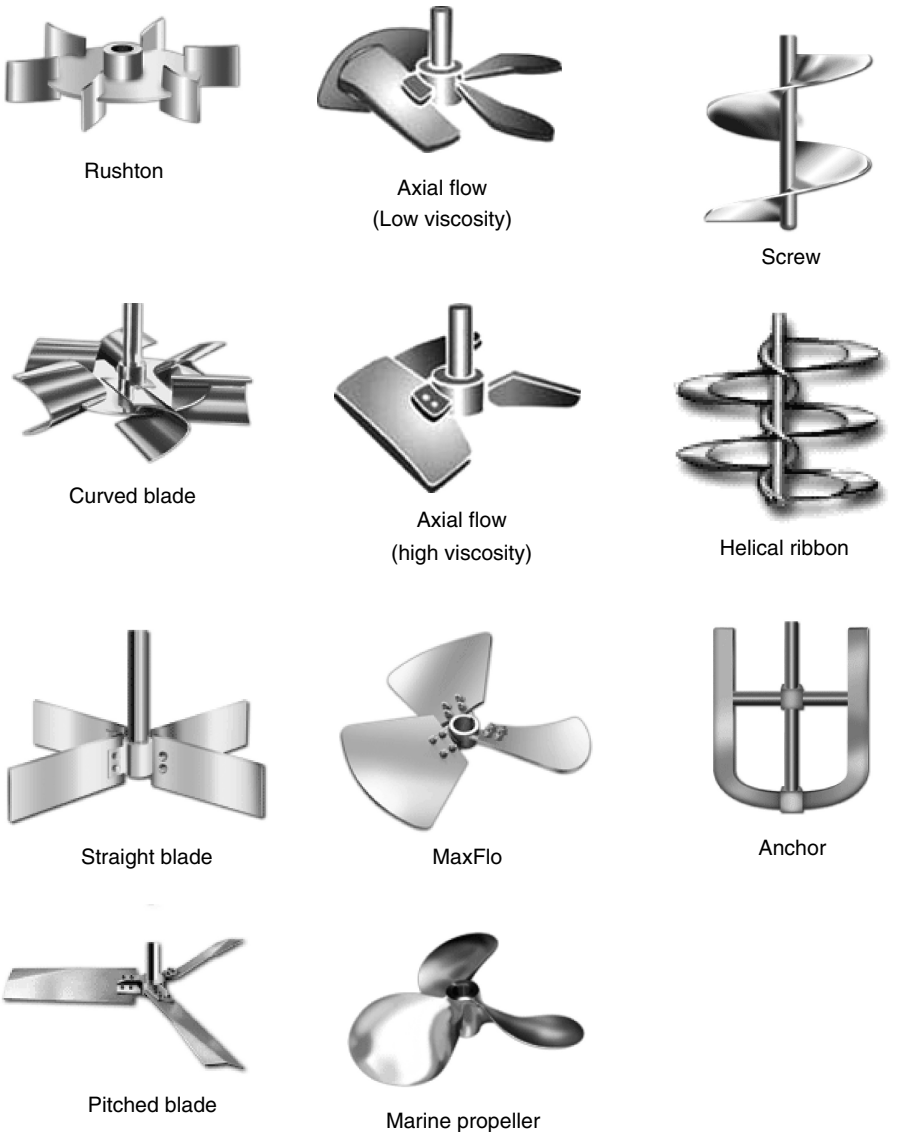

Figure 3.9 Impellers used in stirred tank reactors

flows and does not stretch. Viton™ has good temperature resistance and is quire serviceable, but it hardens.

Rotating Seals: There are two types of rotating seals used in agitated vessels, stuffing box packings and mechanical seals

Stuffing box packings: Stuffing box packings have been used successfully in large fermentors (size 100 m^3 and more), because there is a difficulty in the manufacture of large mechanical seals of size 0.2 m in diameter. The sealing rings in stuffing box packings are compressed in the axial direction first. With subsequent radial deformation, the installed sealing rings are pressed against the stuffing box boring and the spindle.

Mechanical seal: The best choice is a double mechanical seal. Tungsten carbide seats are more expensive than the commonly used ceramic and carbon faces, but they give longer

seal life and less maintenance. The static shaft seals should be EPDM, except for hydrocarbon fermentations, for which Viton is recommended. In the conventional design of double mechanical seals, which derives from the chemical process industries, the seals are mounted back to back. Potential problems with this design are that the housing pressure for this design must be kept higher than the vessel pressure. If the top seal leaks, coolant flows into the vessel. Finally, solids can accumulate in the pocket between the vessel flange and the shaft static seal.

The back to back design works very well for chemical reactors, but in chemical reactor design asepsis is not a consideration. For aseptic operation, the top seal is reversed, and the seal housing is operated at atmospheric pressure. This design eliminates pockets where solids can accumulate, does not allow flow into the vessel, compensates automatically for head pressure variations, and results in lower temperature operation of the seals. Steam flows through the housing during sterilization, and sterile steam condensate flows through it during fermentation to provide lubrication and cooling. This design is simpler than the one which must be used for back to back seals.

In addition to the above seals, magnetic couplings have also been used in small fermentors. Magnetic couplings enable noncontact torque transmission to the vessel without any penetration of the vessel. For fermentation with recombinant organisms or mammalian cells, magnetic couplings are usually employed. Since power transmission ceases whenever the design load is exceeded, magnetic couplings are protected against overload. Magnetic couplings require no external bearings; however, the bearing in the reaction chamber may be susceptible to failure due to particulate solids in the form of cells or media.

Table 3.9
Operating range of impellers with respect to viscosity

Impeller Type	Viscosity Range (mPa s)
Turbines	1–50000
Propellers	1–10000
Anchors	100–5000
Paddles	100–50000
Gate anchors	1000–100000
Helical screw	5000–500000
Helical ribbon	10000–5000000

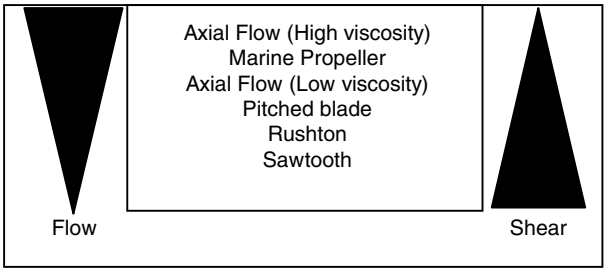

Figure 3.10 Impeller spectrum of different impellers

3.10.4 Power Requirement

The general expression for power consumed by an impeller in an unaerated mixing vessel is given by (202):

$$N_p = K\, N_{Re}{}^{m}.\, N_{Fr}{}^{n} \tag{3.14}$$

where N_p is the power number, which is a constant depending on the impeller type and size, and number of baffles present, N_{Re} and N_{Fr} are the Reynolds and Froude numbers respectively, which describe the kinematic conditions.

The Power: Reynolds and Froude numbers are expressed as:

$$\text{Power number, } N_p = P_o/\rho.N^3.D^5 \tag{3.15}$$

$$\text{Reynolds number, } N_{Re} = D^2.N.\rho\,/\mu \text{ and} \tag{3.16}$$

$$\text{Froude number, } N_{Fr} = D.N^2/g \tag{3.17}$$

where P_o is the power input during unaerated fermentation, D is the impeller diameter, N is the impeller speed, μ is the viscosity, and ρ is the density of the liquid and g is the acceleration due to gravity.

The Reynolds number accounts for the effect of viscosity when viscous forces prevail, while the Froude number accounts for the force of gravity when it plays a part in the motion of the fluid.

The interrelation of impeller speed and diameter, fluid density and viscosity, and physical configuration of the tank and fittings; and consideration of the power necessary to move the impeller have resulted in the formulation of a Rushton plot (203) as shown in Figure 3.11. The Rushton plot is a logarithmic plot of power number (N_p) against the Reynolds number (N_{Re}).

For a particular fermentation system with constant impeller speed, fluid characteristics, and vessel geometry, the Reynolds number for the system, extrapolated to the Y axis in a Rushton Plot can be used to determine the value of N_p. From N_p, P_g/P_o, the ungassed power (P_o) can be calculated.

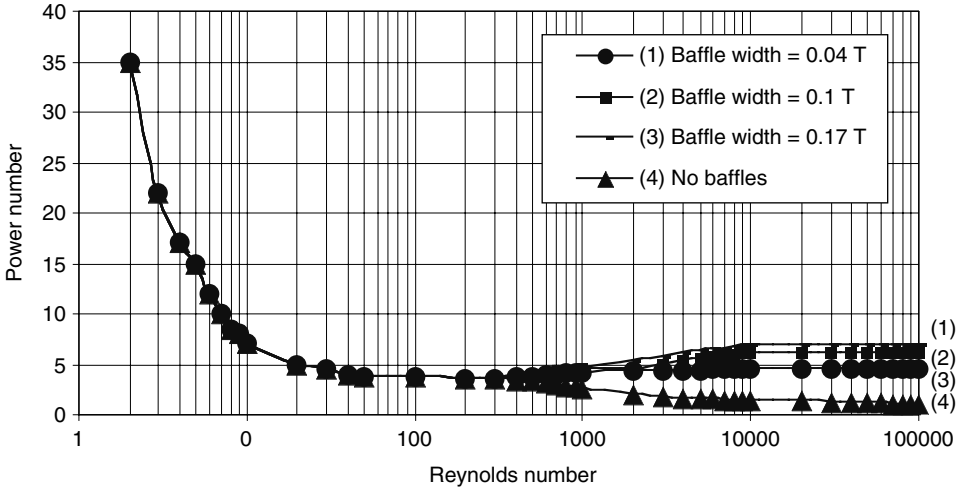

Figure 3.11 Rushton plot for flat blade turbine

The gassed power (P_g) can be determined using correlations expressing the P_g/P_o ratio. The correlation developed by Reuss et al. (204) using dimensional analysis is given by:

$$P_g/P_o = 0.0312.\ (N_{Re})^{0.064}.\ (N_{Fr})^{-1.64}.\ (N_A)^{-0.38}.\ (T/D)^{0.8} \tag{3.18}$$

where N_A is the aeration or flow number and is represented as Q_g/ND^3 where Qg is the volumetric flow rate of gas and T is the diameter of the vessel.

The power aeration curve (Figure 3.12) which is a plot of P_g/P_o versus the aeration number can be determined for a vessel with liquid height to vessel diameter ratio and stirrer speed (205).

3.11 NATURAL BIOREACTORS USING TRANSGENIC TECHNOLOGY

The biotechnology industry is faced with a shortfall of manufacturing facility for production of recombinant therapeutic proteins. The advent of natural bioreactors in the form of transgenic technology in animals, plants, and insects has the potential for large production capabilities at lower capital and operating costs and posttranslational modifications compared to mammalian cell systems, but is limited by slow production rates and regulatory obstacles.

3.11.1 Animal Bioreactors

Transgenic animal bioreactors have the potential to produce complex, biologically active recombinant proteins, and serve as organ donors for transplantations in humans, in an efficient and economic manner (206,207). Transgenic rabbits expressing human genes have been used as a model for cardiovascular disease, AIDS, and cancer research (208). The recombinant proteins can be produced from the milk of transgenic rabbits not only at lower cost but also on a relatively large scale. Transgenic rabbits, which are a relatively larger mammalian transgenic model compared to transgenic mice, can be used as human disease models and live bioreactors for producing human therapeutic proteins. Transgenic zebra fish have been explored as a useful bioreactor for the expression of living color fluorescent

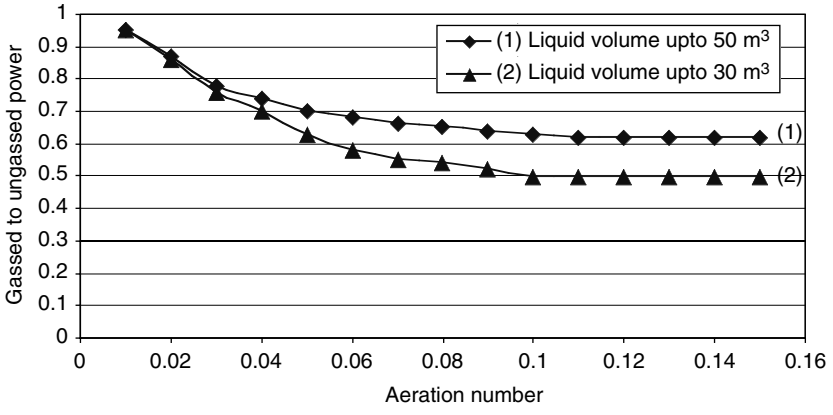

Figure 3.12 Power aeration curve

proteins, namely green fluorescent protein (GFP), yellow fluorescent protein (YFP), and red fluorescent protein (RFP) under a strong muscle specific promoter (209). However, the generation of transgenic animals is perceived as a major problem which limits its applications.

3.11.2 Plant Bioreactors

Transgenic plants are excellent hosts for production of therapeutic proteins in capacities on the order of 10 kg/acre and have been tried out in tobacco, maize, soybean, and alfalfa (210). Transgenic plants have the advantages of accumulation within plants or secretion from roots or leaves, high yields, economic scalability, establishment of permanent lines, containment, and purification (211). Transgenic root systems offer immense potential for introducing additional genes along with the Ri-T-DNA genes for alteration of metabolic pathways and production of useful metabolites (212). The main constraints for commercial exploitation of hairy root cultures for the production of valuable secondary metabolites are the complications associated with scale up. Transgenic potatoes provide a viable alternative to the conventional chemical method for production of high levels of platinose in the storage tissues of the crop (213). Plants can also serve as bioreactors for the production and scale up of functional antibodies used in immunotherapy. Proteins expressed in genetically modified plants (GM-plants) are tested for their potential use as human and animal vaccines (214). To maximize the potential of plants as industrial bioreactors for the production of proteins, efficient expression systems utilizing promoters like cauliflower mosaic virus (CaMV) are widely used (215). From an economical perspective, the production cost of biomolecules using plants is potentially less than that of using a fermentation process, because solar energy, CO_2, and inorganic chemicals are sufficient to drive the plant process; while relatively expensive equipment, substrates, and electric energy are required in fermentation (216).

3.11.3 Insect Cell Bioreactors

Insect cells could also be potential bioreactors and have been cultivated in almost all operation modes of fermentation. The baculovirus insect cell system has been used for the production of high value heterologous proteins, which form an assembly of regular structures called viruslike particles (VLPs) (217). The advantages of the VLPs are that they possess highly immunogenic properties, which have the potential to be used as vaccines. The operation of insect cell expression system is normally by fed batch mode because the baculovirus infection imposes a high metabolic burden on the infected cells thereby inducing cell lysis for the production of VLPs. The significant interdependent variables in the operation of the baculovirus insect system are: multiplication of infection, cell concentration at infection, and harvest time. The scale up of insect cell system to a 25L bioreactor involves consideration of the capability to supply enough oxygen to maintain the high specific oxygen uptake rate during cell infection through sparging of air or O_2 during the cultivation. The cell susceptibility during sparging occurs due to breakage of the bubbles, which can be avoided by the addition of Pluronic F-68. Porcine parvovirus (PPV) is an ethiological agent, which causes reproductive failure of pigs. Using the baculovirus insect cell expression system, production of recombinant self assembling VLPs composed of PPV VP2 capsid protein, which are shown to be highly immunogenic and confer full protection against the disease, was achieved.

3.12 CONCLUSIONS AND FUTURE PERSPECTIVE

Historically, industrial biotechnology has dealt mainly with microbial systems of natural origin. Improvements took place through mutations of the organism by physical and

chemical methods on the one hand, and developments and improvements in the design, construction, and operation of fermentors on the other. The production of penicillin represented the first opportunity to apply chemical engineering principles to fermentation technology in large scale aerated, agitated fermentors in batch, continuous, and fed batch mode. Reactor developments took place in terms of mode of conducting the different phases in the reactor, resulting in the application of techniques of air lift, fluidized bed, microcarrier, and membrane bioreactors.

In the recent decades, with the rapid advances in molecular biology and genetic engineering, and the capability to engineer organisms through recombinant DNA technology and introduce foreign genes of desired capability into host organisms, the potential of industrial biotechnology to produce products of economic importance has enormously increased. This has been particularly so for production of high value molecules such as proteins of therapeutic importance through the use of transgenic technology involving animal and plant cells and. Concurrent with these have been the developments in the design of sophisticated bioreactors involving recombinant DNA, microbial, animal, and plant cell systems.

Bioreactor development is dependent on a synthesis of knowledge of the kinetics of the biological reactions, with the flow and mixing processes in the reactor, to achieve an overall mathematical description of the process that can be useful for design and optimization. However, this has not been effectively accomplished, due to reasons such as our inadequate knowledge of biological kinetics, use of complex growth media with undefined compositions, use of reactors with poorly defined flow and mixing characteristics, and the lack of concerted effort toward more systematic and predictive reactor design. Instead, process scale up has proceeded through rather empirical experimental investigations at increasing scale with smaller steps. One reason this has happened is the rapid growth of the ability of biotechnology to produce new products of high commercial value. Other reasons include the high investments involved in systematic experimental investigations, and the tendency of the industry to guard the confidentiality of their results. However, with increased competition in the industry, process optimization and systematic reactor design will definitely become an important factor in the future, particularly for the production of high value products through biotechnology.

Process Developments in Solid-State Fermentation for Food Applications

Ashok Pandey and Sumitra Ramachandran

CONTENTS

4.1 INTRODUCTION

Solid-state (substrate) fermentation (SSF) has been defined as the fermentation process occurring in the absence or near absence of free water. SSF processes generally employ a natural raw material as the carbon and energy source. SSF can also employ an inert material as the solid matrix, which requires supplementing a nutrient solution to contain necessary nutrients as well as a carbon source. The solid substrate (matrix), however, must contain enough moisture (1–6). Depending upon the nature of the substrate, the amount of water absorbed could be one or several times more than the dry weight, which leads to relatively high water activity (a_w) on the solid–gas interface, in order to allow a higher rate of the biochemical process. Lower water activity conditions result in low diffusion of nutrients and metabolites, and higher water activity causes compaction of the substrate. Thus, maintenance of an adequate moisture level in the solid matrix, along with suitable water activity, are essential elements for SSF processes (2,4,7–10). Solid substrates should generally have a large surface area per unit volume (in the range of 10^3–10^6 m^2/cm^3), to allow for ready growth on the solid–gas interface (11). Smaller substrate particles provide larger surface area for microbial attack, but pose difficulty in aeration and respiration due to the limitation in interparticle space availability. Larger particles provide better aeration and respiration opportunities, but provide less surface area. In bioprocess optimization, it may sometimes be necessary to use a compromised size of particles (usually a mixed range) to maximize cost effectiveness. For example, wheat bran, which is the most commonly used substrate in SSF, is obtained in two forms, fine and coarse. The former contains particles mostly smaller than 500–600 μ, and the latter contains particles mostly larger than these. Most SSF processes use a mix of these two forms, at different ratios, for optimal production (1,2,12–14).

Solid substrates generally provide a good dwelling environment to the microbial flora comprising bacteria, yeast, and fungi. Among these, filamentous fungi are the best studied for SSF, because, due to their hyphal growth they can not only grow on the surface of the substrate particles, but also penetrate through them. Several agro crops such as cassava and barley, and agro-industrial residues such as wheat bran, rice bran, sugarcane bagasse, cassava bagasse, various oil cakes (e.g., coconut oil cake, palm kernel cake, soybean cake, ground nut oil cake), fruit pulps (e.g., apple pomace), corn cobs, sawdust, seeds (e.g., tamarind, jack fruit), coffee husk and coffee pulp, tea waste, and spent brewing grains are the most often, most commonly used substrates for SSF processes (15–23). During growth on such substrates, hydrolytic exo-enzymes are synthesised by the microorganisms and excreted outside the cells, which create and help in accessing simple products (carbon source and nutrients) by the cells. This in turn promotes biosynthesis and microbial activities.

Apart from these, there are several other important factors which must be considered for development of SSF processes. These include physico-chemical and biological factors such as pH of the medium; temperature and period of incubation; age, size and type of the inoculum; nature of the substrate; and type of microorganism employed.

4.2 SIGNIFICANCE OF SSF

SSF has been considered superior in several aspects to submerged fermentation (SmF). It provides several advantages. It is cost effective due to the use of simple growth and production media comprising agro-industrial residues, and it uses small amounts of water and therefore releases considerably less effluent, thus reducing pollution concerns.

SSF processes are simple, use low volume equipment (lower cost), and are effective in that they provide high product titres (concentrated products). Further, the aeration process (availability of atmospheric oxygen to the substrate) is easier. There is a increased diffusion rate of oxygen into moistened solid substrate, supporting the growth of aerial mycelium. SSF can be effectively used at smaller volumes, which makes it suitable for rural areas.

4.3 SSF PROCESSES FOR FOOD APPLICATIONS

Food fermentation involves the action of microorganisms, depending upon the control of environmental conditions, and should ensure the growth of favourable microbial species for the development of desired sensory qualities in indigenous foods. SSF for food application has been used since the development of human civilization. Many kinds of fermented foods, such as single-cell protein (SCP) probiotics, flavoring products, beverages, pigments, and peptide sweeteners, are produced largely by SSF. In addition to these, several enzymes, organic acids, and exopolysaccharides have been produced using SSF.

Fermented foods can be stored for longer periods and used for food supply during the off season. Fermentation also contributes to the digestibility and enhances the nutritional value of the product. It can also increase fibre digestibility. However, there are chances of accidental contamination of SSF food products by mycotoxins, which are a class of unwanted compounds and could be accidentally present or produced in SSF products. This could be due to the use of contaminated raw materials or due to an accidental contamination of the fermentation with a toxigenic strain. Mycotoxins have been reported to occur as contaminants in many agricultural commodities such as nuts, cottonseed, corn, sorghum, millet, grains, and barley. Blanc et al. (163) reported that about 100 mg/kg citrinin was detected in food quality pigments produced by *Monascus* species.

4.3.1 Historical Developments

Historically, SSF processes have been used since ancient time for food applications. Although it is believed that the discovery of fermentation was purely by chance, food fermentation was developed several thousands of years ago. SSF dates back to 6000 BC when Babylonians made beer from natural yeast. Egyptians used this technique for bread making in 2600 BC, using brewer's yeast. Cheese making with *Penicillium roquefortii* was recorded in Asia before the birth of Christ. *Koji* processing reported to be migrated from China to Japan in the seventh century. Miso, tempeh, tamari sauce, soy sauce, ang-kak, natto, tou-fu-ru, and minchin are some of the other ancient fermented foods known for centuries, which are prepared through SSF. Tempeh and tamari sauce are soybean products, the former is an Indonesian food fermented by *Rhizopus* species and the latter is a Japanese food produced by using *Aspergillus tamari.* Soy sauce, a brown, salty, tangy sauce, is obtained from a sterile mixture of wheat bran and soybean flour, fermented initially by lactic acid bacteria, followed by alcoholic fermentation and ripening. A mash of crushed and steamed soybeans is used as a substrate for miso. Normal fermentation is carried out for one week, followed by two months of ripening. The final product is ground into a paste, which is generally used in combination with other foods.

In the eighteenth century, SSF was used to make vinegar from apple pomace. The beginning of the twentieth century marked the use of SSF for the production of enzymes and organic acids using molds. There were several other developments of SSF technology for nonfood application in subsequent years. The period of the 1970s saw a major focus on production of SCP.

4.3.2 New Developments

SSF gained a new dimension for various food and nonfood applications during the last 15–20 years. In food applications, it has been used particularly for the production of enzymes, organic acids, pigments, SCP, exopolysaccharides, and aroma compounds. Biologically active secondary metabolites such as antibiotics, steroids, biopesticides, and biofertilizers, are some nonfood applications of SSF. Attention is also being given to the development of bioreactors (fermentors) of various kinds, using automation.

4.4 SSF PROCESSES FOR FOOD ENZYMES

Enzymes have become an integral part of human need in day-to-day life, playing a varied role in several industries, particularly the modern food industry. Production of a variety of food products, ranging from baked foods, syrups, and fruit juices to flavoring agents and dairy products, commonly involves the use of several food enzymes. Almost all the microbial enzymes can be produced using SSF systems. Industrially important food enzymes, which include alpha amylase, glucoamylase, lipase, protease, pectinase, inulinase, glutaminase, and tannase, have been widely studied (4,5,19,24–33).

Enzyme production in SSF has often resulted in higher yields in comparison to SmF. Studies conducted to examine the reasons why SSF produced higher enzyme yields than SmF have been unable to explain it fully, although some of the characteristics of SSF provide conditions for the microbes more like the habitat from which they were isolated, and this may be the major reason for higher enzyme production. Most of the SSF processes for the production of food enzymes involve agro-industrial residues as the substrate, although inert materials such as polyurethane foam are also used. These have been mentioned earlier and are also indicated in Table 4.1 (15–18,28,34–37).

4.4.1 Amylases

For starch and glycogen hydrolysis, two major classes of amylases have been identified in the microorganisms: α-amylase and glucoamylase. In addition, β-amylase, which is generally of plant origin, has also been reported from a few microbial sources. α-Amylase (endo-α-1,4-D-glucan glucohydrolase, EC- 3.2.1.1) is an extracellular enzyme, which randomly cleaves the 1,4-α-D-glucosidic linkages in the interior of the amylose chain. Amylases which produce free sugars are termed as *saccharogenic* amylases, and those which liquefy starch without producing free sugars are known as *starch-liquefying* amylases. β-Amylase (α-1,4-glucan maltohydrolase, EC- 3.2.1.2) is an exoacting enzyme, which cleaves the nonreducing chain ends of amylose, amylopectin, and glycogen molecules, yielding maltose. Glucoamylase [also known as amyloglucosidase, glucogenic enzyme, starch glucogenase, and gamma amylase (exo-α-1,4-D-glucan glucanohydrolase, EC- 3.2.1.3)] produces single glucose units from the nonreducing ends of amylose and amylopectin in a stepwise manner. Unlike α- and β-amylase, most glucoamylases (GA) are able to hydrolyse the α-1,6 linkages at the branching points of amylopectin, although at a slower rate than 1,4-linkages. Thus, glucose, maltose, and limit dextrins are the end products of GA starch hydrolysis.

Extensive studies have been done on the production of amylases, in particular for α-amylase and GA in SSF, employing several microorganisms and various kinds of agro-industrial residues, among which starchy substrates have been preferred (Table 4.1) (5,7,12,13,28,32,38,39–50). Reports on microbial production of β-amylase are scanty and very few in SSF. A mutant strain of *Bacillus megaterium,* B6 mutant UN12, was described for the comparative production of beta amylase in SmF and SSF. The starchy wastes used as substrates were from arrowroot, arum, maize, potato, pulse, rice, rice husk, tamarind

Table 4.1
SSF processes for production of food enzymes

Enzymes	Microorganisms	Ref.	Substrates	Ref.
α-amylase	*Aspergillus oryzae*	52	Wheat bran	164

	Candida sp.	179		

kernel, cassava, water chestnut, wheat, and wheat bran. Arum and wheat bran gave the highest yields (51).

Although the sources of α-amylases are fairly extensive, the principal commercial preparations are derived from some bacterial and fungal species. These include *Bacillus* sp., *Bacillus amyloliquefaciens, B. coagulans, B. licheniformis*, *B. megatarium, Aspergillus* sp., *A. niger, A. oryzae, A. kawachii, Aeromonas caviae, Pycnoporus sanguineus,* and *Saccharomycopsis capsularia* (28). The *Bacillus* species is considered the most prolific producer of α-amylase by SSF. *B. amyloliquefaciens* and *B. licheniformis* are considered potent species for thermophilic α-amylase (24,28,45,52,53). Among filamentous fungi, *Thermomyces lanuginosa* was reported to be an excellent producer of α-amylase (54). A strain of *Aspergillus oryzae* was used for α-amylase production using spent brewing grain in SSF and the process was considered economically promising (52). Irrespective of enzyme properties (such as temperature, pH optima, and range), SSFs are typically performed at mesophilic temperatures such as 30°C using agro-industrial residues for 24–96 h.

GA production in SSF was first demonstrated in 1914. The production of GA was carried out in shallow trays with *Aspergillus* sp., *A. awamori, A. niger, A. oryzae,* and *Rhizopus* sp., *R. oligosporus,* under SSF. An extensive study was carried out on the production of GA in solid cultures by a strain of *A. niger* (7,12,13,38–44,55–58). The study included screening of various agro-industrial residues, including wheat bran, rice bran, rice husk, gram flour, wheat flour, corn flour, tea waste, and copra waste, individually and in various combinations. Apart from the substrate particle size, which showed profound impact on fungal growth and activity, substrate moisture and water activity also significantly influenced the enzyme yield. Different types of bioreactors, including flasks, trays, rotary reactors, and columns (vertical and horizontal), were used to evaluate their performance. Enzyme production in trays occurred in optimum quantities in 36 h in comparison to the 96 h typically required in flasks. Supplementation of wheat bran medium with yeast extract increased glucoamylase synthesis by the fungal culture.

Several attempts have been made to compare the GA production in SSF and SmF (59–62). Generally SSF yielded higher enzyme titres. However, contrary to the general findings, *Rhizopus* A-11 showed a 4.6-fold lower GA yield from a conventional SSF on wheat bran medium than the yield in SmF, which used metal ion supplemented medium (60). A similar trend was found with a fungal strain of *A. niger,* which produced higher GA titres in SmF (102 U/ml) than in SSF (66 U/ml) in a shorter period (66 h in comparison to 96 h). In an aqueous biphasic system comprising polystrene glycol (PEG 6000) and potassium phosphate, however, both the GA recovery and yields were twice as high as the control system comprising an aqueous phase only (59).

4.4.2 Lipases

Lipases are essential for the bioconversion of lipids from one organism to another or within the organism itself. Microbial lipases (glycerol ester hydrolases, EC 3.1.1.3)

catalyse a wide range of reactions, specifically hydrolysis and interesterification. They also catalyse alcoholysis, acidolysis, esterification, and aminolysis (63). They possess the unique feature of acting as an interface between the aqueous and nonaqueous phase, which distinguishes them from esterases.

Lipases are wide–spread, being found in microbial flora, in the pancreas of mammals such as pigs and humans, and in higher plants such as castor beans and rape seed. Microbial lipases are used for the production of desirable flavor in cheese and other foods, and for the interesterification of fats and oils to produce modified acyl glycerols, which cannot be obtained by conventional esterification (74). The most important species of microorganisms for the synthesis of lipase in SSF include *Candida* species, *Pseudomonas* species, and *Rhizopus* species, with *Candida rugosa* being the most commonly used. *Aspergillus* lipases are highly selective for short chain acids and alcohols (69). *C. rugosa* lipase is more selective for propionic acid, butyric acid, butanol, pentanol, and hexanol (64). The production of flavor esters by the lipases of *Staphylococcus warneri* and *S. xylosus* has been reported (75). *Mucor miehei* and *Rhizopus arrhizus* lipases are more selective for long chain acid and acetates. *M. miehei* lipase is used to prepare gerniol esters, which are important components of fragrances, in a solvent free system (63–72).

Several agro-industrial residues and inert supports have been used to produce lipases in SSF (63–69). These include peanut press cake, coconut oil cake, wheat bran, rice bran, babassu oil cake, olive oil cake, sugarcane bagasse, and amberlite, using various yeast and fungal cultures such as *Candida* sp., *C. rugosa, Neurospora sitophila, A. oryzae, Rhizopus oligosporus, R. delemer, P. candidum,* and *Mucor* sp. Enzyme production in SSF has been reported to be superior in comparison to SmF (yield in SmF was 14 U/ml and in SSF using a polymeric resin, amberlite, as a solid inert substrate, with dextrin as the carbon source, was 96 U/g) (73). Similar observations were reported by Rivera-Munoz et al. (76), who found that the enzyme was more stable. Supplementation of oil cake medium with external carbon or suitable inorganic or organic nitrogen sources resulted in improved enzyme yields (64).

4.4.3 Proteases

Proteolytic enzymes find wide applications in food and other industries. They account for nearly 60% of the industrial market in the enzyme technology. Proteases are produced extracellularly by fungi and bacteria such as *A. oryzae, A. flavus, R. oligosporus, Penicillium citrinum*, *P. chrysosporium, Bacillus subtilis, B. amyloliquefaciens*, and *Pseudomonas* species (80,85,86). In recent years, different types of proteases such as acid, neutral, and alkaline proteases are being produced by SSF. Proteases production is generally inhibited by carbon sources, indicating the presence of catabolic repression of the biosynthesis. This fact makes it logical to use agro-industrial residues as substrates for proteases production; thus an SSF process becomes imperative. It is interesting to note that although a number of substrates such as wheat bran, rice bran, and oil cakes have been employed for cultivating different microorganisms, wheat bran has been the preferred choice (78–85).

Enzyme production in SSF is generally favoured under partial pressure of carbon dioxide. Studies on the effects of O_2 and CO_2 partial pressure on acid protease production by a strain of *Aspergillus niger* ANH-15 in SSF of wheat bran showed a direct relationship between pressure drop, production of CO_2 and temperature increase (81). Acid protease production was increased when the gas had 4% CO_2 (v/v) and it was directly related with the fungus metabolic activity as represented by the total CO_2 evolved. Acid protease production on rice bran using a strain of *R. oligosporus* by making step changes in the gas environment and temperature during SSF to mimic those changes, which arose during SSF due to mass and heat transfer limitation, showed that a decrease of O_2 concentration from 21 to 0.5% did not alter protease production (82,83).

Comparative study on protease production in SSF and SmF generally showed higher enzyme yields in SSF. For example, a study on acid protease production showed that total protease activity in SSF per gram of wheat bran was equivalent to 100 ml broth (79).

4.4.4 Pectinases

Pectinases are a group of hydrolytic enzymes, usually referred as pectolytic enzymes, which find important applications in the food and beverages industries, in addition to various other industries. Pectolytic enzymes degrade pectic material and reduce the viscosity of a solution, making it easier to handle. They are used industrially in fruit processing to facilitate pressing and to help in the separation of the flocculent precipitate by sedimentation, filtration, or centrifugation in the extraction of the clarified juice (95). Pectinases are used for the elimination of pectin in wine making, coffee and tea processing plants, and maceration of vegetable tissue (93,94). Pectinases comprise hydrolases, lyases, and oxidases, and can be obtained from higher plants, microorganisms, and insects (96). Pectinases can be obtained from several fungi, bacteria (including alkalophilic), actinomycetes, and yeast, such as alkalophilic bacteria, actinomycetes, *Aspergillus versicolor, A. niger, A. awamori*,

Rhizopus stolonifer, Penicillium italicum, P. frequentans, Polyporus squamosus, Thermoascus aurantiacus, Clostridium thermosaccharolyticum, *C. felsincum, Tubercularia vulgaris*, *Sclerotium rolfsii, Erwinia* sp., *Erwinia carotovora, Bacillus* sp., *B. subtilis, B. bumilus, B. stearothermophilus, B. polymyxa, Pseudomonas syringae, Rhizoctonia solani, Xanthomonas compestris, Saccharomyces cerevisiae, Kluyveromyces marxianus,* and *Trichosporon penicillatum* (89,93–97,100,101). Extracellular pectinases from *Aspergillus* sp. are of commercial interest and strains of *A. niger, A. carbonarius,* and *A. foetidus* are used. Among these, *A. niger* is considered as the most important for production in SSF. Various agro-industrial residues such as apple pomace (92), citrus waste, orange and lemon peels (91), soy bran (94), sugar cane bagasse (95), wheat bran (97), coffee pulp (87), cocoa pulp, (98) and cranberry and strawberry pomace (99) are used as the substrates. Citrus pulps or peels could be used as inducers for enzyme synthesis (91). In the case of pectinases, generally enzyme yields are higher and the enzyme is said to be more stable (over a wider range of pH and temperature) in SSF in comparison to SmF (88,89,93–97).

4.4.5 L-Glutaminase

L-glutaminase (L-glutamine amidohydrolase - E.C. 3.5.1.2) is an important enzyme deamidating L-glutamine, which plays a major role in the cellular nitrogen metabolism of both prokaryotes and eukaryotes. L-glutaminase is useful in the food industry as it increases the glutamic acid content of the fermented food, thereby imparting a unique flavor. Because the sources for L-glutaminases are limited, the search for potential microbial strains that produce the enzyme in high titres with novel properties for their industrial production is being pursued extensively around the world (31).

L-glutaminase can be produced by many bacterial strains, such as *Escherichia coli, Pseudomonas* sp., *Acinetobacter* sp., *Bacillus* sp., *Proteus morganni*, *P. vulgaris*, *Xanthomonas juglandis*, *Erwinia carotovora*, *E. aroideae*, *Serratia marcescens*, *Enterobacter cloacae*, and *Klebsiella aerogenes.* It can also be produced by *Aerobacter aerogenes*, fungi such as *Aspergillus sojae* and *A. oryzae,* and yeast cultures such as *Hansenula*, *Cryptococcus*, *Rhodotorula*, *Candida scottii, Cryptococcus albidus*, *C. laurentii*, *Candida utilis,* and *Torulopsis candida* (31).

One of the major advantages of SSF system for L-glutaminase production lies in cultivation of salt tolerant microbial cultures, which may have better application in food processes involving high salt concentration, such as soy sauce production which requires as high as 20–25% salt concentration. From this point of view, marine microorganisms

have been explored and exploited. There seems to be enormous scope for the investigation of deriving new products of economic importance from potential marine microorganisms. Considering the fact that the marine environment, particularly sea water, is saline in nature and chemically closer to human blood plasma, it could be anticipated that this could provide microbial products; in particular, enzymes, that could be safer, having less toxicity and fewer side effects, when used for human application (31).

When SSF was carried out using saline tolerant yeast *Zygosaccharomyces rouxii* with agro-industrial substrates such as coconut oil cake, groundnut oil cake, wheat bran, and sesamum oil cake, 2.2 and 2.17 U enzyme/gram dry substrate (gds) were produced from wheat bran and sesamum oil cake, respectively. Under optimized physico-chemical conditions, enzyme yields increased to 7.5 and 11.61 U/gds for these, respectively, which is 3.5–5 times higher than the initial (without optimization) production (34).

L-glutaminase has also been produced in SSF using inert substrates such as polystyrene (100). A marine organism, *Vibrio costicola,* was used for solid culturing (35,100). Another marine isolate, *Beauveria* species, has also been used for L-glutaminase production (101). However, it was necessary to supplement the fermentation medium with NaCl at high concentrations (~10%) or sea-water when using such cultures. In both cases, enzyme production was growth associated.

4.4.6 Inulinase

Microbial inulinases (2,1-β-D-fructan fructanohydrolase EC 3.2.1.7) are usually inducible and exoacting enzymes, which catalyse the hydrolysis of inulin by splitting off terminal fructosyl units (D-fructose) by cleaving the glycosidic linkages in polymer moiety. They play an important role in the hydrolysis of inulin for its commercial exploitation. Inulin, a polyfructan, consists of linear β-2,1 linked polyfructose chains, terminated by a glucose residue attached through a sucrose-type linkage. It is a reserve carbohydrate in the roots and tubers of plants such as Jerusalem artichoke, chicory, or dahlia. Inulinases catalyse the hydrolysis of inulin to D-fructose (fructose syrup), which has gained an important place in human diets today (30).

Microbial inulinases have mostly been produced in SmF; although the technique of SSF has been recently tried using wheat bran and chicory root as substrates. Indigenously isolated bacterial strains of *Staphylococcus* sp. and a yeast strain of *Kluyveromyces marxianus* were cultivated in SSF, which produced extracellular inulinase. When wheat bran was used as the C source, 16 U of enzymes/g dry fermented substrate were produced. Improvements in process parameters and nutritional conditions led to a 6.5-fold increase in enzyme yields by the bacterial strain in SSF (102,103).

4.4.7 Tannase

Tannase, or tannin acyl hydrolase (EC 3.1.1.20), is an inducible enzyme, which catalyses the breakdown of hydrolysable tannins and gallic acid esters. It transforms tannic acid into glucose and gallic acid. Tannase is used in the industrial processing of fruit juices and coffee flavored soft drinks as a clarifying agent, and in the manufacture of instant tea; it is also used in the production of wine and beer.

Generally tannase is obtained form microbial sources. A wide number of bacterial, fungal, and yeast cultures have been reported to produce the enzyme in SmF or SSF. Among these, *Aspergillus awamori, A. niger, A. oryzae* and *A. japonicus* have been considered as the best producers (104). *Fusarium solani, Rhizopus oryzae, Trichoderma viride,* and *Candida* sp. are other important sources of the enzyme. Tannase production in SSF using polyurethane foam showed superiority of SSF in comparison to SmF. The addition of high tannic acid concentrations increased total tannase activity, whereas the supplementation of

glucose proved detrimental (105). SSF is considered to minimize catabolic repression for tannase production.

4.4.8 Recovery of Enzymes from Fermented Matter

Recovery of the enzymes from the fermented matter is a critical factor, which largely affects the cost-effectiveness of the overall process. In SmF, fermented broth is generally subjected to centrifugation or ultrafiltration to remove solid particles and concentrated enzymes, whereas in SSF fermented matter, aqueous extract is prepared to recover the enzyme. Usually distilled water is used for extraction, although buffer solutions or a NaCl solution (0.01M) can also be used. There are several methods which could be used for this purpose. The use of reverse micellar systems for the enzyme extraction has attracted considerable interest, due to their capacity to solubilize specific proteins from the dilute aqueous solutions such as fermented and cell culture media. It represents a new downstream process for the extraction of enzymes without any modification to their conformation. Use of a full forward and backward extraction cycle can remove contaminating matters such as neutral protease, and release of protein can depend on the aqueous phase pH. The temperature of extraction also affects the rate and overall recovery of enzymes. Generally enzymes retain their biological activity fairly well inside the reverse micelles. A work on protease recovery from SSF fermented matter showed that a leaching solution of pH 7 gave the optimum recovery of the enzyme from the fermented matter, although the enzyme had optimum activity at pH 4 (78,79).

4.5 SSF PROCESSES FOR ORGANIC ACIDS

Production of organic acids such as citric acid for food application by SSF has been employed since olden times. For example, citric acid production by SSF (the *Koji* process) was first developed in Japan, and is the simplest production method. SSF can be carried out using several raw materials. Generally, the substrate is moistened to about 70% depending on the water-holding capacity of the substrate. The initial pH is normally adjusted to 4.5–6.0 and the temperature of incubation can vary from 28 to 30°C. One of the important advantages of the SSF process is that the presence of trace elements does not affect citric acid production negatively as it does in SmF (113,119).

Commercially, citric acid is produced mainly using the filamentous fungus *A. niger*, although *Candida* sp. has also been used, employing both molasses- and starch-based media. In SSF, production has been obtained using crops and crop residues such as apple pomace (114), grape pomace (115), coffee husk (116), cassava bagasse, beet molasses (117) pineapple waste (110), and carrot waste (113) as substrates by *A. niger*. Citric acid production is largely dependent on the microorganisms, production techniques, and substrates employed. Generally the addition of methanol increased citric acid production in SSF (118). It has been proposed that overproduction of citric acid was related to an increased glucose flux through glycolysis. At low glucose fluxes, oxalic acid could accumulate. Several studies with different strains of *A. niger* have been made to compare citric acid production in flasks and in different kinds of bioreactors such as trays, packed bed bioreactors (single layered and multilayered), and rotating drums, and varied results have been obtained (106–113,119,120). For example, Tran et al. (109) reported the best production in flasks, and lower yields in tray and rotating drum bioreactors. Lu et al. (111,112) found that a multilayer packed bioreactor improved the mass transfer considerably compared with a single layer packed bed operated under similar conditions. Higher yields were obtained in packed bed than in flasks. In packed bed bioreactors using inert support, heat

Table 4.2
SSF for citric acid production using agro-industrial residues by different strains of Aspergillus niger

Raw Material	Citric Acid
Apple pomace	766–883 g/kg[a]
Grape pomace	413–600 g/kg[a]
Kiwifruit peel	100 g/kg[a]
Cellulose hydrolysate and sugar cane	29 g/kg
Orange waste	46 g/kg
Beet molasses (ca-alginate gel)	35 g/L
Saccharose (sugar cane bagasse)	174 g/kg[b]
Coffee husk	150 g/kg[b]
Carrot waste	29 g/kg[a]
Okara (soy residue)	96 g/kg[a]
Pineapple waste	132–194 g/kg[b]
Glucose (sugarcane bagasse)	21.24 g/L
Kumara (starch containing)	103 g/kg[b]
Mussel processing wastes (polyurethane foams)	300 g/kg
Cassava bagasse	347 g/kg[b]

[a] *based on sugar consumed;* [b] *based on dry matter*

removal by conductive mechanism was the least efficient (8.65%) when compared with convective (26.65%) and evaporative (64.7%) (119). Table 4.2 shows SSF for citric acid production using agro-industrial residues by different strains of *A. niger.*

Another important organic acid required for food applications is lactic acid, which has been produced in SSF using fungal as well as bacterial cultures. The commonly employed cultures belong to *Rhizopus* sp. and *Lactobacillus* sp., e.g., *R. oryzae*, *L. paracasei, L. helveticus,* and *L. casei* (121–123). Different crops such as cassava and sweet sorghum, and crop residues such as sugarcane bagasse, sugarcane press-mud, (122) and carrot-processing waste (123) served as the substrate. A comparative study involving fungal strains of *R. oryzae* to evaluate L-(+) lactic acid production in SmF and SSF showed that SSF was superior in production level and productivity. Fermentation yields were 77% (irrespective of media) and yields were 93.8 and 137.0 g/l in SmF and SSF, respectively (121). The productivity was 1.38 g/l per hour in SmF and 1.43 g/l per hour in SSF. In another comparison using *L. paracasei,* lactate concentrations and yields were 88–106 g/l and 91–95% for SmF, and 90g/kg and 91–95% for SSF, respectively, but the time required for SSF was 120–200 h in comparison to 24–32 h in SmF (123).

4.6 PRODUCTION OF AMINO ACIDS

Use of defined SSF media using inert solid support has been considered a very useful method for microbial cultivation for the production of value added products (1,2,3,19,20,25,26,124). The production of L-glutamic acid in SSF with sugarcane bagasse was used as solid inert substrate and a bacterial strain of *Brevibacterium* sp. was used for the fermentation. The study not only showed good L-glutamic acid synthesis in solid culturing but also demonstrated that with media and process parameters manipulation, bacterial strains can also be successfully cultivated in SSF (125). Yield as high as 80 mg glutamic acid per g dry fermented matter was obtained.

4.7 MUSHROOM PRODUCTION

Mushrooms have entered the new era of food technology as a common universally accepted nutritive food. Their commercial cultivation involving SSF has rapidly spread globally, due to their innumerable applications. They are a rich source of protein, carbohydrates, vitamins, and minerals (2,19). Folic acid content in mushrooms has been found to be higher than in liver and spinach. In addition to their nutritive value, mushrooms also possess medicinal properties (1,2,19,20,127–129). They demonstrate antibacterial, antifungal, and antiprotozoal activities, due to the presence of polyacetylene compounds. Today more than 2000 species of mushrooms are known, although only about 20 are cultivated commercially. Button mushrooms, Japanese mark forest mushrooms, Chinese mushrooms, oyster mushrooms, and winter mushrooms are some of the various types of popular mushrooms being cultivated world wide. However, button mushrooms alone account for about 60% of total world production.

Mushroom cultivation involves SSF at three different stages, namely composting, spawn manufacture, and the growth of mushroom on the moist substrate. In order to produce a selective growth medium on which the mycelia colonize and produce fruiting bodies, the compost is prepared by piling up the substrate for a long period of time. During this period, many changes take place, and the resulting substrate differs from the original. Various physico-chemical factors play a vital role in the process. A temperature range of 22–27°C, substrate moisture content of 55–70%, and a pH of 6.0–7.5 are generally considered as the most suitable conditions. Animal manure from horses and chickens, and agro-industrial residues such as wheat straw, paddy straw, barley straw, rice bran, saw dust, banana, maize stover, tannery waste, wool waste, and sugarcane bagasse are used as substrates.

Spawn or inoculum production involves the growth of mycelia of mushroom on cereal grains such as rye, wheat, sorghum, and millet. These support faster mycelial development because of sufficient nutrients availability, and allow easy handling and steadiness during sterilization. The process is carried out with a pure culture. However, application of these substrates increases the costs input; for this reason other raw materials such as sawdust, cereal bran, or other agro-industrial residues have been recommended for spawn preparation. A mixture of sawdust and coffee husk was found quite suitable for spawn preparation for *Agaricus bisporus, Pleurotus* sp., *Lentinus edodus, Flammulina velutipes, and Volvariella volvacea* (127–129). Depending upon the nature of the substrate, optimum conditions were moisture content at 40–60%, a pH of 6.5–7.0, and an incubation temperature of 25°C. The final product spawn should be stored at 2–5°C.

The development of the fruiting body requires a lower temperature than the optimum for mycelial growth; it also requires proper ventilation, which helps in releasing the accumulated carbon dioxide, which retards the formation of fruiting bodies. The crops are harvested at the second or third stage of sporophore development, namely the button or closed-up stage, respectively. At this stage, substrate moisture should be generally higher than previous stages, (i.e., compost formation and spawn preparation). High relative humidity (80–95%) is also a desirable condition in order to control the heat, mass, and gaseous exchange. After harvesting of the fruiting body, the leftover solid residue can be used as manure or as animal feed, depending upon the raw material used as substrate.

4.8 PRODUCTION OF EXOPOLYSACCHARIDES

SSF use in the production of exopolysaccharides such as xanthan and succinoglycan is growing. Xanthan is nontoxic and does not inhibit growth. It is nonsensitizing and does

not cause skin or eye irritation. On this basis, xanthan has been approved by the United States Food and Drug Administration (FDA) for use as a food additive without any specific quantity limitations (131). Xanthan gum has been used in a wide variety of foods for a number of important reasons, including emulsion stabilization, temperature stability, compatibility with food ingredients, and pseudoplastic rheological properties (131). For recovering the xanthan, the cells are usually removed first, either by filtration or centrifugation (133). Further purification may include precipitation using water-miscible nonsolvents (isopropanol, ethanol, acetone), addition of certain salts, and pH adjustments (133). One SSF-based process for the production of xanthan gum utilized a bacterial culture of *Xanthomonas campestris* (134). The exopolysaccharide was produced on a number of agro-industrial residues or byproducts such as spent malt grains, apple pomace, grape pomace, citrus peels, and sugar beet molasses (137). With most of the substrates, the gum production was comparable to those obtained with SmF (130). Succinoglycan production by SSF with *Agrobacterium tumefaciens* on various solid substrates, including agar medium, spent malt grains, ivory nut shavings, and grated carrots, impregnated with a nutrient solution, showed the highest yield in static cultivation, reaching 42 g/l of impregnating solution, corresponding to 30 g/kg of wet substrate (135). The polymer production in a tray bioreactor was faster, but the final yield was lower (29 g/l of impregnating solution) (135).

SSF was performed using inert solid particles (spent malt grains) impregnated with a liquid medium. The gum was extracted from the fermented mass with seven volumes of water by shaking at 250rpm for 2h. It was filtered, centrifuged at 4000g for 10 min, followed by ultracentrifugation at 25000g for 20 min. The EPS was precipitated from the supernatant by the addition of 2% KCl, with 2–3 volumes of cold acetone. The precipitated xanthan was dissolved in 2% KCl, precipitated again with acetone, dried at 70°C. and weighed (136). The polymer yields obtained from SSF, as referred to the impregnating liquid volumes, were as follows: 38.8 g/litre xanthan from *Xanthomonas campestris*, 21.8 g/litre succinoglycan from *Rhizobium hedysari* and 20.3 g/litre succinoglycan from *Agrobacterium tumefaciens* PT45. These results made this technique promising as a potential application on the industrial scale. A further advantage of this fermentation process could be in the availability and low cost of substrates, which are obtained as byproducts or wastes from the agricultural or food industry (136). A comparison of SmF and SSF for the production of bacterial exopolysaccharides (EPS) showed that the latter technique yielded 2–4.7 times more polymer than the former on the laboratory scale (136).

4.9 PRODUCTION OF PIGMENTS

Pigments are the normal constituents of the cells or tissues that give color. Pigments play a vital role in the food industry, to make food decorative and appealing. Natural pigments contain provitamin A, and have anticancer activity, and other desirable properties such as stability to heat, light, and pH. There are pigments which are chemo-synthetic counterparts of regular food components, that are referred as natural-identical.

Microbial production of pigments has usually been carried out in SmF, though SSF processes have also been applied. *Candida flareri, C. guilliermundii, Debaromyces subglobosus, Hansenula polymorpha, Saccharomyces, Torulopsis xylinus*, *Ashbya gossypi* and *Eremothecium ashbyii* have commonly been used for the production of riboflavin, a yellow pigmented B vitamin. *Monascus* pigments have good properties as food colorants possessing reasonable light and chemical stability, tinctorial strength, and water solubility when complexed with appropriate agents.

Monascus pigments may be used as substitutes for traditional food additives, such as nitrites for the preservation of meats (139), and as a potential replacement for synthetic food dyes (181). They have also been used industrially for several years; e.g., as yellow hydrosoluble pigments for candies (140), or red pigments in red rice wine. *Monoscus anka* and *M. pupureus* are cultivated in SSF for red pigment production (Table 4.3). Steamed rice is used as the substrate, although oats, wheat, and barley have also been used. The culturing period is approximately three weeks. Certain sugars, amino acids, and metals have been found important for the production, and yields are typically 10-fold higher in both SSF and SmF. Pigment formation could be inhibited by the presence of glucose in the fermentation medium, but could be increased by limited aeration in SmF. It was also observed that an increase in the partial pressure of CO_2 increases the pigment production (141). For isolating the pigment from fermented matter, simple extract with solvents such as ethanol is effective (1,137,141).

Table 4.3
SSF processes for other food applications

Products	Microorganisms	Ref.	Substrates	Ref.
Citric acid	*A. niger*	108, 110–112 116, 120	Pineapple waste	109, 110
			Apple pomace	114
			Carrot processing waste	113
			Grape pomace	115
			Coffee husk	116
			Beet molasses	117
Lactic acid	*R. oryzae*	121	Sugarcane press mud	122
	Lactobacillus paracasei	123	Sweet sorghum	123
	L.casei	123		
Glutamic acid	*Brevibacterium* sp.	125	Sugarcane bagasse	125
Mushrooms	*Pleurotus* sp	126, 128	Coffee residues	126, 127
	Lentinus edodes	127	Cotton straw	180
Xanthan	*Xanthomonas campestris*	134	Spent malt grains	134
			Citrus pomace	137
			Apple pomace	137
			Citrus peels	137
Succinoglycan	*Agrobacterium tumefaciens*	135	Spent malt grains	135
			Ivory nut shavings	135
Pigments	*Monascus purpureus*	137, 138	Sugarcane bagasse	138
Aroma compounds	*T. viride*	142	Pre gelatinized rice	142
	Kluyveromyces marxianus	148, 149	Sugarcane bagasse	144
	Ceratocystis fimbriata	144, 145	Coffee husk	147
	Rhizopus oryzae	143	Cassava bagasse	145
	Bacillus subtilis	150	Soybeans	150
Vitamins	*Citrobacter freundii*	152	Rice	152
	Klebsiella pneumoniae	152		
Aflatoxin	*A. flavus*	160	Cassava bagasse	160

4.10 PRODUCTION OF AROMA COMPOUNDS

One of the significant applications of SSF in food applications involves production of food aroma compounds. There are two main advantages of SSF as an alternative technology for the production of aroma compounds: (1) release of the products from the microbial membranes is facilitated by the higher concentration in liquid phase, and (2) sometimes the solid substrates or byproducts can be used directly in SSF without any pretreatment of the starting substrates.

SSF has been successfully employed for the production of food aroma compounds using fungal and yeast cultures, such as *Neurospora* sp., *Zygosaccharomyces rouxii*, *Aspergillus* sp., and *Trichoderma viridae* (142), using pregelatinized rice, miso, cellulose fibres, and agar. *Rhizopus oryzae* cultivation of tropical agro-industrial residues results in the production of volatile compounds such as acetaldehyde and 3-methyl butanol (143). *Neurospora* sp. and *T. viride* produce a fruity odour and coconut aroma in SSF with pregelatinized rice and agar medium, respectively (142). Methyl ketones are produced on a commercial scale from coconut oil using *A. niger,* and the yields are as high as about 40% (1,141,143).

Ceratocystis sp. produces a large range of fruity or flower-like aromas (peach, pineapple, banana, citrus, and rose), depending on the strain and cultivation conditions (144). Among these, *C. fimbriata* has been extensively studied for the production of aroma compounds in SSF. Wheat bran, cassava bagasse, coffee husk, and sugarcane bagasse were used as the substrate. Addition of precursors such as urea, leucine, and valine affected growth and aroma production (144–147).

Kluyveromyces marxianus grown on cassava bagasse in SSF using packed bed column bioreactors under different aeration rates produced 11 volatile compounds, out of which nine were identified and two remained unidentified. Ethyl acetate, ethanol, and acetaldehyde were the major compounds produced, with 0.06 l/h/g aeration rate. Maximum TV concentrations were reached at 24 h with 0.06 l/h/g initial dry matter (IDM), and at 40 h for 0.12 l/h/g IDM. At 0.06 l/h/g aeration rate, ethyl acetate and ethanol were the compounds in highest and almost equivalent concentration (~30%) (148,149).

There are some other aroma compounds which can be produced in SSF. These include 2,5-dimethylpyrazine (2,5-DMP) by *Bacillus natto* (150) and tetramethylpyrazine (TTMP) by *B. subtilis* (151) on soybeans in SSF. Results demonstrated the suitability of SSF for their production.

Production of aroma compounds in SSF using naturally occurring substrates offers potential benefits in production of food and fruity aroma compounds for human consumption at low cost. One major difficulty in this regard is the isolation and recovery of compounds produced, especially if the compounds possess lower volatile temperature. A few attempts have been made to trap such compounds in suitable inert materials such as resins by adsorption. However, much remains to be done in this area.

4.11 VITAMINS

SSF has been used for the formation of water soluble vitamins such as vitamin B-12, vitamin B-6, riboflavin, thiamine, nicotinic acid, and nicotinamide. *Rhizopus oligosporus, R. arrhizus*, and *R. stolonifer* formed riboflavin, nicotinic acid, nicotinamide, and vitamin B-6 (153). The final concentrations of these substances depended on the different strains involved and on the fermentation time. Isolates of *R. oligosporus* were generally the best vitamin producers. The molds did not produce physiologically active vitamin B-12.

Citrobacter freundii and *Klebsiella pneumoniae* showed the best capabilities for physiologically active vitamin B-12 production (152,153).

4.12 MYCOTOXINS

Mycotoxins are toxic compounds produced as secondary metabolites by about 350 species of toxigenic fungi, occurring in food commodities and food stuffs such as cereals, soybeans, corn, sorghum, and peanuts. These are pathogenic and their consumption can lead to mycotoxicoses. Cardiac beriberi caused by toxins of *Penicillium* associated with rice, and alimentary toxic aleukia linked with *Fusarium* molds on wheat, millet, and barley are some of the serious problems faced by human beings. Aflatoxin, sterigmatocystin, zearalenone, patulin, ochratoxin, and fumonisin are some of the toxins which could lead to increased incidence of cancer. Aflatoxins B1, B2, G, and G2 are produced by *A. flavus* and *A. parasiticus* in cereal grains such as corn, wheat, sorghum, oats, barley, millet, and rice. Aflatoxin is heat stable at temperature above 212° F. *A. flavus* generally produces toxins at a optimum temperature of 81–86°F and optimum moisture content of 18–24%. Aflatoxin production by *A. flavus* isolates from peanuts, cottonseed, rice, and sorghum showed a higher percentage of aflatoxin-producing strains in peanuts (154). Milk products such as cheese could be contaminated by aflatoxin M-1 when manufactured with milk from dairy cattle that have consumed aflatoxin B-1 contaminated feeds. Zeralenone and deoxnivalenenol are toxins produced by *Fusarium* sp. *Fusarium trincintum,* and some strains of *Fusarium,* produce T-2 and other toxic trichothecenes. T-2 mycotoxin, the only mycotoxin known to have been used as a biological weapon, is highly stable and resistant to UV light destabilization. Citrinin is produced by *P. expansum* in apple juice and, to a lesser extent, in grape juices (155). Frayssinet et al. (156) have discussed methods for the analysis of mycotoxins in foods. They have also outlined techniques for aflatoxins, trichothecenes, zearalenone, fumonisins, and ochratoxin A detection.

Production of mycotoxin in SSF depends on several factors such as temperature, water activity, food sources, and aeration (157). It was reported that aflatoxin production in SSF increased at higher aeration rates in the range of 0.01 to 0.04 ml of air/g of humid corn/min (158). Gonzalez et al. (160) reported that aflatoxin production on cassava bagasse was higher at 29°C, which decreased 8-fold at 35°C. They also reported that at above 40% moisture there was positive effect on aflatoxin production. Maggon et al. (159) reported that in SmF, depletion of the nitrogen or phosphorus source enhanced aflatoxin biosynthesis. A report by Gonzalez et al. (160) stated that when *A. parasiticus* and *A. niger* were grown together in SSF, aflatoxin production was completely inhibited, proving that mycotoxin production is inhibited by competition. Lindenfelser et al. (161) obtained a yield of 2.4g/kg ochratoxin on wheat, using a rotating drum type fermenter. In a study by Saxena et al. (162), it was found that ergosterol could be used as an indicator for potential mycotoxin production, because the concentration of ergosterol was found to be similar to the concentration of ochratoxin A produced by *A. ochraceus* NRRL 3174 and *P. verrucosum* NRRL 3260 cultured on white rice.

Metabolic Engineering of Bacteria for Food Ingredients

Ramon Gonzalez

CONTENTS

5.1 INTRODUCTION

Metabolic engineering (ME; see Table 5.1 for a complete list of acronyms used in this chapter) has been defined as the directed improvement of product formation or cellular properties through the modification of specific biochemical reactions or the introduction of new ones with the use of recombinant DNA technology (1,2). Therefore, the *analysis* and *modification* of metabolic pathways is of central importance to ME. The *analytical* part uses experimental and modeling techniques [e.g., labeling experiments, Metabolic Flux Analysis (MFA)], which allow the systematic study of cellular responses (in terms of metabolic fluxes) to genetic and environmental perturbations. This facilitates a rational design of metabolic *modifications*, which are implemented using recombinant DNA technology. Both fields, the *analysis* and the *modification* of metabolic pathways, will be covered in this chapter.

Because of the central role of fermentation in food production and preparation, microorganisms are constantly encountered in these processes. ME can rationally improve the properties of these microorganisms and their efficiency for producing different products. Bacteria occupy a central place among these microorganisms, as either the bacteria *per se* (e.g., as starter cultures and probiotics) or products synthesized by bacteria (i.e., used as biocatalyst in the synthesis of amino acids, organic acids, vitamins, and carbohydrates). This illustrates the tremendous potential of ME for improving the bacteria used by the food industry.

Food additives produced by bacteria can be incorporated into foods as nutritional supplements, flavor enhancers, texturizers, acidulants, preservatives, emulsifiers, surfactants, thickeners, or functional food ingredients. A functional food (also referred to as a nutraceutical or pharmaceutical food) is defined as a food that can beneficially affect one

Table 5.1
Acronyms

Acronym	Definition
AcCoA	Acetyl Coenzyme A
AlaDH	Alanine Dehydrogenase
EPS	Exopolysaccharides
GDH	Glutamate Dehydrogenase
GRAS	Generally Regarded As Safe
LAB	Lactic Acid Bacteria
LAC	Lactic Acid
LDH	Lactate Dehydrogenase
ME	Metabolic Engineering
MFA	Metabolic Flux Analysis
PDH	Pyruvate Dehydrogenase
PEP	Phosphoenolpyruvate
PPC	phosphoenolpyruvate carboxylase
PPP	Pentose Phosphate Pathway
PTS	Phosphotransferase System
PYC	Pyruvate Carboxylase
PYR	Pyruvate
TCA	Tricarboxylic Acid
2,5-DKG	2,5-diketo-D-gluconic Acid
2-KLG	2-keto-L-gulonic Acid

or more targeted bodily functions beyond adequate nutritional effects in a way that improves health and well-being and reduces the risk of disease (3). Functional food ingredients include low calorie sugars, polysaccharides, and vitamins.

Applying ME principles and tools to the production of food ingredients by bacteria has resulted in the efficient production of both native and totally novel products by several cultures, including strains of lactic acid bacteria (LAB), *Escherichia coli*, *Bacillus subtilis*, and *Corynebacterium glutamicum*. These microorganisms have been selected based on a variety of criteria including, availability of genetic tools for cloning, expression, disruption, or replacement of genes (i.e., sequenced genome, promoters, plasmids and cloning vectors, gene transfer methods, and gene expression systems); capacity to metabolize a wide spectrum of carbon sources at high fluxes; rapid growth on inexpensive carbon and nitrogen sources; GRAS (generally regarded as safe) status; resistance to bacteriophage attack; well established physiological knowledge; efficient transport of the final product to the extracellular medium and tolerance to its high levels; and use in large-scale fermentations and production at an industrial level. The examples in this chapter (summarized in Table 5.2) will cover the analysis and modification of central metabolic pathways, biosynthetic pathways, and transport systems involved in producing amino acids, organic acids, vitamins, carbohydrates, bacteriocins, low calorie sugars, and aroma compounds. It is worth noting that many of these products are commercially produced.

5.2 AMINO ACIDS

Amino acids have a great variety of current and potential uses as food, pharmaceuticals, and animal feed. Their main application field is food, where about 50% of the product is applied (4). They can be used as nutritional supplements, flavor enhancers, sweeteners, and in pre- and postoperative nutrition therapy (5). This section will discuss using ME to produce some of these amino acids. Recent progress in this field can be divided into three categories (6): (1) modification of central metabolic pathways, (2) modification of biosynthetic pathways, and (3) modification of transport systems. Figures 5.1, 5.2, and 5.3 summarize some of the examples discussed below.

5.2.1 Modification of Central Metabolic Pathways

From reasoning based on metabolic pathways structure, rerouting a carbon source to produce a desired amino acid should start by increasing the availability of precursor metabolites, energy, and reducing equivalents used in its synthesis. Central metabolic pathways meet these criteria, and therefore engineering central metabolism is essential for the efficient production of amino acids. The analytical tools included in the ME toolbox have played an essential role

Table 5.2
Examples of bacteria that have been engineered for the production of food ingredients

Microorganism(s)	Product (Reference)
Corynebacterium glutamicum	L-tryptophan (16), L-phenylalanine (11,12), L-tyrosine (14), L-threonine (15), L-isoleucine (13), and L-histidine (10)
Lactic acid bacteria	L-alanine (21), Vitamins (50), Exopolysaccharides (57), Bacteriocins (61), and Aroma Compounds (67)
Bacillus subtilis	Vitamins (48) and Lactic Acid (44)
Escherichia coli	Succinate (23,24), Pyruvate (33), Lactate (41,42), and Acetate (45)

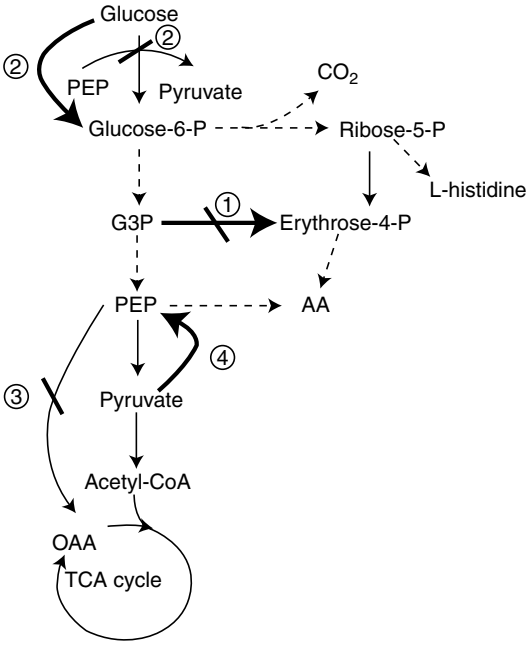

Figure 5.1 Metabolic engineering of central metabolic pathways to increase the synthesis of histidine and aromatic amino acids. Solid and dashed lines represent single and multiple steps, respectively. Solid bars over the arrows represent blocked enzymes, while thick arrows represent amplified enzymes. The following strategies are illustrated. Increasing the production of histidine by increasing the availability of Ribose-5-P, 1- Transketolase-deficient strains. Increasing the production of AA by increasing the supply of erythrose-4-P, 1- Overexpression of transketolases in AA producer. Increasing the production of AA by increasing the availability of PEP, 2- Inactivation of PEP-dependent PTS system for the transport of glucose and amplification of sugar-phosphorylating kinase gene; 3- Inactivation of PEP carboxylase; 4- Amplification of PEP synthase. Abbreviations, AA, aromatic amino acids; G3P, glyceraldehyde-3-P; and PEP, phosphoenolpyruvate.

in elucidating the function of different central pathways and suggesting useful strategies for redirecting carbon flow toward the biosynthesis of amino acids. For example, it has been shown that the pentose phosphate pathway (PPP) supports higher fluxes during the production of L-lysine compared to the production of L-glutamic acid in *C. glutamicum* (7,8). This was attributed to the higher requirements of reducing power (NADPH) in the production of L-lysine. Another example is improving aromatic amino acids and L-histidine production in *C. glutamicum* by increasing the availability of their precursor metabolites, erythrose 4-phosphate and ribose 5-phosphate, respectively, as well as NADPH. This can be done by modifying the flux through the PPP, either by increasing the activity of transketolase (and providing more erythrose 4-phosphate for aromatic amino acids biosynthesis) or by decreasing the activity of transketolase (and providing more ribose 5-phosphate for L-histidine biosynthesis) as shown in Figure 5.1, strategy 1 (6). Both approaches have produced *C. glutamicum* strains with an increased capacity for making aromatic amino acids (9) and L-histidine (10). Figure 5.1 shows additional examples of engineering central metabolic pathways to increase the availability of precursor metabolites used to synthesize aromatic amino acids in *C. glutamicum*. In general, these strategies are based on increasing the availability of erythrose 4-phosphate (strategy 1, Figure 5.1), phosphoenolpyruvate (strategies 2, 3, and 4, Figure 5.1), and ribose-5-P (strategy 1,

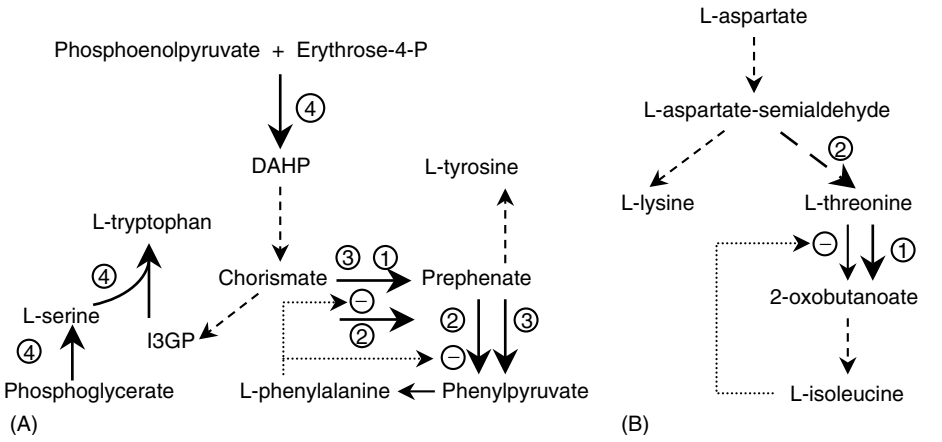

Figure 5.2 Metabolic engineering of biosynthetic pathways to increase the synthesis of aromatic amino acids, threonine, and isoleucine in *C. glutamicum*. See Figure 5.1 for explanation of different types of lines/arrows. In some cases, feedback inhibition has been represented using round dotted lines. Examples illustrated here include amplification of a gene encoding a rate-limiting step, introduction of a heterologous enzyme subjected to a different regulatory mechanism, and redirection of metabolic flux in a branch point (Ikeda (6)). (A) Increasing the synthesis of aromatic amino acids, 1 - Overexpression of chorismate mutase increased L-phenylalanine production; 2- Overexpression of mutated (insensitive to L-phenylalanine) chorismate mutase–prephenate dehydratase from *E. coli* increased the production of L-phenylalanine; 3- Simultaneous amplification of chorismate mutase and prephenate dehydratase resulted in increased production of L-tyrosine and L-phenylalanine; 4- Coexpression of two enzymes catalyzing the initial steps in the biosynthesis of aromatic amino acids (3-deoxy-D-arabino-heptulosonate 7-phosphate synthase) and L-serine (3-phosphoglycerate dehydrogenase) together with tryptophan-biosynthetic enzymes increased tryptophan production. (B) Increasing the synthesis of isoleucine and threonine, 1- Expression of L-isoleucine-insensitive *E. coli* threonine dehydratase (catabolic) enhanced isoleucine production; 2- Amplification of a threonine biosynthetic operon resulted in increased production of threonine in a lysine-producing *C. glutamicum* strain. Abbreviations, DAHP, 3-deoxy-D-arabino-heptulosonate-7-phosphate; I3GP, indole-3-glycerol-phosphate.

Figure 5.1) by inactivating the enzymes involved in their consumption and/or amplifying the enzymes involved in their production (for a review of these strategies, see Reference 6).

5.2.2 Modification of Biosynthetic Pathways

After engineering central metabolic pathways, a sufficient supply of precursor metabolites, energy, and reducing power is ensured, and efforts then need to be focused on engineering biosynthetic pathways that convert precursor metabolites into amino acids. Several strategies have been used to achieve this goal (6), and some of them are illustrated in Figure 5.2. For example, the gene that encodes a rate-limiting enzyme can be amplified, resulting in the release of a bottleneck. Ozaki et al. (11) and Ikeda et al. (12) used this strategy to improve the production of L-phenylalanine in *C. glutamicum*. Overexpression of the gene that encodes chorismate mutase in *C. glutamicum* K38 resulted in a 50% increase in the yield of L-phenylalanine (11). On the other hand, introducing heterologous enzymes subject to different regulatory mechanisms can also result in the release of a bottleneck. For example, overexpressing a mutated (insensitive to L-phenylalanine) *E. coli* gene that encoded the bifunctional enzyme chorismate mutase–prephenate dehydratase in *C. glutamicum* KY10694 led to a 35% increase in the production of L-phenylalanine (12). In addition, expressing the *E. coli* catabolic threonine dehydratase (insensitive to L-isoleucine) in *C. glutamicum*

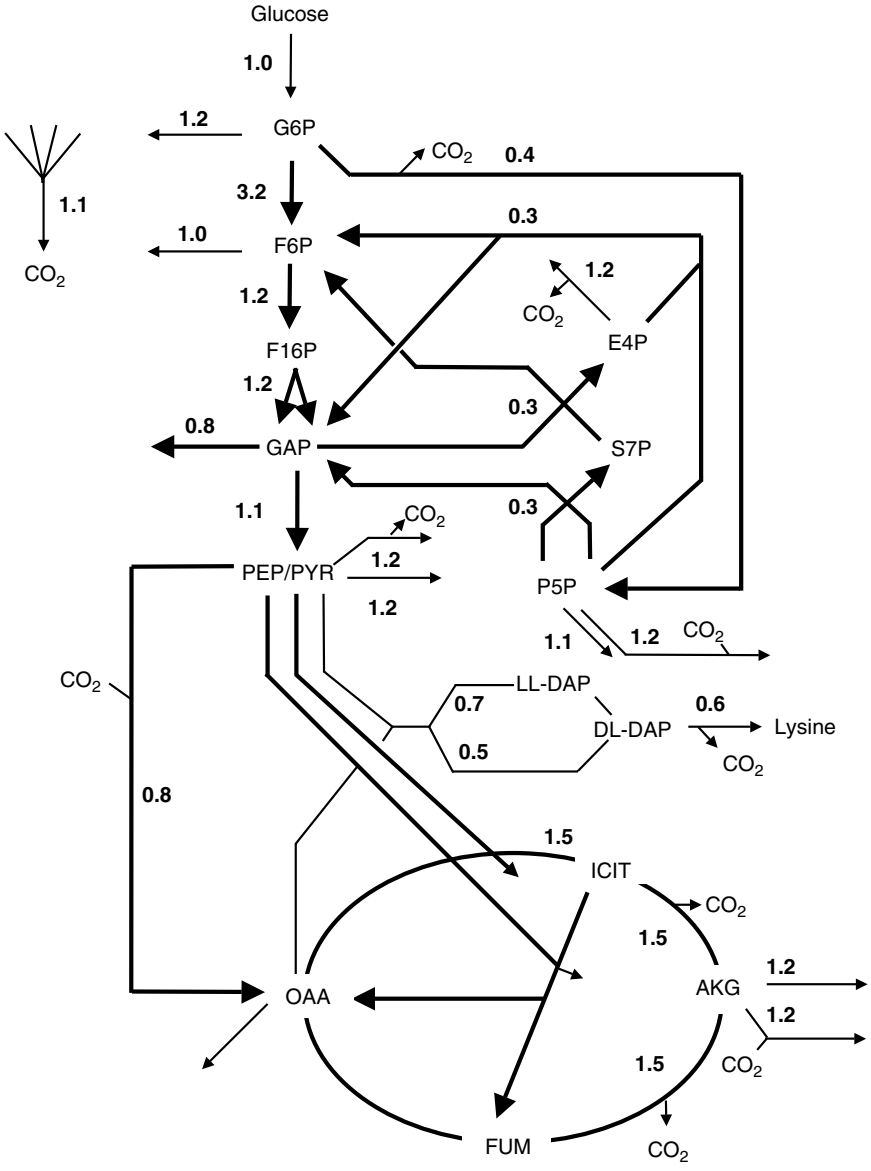

Figure 5.3 Labeling experiments-based MFA of two isogenic glutamate dehydrogenase mutants (homologous, NADPH-dependent, and heterologous, NADH-dependent) of the lysine producer strain *C. glutamicum* MH20-22B. Flux values were converted to flux ratios and expressed as (NADH-dependent mutant)/(NADPH-dependent mutant). Numbers near the thick lines give the estimated net fluxes while those near the thin arrows give the measured fluxes required for biomass synthesis. Adapted from Marx et al. (20). Abbreviations, AKG, α-ketoglutarate; DL-DAP, DL-diaminopimelate; E4P, erythrose-4-P; FUM, fumarate; F16P, fructose-1-6-bisphosphate; F6P, fructose-6-phosphate; GAP, glyceraldehyde-3-phosphate; G6P, glucose-6-phosphate; ICIT, isocitrate; LL-DAP, LL-diaminopimelate; OAA, oxaloacetate; PEP, phosphoenolpyruvate; PYR, pyruvate; P5P, pentose-5-phosphate; S7P, sedoheptulose-7-phosphate.

resulted in increased isoleucine production (13). A second strategy could be the redirection of metabolic flux in a branch point. Ikeda and Katsumata (14) engineered a tryptophan-producing mutant of *C. glutamicum* to produce L-tyrosine or L-phenylalanine in abundance

(26 and 28 g/L, respectively) by overexpressing the branch-point enzymes (chorismate mutase and prephenate dehydratase), catalyzing the conversion of the common intermediate chorismate into tyrosine and phenylalanine. Using a similar approach, Katsumata et al. (15) produced threonine using a lysine-producing *C. glutamicum* strain, by amplifying a threonine biosynthetic operon. Other strategies could include introducing heterologous enzymes that use different cofactors than those used by the native enzyme as well as amplifying the enzyme that catalyzes the steps linking central metabolism and the biosynthetic pathway (6). Ikeda et al. (16) achieved a 61% increase in tryptophan yield (50 g/L of tryptophan) in a tryptophan-producing *C. glutamicum* KY10894 by coexpressing two enzymes catalyzing the initial steps in the biosynthesis of aromatic amino acids (3-deoxy-D-arabino-heptulosonate 7-phosphate synthase) and serine (3-phosphoglycerate dehydrogenase) together with tryptophan biosynthetic enzymes.

5.2.3 Modification of Transport Systems

By altering amino acid transport systems, one could expect to decrease their intracellular concentration and avoid feedback inhibition. The following two examples illustrate that show the significance of this strategy. During the production of L-tryptophan by *C. glutamicum*, the accumulation of this product in the extracellular medium resulted in a backflow into the cells, which produced severe feedback inhibition in the biosynthesis of tryptophan (6). Ikeda and Katsumata (17) solved this problem by creating mutants with lower levels of tryptophan uptake, which resulted in an accumulation of 10 to 20% more tryptophan than in their parent. Another example of transport engineering is the increase in the fermentation yield of cysteine by overexpressing multidrug efflux genes (*mar* genes) in a cysteine-producing strain of *E. coli* (6).

5.2.4 Use of Analytical Tools in the ME Toolbox

In this section, I will give some examples of using MFA [See reference (2) for a detailed description of MFA] to improve the production of specific amino acids, including the two amino acids with the largest production volume worldwide (L-glutamic acid with 800,000 tons/year and L-lysine with 600,000 tons/year).

Glutamate. As with other amino acids, analysis and modification of central metabolic and biosynthetic pathways in glutamate-producing *C. glutamicum* strains have contributed to their improvement. MFA, including estimation of fluxes using labeling experiments, has elucidated the relative contribution of different pathways (e.g., Embden-Meyerhof and hexose monophosphate) under various physiological conditions and genetic backgrounds [(18) and references therein]. For example, MFA has established the relationship between the decline of oxoglutarate dehydrogenase complex and the flux distribution at the metabolic branch point of 2-oxoglutarate glutamate. This suggests that metabolic flux through anaplerotic pathways could be limiting the production of glutamate. Many of these findings have either been verified by genetic approaches or have led to a rational modification of metabolic pathways to improve the production of glutamate [(18) and references therein].

L-lysine. L-lysine production is another example of the application of labeling experiments-based MFA. Very comprehensive approaches have been used to assess all major fluxes in the central metabolism of *C. glutamicum*, which reveal patterns that can be used for designing ME strategies. In a comparison of six metabolic patterns, several metabolic fluxes that depend significantly on the physiological state of the cells were identified [(19) and references therein]. These included the coordinated flux through PPP and the tricarboxylic acid (TCA) cycle, the high capacity for the reoxidation of NADPH, and futile cycles between C3-compounds of glycolysis and C4-compounds of the TCA cycle. As an example, Figure 5.3 shows a comparison of the metabolic flux distribution between

two isogenic glutamate dehydrogenase mutants (homologous, NADPH-dependent, and heterologous, NADH-dependent) of the L-lysine producer strain *C. glutamicum* MH20-22B (20). Metabolic flux patterns revealed that the PPP flux was high only for a high demand of NADPH and a low TCA cycle flux. The heterologous, NADH-dependent, glutamate dehydrogenase mutant required more NADH, resulting in an increased TCA cycle flux and then more NADPH supplied by the isocitrate dehydrogenase step in the TCA cycle. This led to a decreased flux of the PPP due to lower NADPH requirements (TCA cycle already produced part of it). The inverse is true for the homologous, NADPH-dependent, glutamate dehydrogenase mutant. There is a higher NADPH requirement, the PPP flux is higher, and the TCA cycle flux is lower.

5.2.5 Use of LAB in the Production of Amino Acids

LAB also has been used to produce different amino acids. *Lactococcus lactis* (21) has been engineered to produce L-alanine as the only end product of fermentation (more than 99%). Rerouting the carbon flux toward alanine was achieved by expressing *Bacillus sphaericus* alanine dehydrogenase (AlaDH) in lactate dehydrogenase (LDH) deficient strains. Finally, stereospecific production ($>$ 99%) of L-alanine was achieved by disrupting the gene encoding alanine racemase.

5.3 MULTIFUNCTIONAL ORGANIC ACIDS

The ability to produce organic acids via fermentation is of great interest to the food industry due to the acids' widespread use as acidulants, food preservatives, beverage ingredients, sweeteners, and flavor enhancers.

Many bacteria, such as *E. coli*, carry out mixed acid fermentation of sugars (e.g., glucose) in which the principal products are formate (or CO_2 and H_2), acetate, lactate, succinate, and ethanol (Figure 5.4) (22). Under these conditions, anaerobic fermentative pathways have two main functions: to produce energy in an anaerobic environment via substrate level phosphorylation, and to provide a source of regeneration of NAD+, closing the redox balance. The aforementioned products can be organized in three groups according to the redox properties of the homofermentative pathway used in their synthesis: (1) net regeneration of redox equivalent by the homofermentative pathway (e.g., lactate, fumarate, and malate), (2) net production of redox equivalents by the homofermentative pathway (e.g., acetate and pyruvate), and (3) net consumption of redox equivalent by the homofermentative pathway (e.g., succinate).

In this section, I will present some examples of ME of *E. coli* for the homofermentative production of some of these organic acids, including succinate, pyruvate, lactate, and acetate. In general, all strategies have been focused on altering the carbon flux ratio at three branch points, phosphoenolpyruvate (PEP), pyruvate (PYR), and acetyl coenzyme A (AcCoA).

5.3.1 Succinic Acid

The production of succinate by several bacterial strains, including the obligate anaerobe *Anaerobiospirullum succiniciproducens*, *Actinobacillus* sp., and *Enterococcus* sp. have been reported. However, ME efforts have focused on engineering *E. coli* to produce succinate as the main fermentation product. In what follows I will summarize those results, which are also schematically represented in Figure 5.5.

E. coli wild-type strains produce succinate only as a minor product of fermentation. Genetic manipulations are required to increase succinate production and reduce byproduct formation. For example, increasing flux at the first step in the succinate branch by

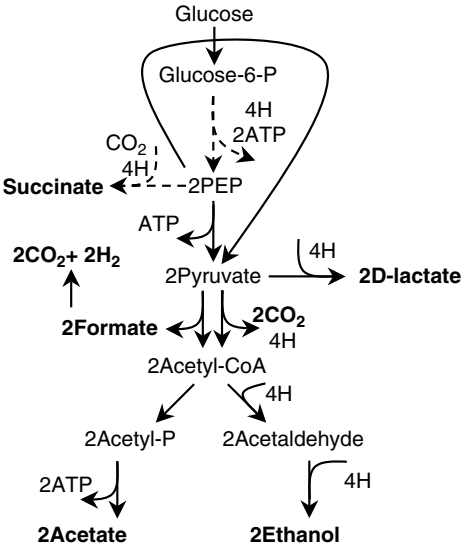

Figure 5.4 Anaerobic fermentation of glucose in *E. coli*. Only relevant central metabolic pathways have been included and it has been considered that glucose is transported into the cell only by the PEP-dependent PTS. Not all steps and metabolites are shown. Solid and broken lines represent single and multiple steps, respectively. Primary fermentation products are indicated in bold. Abbreviations, PEP, phosphoenolpyruvate.

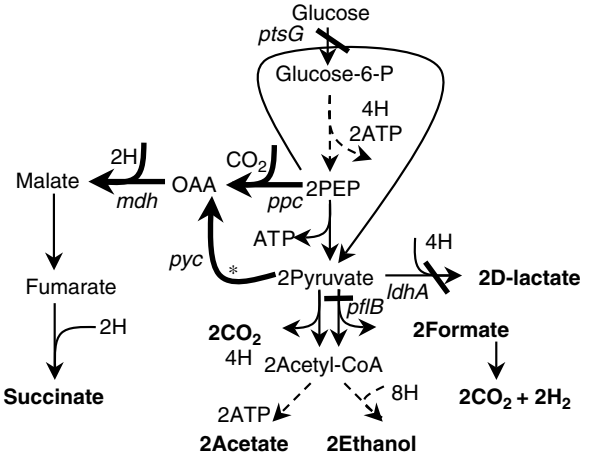

Figure 5.5 Metabolic engineering of *E. coli* to produce succinate. See Figure 5.1 for explanation of different types of lines/arrows. Genes involved in engineered steps are indicated by italics. Primary fermentation products are indicated in bold. Strategies include the blocking (genes *ldhA*, *pflB*, and *ptsG*) and amplification (genes *ppc* and *mdh*) of homologous enzymes as well as the introduction of heterologous enzymes (*R. etli pyc* gene). The asterisk (*) indicates that this step does not exist in *E. coli*. Abbreviations, *ldhA*, gene encoding D-lactate dehydrogenase; *mdh*, gene encoding malate dehydrogenase; PEP, phosphoenolpyruvate; *pflB*, gene encoding pyruvate-formate lyase; *ppc*, gene encoding PEP carboxylase; *ptsG*, gene encoding the enzyme $IICB^{Glc}$ of the PTS system; *pyc*, gene encoding *R. etli* pyruvate carboxylase.

overexpressing PEP carboxylase results in an increase in succinate percentage yield (molar basis) from 12 to 45% (23). PEP is also a required cosubstrate for glucose transport via the phosphotransferase system (PTS) in wild-type *E. coli*. Thus, another approach is to direct pyruvate to the succinate branch. This is achieved by transforming a wild-type *E. coli* strain with plasmid pTrc99A-*pyc*, which expresses *Rhizobium etli* pyruvate carboxylase. This strategy results in an increase in both succinate percentage yield (17%) and productivity (0.17 g/L/h) (24). In order to prevent the accumulation of other undesired products, mutations in genes involved in producing lactate (*ldhA*, encoding lactate dehydrogenase) and formate (*pflB*, encoding pyruvate–formate lyase) were introduced, obtaining the strain *E. coli* NZN111, that grew poorly on glucose under anaerobic conditions. When the gene encoding malic enzyme from *Ascaris suum* was transformed into NZN111, succinate percentage yield and productivity were further increased to 39% and 0.29 g/L/h, respectively (25,26). Expression of *mdh* gene encoding malate dehydrogenase also resulted in improved production of succinate by *E. coli* NZN111 (27).

Donnelly et al. (28) reported an unknown spontaneous chromosomal mutation in NZN111, which permitted anaerobic growth on glucose, and this strain was designated as AFP111. When AFP111 was grown anaerobically under 5% H_2 and 95% CO_2, a succinate percentage yield of 70% and a succinate–acetate molar ratio of 1.97 were obtained. Further improvements of succinate production with this strain included dual phase fermentation (aerobic growth for biomass generation follow by anaerobic growth for succinate production) that resulted in a succinate percentage yield of 99% and a productivity of 0.87 g/L/h (29). AFP111 mutation was mapped to the *ptsG* gene, encoding an enzyme of the PTS (30).

Gokarn et al. (31) found that the expression of *R. etli* pyruvate carboxylase (PYC) in *E. coli* during anaerobic glucose metabolism caused a 2.7-fold increase in succinate concentration, making it the major product by mass. The increase came mainly at the expense of lactate formation. However, in a mutant lacking lactate dehydrogenase activity, expression of PYC resulted in only a 1.7-fold increase in succinate concentration. An accumulation of pyruvate and NADH, metabolites that affect the interconversion of the active and inactive forms of the enzyme pyruvate formate-lyase, may have caused the decreased enhancement of succinate. The same group (32) had previously shown that the presence of the *R. etli pyc* gene in *E. coli* (JCL1242/pTrc99A-pyc) restored the succinate producing ability of *E. coli ppc* null mutants (JCL1242), with PYC competing favorably with both pyruvate formate lyase and lactate dehydrogenase. Flux calculations indicated that during anaerobic metabolism the *pyc*(+) strain had a 34% greater specific glucose consumption rate, a 37% greater specific rate of ATP formation, and a 6% greater specific growth rate than the *ppc*(+) strain. The results demonstrate that when phosphoenolpyruvate carboxylase (PPC) or PYC are expressed, the metabolic network adapts by altering the flux to lactate and the molar ratio of ethanol to acetate formation.

5.3.2 Pyruvic Acid

Several bacterial strains have been used to produce pyruvic acid via the fermentation of different sugars. These include strains of *Escherichia*, *Pseudomonas*, *Enterococcus*, *Acinetobacter*, and *Corynebacterium* (33). The most successful processes (highest yield and concentrations, and shortest fermentation times) are those involving *E. coli* strains. The main strategy used has been limiting pyruvate consumption by pyruvate dehydrogenase complex (PDH) under aerobic conditions. Considering that lipoic acid is a cofactor of PDH, a screen by Yokota et al. (34) identified a lipoic acid auxotroph, *E. coli* W1485*lip2*, which accumulated 25.5 g/L pyruvate from 50 g/L glucose at 32 hours. Pyruvate production was further improved by introducing a mutation in F_1-ATPase, obtaining strain TBLA-1 (35). Strain TBLA-1 exhibited a higher capacity for producing pyruvate, more than 30 g/L of pyruvate

were produced from 50 g/L of glucose in only 24 hours. The growth of TBLA-1 decreased to 67% of that in the parent strain, due to lower energy production (TBLA-1 is an F_1-ATPase-defective mutant). The enhanced pyruvate productivity in strain TBLA-1 was thought to be linked to increased activities of some glycolytic enzymes (36). Although there was an increase in glycolytic flux due to a decrease in ATP production (i.e., an F_1-ATPase mutation), the physiological mechanism mediating these changes was not identified. Recently, it was shown that the glycolytic flux in *E. coli* is controlled by the demand for ATP (37). By increasing the ATP hydrolysis, the glycolytic flux was increased by approximately 70%, indicating that glycolytic flux is mainly ($> 75\%$) controlled by reactions hydrolyzing ATP. In light of these results, it is clear that increased pyruvate production in strain TBLA-1 when compared to its wild type *E. coli* W1485*lip2* is due to lower ATP production in TBLA-1, which in turn is driving glycolysis and resulting in higher glycolytic fluxes.

5.3.3 Lactic Acid

Many microorganisms produce D-lactic acid (D-LAC), and some LABs, such as *Lactobacillus bulgaricus*, produce highly pure D-LAC (38). L-LAC has also been produced using other LABs, such as *Lactobacillus helveticus*, *Lactobacillus amylophilus*, and *Lactobacillus delbruekii* (39). Since LABs have complex nutritional requirements and low growth rates, and exhibit incomplete or negligible pentose utilization (40), other bacterial strains have been engineered to produce optically pure D- or L-LAC including *E. coli* (41,42), *Rhizopus orizae* (43), and *B. subtilis* (44). Chang et al. (41) engineered *E. coli* to produce optically pure D- or L-LAC. A *pta* mutant of *E. coli* RR1, which was deficient in the phosphotransacetylase of the Pta-AckA pathway, was found to metabolize glucose to D-LAC and to produce a small amount of succinate byproduct under anaerobic conditions. An additional mutation in *ppc* (encoding PPC) made the mutant produce D-LAC like a homofermentative LAB. In order to produce L-LAC, a nonindigenous fermentation product, an L-lactate dehydrogenase gene from *Lactobacillus casei* was introduced into a *pta ldhA* strain, which lacked phosphotransacetylase and D-LAC dehydrogenase. This recombinant strain was able to metabolize glucose to L-LAC as the major fermentation product, and produced up to 45 g/L of L-LAC. Zhou et al. (42) constructed derivatives of *E. coli* W3110 capable of producing D-LAC in a mineral salts medium. They eliminated competing pathways by chromosomal inactivation of genes encoding fumarate reductase (*frdABCD*), alcohol/aldehyde dehydrogenase (*adhE*), and pyruvate formate lyase (*pflB*). D-LAC production by these new strains approached the theoretical maximum yield of two molecules per glucose molecule and a chemical purity of D-LAC of ~98% with respect to soluble organic compounds. The cell yield and LAC productivity were increased by a further mutation in the acetate kinase gene (*ackA*). The aforementioned ME strategies used to engineer homolactic pathways in *E. coli* are summarized in Figure 5.6.

5.3.4 Acetic Acid

Acetic acid obtained through fermentation is mainly used in the food market (vinegar, meat preservative). Microorganisms currently used in its production are *Saccharomyces cerevisiae*, *Acetobacter aceti*, and *Clostridia* species. *E. coli* W3110 was recently engineered to produce acetic acid from glucose (45). The resulting strain (TC36) converted 60 g/L of glucose into 34 g/L of acetate in 18 h. Strain TC36 was constructed by sequentially assembling deletions that inactivated oxidative phosphorylation (Δ*atpFH*), disrupted the cyclic function of the tricarboxylic acid pathway (Δ*sucA*), and eliminated native fermentation pathways (Δ*focA-pflB,* Δ*frdBC,* Δ*ldhA,* and Δ*adhE*). These mutations minimized the loss of substrate carbon and the oxygen requirement for redox balance. Although TC36 produces only four ATPs per glucose, this strain grows well in a mineral salts medium and

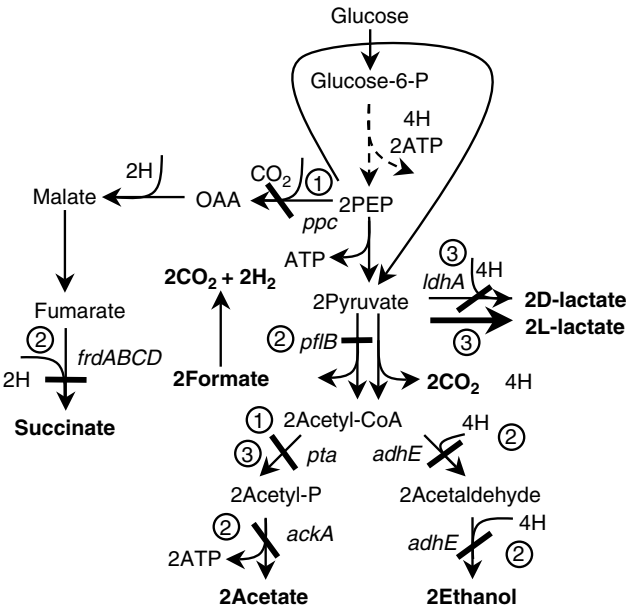

Figure 5.6 Metabolic engineering of *E. coli* to produce D- and L-lactate. See Figure 5.1 for explanation of different types of lines/arrows. Genes involved in engineered steps are indicated by italics. Primary fermentation products are indicated in bold. 1- Engineering a homo-D-lactic pathway by introducing mutations in *pta* and *ppc* genes; 2- Engineering a homo-D-lactic pathway by introducing mutations in *frdBC*, *ackA*, *adhE*, and *pflB* genes; 3- Engineering a homo-L-lactic pathway by introducing mutations in *pta* and *ldhA* genes and expressing an L-lactate dehydrogenase gene from *L. casei*. Abbreviations, *adhE*, gene encoding acetaldehyde/alcohol dehydrogenase; *ackA*, gene encoding acetate kinase; *frdABCD*, operon encoding fumarate reductase; *ldhA*, gene encoding lactate dehydrogenase; PEP, phosphoenolpyruvate; *pflB*, gene encoding pyruvate–formate lyase; *ppc*, gene encoding PEP carboxylase; *pta*, gene encoding phosphotransacetylase.

has no auxotrophic requirement. Glycolytic flux in TC36 (0.3 μmol·min^{-1}·mg^{-1} protein) was twice that of the parent. Higher flux was attributed to a deletion of membrane-coupling subunits in $(F_1F_0)H^+$-ATP synthase that inactivated ATP synthesis while retaining cytoplasmic F_1-ATPase activity. The oxygen requirements of this system are energy intensive, so in terms of commercial production of acetate it would be highly desirable to have an anaerobic system able to efficiently produce acetic acid. Our laboratory is currently engineering *E. coli* to produce acetate as the main fermentation product under anaerobic conditions (data not published). The general strategy is based on first eliminating competing pathways (by inactivating correspondent genes) in order to redirect the carbon flux toward the synthesis of acetate, and then transforming the engineered pathway into a viable alternative for cell growth (by introducing modifications that will balance consumption and production of NADH).

5.4 VITAMINS

Vitamins are nutraceuticals or functional foods. They serve as the cofactors of many of the enzymes involved in several metabolic reactions, and so are essential components in the human diet. In this section I will give some examples of using ME to produce three vitamins (riboflavin, folate, and ascorbic acid) in bacterial strains.

5.4.1 Riboflavin (Vitamin B2)

Both *B. subtilis* and *Lac. lactics* have been engineered to produce riboflavin. In *B. subtilis* overexpression of the *rib* genes (involved in the synthesis of riboflavin), which are organized in a cluster (46), is achieved by replacing the two regulated promoters with constitutive ones derived from a phage (47). Although multiple copies of this four gene construction were inserted at two different sites in the genome, a separate overexpression of *ribA* was necessary to reach maximum productivity (48). The *ribA* gene encodes a bifunctional protein with dihydroxy–butanone phosphate synthetase activity at the N-terminal, and GTP cyclohydrolase II activity at the C-terminal. This showed that the initial steps of riboflavin synthesis limited productivity in the last published stage of strain improvement. A metabolic analysis of the wild-type and riboflavin-producing *B. subtilis* strains found that the flux of the oxidative branch of the pentose phosphate pathway was increased in the production strain (49). Therefore, this branch may become rate limiting and new ME strategies may be needed for future strain improvement. *Lac. lactis* is also being engineered to produce riboflavin by overexpressing the gene (*ribA*) encoding the enzyme (GTP cyclohydrolase) catalyzing the first reaction for its synthesis from GTP. This enzyme had been previously reported to limit flux (48) and overexpression of *ribA* resulted in a three-fold increase in riboflavin production (50).

5.4.2 Folate (Vitamin B11)

Lac. lactis has been engineered to produce folate (50). Strategies include the expression of several genes involved in the biosynthesis of folate from GTP, either individually or in combination, and the expression of heterologous γ-glutamyl hydrolase (from humans and rats). These approaches have resulted in three- to six-fold increases in the production of folate and an alteration in the folate spatial distribution (i.e., a shift from mainly intracellular to extracellular accumulation).

5.4.3 L-Ascorbic Acid (Vitamin C)

Almost all biological processes for synthesizing L-ascorbic acid end with the synthesis of 2-keto-L-gulonic acid (2-KLG), which is later converted into ascorbic acid by conventional chemical processing technology (i.e., esterification and lactonization). Therefore, efforts have been focused on engineering strains capable of efficiently producing 2-KLG from different sugars. Two strains of *Gluconobacter oxydans* were engineered to convert sorbitol into 2-KLG. Genes encoding the enzymes sorbitol dehydrogenase and sorbose dehydrogenase were cloned from *G. oxydans* T-100 into *G. oxydans* G624, allowing the production of 2-KLG in three steps (51). An *Erwinia herbicola* has been engineered to produce 2-KLG from glucose in a single fermentation step (52). *E. herbicola* naturally produces 2,5-diketo-D-gluconic acid (2,5-DKG) via glucose oxidation, but lacks the enzyme 2,5-DKG reductase, which can convert 2,5-DKG into 2-KLG. Therefore, *E. herbicola* was engineered by expressing the gene encoding 2,5-DKG reductase from *Corynebacterium* sp., resulting in a recombinant strain capable of converting glucose into 2-KLG in a single fermentation step. This process has been further simplified and 2-KLG concentrations $>$ 120 g/L have been achieved (53).

5.5 CARBOHYDRATES

Several nondigestible polysaccharides have a positive effect on the development of beneficial intestinal microflora, and therefore are known by their function as prebiotics

(i.e., nondigestible food ingredients that provide specific nutrients to beneficial bacteria hosted in the colon). Among them are fructo-oligosacharides, galacto-oligosacharides, gluco-oligosacharides, transgalacto-oligosacharides, isomalto-oligosacharides and xylo-oligosacharides (50). LABs are a good source of nondigestible polysaccharides, mainly exopolysacharides (EPS), which are also recognized by their contribution to the texture, mouth feel, taste perception, and stability of the final food product (54). Based on the available genetic information on genes required for EPSs biosynthesis in LABs, heterologous production of EPSs has been achieved in a LAB strain that did not have the capacity to produce them (55). A similar experiment has shown that EPSs with different compositions can be produced from expression of the same cluster of genes due to either selectivity in the export and polymerization system or limitation in the supply of precursors (56). Van Kranenburg et al. (57) have shown that EPS production in *Lac. lactis* can be increased by overexpressing the *epsD* gene, encoding a priming glucosyltransferase. I will give two other examples of using ME strategies to improve EPS production and modify EPS composition in *Lac. lactis*. Looijesteijn et al. (58) showed that overexpression of the *fbp* gene encoding fructose bisphosphatase resulted in increased *Lac. lactis* growth and EPS synthesis using fructose as a sugar source. In addition, Boels et al. (59) studied the UDP-glucose pyrophosphorylase (*galU*) and UDP-galactose epimerase (*galE*) genes of *Lac. lactis* MG1363 to investigate their involvement in the biosynthesis of UDP-glucose and UDP-galactose, which are precursors of glucose- and galactose-containing EPS in *Lac. lactis*. Overexpression of both genes increased the intracellular pools of UDP-glucose and UDP-galactose. These examples clearly illustrate the role ME plays (and will play in the future) in the bacterial production of polysaccharides.

5.6 BACTERIOCINS

One of the most important properties of a starter culture is its capacity to synthesize antimicrobial metabolites, including bacteriocins, which, in turn, can help improve the quality of fermented products (i.e., control of pathogens, extension of shelf life, and improvement of sensory qualities). For example, ability of LAB to act as a preservative in foods is partially attributed to the production of bacteriocins [for a review of bacteriocins produced by LAB with potentials as biopreservatives in foods see O'Sullivan et al. (60)]. Bacteriocins are a diverse group of ribosomally synthesized antimicrobial proteins or peptides, some of which undergo posttranslational modifications (Rodriguez et al. (61)). Bacteriocins can be incorporated into food after they are produced in an individual process or by using live cultures that produce bacteriocins *in situ* in the food. The second option seems to be more cost effective and acceptable (i.e., most strains have a GRAS status). A potential problem associated with the use of bacteriocins in food preservation is the development of resistant populations of pathogenic bacteria. ME plays a central role in solving this problem by enabling the creation of multiple bacteriocin producers (62,63). Horn et al. (64) took advantage of the similarities in the production and secretory systems of pediocin PA-1, from *Pediococcus acidilactici*, and lactococcin A, from *Lac. lactis* bv. diacetylactis WM4. By using the lactococcin$^-$A secretory system, they engineered a lactoccocus strain for expressing and secreting pediocin PA-1. This heterologous expression system has been used to coproduce enterocin-A and pediocin PA-1 (62), and pediocin PA-1 and nisin (63). Recently, O'Sullivan et al. (60) have examined the coproduction of lacticin 3147 and lacticin 481. Rodriguez et al. (61) recently published an excellent review of the heterologous production of bacteriocins by LAB. In the future, ME analytical tools (e.g., MFA) could play an important role in improving the heterologous production of bacteriocin in bacteria.

This assertion is based on its contribution to the study of the synthesis of heterologous proteins in yeast (65).

5.7 LOW CALORIE SUGARS

Low calorie sugars, like mannitol, sorbitol, tagatose, and trehalose, contribute to weight loss, which is one reason there is such a high consumer demand for them. Tagatose is a low calorie sweetener that is poorly degraded by the human body. It is considered both a prebiotic and an antiplaque agent (www.tagatose.dk). Recently, *Lac. lactis* has been engineered to produce tagatose by disrupting the *lacC* and/or *lacD* genes, which resulted in the production of either tagatose 6-phosphate or tagatose 1,6-diphosphate (66). Further genetic modifications resulted in the production of tagatose 1,6-diphosphate as the sole end product. Current efforts are focused on the dephosphorylation of tagatose 1,6-diphosphate and excretion of the final product, tagatose.

5.8 AROMA COMPOUNDS

Diacetyl is an important flavor compound in many dairy products like butter, buttermilk, and cheeses (it provides a buttery flavor). *Lac. lactis* has been engineered to synthesize diacetyl as the main fermentation product (67). Efficient diacetyl production resulted from inactivation of the *aldB* gene (encoding α-acetolactate decarboxylase) and overproduction of NADH-oxidase activity as illustrated in Figure 5.7. This approach resulted in the conversion of 80% of the carbon source into diacetyl. Another important group of aroma compounds is obtained from enzymatic degradation of amino acids including isovalerate, isobutyrate, phenylacetate, phenylacetaldehyde, and indole. Rijnen et al. (68) have shown that overexpression of a heterologous glutamate dehydrogenase (GDH) gene in *Lac. lactis*

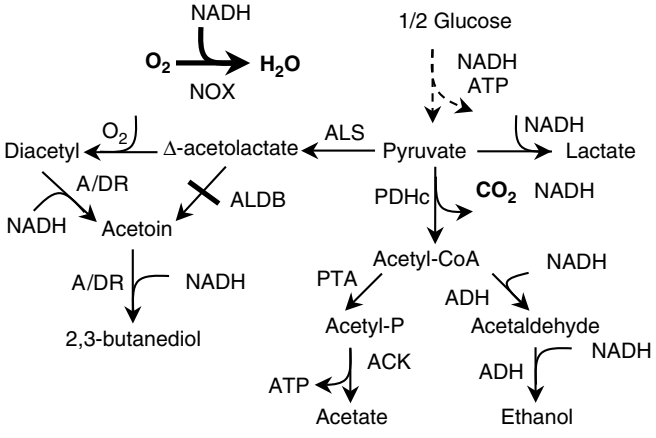

Figure 5.7 Metabolic engineering of *Lac. lactis* to produce diacetyl (ALDB-deficient and NOX overexpressed). Adapted from Hugenholtz et al. (67). See Figure 5.1 for explanation of different types of lines/arrows. Enzymes involved in reactions of interest are indicated. Abbreviations, ACK, acetate kinase; ADH, aldehyde/alcohol dehydrogenase; A/DR, acetoin/diacetyl reductase; ALDB, α-acetolactate decarboxylase; ALS, α-acetolactate synthase; NOX, NADH oxidase; PDHc, pyruvate dehydrogenase complex; PTA, phosphotransacetylase.

increased the conversion of amino acids into aroma compounds. Therefore, instead of adding α-ketoglutarate to cheese, a GDH-producing lactococcal strain could be used to enhance amino acid degradation in aroma compounds.

5.9 FUTURE TRENDS AND POTENTIALS

In the foreseeable future, ME will continue to play a central role in the use of bacteria to produce food ingredients. One potential area for the application of ME is the removal of undesirable sugars present in many foods. A typical example is lactose, which is present in liquid dairy products. Many people are lactose-intolerant and cannot consume products in which lactose is present. Engineering LAB to obtain starter cultures with elevated β-galactosidase activities has been proposed as a way to eliminate lactose (50). Raffinose is another example. Due to the absence of α-galactosidase, it cannot be degraded intestinally by humans. Consuming it causes intestinal disturbances. Engineering LAB to produce high levels of α-galactosidase and using it as starter cultures for removing raffinose has been proposed as a good solution to this problem (50). As a first step, the gene *melA* encoding α-galactosidase from *Lactobacillus plantarum* has been cloned (69) and is being expressed in *Lac. lactis* (50).

Energy metabolism is beginning to attract attention as a new target for ME, especially for engineering central metabolic pathways and transport systems. It was recently shown that an increase in ATP hydrolysis results in an increase in the glycolytic flux of *E. coli* (~70%), indicating that glycolytic flux is mainly (>75%) controlled by reactions hydrolyzing ATP (37). Therefore, one could engineer energy metabolism in order to improve the synthesis of products, such as organic acids, for which the glycolytic flux is a determinant (i.e., the introduction of an independent ATP "sink" would increase the glycolytic flux and the synthesis of the organic acid). One could even think that a similar approach will also be valid for synthesizing secondary metabolites whose precursors are provided by the glycolytic pathway. A second approach points toward a completely different direction, the creation of an energy surplus (in contrast to the energy "sink" created in the previous approach). For example, let us consider that the excretion of a certain product P (e.g., an amino acid) is an energy-requiring process. If a condition of energy surplus is created, cells will use any energy consuming process to dissipate the excess of energy, and therefore the secretion of product P will be stimulated.

The existence of sequenced genomes for several bacteria involved in producing food ingredients (e.g., *Lac. lactis, C. glutamicum, B. subtilis, E. coli*) will dramatically impact ME opportunities. Once genome sequences are available, technologies such as cDNA microarrays can be used to simultaneously monitor and study the expression levels of individual genes at genomic scale (known as the field of transcriptomics). This technology has already played an important role in understanding bacterial metabolism under a great variety of conditions, and in the improvement of numerous bacterial strains (70–74). However, the main contributions from the area of functional genomics are still to come and will result from the combined use of technologies that permit large-scale study of cell functioning and its interaction with the environment (i.e., combined analysis using genomic (DNA), transcriptomic (RNA), proteomic (protein), metabolomic (metabolites), and fluxomic (fluxes/enzymes) information). The era of functional genomics will contribute to an improved understanding of the molecular mechanisms underlying the relationships between microorganism and environment and in that way will establish the link between genotype and phenotype. Thus, in the future, functional genomics is expected to play a large role in the development of bacterial strains for the food industry.

Technologies Used for Microbial Production of Food Ingredients

Anthony L. Pometto III and Ali Demirci

CONTENTS

6.1 INTRODUCTION

The goal of this chapter is to supplement the industrial microbiology components in the first edition of *Food Biotechnology* by Knorr (1) and to present an updated overview of various technologies currently under investigation and employed by the food industry for the production of microbial food ingredients. For the detailed description of industrial microbiology principals, Demain and Davies *Manual of Industrial Microbiology and Biotechnology*, 2nd edition (2) is highly recommended.

For the food industry, the bottom line is cost. They are selling commodity products (food) with various levels of preconsumer processing. The goal is always to produce the most nutritious and safe product at the lowest possible cost.

For centuries microorganisms have been employed for the production of fermented food products (i.e., cheese, soy sauce, sauerkraut, wine, and bread). The consumption of some live microbial cultures (probiotics) has proven to provide a health benefit to humans and animals (3,4). Some foods containing live cultures are yogurt, buttermilk, and acidophilus milk. These microbial fermented food products also have an extended shelf-life

compared to the perishable starting raw material. Thus, microorganisms not only provide a nutritional benefit to humans but act to extend the shelf-life of the food supply.

Microorganisms employed by the food industry include bacteria, yeasts, and molds. These microorganisms have several morphological and physiological differences. Morphologically bacteria are small and difficult to remove, yeasts are larger and will sometime settle out of solution, whereas molds are filamentous and are typically removed by filtration. Physiologically they differ in pH preferences (yeasts and molds prefer a lower pH than bacteria), nutrient requirements (different concentrations and types of nitrogen and other trace elements), growth rates (bacteria grow much faster than yeasts and molds), and more. Thus, different culture media, fermentation methods, and product recovery methods are required depending on the microbial system being cultured.

6.2 MICROORGANISM SELECTION AND DEVELOPMENT

Microorganisms are the biocatalysts that produce and maintain a host of enzymatic pathways that are used to produce the food component of interest. The characteristics of a good industrial microorganism for the production of food ingredients are (1) it must be effective in producing large quantities of a single product, (2) it can be efficiently isolated and purified, (3) it is easy to maintain and cultivate, (4) it is genetically stable, (5) it grows best in an inexpensive culture medium, and (6) it is safe for human consumption. The first step is to isolate the hardiest starter culture possible, then to begin strain improvements via classical mutagenesis or genetic engineering.

A classic example would be the production of L-phenylalanine for the artificial sweetener aspartame (NutraSweet® J.W. Childs Equity Partners II L.P.), which is a dipeptide of L-phenylalanine and L-aspartic acid. When NutraSweet first entered the market in 1981, the L-phenylalanine supply became the bottleneck for production. L-Phenylalanine, L-tyrosine, and L-tryptophan are produced via the shikimic acid pathway in all organisms. To develop a bacterium which over produced L-phenylalanine, first classical chemical mutagenesis of an L-tyrosine auxotroph of *Corynebacterium glutamicum* was employed using -phenylalanine analog resistance in an effort to reduce end product inhibition, and L-tyrosine production (5). Analogs such as *p*-aminophenylalanine, *p*- and *m*-fluorophenylalanine, and β-2-thienylalanine were incorporated into the cellular protein thus poisoning the cell. To combat this poison, surviving mutants must overproduce L-phenylalanine, thus neutralizing the toxic effects of the analogs. This process was repeated several times with mutants resistant to increasing concentrations of analogs. The final analog resistant bacterium selected by Hagino and Nakayama (5) produced 9.5 g/L of L-phenylalanine.

The over producing bacterium was then transformed with plasmids containing L-phenylalanine analog resistant chorismate mutase and prephenate dehydratase genes (6). These are two key enzymes in the shikimic acid pathway for L-phenylalanine production. Except for constitutive enzymes, most enzymes in the cell have a short half life in the cell. Thus, an increase in key enzyme concentrations and residence time in the cell will also increase production. Ozaki et al. (6) transformates produced 19.0 g/L of -Lphenylalanine, thus, illustrating how classical mutagenesis and molecular genetic techniques are employed to further enhance production of some desired metabolites for the food industry.

Another alternative method was whole bioconversion developed by Yamada et al. (7) which produced L-phenylalanine from trans-cinnamic acid via L-phenylalanine ammonia lyase (PAL) reversal in *Rhodotorula glutinis*. In the presence of concentrated ammonium hydroxide, the PAL reversal demonstrated a 70% conversion yield which produced 17.5 g/L of L-phenylalanine. By utilizing a whole cell bioconversion process, no enzyme

purification step was needed and the enzyme proved to be more stable within the yeast under the harsh conditions employed. This process was used to produce some of the initial L-phenylalanine used for the production of NutraSweet. Eventually, however, production by the genetically engineered bacterium exceeded the levels in fed-batch fermentation, which did not involve caustic chemicals, and thus, became the method of choice. L-Phenylalanine purification is performed by ion exchange chromatography for all methods.

The genetic stability of cultures requires minimum culture transfers and long term storage capabilities. Fermentation media are inoculated from working cultures which are produced every few months from master cultures depending on the microorganism. The most common procedures for long term storage are freeze drying ($<-18^{\circ}C$) and ultra-low temperature storage ($-70 - -80^{\circ}C$). Freeze drying requires a cryoprotectant, such as sterile skim milk, followed by freeze drying and vial sealing under a vacuum (2). Sealing under nitrogen gas can also help to stabilize the culture and extend the shelf life. Ultra-low temperature storage is in a rich culture medium with 20% sterile glycerol. Some cultures are sensitive to freeze drying, thus, ultra-low is the most common method employed today, because of long-term culture viability. The risk is loss of electrical power and refrigeration problems.

Suspended cell cultures or spore suspensions are used as inocula for these industrial scale fermentations. Purity is constantly checked until inoculation. For suspended cell inoculation the sequence employed would be culture slant, shake-flask culture, benchtop fermentor, pilot-scale fermentation, then into full scale fermentation. Many fungal fermentations, such as citric acid and soy sauce fermentations, required a suspension of viable fungal spores as the inoculum. These spore suspensions are generated on large agar trays, and then are aseptically transferred into culture bottles suspended in sterile water or saline (2).

Microbial systems frequently constitute efficient mechanisms for the production of nutritionally important ingredients at a relatively low cost, for example, the production of selenomethione in yeast. A slight modification in the yeasts culture medium will force the yeast to substitute the sulfur group in methionine and cysteine with a selenium in standard fed-batch fermentation (8,9). To identify this medium change, Demirci and Pometto (8) developed a gradient delivery unit producing a gradient of sodium selenite or sodium selenate in a continuous bioreactor (Figure 6.1). It has been shown that selenium has several health benefits (10) including a cancer-protective effect (11), and a profound effect on the survival of HIV-infected patients (12).

Furthermore, microbial systems are ideal for the production of essential micronutrients such as amino acids, vitamins, and enzymes, and bulk ingredients such as organic acids and alcohols, whole cell flavor enhancers, and polysaccharides.

6.3 CULTURE MEDIA AND UPSTREAM COMPONENTS

The ideal culture medium will use inexpensive components to supply their complex nutrient requirements. Miller and Churchill (13) provide an excellent summary of inexpensive media components and their makeup. These ingredients are crop, animal, marine or yeast based components. The culture medium alone can represent 30 to 70% of the fermentation production costs. Slight changes in medium micronutrients can have a major impact on the fermentation (14,15). Thus, the food industry demands a consistent product from suppliers of these complex components. Failure to provide a consistent product will eliminate the commercial use. What decides the culture medium makeup? Essentially, it is the nutritional requirements of the microorganism of choice and its ability to biosynthesize essential elements such as amino acids, vitamins, lipids, and carbohydrates. For example, bacteria and yeast are high in protein (40–50%), whereas molds are not (10–25%). Yeast

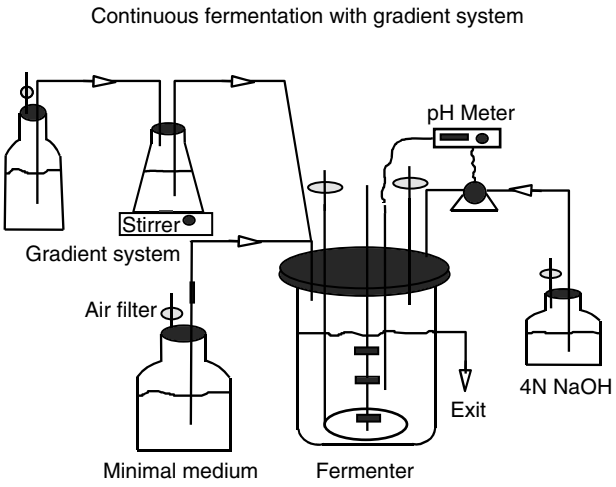

Figure 6.1 Continuous bioreactor gradient delivery system design used for developing the production protocols for selenomethionine production in yeast.

can generally grow in a minimal medium, whereas lactic acid bacteria, essential for the fermented dairy products, require a host of micronutrients to grow.

Each microorganism has different micronutrient requirements. Typically the exact micronutrient which benefits the fermentation that is being supplied by the complex nutrient employed is unknown. Generally it involves specific amino acids, vitamins, trace elements, and lipids. Furthermore, the concentration ratio of carbohydrate to nitrogen and phosphorous has a dramatic impact on microbial growth. Carbon–nitrogen imbalances can result in the production of other byproducts such as extracellular polysaccharide, and fermentation end products such as ethanol. In the case of ethanol production in yeast, excess glucose in the presence of oxygen will direct yeast to produce ethanol. This is called the Crabtree effect (16,17). Yeast cells typically consist of 48% carbon and 8% nitrogen on a dry weight basis. When the C:N ratio is 10:1, yeasts grow aerobically consuming little substrate while producing maximum cell mass, CO_2 and H_2O, but when the C:N ratio is 50:1 yeasts grow anaerobically, consuming much substrate while producing little cell mass, and much CO_2 and ethanol. This difference in yeast growth is also called the Pasteur effect (18).

Why the increase in industrial microbiology fermentation processes over the past 20 years? It is the result of the corn syrup sweetener industry and computer technology. Corn is 70% starch, and when dried to $<$19%, it can be stored for more than two years. Annually 10 billion bushels of corn are produced in the Unites States of America. Thus, the liquefaction of corn starch to glucose syrups for the production of high fructose corn sweeteners represents a consistent, low cost supply of substrate for most industrial microbiology fermentations. Not only is glucose produced, but customized substrates can be also produced. For example, corn syrups containing 19% dextrose, 14% maltose, 12% maltotriose, and 55% higher saccharides are used to control microbial growth rates and biological heat production in many fermentations. Thus, glucose is the platform chemical used for the microbial production of organic acids, amino acids, vitamins, and more. In fact some food grade fermentation facilities have located adjacent to a corn sweetener facility to permit glucose syrup to be piped directly to their fermentors. Glucose corn syrup is also shipped via truck or rail cars as liquid or dried product.

Furthermore, the advent of computer process controls of industrial scale fermentors has removed many of the fears associated with commercial scale fermentation by providing

reliable and easy to operate dissolved oxygen, pH, foam, temperature, and sterilization controls of the process. Sirakaya et al. (19) described fermentation software to monitor and control the utilization fermentation process.

6.4 BIOREACTOR MONITORING SYSTEMS AND DESIGN

The stirred tank bioreactor design is the most common fermentor and consists of agitator, baffles, aeration sparger for aerobic culture growth, sterilizable monitoring probes for pH, dissolved oxygen, temperature, and antifoam, filling and draining ports, and often culture medium sterilization capabilities in the reactor tank. Reactor agitation is essential for temperature control, pH adjustments, oxygen absorption into the liquid medium, overall culture health, and mixing of any required additions of substrate, and nutrients. Typical commercial reactor working volumes for food grade ingredients are 5,000 to 40,000 gallons.

Fermentation health requires real time monitoring system. Microbial growth can be monitored via several methods. The most common method is indirect measurement of biomass by absorbance of the fermentation broth at 620 nm by using a spectrophotometer. The measured absorbance values can then be used to estimate biomass concentrations by using a standard curve. Standard curves are developed by collecting fresh log phase cells via centrifugation, washing cells with water or 0.1 M ammonium acetate pH 7.0 buffers, then serially diluting the pellet (20). Absorbance for each dilution is then determined spectrophotometrically at 620 nm. The actual dry weight biomass (g/l) is determined for each dilution via direct biomass measurement after oven drying of each dilution in preweighed boats at 70°C for 24–36 hr. This needs to be performed in at least replicates of three. By washing biomass with water, any influence of culture medium on dry weights can be eliminated or minimized. Finally, a standard curve can be constructed by plotting absorbance versus actual dry biomass weight (g/l). This method allows for quick, reliable, and easy conversion of absorbance to dry biomass (g/L).

For determining microbial health, viable cell counts can be rapidly performed by using an EPICS XL-MCL flow cytometer (Beckman-Coulter, Miami, FL) in conjunction with the Live/Dead BacLight™ bacterial viability test kit (Molecular Probes, Eugene, OR) (21). BacLight uses a mixture of Syto 9 fluorescence, which is measured as a log FL1 (525 nm) signal, and the propidium iodide fluorescence which is measured as a log FL4 (675 nm) signal. A two color histogram is collected with gating on the bacteria only population from the two parameter light scatter distribution and is used for the analysis of green only (live bacteria), red only (dead bacteria), and both colors (stressed bacteria).

Substrate consumption and product formation rates can be monitored by high pressure liquid chromatography (HPLC) or by membrane bound enzymes biosensors, which requires 20 and 1 min to run, respectively. HPLC analysis is time consuming, but the concentration of multiple metabolites can be monitor simultaneously. HPLC does not provide real time feedback on the health of the fermentation, and it has long sample preparation and run times. In contrast, membrane bound enzyme biosensors such as YSI 2700 select analyzer (Yellow Springs Instruments, Yellow Springs, OH) can analyze a sample in 1 min. However, these units are restricted by the availability of substrate specific oxidases which generate H_2O_2, the measurable product by their electrode. Some compounds currently measurable are glucose, ethanol, maltose, lactic acid, and lysine. Sample preparation is simply filtration (0.45 :m) and dilution with water if the value falls outside the instrument window.

Organic acid production can be continuously monitored via alkali addition rates for pH control. Alkali consumption can be easily monitored by feeding alkali solution from a sterile burette (22). Microbial respiration for aerobic cultures can be continuously

monitored via dissolved oxygen probe or the concentration of CO_2 in the exit gas, which can be monitored via off gas analyzers or simply via alkali (4 N NaOH) traps followed by pH titration. However, more technologies are needed to acquire real time measurements of microbial growth, ensuring optimal fermentation time, and product formation in the shortest time possible.

For rapid analysis of biomass, substrate and product concentrations without any sample preparation, Fourier transform mid infrared (FT-MIR) spectroscopy has been successfully utilized for lactic acid (23) and ethanol (24) fermentation. Calibration models have been developed by using principle least square (PLS) and principle component regression (PCR) on suitable spectral wavenumber regions. This calibration model is then used for unknowns. The advantage of this system is that not only no sample preparation required, but it also provides analysis for substrate, product and biomass at the same time. This method can be used for online, real time analysis for monitoring and process control purposes.

For aerobic culture fermentation, house air is generally supplied under pressure. Oxygen transfer into the culture medium depends on the air bubble residence time in the culture medium and bubble size. The smaller the air bubbles the greater the O_2 transfer. Thus, all stirred tank reactors have aeration spargers that generate bubbles right beneath the first agitator blade. The exiting air bubble collides with the standard flat Rashton turbine agitator blade which strikes the bubbles hard and fast as they leave the sparger generating smaller air bubbles for improved oxygen transfer. Many commercial fermentations then follow up the agitator shaft with a series of down draft marine agitator blades, which look like a motor boat propeller (Figure 6.2). This series of down draft marine blades push the air bubble back down as it migrates up the reactor. This increases gas bubble residence time in the liquid medium before exiting out the top. In some fermentations, the rate limiting

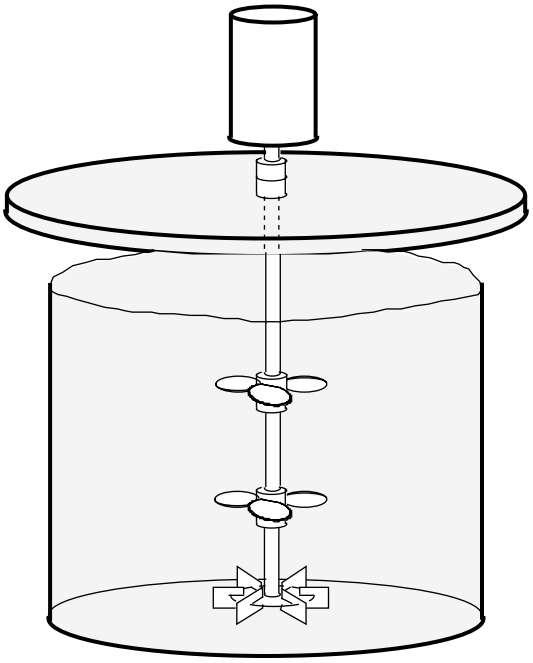

Figure 6.2 Diagram of stirred tank reactor with Rashton turbine agitator blade at the reactor bottom to break up air bubbles followed by a series of down draft marine blades to increase bubble residence time in the culture medium.

substrate will be oxygen. Thus, along with the series of down draft marine agitator blades a supply of pure oxygen may be needed. Pilot scale recombinant *Pichia* fermentations often require pure oxygen supplements to ensure optimal growth.

It is obvious that each microorganism differs in oxygen uptake rate (OUR). Therefore, oxygen transfer rates (OTR) (the rate of oxygen transfer from bubble to fermentation medium) must be equal to or higher than OUR. Maximum OTR can be calculated by using the following equation:

$$\text{OTR (mg } O_2\text{/min)} = k_L a\, C_L^*\, V_L$$

where C_L^* = Equilibrium dissolved oxygen level (mg O_2/L), $k_L a$ = Mass transfer coefficient (min−1), and V_L = Liquid volume in tank (L).

Thus, $k_L a$ is a critical parameter affecting OTR and the desired dissolved oxygen concentration in a fermentation broth during fermentation, and $k_L a$ can be determined experimentally. Briefly, the percentage dissolved oxygen (%DO) level is reduced to almost zero by sparging nitrogen into the culture medium. Then, air or oxygen gas is sparged at the desired temperature, agitation, and aeration conditions. Percent DO values are recorded over time until %DO reaches to saturation level. After converting %DO values into dissolved oxygen concentrations (C_L), plotting ln ($C_L^* - C_L$) versus time gives a straight line with a negative slope which is equal to "$-k_L a$". By knowing $k_L a$, one can calculate OTR with the given aeration and agitation. If OTR is less than OUR, some changes can be implemented to improve OTR, such as increasing aeration rate or agitation. Even utilization of various types of propellers can be compared by calculating OTR under each condition.

Agitation and aeration of stirred tank fermentors may also generate foam, which is the entrapment of gas in lipid, polysaccharide, or protein matrix (25). If not controlled, a foam buildup can literally empty the reactor. Mechanical foam breakers are like giant fans which physically break the foam and blow it back down. Mechanical foam breakers have their limitations and ultimately food grade antifoams are employed to control culture broth foam. A list of common antifoams can be found in Hall et al. (25).

Modification to this basic bioreactor design occurs from specific microbial needs. For example, if your production microorganism is sensitive to agitator shear then an air lift bioreactor is employed. Air lift bioreactors consists of a central or an external draft tube whereby air bubbles passing up these tubes generate convection mixing of the medium (26). Many fungal fermentations require the production of fungal balls for maximum product formation. These fungal balls are very sensitive to the shear caused by the agitator blades. For example, *Aspergillus niger* citric acid fermentation requires a defined medium with specific concentrations of trace elements (i.e., copper, manganese, magnesium, iron, zinc, and molybdenum). The bioreactor is typically lined with glass to prevent the addition of any stray trace elements. A fungal spore suspension is used as an inoculum, and mycelium, for optimal production rates, consists of very small solid pellets, or spheres which require a bioreactor with minimum shear. Throughout the entire fermentation period, the minimum dissolved oxygen concentration of 20–25% of saturation is required (27). Thus, tall air lift fermentors are the bioreactors of choice for these types of fermentations.

Biological heat can also be a problem. Bacteria, yeast, and molds will generate different levels of biological heat because their growth rates are so different. All bioreactors require some kind of jacketed cooling and heating system. Also, the time of year and location of the facility will also dictate the level of cooling required. Biological heat is directly related to growth rates. The faster the growth rate the more heat generated. Thus, a rate limiting substrate can be used to control microbial growth. One example is the use of a substrate containing mono, di, oligo, and poly saccharides. For example, a liquefied corn starch described above containing 19% dextrose, 14% maltose, 12% maltotriose, and 55%

higher saccharides is commonly used to control microbial growth rates. Enzymatic hydrolyses of the di, tri, and oligo saccharides will dictate the level of available glucose in the fermentor, and thus, control microbial growth rates.

6.5 FERMENTATION TYPES EMPLOYED: THE ACTUAL PRODUCTION PROCESS

The work horse of the industry is batch and fed-batch fermentation. Batch fermentations are closed fermentations (28). The fermentation sequence starts with medium sterilization, reactor inoculation [1 to 2% (v/v) typically], incubation for complete microbial growth cycle with lag, log, and stationary phases, fermentation termination, draining the reactor for product recovery down stream, cleanup of the reactor, and starting over. Percentage yield is calculated by taking the concentration of the product formed (g/l) divided by the concentration of substrate consumed (g/l) times 100%, whereas productivity is a measure of the product formation rates. It is calculated by dividing the product concentration (g/l) by the fermentation time (hours); thus, it is presented in g/l/hr.

In fed-batch fermentation, additional carbohydrate is supplied to the batch fermentation during the run (28). High carbohydrate concentrations in the initial culture medium are toxic to many microorganisms. Thus, an optimal carbohydrate concentration is employed initially, which permits maximum culture growth to late log phase. When the carbohydrate concentration is reduced to almost zero, additional sterile carbohydrate is injected into the bioreactor to bring the carbohydrate concentration back to the starting level. When this is consumed, the process is repeated until end product inhibition forces the whole bioconversion to stop. Ideally, at the end of the fermentation you will have a product concentration which is three to four times greater than single batch fermentation with no residual carbohydrate. This will generate the highest yield possible. Also, due to increased end product accumulation with each carbohydrate addition, culture production rates will decrease. Thus, the decision as to how many fed-batch fermentations to perform before harvest is based on the desired final product concentration and the optimal fermentor use time. For example, in lactic acid fermentations a final product concentration $>$120 g/l is desired to enhance product recovery (29). For *Lactobacillus casei* this concentration can only be achieved via fed batch fermentation for a total fermentor run time of eight days.

Continuous fermentations are open fermentations, whereby fresh medium is continually added to the bioreactor, while spent culture medium, cells, and product are continually leaving (28). This fermentation is desired by the industry, because the reactor volume is 10 to 100 times smaller than batch fermentations, a steady stream of fermentation product is produced which will optimize downstream processes, bioconversion rates are always at maximum, operation costs are less, and the system can be fully automated and computer controlled to the point where only two operators are needed to manage the fermentation each day. However, it requires a continuous supply of sterilized or pasteurized culture medium, dilution rates are linked to microbial growth rates and the operational speed of downstream recovery process. Startup is slow, so any facility shut downs have an impact on production, and you are constantly fighting contamination (30). Thus, not all fermentations can be operated this way. The best example is ethanol production for gasohol, which is commonly a continuous fermentation with a four bioreactor train with increasing working volumes in each bioreactor. Thus, the dilution rate is decreasing in each bioreactor over the course of the fermentation. This dilution gradient in the train is critical, because as ethanol builds up in the culture medium, the yeast growth rate slows. Specific growth rate equals dilution rate. Finally a holding tank at the end is used to ensure

Figure 6.3 Example of *Lactobacillus casei* biofilm development on PCS tubes mounted on the agitator shaft for repeat batch fermentation. PCS blend employed contained 50% (w/w) polypropylene, 35% (w/w) ground soybean hulls, 5% (w/w) bovine albumin, 5% (w/w) Ardamine Z yeast extract, and 5% (w/w) soybean flour.

complete bioconversion of any residual sugars to ethanol. The CO_2 is collected and concentrated, then sold as another valuable byproduct. Fermented beverages (i.e., wine and beer) are still performed in batch.

For some continuous fermentations, an increased concentration of biomass in the reactor is required. This can be achieved by cell recycling, immobilized cell, and biofilm fermentations. Cell recycling reactors employ a filtration unit that allows for the constant bleeding of culture supernatant while retaining biomass (26). However, filtration unit fouling is a problem and must be constantly monitored. This type of operation has found use in the treatment of food processing from some starchy food waste streams (26).

6.6 NOVEL BIOREACTOR DESIGNS

One of the most common forms of immobilized cell bioreactor is entrapment, where high concentrations of cells are trapped in a polymer matrix such as alginate and κ-carrageenin (28,31). Thus, a high cell density is continuously retained in the fermentor while substrate is continuously converted to product. This higher concentration of biocatalysts in the reactor results in higher productivities and yields. The disadvantages of this method are migration of substrate through the matrix to the cell and the migration of product out, potentially high concentrations of product around the cells causing end product inhibition, cell leakage from the polymer matrix due to cell growth, and bead swelling and disintegration over time causing the whole fermentation to be stopped, cleaned, and restarted.

Biofilms are a natural form of cell immobilization in which microorganisms are attached to a solid surface (32). In this bioreactor, cells are continually growing, and sloughing off. Thus, the reactor is a mixture of immobilized and suspended cells. Continuous biofilm fermentations are truly open immobilized cell bioreactors (30). Their operation is equivalent to a suspended cell continuous fermentation with the added advantage of increase biomass concentrations in the bioreactor. Biofilms are typically resistant to harsh conditions, and can tolerate changes in the fermentation feed and conditions. However, not all microorganisms form biofilms. Filamentous microorganisms such as fungi and actinomycetes are natural biofilm formers. For nonfilamentous bacteria to form a biofilm, an extracellular polysaccharide needs to be generated by the bacterium (32).

Some bacteria will form biofilms on any surface such as metal, plastic, and glass. However, certain bacteria, such as lactobacilli, require something to stimulate this biofilm development (33). Plastic composite support (PCS) developed at Iowa State University has proven to stimulate biofilm development of *Lactobacillus casei* (22,34,36), *Zymomonas mobilis* (37,38), *Saccharomyces cerevisiae* (37,38,39), and *Actinobacillus succinogenes* (40). PCS is a high temperature extruded material consisting of at least 50% polypropylene, plus ground soybean hulls, bovine albumin and various culture micronutrients. Soybean hulls keep the extruded product porous due to the release of steam as the PCS leaves the extruder die. Bovine albumin performs as a natural plastizer which protects the temperature sensitive micronutrients. Micronutrients are selected based on the specific cultural requirements for amino acids, vitamins, and lipids. Monosaccharides are avoided due to poor PCS production. For example, the PCS blend for lactobacilli contains 50% (w/w) polypropylene, 35% (w/w) ground dried soybean hulls, 5% (w/w) bovine albumin, 5% (w/w) yeast extract, 5% (w/w) soybean flour, and mineral salts (35). PCS have been evaluated in batch (22), fed-batch (29), and continuous (30) lactic acid fermentations (Figure 6.3). In every application the percentage yields and productivity rates were significantly higher than suspended cell lactic acid fermentations. Furthermore, repeat batch fermentations have operated for more than 1.5 years with virtually no change in percentage yields and productivities. This longevity is attributed to the fact that once a biofilm has established on these customized materials, it will continue to grow as a biofilm. This is supported by the fact that a PCS biofilm reactor washed with concentrated ammonium hydroxide, rinsed with mineral salts solution, and then reinoculated with a fresh culture and medium will reestablish itself overnight. Commercially, the quick vinegar process is the most common biofilm process in current operation which uses wood chips for supports and *Acetobacter aceti* for production (27).

Solid substrate fermentation is when a substrate such as soybeans is ground, inoculated with *Aspergillus oryzae*, then incubated for three days for the production of soy sauce (27). It is a simple fermentation process and commonly used for aerobic fermentation due to its large surface area. Thus, oxygen concentration is high without using any mechanical forced air systems. Solid substrate fermentations require large areas or incubation space. A temperature controlled environment, intermittent monitoring for contamination and quality of starting material is essential for success.

6.7 FUTURE RESEARCH

Research is still needed for isolation of new microbial strains with improved production efficiencies and higher yields. More real time measurements are needed for culture conditions and metabolite formation. Recovery will continue to be the key factor associated with final product purity and cost. As an industry we cannot rely solely on genetic engineering

as our method of improving current fermentations. As we have illustrated, there are many other techniques which can be employed to improve productivity and yield, including new inexpensive medium ingredients, more continuous fermentation processes, and new exotic microbial reservoirs in nature and in the food industry.

Production of Carotenoids by Gene Combination in *Escherichia coli*

Gerhard Sandmann

CONTENTS

7.1 CAROTENOIDS: PROPERTIES, COMMERCIAL ASPECTS, AND BIOLOGICAL FUNCTION IN HUMAN HEALTH

Carotenoids are water-soluble natural pigments of 30–50 carbon atoms. Even shorter structures called apocarotenoids result from their oxidative cleavage. Carotenoids are synthesized de novo by archaea, bacteria, fungi, and higher and lower plants. Animals are supplied with carotenoids from their food and are able to further modify the chemical structure. More than 600 carotenoids are known as intermediates or end products of different biosynthetic branches in various organisms. Most carotenoids consist of 40 carbon atoms; possess an acyclic chain; or carry β-ionone, ε-ionone, or aromatic end groups. Acyclic carotenoids are often modified at C-1 and C-2, e.g., by 1-HO, 1-CH_3O, or 2-keto groups. Typical substitutions of a β-ionone end are 3-hydroxy, 4-keto, and 5,6-epoxy moieties. The 3-hydroxy group can participate in glycosilation or formation of fatty acid esters. The most prominent feature of a carotenoid molecule is the polyene chain. Delocalization of the Π-electrons is responsible for their color and their antioxidative potential. Carotenoids can interact with radical chain reactions and are capable of energy dissipation from photosensitizers as heat. In photosynthesis, carotenoids function as light-harvesting antenna, transferring light

energy to chlorophyll. More details on the structure and function of carotenoids can be found in References 1 and 2.

The commercially most important carotenoids are astaxanthin and β-carotene (structures 7.1 and 7.2, Figure 7.1) (3). Most of the carotenoids on the market is produced by chemical synthesis. A chemical process for the synthesis of lycopene (structure 7.3, Figure 7.1) has recently been established. The industrial use of carotenoids involves their application in nutrient supplementation, for pharmaceutical purposes, as food colorants, and in animal feeds. β-Carotene or other carotenoids with an unsubstituted β-ionone group are essential in human nutrition as a provitamin A. Taken up by the body, they are then metabolized to vitamin A, an integral component of the visual process. Lutein and zeaxanthin (structures 4 and 5, Figure 7.1) are constituents of the yellow eye spot, the macula lutea. There, both carotenoids act as protectants, preventing the retina from photodamage (4). Other carotenoids have a less defined role in human health. Evidence is accumulating that various carotenoids stimulate the immune system and play an important role in the prevention of degenerative diseases and cancer (5).

In addition to chemical synthesis, some biological systems for carotenoids are in use (6). Astaxanthin is accumulated in the green alga *Haematococcus pluvialis* or in the fungus

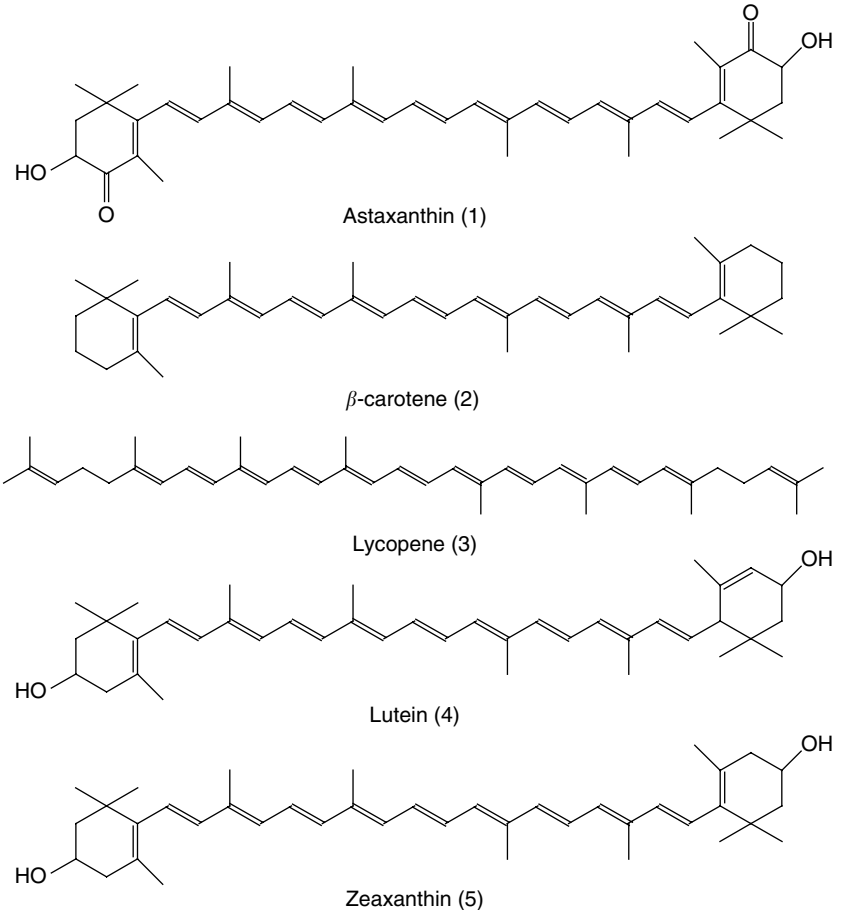

Figure 7.1 Chemical structures of carotenoids of commercial interest or with an effect on human health.

Phaffia rhodozyma (synonymous to *Xanthophyllomyces dendrorhous*). β-Carotene is produced by cultivation of the green alga *Dunaliella salina* or the fungus *Blakeslea trispora*. Palm kernel oil is another source for β-carotene. Natural sources of other carotenoids are flowers of *Tagetes erecta* for lutein (as fatty acid esters), red fruit of *Capsicum annuum* for capsanthin, and capsorubin or tomato for lycopene.

In recent years, several transgenic microorganisms have been explored as production hosts for carotenoids. These were the fungi *Saccharomyces cerevisiae* and *Candida utilis* as well as the bacteria *Zymomonas mobilis, Agrobacterium tumefaciens,* and *Escherichia coli* (*E. coli*) (7–9). Among them, *E. coli* is the most advanced production system.

7.2 *ESCHERICHIA COLI* AS A CAROTENOID PRODUCTION SYSTEM

Escherichia coli was the first host for functional expression of carotenogenic genes in order to analyze the function of the corresponding enzymes (10,11). Later, this bacterium was very useful in the heterologous overexpression of individual carotenogenic enzymes as functional proteins for their purification and biochemical characterization (12).

Escherichia coli is a very convenient host for heterologous carotenoid production. Because of its fast and easy cultivation in substantial quantity, it can be transformed simultaneously with several plasmids as long as they belong to different incompatibility groups, i.e., possessing different origins of replication. For their stable maintenance in the cells, it is essential that each plasmid carries a different antibiotic resistance. Only when this selection pressure is maintained spontaneous plasmid loss prevented. Several useful plasmids for cotransformation are available. Convenient vectors are pUC-related plasmids with the pMB1 origin of replication and ampicillin resistance, pACYC184 with a p15A origin of replication and chloramphenicol resistance, pRK404 with an RK2 origin of replication and tetracycline resistance, and pBBR1MCS2 with a SC101 origin of replication and kanamycin resistance. These plasmids can be used for expression of individual genes or groups of genes which mediate the formation of certain basic carotenoid structures. For example, one plasmid may carry the genes necessary to obtain certain carotenoid intermediates and others the genes for systematic modifications of the structure (13,14). It should be pointed out that *E. coli* is noncarotenogenic which increases the flexibility to build up a desired carotenoid synthesis pathway. However, *E. coli* has to cope with the drain of prenyl pyrophosphates when carotenogenesis is established. Other plasmids may be used to overexpress certain genes to enhance the *E. coli* metabolic capacity for the supply of carotenoid precursors. Details on the choice of plasmids and growth conditions for carotenoid producing *E. coli* transformants are given in a recent publication (15).

In the majority of bacteria, including *E. coli*, formation of prenyl pyrophosphates, which are the precursors of carotenoids, proceed via a reaction sequence which is different from the mevalonate pathway typically found in fungi and animals (16). It is referred to either as the 1-deoxyxylulose-5-phosphate pathway, because this is the first intermediate, or as the 2-C-methyl-D-erythritol-4-phosphate pathway, because this is the first product which is converted to prenyl pyrophosphate exclusively. To date, most of the reaction steps have been elucidated. Initially, a C_2 unit from pyruvate is condensed to glyceraldehyde by a thiamin-dependent 1-deoxyxylulose-5-phosphate synthase (Figure 7.2). Then, the product is converted to 2-C-methyl-D-erythrol-4-phosphate by 1-deoxyxylulose-5-phosphate reductoisomerase. The following reactions involve the formation of 4-diphosphocytidyl-2-C-methylerythrol in a CTP-dependent reaction and phosphorylation at position 2 by adenosine triphosphate. Subsequently, cytidine-5-phosphate is released and via 2-C-methyl-D-erythritol-2,4-cyclodiphosphate 1-HO-2-methyl-2-butenyl-4-diphosphate is formed.

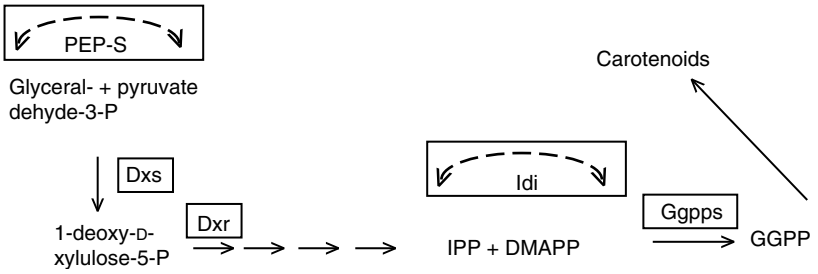

Figure 7.2 Metabolic engineering of the *Escherichia coli* deoxyxylulose-5-phosphate pathway and prenyl pyrophosphate formation for optimum precursor supply. Overexpression of the indicated enzymes either relieve a limitation of the metabolic flow or provide a more favorable balance for two-substrate reactions. PEP-S, phosphoenolpyruvate synthase; Dxs, deoxyxylulose-5-phosphate synthase; Dxr, deoxyxylulose-5-phosphate reducto isomerase; Idi, isopentenyl pyrophosphate isomerase; Gggpps, geranylgeranyl pyrophosphate synthase.

This product may be the branching point for independent routes to isopentenyl pyrophosphate (IPP) and dimethylallyl pyrophosphate (DMAPP). However, the details of the final steps to IPP and DMAPP are not fully understood yet. See Reference 17 for the newest insight into later reactions of this novel pathway.

Precursor supply for carotenogenesis can be increased in *E. coli* by overexpression of limiting enzymes of the deoxyxylulose-5-phosphate pathway and subsequent reactions. Supply of prenyl pyrophosphates and subsequent carotenogenesis was stimulated by transformation with the genes encoding 1-deoxy-D-xylulose-5-phosphate synthase, 1-deoxy-D-xylulose-5-phosphate reductoisomerase, and IPP isomerase under a strong promoter (Figure 7.2). Because geranylgeranyl pyrophosphate is the direct substrate for the formation of the first carotenoid in the pathway and its level is comparably low in *E. coli*, high expression levels of geranylgeranyl pyrophosphate synthase are very important for carotenogenesis (18). Another bottleneck for carotenoid biosynthesis in *E. coli* was relieved in the pathway by overexpressing the gene which encodes phosphoenolpyruvate synthase, a pyruvate consuming enzyme, indicating that the pools of glyceraldehyde 3-phosphate and pyruvate, which both are substrates of 1-deoxy-D-xylulose 5-phosphate synthase, have to be more balanced in the direction of glyceraldehyde 3-phosphate (19). By overexpression of different combinations of the limiting enzymes mentioned above, concentrations of various carotenoids to a final yield of 1.5 mg/g dry weight could be reached (20).

7.3 PRINCIPLES OF CAROTENOID BIOSYNTHESIS

C_{40} carotenoids are synthesized by head-to-head condensation of two molecules of C_{20} geranylgeranyl pyrophosphate catalyzed by the enzyme phytoene synthase (Figure 7.3A). A very similar condensation reaction from C_{15} farnesyl pyrophosphate leads to the formation of C_{30} carotenoids. In the next steps, the conjugated double bond system of C_{30} and C_{40} carotenes is sequentially extended, each time integrating one of the isolated double bonds. Different phytoene desaturases exist with respect to the catalyzed number of desaturation steps. The enzyme Pds from plants inserts only two double bonds symmetrically at positions 11 and 11′ (Figure 7.3B). The bacterial phytoene desaturase from *Rhodobacter capsulatus*, $CrtI_{Rc}$, carries out a 3-step desaturation with an additional

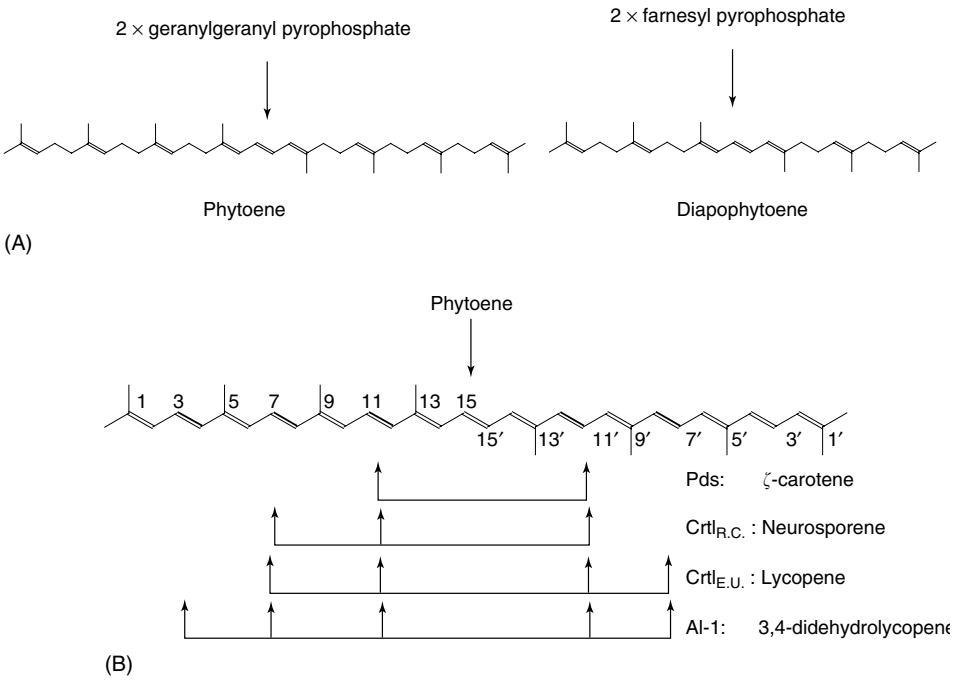

Figure 7.3 Principles of the biosynthesis of acyclic carotenoids with different polyene chains. (A) Establishment of the basic C_{30} and C_{40} carbon chain. (B) Extension of the conjugated double bond system. Double bonds in bold are introduced by the individual phytoene desaturases as indicated by the arrows yielding the specified carotenes.

double bond at position 7. The most abundant bacterial phytoene desaturase like $CrtI_{Eu}$ catalyzes a 4-step desaturation with additional double bonds at position 7 and 7′. The enzyme Al-1 from the fungus *Neurospora crassa* catalyzes a 5-step desaturation with an additional double bond at position 3. These individual desaturation reactions lead to the formation of the products ζ-carotene, neurosporene, lycopene, and 3,4-didehydrolycopene, respectively.

Lycopene can be modified at the terminal double bonds by addition of water, resulting in 1-HO derivatives which can be methylated to 1-CH_3O carotenoids (Figure 7.4). Desaturation at position 3,4 requires the presence of the 1-HO or 1-CH_3O group. These types of carotenoids are typical for photosynthetic bacteria. Finally, a 2-keto group can be introduced under aerobic growth. Another addition to the 1,2 double bond of lycopene is involved in the synthesis of C_{45} and C_{50} carotenoids. This chain elongation at C-2 proceeds via addition of one or two dimethyl allyl cation. Then, the molecule is stabilized by abstraction of a proton from C-17 and C17′.

Cyclization of lycopene ends to ionone groups involves protonation of the 1,2 double bond and the addition of the resulting carbo cation to the 5,6 double bond (Figure 7.4). Stabilization occurred by proton abstraction from either C-6 or C-4 yields β- or ε-rings, respectively. The possible individual substitutions of a β-ionone end group are summarized in Figure 7.4. A cyclic carotenoid may carry a 3-HO, 4-keto, and/or 5,6-epoxy moiety. It should be pointed out that only the combinations of 3-HO and 4-keto, or 3-HO and 5,6-epoxy are known. Details on the carotenogenic pathway can be found in many reviews (1,21,22).

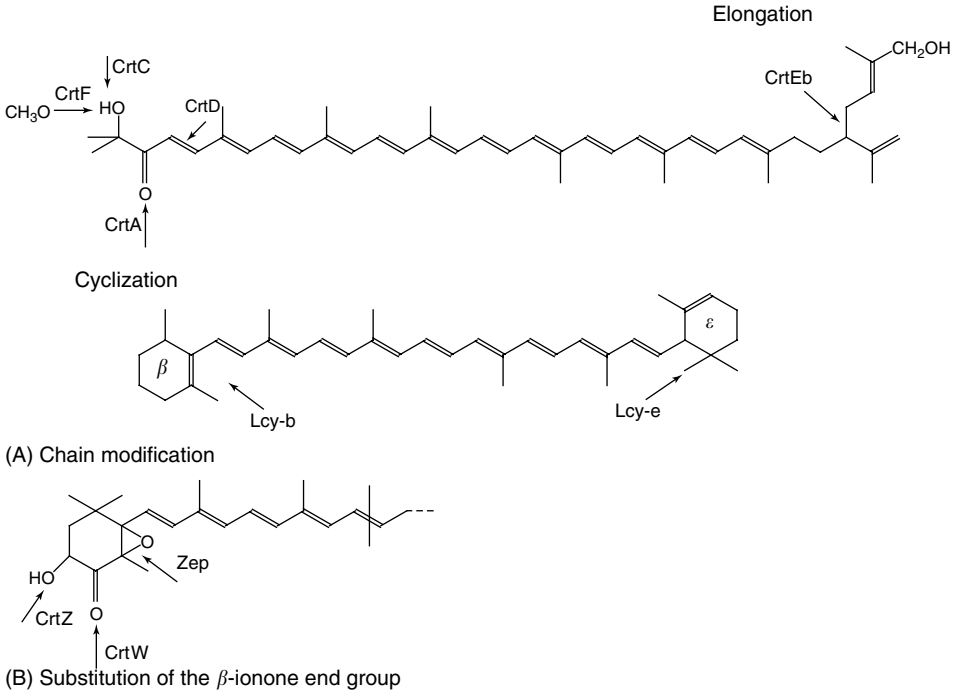

Figure 7.4 Reactions modifying the lycopene molecule (A) or a β-ionone ring (B).

7.4 PRODUCTION OF CAROTENOIDS IN *ESCHERICHIA COLI*: ACHIEVEMENTS AND PERSPECTIVES

Escherichia coli was the first noncarotenogenic organism into which carotenoid biosynthesis was engineered (10,11). Carotenogenic cells were obtained when gene clusters from *Erwinia* species was functionally analyzed. The expression before and after deletions of individual genes lead to the accumulation of the end product zeaxanthin diglucoside and all intermediates like phytoene, lycopene, β-carotene, and zeaxanthin. Many different carotenoids have been produced since, by using genes from many different organisms. Depending on the structure and the amount of carotenoids formed, pigmentation of *E. coli* can be very strong ranging in color from yellow to orange and red.

Genes used for heterologous carotenoid production in *E. coli* originated not only from bacteria but also from fungi, algae, and higher plants. An example is given in Figure 7.5 that demonstrates how genes from all theses organisms were combined in *E. coli,* interacting simultaneously in carotenogenesis. Initially, formation of lycopene is catalyzed by three enzymes encoded by bacterial genes, crtE, crtB, and crtI. Then, a fungal monocyclase Al-2 takes over, forming γ-carotene. Into this molecule, a plant hydroxylase Bhy introduces a 3-hydroxy group. Due to the functionality of all these enzymes in the foreign host *E. coli*, the final product 3-hydroxy-γ-carotene is obtained. The production of this carotenoid is also an example of the synthesis of a carotenoid which is not formed in any of the organisms from which these genes originated. The synthesis of novel carotenoids by combining genes from different organisms only works because the substrate specificity of the enzyme is such that it does not need to recognize the entire substrate molecule, but only certain regions of the molecule which are suitable for conversion. This combinatorial approach can result in the formation of totally novel carotenoids. For example, 1-hydroxylated acyclic

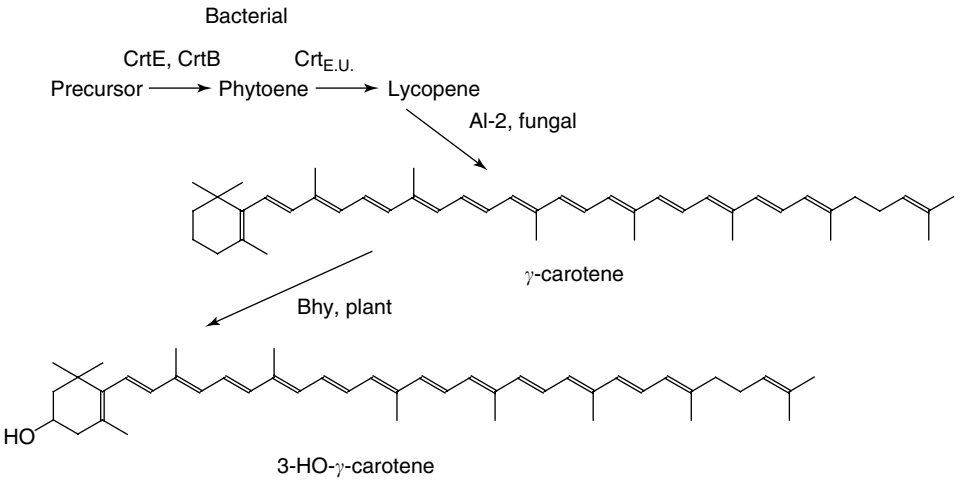

Figure 7.5 Example of heterologous production of the carotenoid 3-HO-γ-carotene by combination of genes from bacteria, fungi and plants.

structures with up to 13 conjugated double bonds were designed with an antioxidative potential which was superior to other related carotenoids (23).

The production of many other carotenoids was successful in the factory *E. coli*. Their synthesis was assembled in a modular way by transformation with the appropriate genes which encode the enzymes responsible for the individual catalytic steps. For this approach, it is important to know the substrate and product specificity of the encoded enzymes. Sometimes, the products of highly homologous genes do not catalyze the same reaction. The 3,4-carotene desaturases $CrtD_{Rg}$ and $CrtD_{Rs}$ from the photosynthetic purple bacteria *Rubrivivax gelatinosus* and *Rhodobacter sphaeroides*, respectively; both enzymes catalyze the conversion of 1-HO-neurosporene and 1-HO-lycopene. However, only the enzyme from *R. gelatinosus* is able to desaturate 1-HO-3′,4′-didehydrolycopene as indicated in Figure 7.6A (24).

A list of genes for the synthesis of different carotenoid structures together with the necessary information on the catalytic function of their products can be found in Reference 25. Table 7.1 comprises the individual carotenoids which can be synthesized in *E. coli*. They include carotenoids of different chain lengths, cyclic and acyclic structures with shorter or longer conjugated double bond systems, unsubstituted hydrocarbons or hydroxy, and keto and epoxy derivatives. All these carotenoids can be produced in *E. coli* in quantities of up to 1–1.5 mg/g dry weight. Many of the carotenoids in Table 7.1 are found in suitable organisms only as biosynthetic intermediates which accumulate only in trace amounts, making it very difficult to extract and purify them. Others have not been detected in biological material before. These carotenoids are marked in bold face. Experimental details for the heterologous production of carotenoids in *E. coli* were recently published (15). Several of the double bonds in a carotenoid molecule can be formed in a cis or trans configuration. For some of the carotenoids produced in *E. coli*, the composition of these geometrical isomers has been determined (26). In general, the all-trans isomer is dominating. In the case of β-carotene, small quantities of 9-, 13-cis, and 9,13,13′-tetracis isomers were also formed. The formation of the major lycopene isomers is determined by the type of gene used to transform *E. coli*. With crtI related genes, mainly all-trans and smaller amounts of 5-, 9- and 13-cis isomers accumulate.

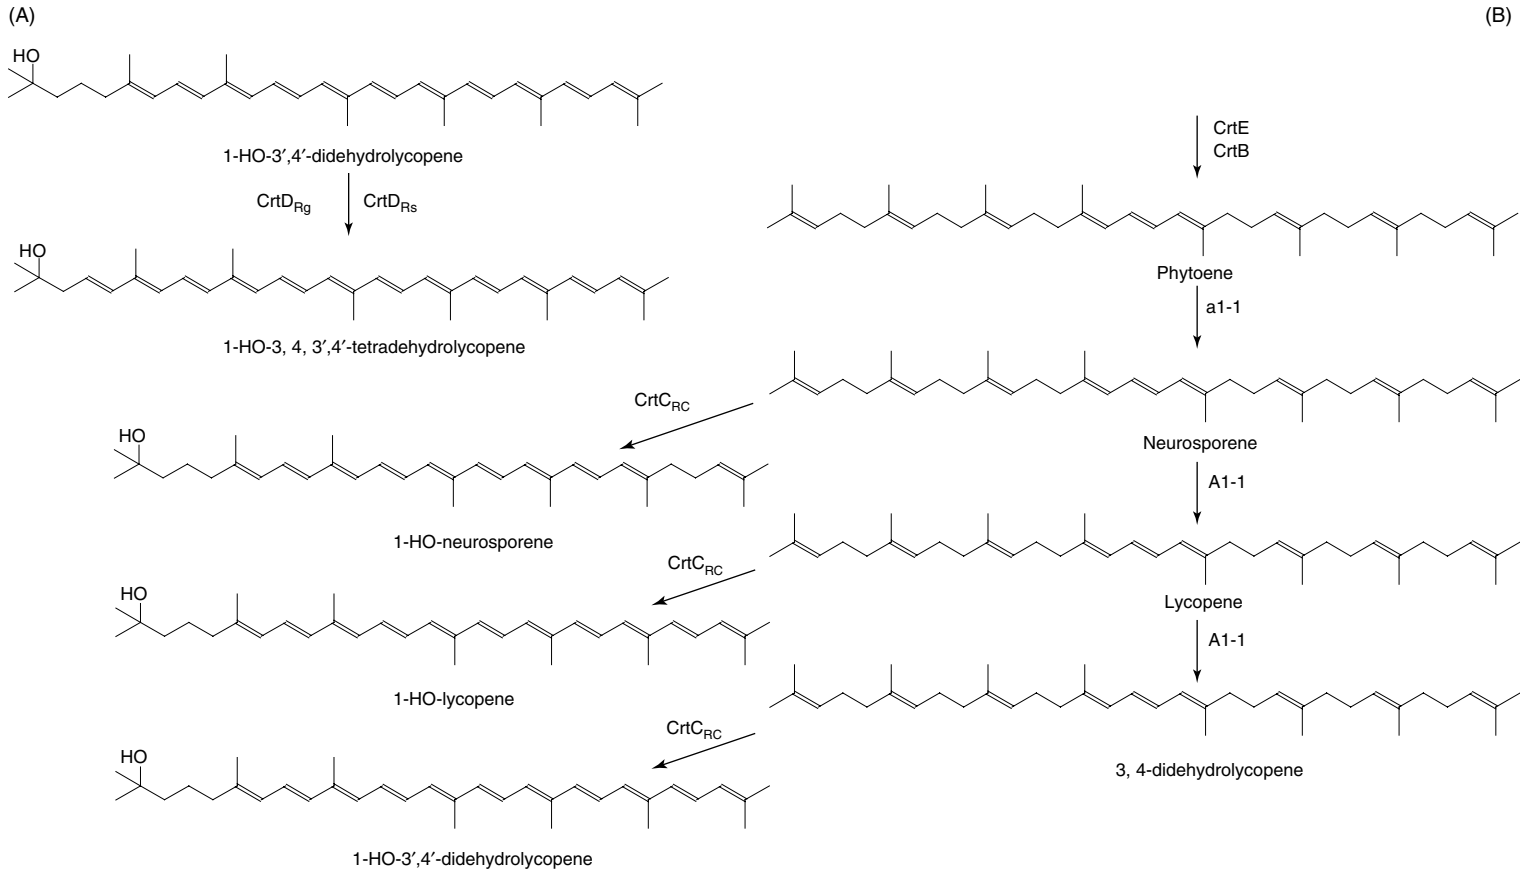

Figure 7.6 Species-specific catalysis of 1-HO-3,4,3′,4′-tetradehydrolycopene formation from 1-HO-3′,4′-didehydrolycopene by enzymes originating from highly homologous genes (A) and an example of intermediate flow into side reactions in the pathway leading to 1-HO-3′,4′-didehydrolycopene (B).

When the crtI gene is replaced by another phytoene desaturase gene crtP together with the ζ-carotene desaturase gene crtQb, prolycopene (=7,9,7′,9′-tetracis) dominates and all-trans lycopene is minor.

In some cases, the end product of an established carotenoid pathway may be much lower than expected. Instead, a mixture of structurally related compound is obtained. This may be the case when the enzymes react, not one after the other in a fixed sequence, but due to their broad substrate specificity in a metabolic web. When, e.g., the desaturase Al-1 and the 1,2-hydratase CrtC interact, not only the end product of the desaturation reaction 3,4-didehydrolycopene but also the intermediates neurosporene and lycopene are modified to the corresponding 1-HO derivatives by the hydratase (Figure 7.6B).

The major advantage of *E. coli* for carotenoid production is the versatility for the generation of very diverse structures. However, compared to the biological carotenoid

production systems like *Dunaliella*, *Haematococcus*, *Blakeslea,* and *Phaffia* mentioned before, the yields are lower. Metabolic engineering of the *E. coli* terpenoid biosynthetic reactions led to a considerable increase of carotenoid production and there are indications that precursor supply is not limiting in these engineered strains. The major problem for *E. coli* seems to be carotenoid storage. All the lipophilic carotenoids are sequestered in the cell membranes. Therefore, future activities may aim to extend the carotenoid storage capacity by genetic modification of the density of membranes in *E. coli* cells or by establishing plastoglobuli-like structures.

Production of Amino Acids: Physiological and Genetic Approaches

Reinhard Krämer

CONTENTS

8.1 INTRODUCTION

Amino acids are the basic constituents of cellular proteins, as well as important nutrients for all living cells. Their importance is closely related to their nutritional value, in particular for those amino acids which are essential for man and animals (lysine, threonine, methionine, tryptophan, phenylalanine, valine, leucine, isoleucine, and, to some extent, arginine and histidine). Amino acids are used for a variety of purposes, depending on their taste, nutritional value, other physiological activities, and chemical properties. Besides their application in human nutrition (flavor enhancers, sweeteners), they are used as feed supplements (animal nutrition), as well as for cosmetics, in the pharmaceutical

industry (infusion solutions, dietary food), and as building blocks for chemical synthesis (Table 8.1).

The use of amino acids in food consumes nearly 40% of total amino acid production. Major products used in the food industry are L-glutamate (monosodium glutamate, MSG), L-aspartate, L-phenylalanine, glycine, and L-cysteine. These amino acids are produced by a variety of companies in East Asia, the USA, and Europe (1).

The history of amino acid production is, to a large part, the history of the major producing organism, namely *Corynebacterium glutamicum*. In 1908, K. Ikeda discovered that sodium glutamate was responsible for the specific flavoring component of kelp, a traditional taste enhancing material in Japanese cooking. For a long time, sodium glutamate was commercially isolated from vegetable proteins, because chemical synthesis of glutamate leads to the formation of racemate (racemic acid ester). The sodium salt of the D-isomer, however, is tasteless. In 1957 a screen for bacteria with the capacity to excrete amino acids, in K. Kinoshita and S. Udaka were successful in finding a Gram-positive soil bacterium that was auxotrophic for the vitamin biotin and that spontaneously excreted glutamate under conditions of biotin limitation (2). Since then, a number of bacteria have been isolated that were also characterized by the peculiar capacity of excreting glutamate. Later, they were all reclassified as *C. glutamicum* (3). *Corynebacterium glutamicum*, a soil bacterium, belongs to the group of mycolic acid containing actinomycetes, together with *Nocardia* and *Mycobacteria*. After the successful introduction of *C. glutamicum* for commercial production of large quantities of amino acids, other bacteria, namely *Escherichia coli*, have also successfully been used for this purpose. Interestingly, a bacterium closely related to *C. glutamicum*, namely *Corynebacterium ammoniagenes*, is commercially used for the production of large quantities of nucleotides, another important flavor enhancer in food biotechnology. Recently, the importance of glutamate as a flavor enhancer has been explained by the discovery of special receptor proteins in the human tongue responsible for sensing the taste of glutamate (4).

The majority of amino acids used in the food industry are used as flavor enhancers (mainly L-glutamate, but to some extent also glycine and L-phenylalanine), as sweeteners (L-aspartate and L-phenylalanine, the building blocks for the sweetener aspartame), and for

Table 8.1
Currrent production and application of amino acids. (Data are estimated values for the year 2003)

Amino Acid	Estimated Production (t/y)	Preferred Production Method	Major Use
L-Glutamate	1.100.000	Fermentation	Flavor enhancer
L-Lysine	550.000	Fermentation	Feed additive
D,L-Methionine	550.000	Chemical synthesis	Feed additive
L-Threonine	50.000	Fermentation	Feed additive
Glycine	22.000	Chemical synthesis	Food additive
L-Aspartate	10.000	Enzymatic catalysis	Sweetener (Aspartame)
L-Phenylalanine	10.000	Fermentation	Sweetener (Aspartame)
L-Cysteine	3.000	Enzymatic method	Food additive
L-Arginine	1.000	Fermentation	Pharmaceutical
L-Tryptophan	500	Fermentation	Pharmaceutical
L-Valine	500	Fermentation	Pharmaceutical
L-Leucine	500	Fermentation	Pharmaceutical

a variety of purposes as food additives (e.g., cysteine as a flour additive). In addition, essential amino acids are used as ingredients in dietary food.

In addition to the importance of amino acids as food supplements, there is a huge market for amino acids as additives to animal feed (Table 8.1). The basic goal is to improve the value of animal feed, which typically lacks the essential amino acids lysine, methionine, threonine, and tryptophan as well as other essential amino acids to a minor extent (5,6). The economic driving force for manufacturing and adding amino acids to animal feed is twofold: improvement of the quality of feed leads to a reduction of the quantity needed, which leads to cost reduction; and an enormous reduction of animal waste (manure), because the individual animal will take in as much food as necessary to obtain a sufficient amount of the most limiting nutrients, which, in general, are essential amino acids. The second aspect is thus not only of economic, but also of high ecologic impact. Some aspects of the production of amino acids which are used as feed supplements will also be included in this chapter, because a number of highly relevant and interesting scientific developments in terms of physiology, biochemistry, and molecular approaches have been made in connection with these amino acids, particularly lysine. The results and tools developed in this field will certainly also find their application in the production of amino acids as food additives.

Amino acids which are used in bulk quantities in food and feed applications can be divided into four categories: (1) Those that are mainly synthesized by chemical procedures leading to racemic mixtures. The main example for this class is methionine, because animals (and humans) are able to convert the D-form of this amino acid into the L-form. The achiral amino acid glycine can also be produced by chemical synthesis. (2) Those that are synthesized by enzymatic synthesis, frequently using the enzymes of immobilized bacterial cells. A typical product manufactured by this method is aspartate, for which the enzyme aspartase is used, either from *E. coli* cells immobilized with organic polymers or from *Pseudomonas putida* cells fixed in the natural polymer carrageenan (6). (3) Those that are produced by gene tailored organisms. Glutamate, which is produced by *C. glutamicum*, represents the oldest biotechnological product in this field, and is at the same time the amino acid produced in the largest quantities. (4) The rest of the amino acids, namely lysine, threonine, and phenylalanine, which are produced by using fermentative techniques and microorganisms. The processes for their production substantially differ from those developed for glutamate. In addition, more sophisticated chemical procedures are used in some cases, which lead to stereospecific synthesis of particular amino acids. Most probably, these processes will be replaced in the future by biotechnological techniques based on the use of engineered microorganisms, if the market volume for these amino acids becomes large enough to call for the development of appropriate processes.

The organisms used for biotechnological processes of amino acid production are mainly *C. glutamicum* (glutamate, lysine, aromatic amino acids) and *E. coli* (threonine, aromatic amino acids). A number of other organisms have also been used, e.g., *Serratia marcescens*, a relative to *E. coli*, and others (5,6), these processes, however, are not of high economic impact so far. There is a clear tendency to use only the two major organisms (*C. glutamicum* and *E. coli*) as biotechnological workhorses and, on the basis of the wealth of knowledge on the genetic, biochemical, and in particular physiological level, to adapt their extraordinary capacities to the needs of producing the desired metabolite.

This chapter will have two foci. First, the physiological basis of amino acid excretion in bacteria, a phenomenon that does not seem to be very "physiological" at first view, will be discussed. Second, genetic and biochemical strategies that have been used to improve and to optimize the production of amino acids in a biotechnological scale will be described.

A detailed understanding of the background of amino acid production in terms of physiology, biochemistry, and genetics has proven to be absolutely essential for applying rational strategies to the optimization of amino acid production by metabolic design.

8.2 PHYSIOLOGICAL, BIOCHEMICAL, AND GENETIC BACKGROUND OF AMINO ACID PRODUCTION

It may be argued from a phenomenological point of view that amino acid producing strains can simply be classified into three different categories: wild-type strains able to excrete particular amino acids under specific culture conditions; regulatory mutants from which feedback control of amino acid biosynthesis has been removed; and (3) genetically modified strains in which the biosynthetic capacity has been amplified. These categories may also be combined, as well. This does not, however, fully explain the complexity of the metabolic background behind the peculiar capability to excrete amino acids.

A rational approach to amino acid production is based on a detailed understanding of the particular physiological reasons leading to amino acid excretion. As a matter of fact, amino acid excretion was for a long time interpreted as not being a physiological event, and this perception is still commonly accepted: "The secretion of amino acids serves no purpose for a microbe (7)." Amino acid excretion was thought to result from the impact of biotechnological techniques on the metabolic situation and the integrity of bacterial cells. On the contrary, we now know that amino acid production in most cases has to be rationalized in terms of exploiting and optimizing the physiological property of active amino acid excretion that is already naturally present in many, if not all bacterial organisms (8,9).

Consequently, discussion of the physiological, biochemical, and genetic background of amino acid production necessarily should start by raising and answering the following question. Why would microorganisms, which are generally thought to apply economic strategies in order to survive and to outcompete their neighbors, waste precious compounds such as amino acids, which have to be synthesized at high cost of carbon, nitrogen, and energy? In other words: what is the physiological meaning of the presence of amino acid excretion systems in microorganisms?

Before discussing details of cellular metabolism, one should be aware of a basic misunderstanding. When describing bacterial energy metabolism, F. Harold has conclusively stated: "It must be concluded that the bacterial solution to energy surplus is in general to waste it (10)." Under conditions of carbon and energy surplus, the major survival strategy of bacteria is not the optimization of metabolism in terms of economy and efficiency but in terms of metabolism or growth speed.

On a more detailed level, there are actually at least two plausible reasons that may cause amino acid excretion under physiological conditions (Figure 8.1). They will be explained predominantly in *C. glutamicum*, because of its widespread use in amino acid production. As a soil bacterium, *C. glutamicum* uses all available materials from its natural surroundings as carbon and energy sources. Peptides, derived from decomposing organic matter, are certainly an important source for these needs, and, like most bacteria, *C. glutamicum* harbors efficient uptake systems for peptides. On the other hand, this organism is not very well equipped with efficient degradation systems for various amino acids, e.g., lysine, arginine, branched chain, and aromatic amino acids. If peptides are used as carbon and energy sources, amino acids close to the central metabolism, e.g., glutamate, aspartate, or alanine, are efficiently metabolized. Those amino acids that are not efficiently metabolized, however, will accumulate and will lead to problems due to high internal concentrations. This has been demonstrated by the addition of peptides that contain lysine,

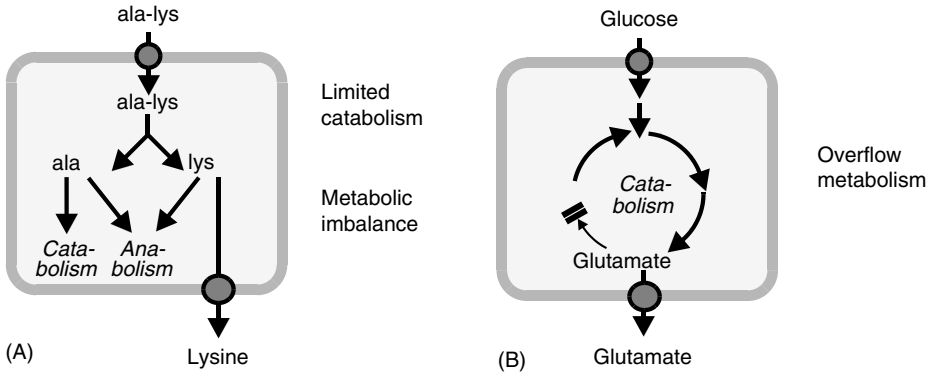

Figure 8.1 Physiological concepts of amino acid excretion. Two major concepts explaining excretion of amino acids based on physiological reasons. (A) Amino acids which are accumulated because of limited catabolic capacity or of a metabolically imbalanced situation are excreted (examples L-lysine in *C. glutamicum*, L-threonine in *E. coli*). (B) Amino acid excretion occurs under conditions of metabolic overflow, i.e., when a metabolic limitation occurs in the presence of a surplus of carbon, nitrogen and energy (example L-glutamate in *C. glutamicum*).

threonine, or isoleucine, as substrates, which leads to high cytoplasmic accumulation (11–13). Even more convincing, it was shown that deletion of the specific lysine excretion system in *C. glutamicum* may cause internal lysine concentrations of more than 1 M as a result of peptide feeding (14). This experiment is actually the most convincing explanation for the physiological necessity of amino acid excretion systems, at least in *C. glutamicum*. This explanation has been designated "metabolic imbalance." In a broader sense, this concept may hold for any imbalanced situation in the cell that can be corrected via export activity. A recent, very interesting example is documented by the discovery of a novel cysteine export system in *E. coli*, the function of which seems to be maintaining redox balance in connection with cytochrome biosynthesis (15).

In addition to lysine, this concept holds for a number of amino acids in *C. glutamicum*, such as threonine and branched chain amino acids, but is not applicable, of course, for glutamate, a metabolite too closely related to the central metabolism. Furthermore, this concept does not easily explain amino acid excretion in other organisms, for example *E. coli*, which is able to degrade those amino acids. Nevertheless, even in those cases it may be an obvious advantage for the bacterial cell to be able to effectively control the steady state concentration of cytoplasmic pools of some amino acids which are not closely related to the central metabolism by efflux, and not only by degradation, in times of a surplus of carbon sources.

In the case of glutamate excretion in *C. glutamicum*, however, a completely different explanation which is based on more general metabolic situations, has been found to apply. It has been studied in a number of microorganisms besides *C. glutamicum*, in particular *E. coli*, and may thus hold for several other cases also (17). If there happens to be an unlimited supply of carbon and nitrogen as well as of energy, and if at the same time some other metabolic limitation occurs which leads to decreased growth or even growth arrest, bacterial cells in general decide not to limit substrate uptake, but to continue the central metabolism at high speed and to waste the surplus of resources instead of switching down their metabolic activity to save nutrients. This situation is called "overflow metabolism" (16), and it is typical for glutamate overproduction in *C. glutamicum* (11). Acetate overproduction in *E. coli*, an unwanted side reaction frequently observed in high cell density fermentation and under oxygen limitation, is caused by the same factors. Limitations leading to overflow

mechanisms can naturally occur for different reasons or can be artificially introduced in various ways, including lack of essential metal ions or cofactors. This holds for glutamate production in *C. glutamicum*, where limitation may occur due to lack of the essential cofactor biotin. This type of metabolic condition, leading to overproduction of metabolites in general and amino acids in particular, has also been used for optimization of amino acid production. In principle, introducing auxotrophies for amino acids other than those excreted in production strains leads to controlled growth limitation, and thus may enhance amino acid overproduction. As a matter of fact, glutamate production in *C. glutamicum* seems to be more complicated than the general scenario described above. As will be explained in more detail in section 8.5, in addition to growth limitation, glutamate excretion in *C. glutamicum* is somehow related to alterations in the organism's cell wall, as well as to changes in the activity of cytoplasmic enzymes.

In a number of amino acid production processes, however, these two concepts do not explain the actual situation during fermentation. Under conditions when the flux through central and peripheral pathways is strongly increased due to mutations and engineered enzymatic steps, the pressure for amino acid excretion is much higher as compared to normal physiological situations. Consequently, the basic concepts discussed above still hold as an explanation for the presence of effective excretion transport systems, but they are not applicable to the actual metabolic situation.

Nevertheless, given that amino acids have been shown not to passively cross the permeability barrier of the plasma membrane under production conditions (11,17), it is accepted that most, if not all, amino acid production processes necessarily depend on the presence of active export systems for two reasons. In addition to the trivial argument that most amino acids simply cannot cross the phospholipid bilayer without the help of transport proteins, it is also important to keep the internal amino acid concentration sufficiently low by active extrusion in order to avoid undesired feedback inhibition. This can be achieved only by energy dependent, active export systems, which guarantee that in spite of high rates of biosynthesis as well as increasing external product concentrations, the cytoplasmic amino acid concentration will remain at a relatively low level, compatible with normal physiological situations.

These considerations are also relevant for another situation, which is interesting both from a fundamental and an applied point of view, namely the question of whether amino acid production is coupled to cell growth or not. Whereas this seems to be clear for the basic physiological concepts discussed above, it is no longer obvious for typical production strains. Amino acid excretion as explained by metabolic imbalance may certainly be coupled to growth, but the concept of metabolic overflow at least requires limitation of growth if not growth arrest. On the other hand, with the exception of glutamate production, in typical production strains amino acid excretion is the result of the pressure of an engineered flux increase in the direction of the desired product, and amino acid export just enlists the available efflux systems. Consequently, whether production is coupled to growth or not is more likely to be governed by technical aspects, such as whether the production phase is specifically turned on during fermentation (e.g., threonine in *E. coli*) or not (e.g., lysine in *C. glutamicum*).

For bulk amino acid production, only a small number of microorganisms are used, namely *C. glutamicum* (glutamate, lysine, and aromatic amino acids), *E. coli* (threonine, aromatic amino acids, and cysteine), and, to some extent, *Serratia marcescens* (arginine and histidine). In view of this fact and on the basis of the available models explaining the physiological background of amino acid production, the question arises whether these organisms may have special capacities with respect to amino acid excretion. *Escherichia. coli* is on this list precisely because it is the major source of physiological and biochemical knowledge

available. There are already genetic tools at hand that directed the choice of this organism for its use in amino acid production. The same argument holds true for *C. glutamicum* at another level, given that this organism is presumably the best studied bacterium with respect to technical fermentation.

On the other hand, it has frequently been argued that those bacteria would be particularly suitable for the purpose of metabolite production that have a less tightly regulated central and peripheral metabolism. This argument was put forward for *E. coli* and *S. marcescens*, the latter being identified as less tightly regulated. The success of *E. coli* in amino acid production, however, clearly argues against this interpretation. In the same line, *C. glutamicum* is designated as having a less well organized and regulated central and peripheral metabolism as than *E. coli*. There are, for example, three aspartokinase isoenzymes found in *E. coli* at the entrance to the biosynthesis pathway of the aspartate family of amino acids which are separately inhibited by lysine, threonine, and isoleucine, whereas *C. glutamicum* has only one enzyme, which is feedback inhibited in a concerted manner by lysine and threonine. It is, however, not obvious why concerted feedback control should in principle be inferior to control of individual enzymes. Moreover, in the meantime *C. glutamicum* was found to have a number of highly elaborated regulation networks, for example with respect to nitrogen control (9,18), or for the cellular response to osmotic stress (19).*Corynebacterium glutamicum* seems to be especially well equipped in some metabolic control regions, particularly the anaplerotic pathways. A somewhat loose pathway regulation, however, seems in fact to be present in *C. glutamicum* at least in some cases. It has been shown, for example, that simple addition of methionine, which, after being taken up and inhibiting its own biosynthesis, leads to overflow in the direction to lysine biosynthesis, which subsequently causes lysine excretion (20). The argument that less tightly regulated species are more favorable production organisms in general is also contradicted by the fact that *E. coli* seems to be clearly better suited for threonine production than *C. glutamicum*, in spite of the fact that its biosynthesis pathway is much better regulated.

Taken together, the reason for choosing a particular production organism does not seem to be directly derived from its physiological or genetic suitability for this purpose. The choice is obviously driven by the amount of genetic and physiological knowledge available, and by the recognition of a particular organism to be productive (*C. glutamicum*) or easy to handle (*E. coli*).

Nevertheless, *C. glutamicum* and related species seem to be an exception, at least in two aspects: Its physiological capacity to excrete large amounts of glutamic acid already under natural conditions seems to be exceptional, and the peculiar situation that some treatments affecting the state of the cell wall or plasma membrane trigger an increase in the propensity to excrete amino acids has not been reported for any other bacterium. It is important to note that this particular property does not seem to be restricted to glutamate excretion only.

With respect to the central and peripheral metabolism in amino acid producing bacteria, there are a number of specific strategies for metabolic design, which are relevant for metabolite overproduction in general and for amino acid production in particular. Schematically, the metabolic network related to metabolite production can be divided into several individual components (Figure 8.2). Basically, we can discriminate four different major steps being involved: substrate uptake, central metabolic pathways, amino acid biosynthesis, and amino acid excretion. This simple view has to be extended by further important considerations, in particular specific (local) regulatory mechanisms both on the level of gene expression and enzyme activity. Furthermore, the integration into global regulatory networks such as carbon control and nitrogen control has to be considered, as well as the importance of cellular metabolic balances like energy balance and redox balance.

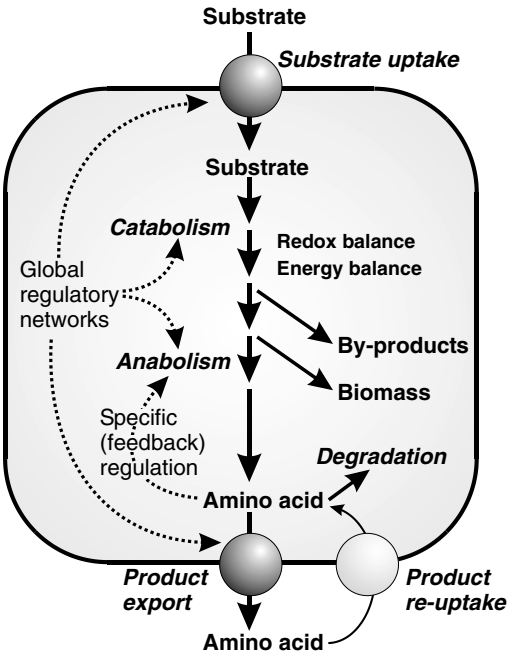

Figure 8.2 Basic steps involved in amino acid production. Summary of major metabolic and regulatory events important for amino acid production by bacteria (see text).

Moreover, specific situations have to be taken into consideration, such as amino acid degradation pathways or product reuptake by amino acid uptake systems.

Most of these aspects will be discussed in detail in section 8.5, in connection with processes used for the production of individual amino acids. This holds for regulatory concepts, as well as for more specific questions like redox balance in the case of lysine, or degradation activity in the case of threonine. The general pathway architecture, i.e., particular reactions as well as general regulation patterns of the major pathways of substrate degradation (e.g., glycolysis, pentose phosphate pathway), central metabolism (e.g., tricarboxylic acid cycle, glyoxylate cycle, anaplerotic reactions), and the common anabolic pathways of amino acid biosynthesis are in principle well known and studied in detail. The special situation of massive overproduction of an anabolic end product, i.e., an amino acid, which is largely different from the usual state under growth conditions, makes it necessary to focus in detail on particular parts of the process. A rational strategy for metabolic design seems to be relatively easy in the case of the final steps, i.e., the anabolic reaction sequences directly leading to the particular amino acid, where a straightforward deregulation or overexpression strategy seems promising. It is, however, obviously not that simple in the case of catabolic and central metabolic pathways involved in the supply of precursor molecules of amino acid biosynthesis, because these pathways also have to fulfil many other purposes in the cell, which may be in conflict with the basic biotechnological goal. This holds in particular for aspects of biomass production (growth), of energy consumption (efficiency), and the balance between desired and undesired pathways (yield).

Many studies have been done on the importance of central metabolic pathways in *C. glutamicum* for the efficient synthesis of products such as lysine or glutamate (21). In these studies, the core significance of anaplerotic reactions within this metabolic node has been demonstrated, making the set of anaplerotic reactions a particularly fascinating target

of metabolic engineering. Because of the central position of these reactions, the results obtained are certainly of high relevance for the production of any amino acid the precursors of which are provided by reactions or side reactions of the citric acid cycle. Two precursor metabolites oxaloacetate and pyruvate, which serve as precursors for about 35% of cell biomass and metabolic products, are generated in the anaplerotic node. Several research groups have shown that altogether at least 5 individual enzymes are present in this complex metabolic process. The glyoxylate cycle also fulfils anaplerotic functions (Figure 8.3). By disruption of the gene encoding the phospho*enol*pyruvate carboxylase (22) and by detailed flux analysis using ^{13}C NMR techniques (23,24), it was shown that the pyruvate carboxylase plays a major role in *C. glutamicum*. Altogether, a surprisingly complicated metabolic pattern is found: pyruvate dehydrogenase providing acetyl-CoA for the citric acid cycle; pyruvate carboxylase together with phospho*enol*pyruvate carboxylase supplying oxaloacetate, as well as oxaloacetate decarboxylase, phospho*enol*pyruvate carboxykinase, and the malic enzyme. In addition, the glyoxylate cycle provides C4 precursor compounds. This may not be complete, given that the presence of a pyruvate oxidase was also revealed in the genome of *C. glutamicum*. It may be concluded that the anaplerotic node with its complex scenario of partly counteractive reactions is one of the "secrets" of *C. glutamicum* that explains its exceptional metabolic flexibility and versatility. In addition to obviously being an interesting target for rational metabolic design, it is also an instructive example, in which it has been shown that analysis of the significance of individual enzymes in these processes is not possible by in vitro enzyme tests, nor by genetic studies, but only by applying refined methods of metabolic flux analysis (25–28).

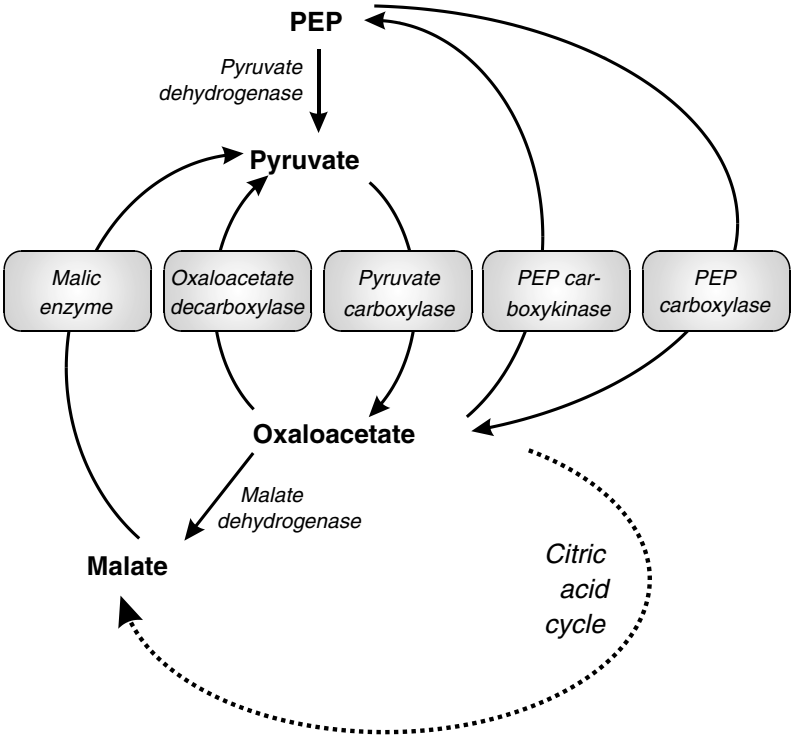

Figure 8.3 Anaplerotic pathways of *C. glutamicum.* Complexity of anabolic reactions in *C. glutamicum*. The figure represents a minimum setup of reactions present (see text).

8.3 PHYSIOLOGICAL, BIOCHEMICAL, AND GENETIC TOOLS USED TO IMPROVE AMINO ACID PRODUCTION

In the past decades, classical approaches including many rounds of mutation, selection, and screening, in some cases combined with molecular biology techniques such as threonine production, have led to impressively efficient strains of *C. glutamicum* and *E. coli* that are used in amino acid production. After introduction of modern genetic tools and sophisticated methods for pathway analysis, the era of rational metabolic design was begun (29,30). Now additional aspects have come into scientific focus, namely substrate uptake, precursor synthesis by central pathways, further steps within the anabolic pathway, redox and energy balance, and last but not least, active product excretion. At the beginning, straightforward molecular approaches such as direct deletion or overexpression of particular genes were, in general, not as successful as conservative methods of strain breeding. This is most likely due to the fact that optimum productivity with respect to a single anabolic end product, i.e., an amino acid, is based on fine tuning of the whole cellular network of pathways and regulation circuits. In order to render modern approaches of metabolic design more efficient than classical procedures, detailed knowledge of the metabolic web, on all possible levels of understanding, is needed. This will include everything from pathway architecture and regulation of the individual enzymes involved, to the sum of carbon, nitrogen, energy and redox fluxes including the construction of the related regulatory circuits. In the genomic and postgenomic era, the full set of information on the level of the genome, the transcriptome, the proteome, and the metabolome becomes more and more available. In the near future it will be fully complemented by dynamic information on metabolic pools and fluxes (the fluxome).

In addition to approaches of optimizing biosynthesis and excretion of amino acids based on the pathway architecture, which are already present in the respective production organisms, metabolic design certainly offers the possibility of introducing new reactions and pathways not so far found in the particular bacterium under study.

As targets for improving a producer organism, all of the different compounds of the metabolic network responsible for amino acid biosynthesis and excretion have to be considered. The vast majority of efforts have been spent on strategies to modify the terminal anabolic pathways (5,31). The most direct approach, which has been applied in all processes except glutamate production, is the amplification of the biosynthetic flux through a reaction which has high control strength on the whole pathway, frequently called a "bottleneck." This may be achieved by deregulation, i.e., release from feedback control by the respective end products of the pathway, a typical result of classical strategies in which high concentrations of substrate analogues were added, giving rise to inhibition insensitive mutant forms of originally feedback inhibited enzymes. Another strategy involves increased or decreased synthesis of enzymes at the corresponding metabolic branch points. An instructive example is lysine production, where a decrease in the dihydrodipicolinate synthase (DapA) increased the flux to lysine. A similar example is redirection of metabolic flux from tryptophan to tyrosine or phenylalanine in *C. glutamicum* (31).

Such strategies can be applied to all other aspects of the metabolic network involved in amino acid production (Figure 8.1). Particularly interesting and successful are the strategies directed toward influencing the connections of anabolic pathways to the central metabolism (precursor supply), decreasing degradation activity, and engineering of transport systems (avoiding futile cycles). Some aspects have not yet been fully exploited, such as optimization of substrate uptake and product excretion, and some fields are not really well understood to a level sufficient to be approached by a rational metabolic design, e.g., global regulatory mechanisms, and energy balance. These will briefly be discussed in section 8.6.

Biochemical and genetic information was successfully used in the case of precursor supply, most prominently concerning anaplerotic reactions. After the set of reactions within the anaplerotic node had been elucidated in *C. glutamicum* (3), the significance of phospho*enol*pyruvate carboxykinase (32) and, in particular, of pyruvate carboxylase, for amino acid production was elucidated. The importance of the latter enzyme for lysine and glutamate production was demonstrated by deletion and overexpression of the corresponding gene (33,34). Further examples of the successful optimization of precursor supply, threonine and aromatic amino acid production in *E. coli* and *C. glutamicum,* are described in section 8.5.

Another obvious strategy involves the inactivation of amino acid degradation pathways that are interfering with high product yield. This is not that important in *C. glutamicum* in view of the limited catabolic capacity of this organism, but it is very important in *E. coli*. An example of this strategy is threonine production in *E. coli*.

Although certainly significant for bacterial metabolism under production conditions, energy and redox balance has not yet been studied in great detail. Because of the obvious need of a sufficient supply of redox equivalents (NADPH) in the case of lysine production, the relation of metabolic flux through glycolysis versus the pentose phosphate pathway has been analyzed using ^{13}C NMR or MS flux analysis (section 8.5). Direct approaches by introducing NADH dependent instead of NADPH dependent enzymes have not yet been successful.

Transport reactions are important in amino acid production and are thus candidates for optimization in three different ways. First, highly active nutrient uptake is a prerequisite for efficient synthesis of amino acids, which, second, have to be actively secreted in order to be accumulated in the surrounding medium. Third, the latter process may be counteracted by the activity of amino acid uptake systems. Sugar uptake via phospho*enol*pyruvate dependent phosphotransferase systems (PTS) has been very well studied in *E. coli* (35), but unfortunately little information is available for *C. glutamicum*. (36–38). PTS systems are highly interesting in connection with amino acid production not only because they are responsible for sugar uptake, but also due to their impact on regulatory networks in the cell with respect to control of carbon metabolism, including various transport systems. Amino acid excretion was not taken into consideration as a relevant aspect of amino acid production for a long time. First on the biochemical level (8), and in recent years by successful molecular identification (39), the discovery of an increasing number of specific and energy dependent amino acid exporters has opened a new world of transport reactions and, at the same time, targets for optimization strategies (Table 8.2). Several new families of transporters are known now: the lysE family (40), the RhtB family, the ThrE family, and the LIV-E family (39). All these families have a number of members found in the genomes of a variety of bacteria. It is interesting that all carriers related to amino acid excretion identified so far belong, with one exception, to the class of secondary carriers, i.e., they are coupled to the electrochemical potential as the driving force. So far, only a single ABC-type, primary carrier has been detected (Table 8.2). It should be mentioned, however, that glutamate excretion was found to depend on the cytoplasmic ATP concentration (41). The first members known were *LysE*, the lysine exporter in *C. glutamicum* (14), *RhtB* and *RhtC* from *E. coli* which are involved in threonine production by this organism (42), *ThrE*, the threonine exporter in *C. glutamicum* (43), and *BrnFE*, the leucine, isoleucine, and valine exporter in *C. glutamicum* (44). Further examples of newly discovered amino acid export systems are the two exporters involved in cysteine and O-acetylserine efflux in *E. coli*, which belong to completely different transporter families from those described above (45,46). The surprisingly large number of homologues found in the genomes of numerous bacterial species indicates that, in clear contrast to the previous perception, amino acid excretion seems to be a common event in the prokaryotic world.

Table 8.2
Amino acid excretion systems identified on the molecular level

Organism	Gene	Transporter Family[1]	Substrate	No. of Putative Transmembrane Segments
C. glutamicum	*lysE*	LysE	L-lysine, L-arginine	5–6
E. coli	*rhtB*, *rhtC*	RhtB	L-threonine[2], L-homoserine[2], L-homoserine lactone[2]	5–7
E. coli	*ydeD*	PecM	O-acetyl-L-serine, L-cysteine, L-glutamine, L-asparagine	9–10
C. glutamicum	*thrE*	ThrE	L-threonine	10
C. glutamicum	*brnFE*	LIV-E	L-isoleucine, L-leucine, L-valine	7 and 4[3]
E. coli	*yfiK*	RhtB	O-acetyl-L-serine, L-cysteine	5–7
E. coli	*cydDC*	ABC-type[4]	L-cysteine	

[1] The transporter family within the class of secondary transporters is indicated.
[2] Only resistance to the substances listed but no transport was measured.
[3] BrnFE is a transport system consisting of two different subunits.
[4] In contrast to all other transporters listed in Table 8.2, CydDC is an ABC-type transporter.
For references, see text.

It has been demonstrated that amino acid uptake systems may be of significance for amino acid production in two different ways. Tryptophan production by *C. glutamicum* was found to be improved when the uptake system for aromatic amino acids was decreased in its activity. A similar situation was found for threonine production. The advantage of decreasing the activity of amino acid uptake for production may be twofold: a possible energy consuming futile cycle of energy dependent uptake and export can be avoided, and feedback inhibition as well as repression by high internal amino acid concentrations will not occur. For glutamate excretion, it has been shown that the risk of energy consuming futile cycling seems to be avoided by alternative regulation of uptake and excretion systems (47).

In addition to the list of targets for optimization, based on the dissection of metabolic and regulatory events, there are a number of additional aspects to consider. A highly interesting point which frequently is discussed in connection with strain optimization is the presence of auxotrophies for amino acids or related compounds in production strains. Amino acid auxotrophies in strains obtained by classical breeding techniques are in general interpreted as causing release from feedback control or decreasing alternative branches in anabolic metabolism, a conclusive example being lysine production strains (5,6). This explanation, however, is not always conclusive, because frequently auxotrophies for amino acids other than those related to the biosynthesis pathway of the amino acid excreted are found in producer strains. It should be considered that growth limitation may have an effect on productivity as has been discussed in connection with models for overflow metabolism. The disadvantage of the presence of auxotrophies in production strains, i.e., that fermentation media need substantial and defined supplementation with the respective

compounds, have been overcome by the introduction of "leaky" strains. A leaky biosynthetic pathway is still functional, but its activity is reduced to a level where it can provide only limited amounts of the required metabolite. Examples are strains with reduced activity of citrate synthase (48) or homoserine dehydrogenase (49). Consequently, the respective amino acid as the end product of the leaky pathway will become growth limiting (metabolic overflow situation) and the cytoplasmic concentrations will be very low (release of feedback control).

A particularly interesting property in this respect is the importance of cell wall integrity for amino acid production in *C. glutamicum*. As discussed in section 8.5 in detail, interfering with cell wall integrity of *C. glutamicum* using a variety of methods causes this organism to excrete glutamate. It is necessary to emphasize, however, that this turns out to be a more general situation, obviously not restricted to glutamate excretion only. It has been shown that modification of the lipid composition (50) as well as the content of mycolic acids in the cell wall (51), also leads to an increase in the excretion of other amino acids. This exceptional property of *C. glutamicum*, however, has not yet been exploited in a rational way, because the molecular basis of these events is still not understood.

A chapter on optimization strategies for amino acid producing strains necessarily should include a brief overview on the modern methods used for this purpose. When developing metabolic concepts of amino acid overproduction, a number of tools from different scientific disciplines have been used and integrated in recent years. These approaches have, of course, been successfully employed also for purposes of rational metabolic design. They include molecular tools on the level of functional genomics, i.e., identification, modification, and controlled expression of genes coding for enzymes involved in amino acid synthesis pathways, in pathways responsible for precursors and supplementary building blocks, and in pathways leading to side products branching off the respective biosynthesis pathway, as well as modulation of the expression of genes coding for regulatory proteins. Analysis of the transcriptome as well as the proteome provides a more detailed understanding of regulatory networks working in the cell. Substantial and successful efforts have been made in *C. glutamicum* in this direction in recent years. With the methods of metabolome analysis, a completely new level of insight into the cell is starting to become available, in particular if its dynamics, i.e., the metabolic fluxes in the cell (fluxome) are also determined. A reasonably well characterized metabolome and the pattern of metabolic fluxes would be a solid basis for the rational understanding of amino acid production and metabolic design. We are, however, far from this situation, because a basic inventory of metabolites (metabolome) of not a single bacterial cell is available.

The genome of *C. glutamicum* has been sequenced independently several times (30), and a number of global studies on the transcriptome are now available (30,52–56). At the same time, proteome analysis has successfully been adapted to *C. glutamicum*, too (57–59), and has recently been extended to phosphoproteome analysis (60).

The metabolome approach, i.e., focusing on metabolic pools and their dynamics, has been applied on a more conceptual level already long before serious efforts at unravelling the metabolome of the cell and the metabolic fluxes have been started. This refers to attempts of identifying and quantifying limiting metabolic steps or "bottlenecks," which was a highly influential concept in the field of amino acid production. Earlier perceptions, which suggested that there would exist one major and dominating "bottleneck" controlling the flux through a particular pathway, were soon proven to be not fully correct or not very useful in application. Certainly, the first entrance step into an amino acid biosynthesis pathway is in general a true bottleneck, because it controls the flux through the consecutive anabolic pathway. In general, however, it is not sufficient to simply deregulate the first control point in order to make possible effective overproduction of a particular metabolic

end product. The instructive work of Niederberger et al. (61) may serve as an example, where it has been shown by detailed analysis of aromatic amino acid biosynthesis in yeast that flux control is, in general, distributed among a series of enzymes, and is not confined to a single enzymatic step. There have been a large number of approaches to understand metabolic fluxes on the basis of theoretical considerations as well as experimental measurements (25). Well known, among others, are the concepts of control analysis (62,63) as well as metabolic balancing techniques (64,65). The latter have been extensively applied to studying fluxes in *C. glutamicum* under conditions of amino acid production (21,66–68). These concepts have certainly contributed to understanding the complex situation of interrelated fluxes in cells. The basic problem of most of these methods, however, lies in the fact that in general the complete and exact set of data on metabolite pools, and in particular on their dynamic behavior, is not available to a sufficient extent. Only after application of the sophisticated techniques of nuclear magnetic resonance spectrometry (NMR) (21,26,69) or mass spectrometry (28,67–70) to the analysis of fluxes in *C. glutamicum* was a better understanding of the dynamic aspects of bacterial metabolism provided. In particular, the novel combination of metabolite balancing and MALDI-TOF mass spectrometry seems to be a very useful tool in unravelling dynamic fluxes in bacterial cells (71). For a full understanding, however, a detailed analysis of the metabolome, in addition to the major metabolites which also have been identified in the studies mentioned above, is necessary.

8.4 AMINO ACID PRODUCTION: TECHNICAL ASPECTS

Since the discovery of *C. glutamicum* as a bacterium with the ability to produce large amounts of glutamate directly from sugar and ammonia, new processes of amino acid production were developed, and a new industry started, manufacturing these products by using fermentative techniques. In view of the main goal of this article, namely to understand the physiological, biochemical, and genetic background of amino acid production, it seems valuable to have a brief look at the processes applied for amino acid fermentation. Among many techniques used namely extraction, chemical synthesis, enzymatic synthesis, and fermentation, only the latter, which, except for the production of methionine, is used for all large scale bulk amino acids, is discussed here. It is furthermore obvious that amino acid fermentation is just one step in the whole technical process, followed by downstream processing and wastewater treatment, which are also not discussed here.

Fermentation techniques used can be divided into batch and fed batch cultures, and continuous culture. Industrial amino acid fermentation is mostly performed using the former two procedures. Figure 8.4 shows a typical lysine fermentation procedure with *C. glutamicum*. In general, fed batch processes, in which the substrate is not only provided at the beginning of the process but is added repeatedly during fermentation, lead to higher productivity as compared to batch processes because of several reasons. By lowering the initial concentration of nutrients (sugar), the lag time can be shortened and growth as well as yield can be increased. This is mainly due to osmotic stress caused by high nutrient concentrations (72). Frequently, auxotrophic strains are used. In that case, excess supply of the required nutrient at the beginning of the fermentation may result in a decreased production yield, because of feedback effects caused by the nutrient. Very high growth rates under unlimited supplies of substrate may lead to oxygen limitation in large fermentors, which results in a decreased yield and an increased formation of byproducts, mainly organic acids.

Continuous culture has a number of advantages, as well as disadvantages, in the case of amino acid production. (31,72). The production phase can be controlled much better, and studies have been published where the yields were significantly higher as compared to

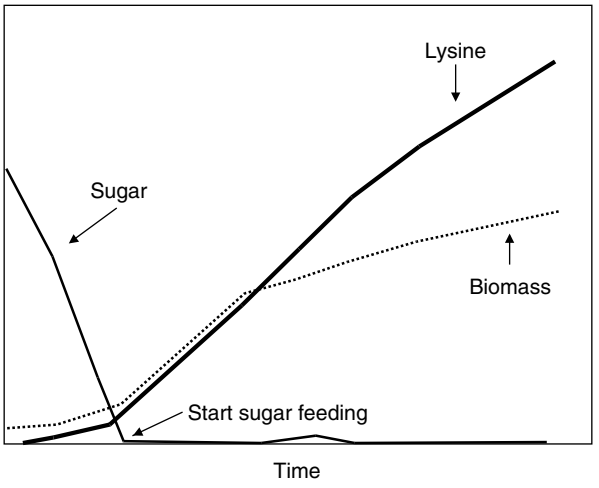

Figure 8.4 Technical l-lysine production process with *C. glutamicum.* Starch hydrolysate or sucrose is used as carbon source and ammonium sulfate as nitrogen source. After consumption of the initial amount of sugar, substrates are added continuously and lysine accumulates up to 170 g/l. The figure was kindly provided by Dr. L. Eggeling, Research Center Jülich.

the same process in fed batch mode (31). As a matter of fact, it has been reported for glutamate production, for example, that the volumetric productivity with 5–8 g L^{-1} h^{-1} of continuous cultivation was at least twice as high as in fed batch fermentations (73). On the other hand, continuous fermentation is technically very demanding, as it requires continuous feeding of sterilized fresh media and sterile air. Furthermore, bacteria often undergo spontaneous mutations which, under the metabolic pressure of amino acid fermentation, may lead to reduced productivity during continuous culture for a long period of time.

It is worth noting that continuous culture is in principle only possible if amino acid excretion occurs during growth. There are several processes in which the production phase is clearly [L-threonine fermentation by *E. coli* (74)] or, to a significant extent (glutamate production by *C. glutamicum*), separated from the growth phase. Because cells are constantly kept in the growth phase in continuous culture, this procedure would not easily be applicable in these cases. Apart from that, continuous culture is a much better tool for studying microbial physiology in response to environmental conditions than batch culture. Consequently, the information obtained from continuous culture experiments is useful for optimizing conditions and feeding strategies in fed batch processes.

8.5 SELECTED EXAMPLES OF AMINO ACIDS

Besides those amino acids which are currently of core interest in the food industry, e.g., glutamate, phenylalanine, aspartate, and cysteine, a number of other amino acids are used for different purposes, namely as feed additives and for the pharmaceutical and cosmetic industry. Some of the latter will be briefly discussed here, because they represent instructive examples of production process development, the physiological and genetic background of which is reasonably well studied.

8.5.1 Glutamate

By far the most important amino acid in food biotechnology, and the first amino acid to be produced by fermentation, is glutamate (monosodium glutamate, MSG). In spite of this fact,

and in spite of numerous scientific investigations, it is still less well understood from the physiological and genetic point of view as are, for example, lysine or threonine production.

The historical background of glutamate production, as well as some of its fundamental aspects with respect to the importance of central metabolism and cell wall properties has already been mentioned. For the production of L-glutamate, only *C. glutamicum* is used, although *E. coli* and other organisms are also able to excrete glutamate. Currently, more than 1,000,000 tons of glutamate are produced annually.

The physiological and biochemical background of glutamate production in *C. glutamicum* is highly interesting, and differs significantly from that which is presumably responsible for the excretion of other amino acids as well as from amino acid excretion in other bacteria. L-glutamate is closely related to the central metabolism, synthesized from oxoglutarate by the NADPH dependent glutamate dehydrogenase, which, at the same time, represents the major reaction of nitrogen assimilation under conditions of nitrogen excess in the environment. Under nitrogen limiting conditions, the ATP dependent glutamate synthase glutamate oxoglutarate glutamine aminotransferase system (GS/GOGAT) is predominantly used. The first attempt to explain the property of *C. glutamicum* being an exceptionally good glutamate producer was based on the observation that the activity of the oxoglutarate dehydrogenase (OHDC), i.e., the citric acid cycle reaction following the branching point to glutamate, was surprisingly low. The straightforward explanation of the carbon flow being redirected to glutamate because of the insufficient activity of a major enzyme, thus leading to massive glutamate over synthesis and ultimately to glutamate production, appears convincing.

However, it turned out not to be true, at least in its simple meaning. Later on, it was revealed that *C. glutamicum* in fact possesses significant OHDC activity, which was found to be strongly reduced under conditions which lead to glutamate excretion (75). It has been proven by many investigations studying carbon flux under glutamate production conditions that in fact a flux redirection from oxoglutarate to glutamate is observed under glutamate production conditions (76–78). Moreover, disruption of the OHDC in *C. glutamicum* led to glutamate production comparable to that observed under biotin limited conditions (79). Unfortunately, the reason for the observed reduction of stability and activity of OHDC is not understood so far. It should be mentioned here that another concept has recently been put forward to explain the observation of a reduced flux through the second part of the citric acid cycle, based on the fact that Gram-positive bacteria similar to *C. glutamicum* may need energy input into the succinate dehydrogenase (SDH) reaction. The SDH reaction, which would then depend on the electrochemical proton potential, might possibly not function properly under conditions where the membrane surrounding it is somehow altered, as is suggested after treatments leading to glutamate excretion (80).

For these considerations and their possible consequences in understanding the physiological and biochemical background of glutamate excretion, a critical evaluation of the methods used for inducing glutamate production by *C. glutamicum* is necessary (79). Several different kinds of treatments lead to glutamate excretion. Based on the original observations, glutamate was found to be excreted under conditions of biotin limitation (2). *Corynebacterium glutamicum* requires biotin for growth. Biotin is a cofactor of several enzymes, most importantly of pyruvate carboxylase and acetyl-CoA carboxylase, which is essential for fatty acid synthesis. Glutamate overproduction can also be induced by addition of some kind of detergents, e.g., polyoxyethylene sorbitane monopalmitate (Tween 40) or polyoxyethylene sorbitane monostearate (Tween 60). The reason for induction of glutamate excretion is definitely not simply an increase in membrane permeability, because closely related detergents like the monolaurate (Tween 20) or monooleate esters (Tween 80) are not effective. Consequently, it is assumed that the detergents used exert a regulatory effect

rather than a direct increase in permeability. Addition of β-lactam antibiotics (penicillin), which are known to interact in cell wall biosynthesis, leads to glutamate excretion. Strains which are auxotrophic for precursors required in phospholipid biosynthesis, such as glycerol or fatty acids, are able to excrete glutamate into the surrounding medium. The apparently simple method of applying increased temperature also leads to increased glutamate excretion, in particular in the case of temperature sensitive mutants (81). Recently, it was shown that direct changes in the architecture of the cell wall, brought about by disrupting enzymes involved in the synthesis of cell wall components in *C. glutamicum*, such as fatty acids (50) or trehalose (51), lead to increased glutamate excretion, too. In addition to these procedures, also general membrane acting factors, such as addition of local anaesthetics or application of osmotic stress, may induce glutamate excretion in *C. glutamicum* (82,84).

The cell wall of *C. glutamicum* has a very complex structure, consisting of an inner layer composed of cross linked structures of arabinogalactan, peptidoglycan, lipomannan, and lipoarabinogalactan (Figure 8.5). In the middle part, a mycolic acid bilayer structure is present, which, as a true bilayer, is an exception among Gram-positive bacteria, shared only with the other members of the mycolata (*Mycobacteria* and *Nocardia*). The outer layer of the cell wall, finally, is mainly composed of polysaccharides also containing free lipids like trehalose mono- and dimycolates (85,86). It seems to be obvious that all treatments and conditions, inducing glutamate excretion, although they appear to be very diverse, may influence synthesis and composition of the plasma membrane or the cell wall of *C. glutamicum*. Based on this fundamental interpretation, the basic explanation for the trigger being responsible for glutamate excretion was for a long time the concept of an increased leakiness of the membrane or cell wall of *C. glutamicum* (79). In 1989, however, it was shown that glutamate excretion is not due to increased leakiness but, on the contrary, mediated by a specific, energy dependent transport system (8,87). This export system was shown to be responsible for glutamate excretion under conditions of a metabolic overflow situation. Unfortunately, in contrast to lysine, threonine, and isoleucine, the gene or genes encoding this excretion system were not identified until now. The fact that glutamate excretion has been experimentally demonstrated to depend on the presence of a specific export system, however, does not directly help to understand the influence of factors triggering glutamate export or the involvement of the cell wall in this process. This situation led to a revival of the "barrier hypothesis" (82) in which the permeability properties of the cell wall were directly made responsible for the ability to effectively excrete glutamate. All these concepts have to take into account that glutamate uptake systems are located in the plasma membrane, which, under conditions where no glutamate excretion can be observed, take up glutamate with high activity (41,88). Consequently, this requires efficient permeation of glutamate through the cell wall barrier. Thus, glutamate uptake has to take place at the same time that the barrier concept argues for a strictly limited permeability in the direction of efflux, making this concept unlikely for thermodynamic reasons. Furthermore, porin proteins have been identified in the *C. glutamicum* cell wall, providing permeability for hydrophilic solutes (85,89–91).

Concerning a direct involvement of the plasma membrane in glutamate efflux, it has been shown that an increase in passive glutamate permeability is not responsible for glutamate excretion (87). The concept that the observed increase in efflux is correlated with a change in the lipid composition also has to be abandoned, at least in the strict sense that membrane alteration is an essential prerequisite for glutamate export activity (92). It has recently been shown that *C. glutamicum* strains in which the OHDC has been disrupted become efficient glutamate producers without having a changed membrane composition (79). Another concept, related to changes of the physical state of the membrane triggering glutamate excretion, was based on the assumption of a changed viscosity of the cell wall

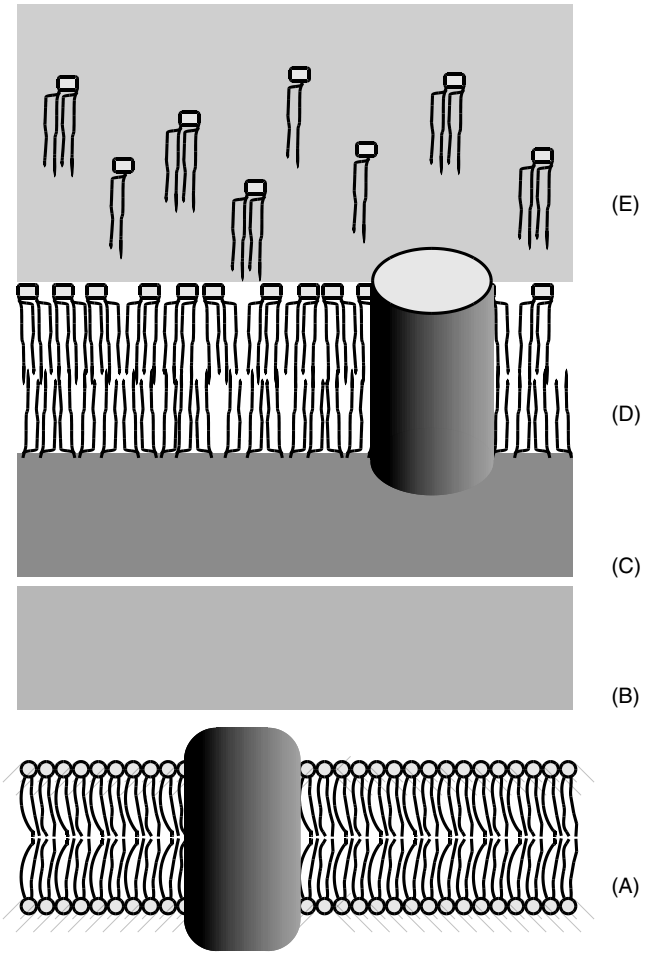

Figure 8.5 Cell wall of *C. glutamicum.* A) Phospholipid bilayer of the plasma membrane with embedded membrane proteins, e.g., amino acid transport systems. B) Peptidoglycan layer. C) Arabinogalactan layer. D) Mycolic acid bilayer of the cell wall. The inner leaflet consists mainly of bound mycolic acids covalently linked to the arabinogalactan layer, whereas free mycolates make up the outer leaflet. Porin channels are embedded in the mycolic acid layer. E) The outer layer mainly composed of polysaccharides also contains trehalose mono- and dimycolates, and in addition, proteins. Drawn after (85).

or plasma membrane under these conditions (93), which, however, was contradicted by results obtained later (82). Nevertheless, the fact remains that the capacity of glutamate excretion seems somehow to be correlated to the state of the membrane or cell wall.

Recently a gene was identified (*dtsR*), which has structural similarity to genes of acetyl-CoA carboxylases, the deletion of which led to fatty acid auxotrophy, a decrease in ODHC activity, and glutamate excretion even in the presence of biotin. Consequently, *dtsR* was proposed to be the real target in detergent treatment as well as under biotin limitation. The future development of this line of research seems to be highly promising.

A possible conceptual way out of this dilemma is based on a hypothesis derived from experiments on the contribution of cell wall biosynthesis to cell division (94, M. Wachi, personal communication). In this concept, the obvious impact on cell wall integrity is thought to trigger a regulatory signal transduced to the cytoplasm via the plasma membrane

in *C. glutamicum*, leading to unknown mechanisms resulting in down regulation or inactivation of the oxoglutarate dehydrogenase, and possibly to activation of the glutamate excretion system.

In addition to the impact of cell wall properties on glutamate efflux, particular properties of the central metabolism, particularly the availability of precursor molecules, such as oxaloacetate, in *C. glutamicum* are also of significance for glutamate production. Consequently, both understanding and possible manipulation of the anaplerotic node in *C. glutamicum*, responsible for the supply of oxaloacetate, especially the activity of pyruvate carboxylase, play a pivotal role for effective glutamate production (21,79). The relative contribution of several enzymes being in principle able to contribute to oxaloacetate (the essential precursor compound) supply, namely phospho*enol*pyruvate carboxylase (PEPC), phospho*enol*pyruvate carboxykinase (PEPCk), pyruvate carboxylase (PC), malic enzyme (ME), and the glyoxylate pathway, has been estimated in a number of articles. Most investigations show that PC may possibly be responsible for the greatest contribution to the oxaloacetate pool (24,95,96), whereas the authors of another study using high temperature triggered glutamate excretion came to the conclusion that PEPC may be the most important enzyme (81,96). This result is highly relevant, in particular because PC contains biotin and the latter study was carried out under conditions of biotin limitation.

Flux analysis using NMR spectrometry has turned out to be very helpful in interpreting the metabolic changes related to conditions of active glutamate excretion. The carbon flux distribution within the central metabolism has been evaluated (Figure 8.6). The relative contribution of glycolysis in comparison to the pentose phosphate pathway was found to be increased under conditions of glutamate excretion (37,97), and the bidirectional carbon flux between pyruvate and oxaloacetate was decreased significantly (97). It should be mentioned

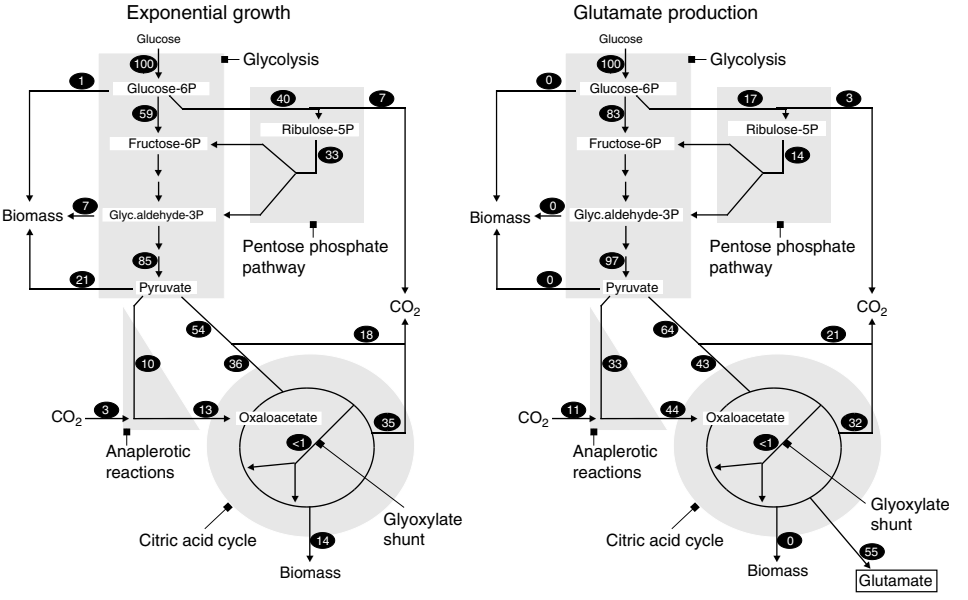

Figure 8.6 Metabolic flux distribution in *C. glutamicum* under conditions of growth and glutamate production. The major metabolic pathways starting from the substrate glucose and leading to biomass, CO_2 and glutamate are represented. The numbers give relative values of metabolic fluxes (see text). Adapted from (112).

that an opposite effect was found for lysine production in both cases. Also, massive flux redirection occurs with respect to anaplerotic reactions and biomass formation (Figure 8.6).

8.5.2 L-phenylalanine

Phenylalanine production is particularly important because of its use in the synthesis of the low calorie sweetener aspartame (methyl ester of the dipeptide L-aspartyl-L-phenylalanine), which is 150–200 times sweeter than sucrose. Besides fermentation, phenylalanine is also produced using chemical synthesis. For microbial production of L-phenylalanine mainly *E. coli* and *C. glutamicum* (and related species) are used (98). Strains have been obtained which are able to produce up to 50g/l of L-phenylalanine (99).

The biosynthetic pathway of aromatic amino acids is divided into a common part leading to chorismate from which the three terminal pathways to L-phenylalanine, L-tyrosine and L-tryptophan branch off (100). This pathway is efficiently regulated in *E. coli* by several different mechanisms both on the level of gene expression and protein activity (Figure 8.7).

Development of phenylalanine production in *E. coli* was based on several strategies to increase the carbon flow of aromatic amino acid biosynthesis. (31,101). The availability of an essential precursor molecule, erythrose-4-phosphate has been increased by modifying the expression of enzymes of the pentose phosphate pathway, namely transketolase (102) and transaldolase. PEP is a key intermediate in the synthesis of aromatic amino acids as well as in many other metabolic reactions. Consequently, efforts have been made to improve the supply of this compound either by direct means (31,101), e.g., by inactivating enzymes that compete for PEP, increasing the flux to PEP, and reducing the use of PEP for sugar uptake via the PTS, or by modulating general networks of carbon control in *E. coli* (103). In addition to increasing the availability of precursors, the specific

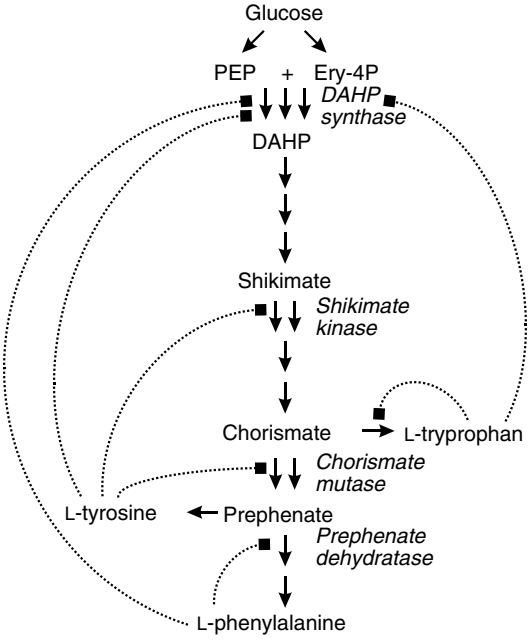

Figure 8.7 Biosynthesis pathways of aromatic amino acids. Simplified version of L-phenylalanine synthesis in *E. coli* including pathways to L-tryptophane and L-tyrosine. The dotted lines indicate regulation mechanisms, both feedback and transcriptional control are active at the indicated points.

pathways responsible for aromatic amino acid biosynthesis have also been successfully engineered. Alleviation of feedback inhibition of 3-deoxy-d-arabino-heptulosonate 7-phosphate synthase (DAHP) synthase isoenzymes by phenylalanine and tyrosine has been achieved, previously through application of appropriate amino acid analogues, and presently by site specific mutation. The genes encoding the enzymes chorismate mutase and prephenate dehydratase have been over expressed to increase the flux toward phenylalanine (101). In general, phenylalanine producers are tyrosine auxotrophs. Consequently, enzymes of the common pathway of aromatic amino acid synthesis are no longer feedback inhibited by this amino acid; moreover, tyrosine accumulation as a result of the shared pathway is prevented. A further beneficial effect is the possibility of a controlled growth limitation during the production phase by appropriate tyrosine feeding.

8.5.3 L-tryptophan

L-tryptophan is an amino acid with increasing potential commercial interest. It is currently mainly used as feed additive, despite its value as an essential amino acid, because of a number of casualties of eosinophilia myalgia syndrome (EMS) in humans which occurred due to the consumption of impure L-tryptophan manufactured by fermentation. L-tryptophan is produced by strains of *E. coli* (104) and *C. glutamicum* (105). In order to obtain effective tryptophan producing organisms, similar alterations of precursor pathways and of the biosynthetic route as described above for phenylalanine production have been carried out. In *E. coli*, it was not necessary to block the route to phenylalanine and tyrosine within the common pathway to aromatic amino acids, which would have led to auxotrophy for these two amino acids (106). Overexpression of the gene encoding the anthranilate synthase (*trpE*), which is the first specific enzyme in the tryptophan synthesis pathway, was sufficient to divert carbon flux to L-tryptophan. In addition, the gene encoding tryptophanase (*trnA*), the enzyme responsible for tryptophan degradation in *E. coli*, was removed in order to optimize tryptophan production (107).

Tryptophan production in *C. glutamicum* is an example where it has been shown that product uptake or reuptake may, in fact, be important in the production process. Engineering a decrease in tryptophan uptake led to a significant enhancement of tryptophan production (108). It was argued that removal of tryptophan uptake results in lower internal tryptophan concentrations and thus reduced feedback effects. Most interestingly, it was shown that tryptophan accumulation by the mutant lacking L-tryptophan uptake was improved mainly in the final part of the fermentation, when high external tryptophan concentrations were accumulated at the outside (31), thus illustrating the advantage of this strategy under conditions of a high backpressure from the external product.

8.5.4 L-lysine

Although lysine is used predominantly as a feed and not as a food additive, it is the best studied example of an amino acid production process in terms of molecular and biochemical aspects. Lysine biosynthesis and production have been intensively investigated with respect to the anabolic pathways involved, pathway regulation, and excretion. Consequently, it may serve here as a paradigm for understanding the tools available and the approaches used in the production of these kinds of amino acids. This holds true for several aspects which seem to be similar in the production of a number of these metabolites, namely pathway fine tuning and regulation, as well as metabolic connection to related pathways; the significance of central pathways for precursor supplementation, in particular the importance of the anaplerotic node; the impact of the cytoplasmic redox and energy balance; the demonstration of how helpful flux analysis may turn out to be in understanding amino acid biosynthesis pathways within the complex cellular metabolic network; and the fundamental

demonstration of how important active and energy dependent export systems may be in the course of amino acid production.

Lysine is solely produced by various strains of *C. glutamicum* in fermentative processes, and is used predominantly as a feed additive. Large scale production started in 1958 in Japan. Worldwide production is about 550,000 tons of L-lysine annually (72).

Lysine, like methionine, threonine and isoleucine, is a member of the aspartate family of amino acids. In *C. glutamicum*, the biosynthetic pathway is split into two branches in its lower part (Figure 8.7). The first enzyme of this pathway, aspartokinase, represents the major control point of carbon flow. It is inhibited in *C. glutamicum* by its end products lysine and threonine; consequently, all lysine producing strains contain a deregulated form of this enzyme, which, in general, carries a single amino acid exchange at position 279 of the α-subunit (109). The following were identified as being important in the flux control of this pathway (110,111): (1) deregulation of the aspartokinase (*LysC*); (2) increase of the activity of a feedback resistant aspartokinase, typically by overexpression; (3) increase in the activity of the dihydrodipicolinate synthase (*DapA*), the enzyme situated right after the branching point to the other members of the aspartate family of amino acids; (4) availability of oxaloacetate as precursor for aspartate; (5) availability of NADPH as reducing equivalent: redox balance; and (6) high activity of a specific, energy dependent lysine excretion system *(LysE)*.

Another interesting point about lysine biosynthesis in *C. glutamicum* is that the pathway is split at the level of piperideine-2,6-dicarboxylate (Figure 8.8). In contrast, *E. coli* possesses only the succinylase variant, and some *Bacillus* species only the dehydrogenase variant. One reason for this redundancy is the fact that D,L-diaminopimelate is an essential precursor for cell wall biosynthesis. Only flux analysis using NMR spectrometry revealed that the two pathways are used to highly different extents under differing environmental conditions (112). Because of a low affinity toward its substrate ammonium, the dehydrogenase cannot contribute significantly to lysine biosynthesis at low ammonium concentrations. At high concentrations, however, this pathway is responsible for about 75% of total flux to lysine. If either the succinylase or the dehydrogenase variant is inactivated, lysine production is reduced to about 40%. Consequently, both pathways are functionally combined to ensure the proper supply of D,L-diaminopimelate for the cell.

Last but not least, lysine is an ideal example to demonstrate the importance of the presence of an appropriate excretion system for amino acid production. By 1991, lysine export was shown to depend on the presence of a specific excretion system (11,113). Lysine export is coupled to the electrochemical proton potential, which provides the driving force for its active extrusion from the cytoplasm. Moreover, this system was the first amino acid export system, the encoding gene of which had been identified (14). *LysE*, the lysine excretion carrier, represents a relatively small membrane protein of 25.4 kDa with 5-6 transmembrane domains, presumably being present as a dimer in its active state. If this transport system is deleted, no further export of lysine is possible. Upon addition of lysine containing peptides, the internal lysine concentration reaches toxic values of up to 1 M in this mutant strain of *C. glutamicum*, thus providing an elegant proof for the significance of amino acid excretion carriers in cases of internal amino acid accumulation. *LysE* was the first member of a growing family of transport proteins involved in metabolite export. In addition to the lysine exporter *LysE*, a corresponding transcription factor, named *LysG*, was identified and later characterized (14).

Lysine production is one of the best studied examples of flux analysis in bacteria. Several techniques have been employed for the elucidation of flux distribution in *C. glutamicum* under conditions of lysine production in comparison to normal growth conditions (25). Moreover, methods of flux analysis using ^{13}C-NMR spectrometry

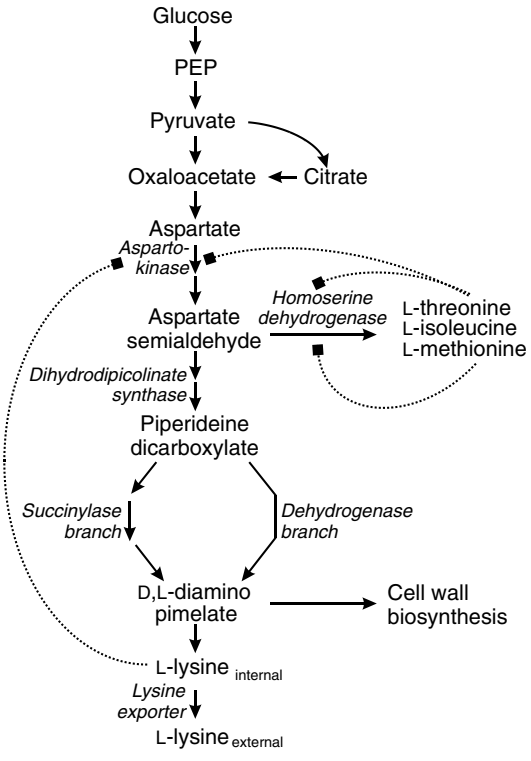

Figure 8.8 Lysine biosynthesis pathway and regulation in *C. glutamicum*. Simplified version of the biosynthesis pathway of the aspartate family of amino acids branches at aspartate semialdehyde to lysine, and to methionine, threonine and isoleucine, respectively. Some reactions of precursor supply are also indicated. The lysine anabolic pathway is split at the level of piperideine-2,6-dicarboxylate into the succinylase branch (4 enzymes, supply of succinyl-CoA and glutamate) and the dehydrogenase branch (1 enzyme, supply of NADPH and NH_4). NADPH is further needed in the steps leading to aspartate semialdehyde and piperideine-2,6-dicarboxylate. Pyruvate is added at the dipicolinate synthase. D,L-diaminopimelate is a precursor of cell wall biosynthesis. Feedback control mechanisms are indicated by dotted lines.

(21,69,95,97,114) as well as MALDI-TOF mass spectrometry (28,67–71) led to a detailed description of the activity of particular enzymes of central and peripheral pathways during lysine production. This made quantification of anaplerotic fluxes, of glycolysis in relation to the pentose phosphate pathway, and the individual share of the two branches of the split lysine pathway possible. Furthermore, particular modifications applied during metabolic engineering approaches could be controlled with respect to their impact on individual fluxes within the reaction network related to lysine production.

An interesting application of this approach concerns the redox balance under production conditions. For several steps within lysine biosynthesis, reducing power in the form of NADPH has to be provided. By using ^{13}C-NMR analysis, the supply of NADPH by the pentose phosphate pathway and by isocitrate dehydrogenase could be calculated. The share of the carbon flux through the pentose phosphate pathway (NADPH generating), in the total flux through the sum of glycolysis (NADH generating), and in the pentose phosphate pathway was found to be significantly increased under lysine production due to the demand of NADPH (68,97). A comparison of this flow and the total flow of NADPH in *C. glutamicum* under conditions of effective lysine production indicated that a limitation

by the availability of NADPH is likely. In a recent study in which various lysine producing strains with different lysine yields were systematically compared, an interesting close correlation of lysine yield and the extent of flux through the pentose phosphate pathway as well as the extent of anaplerotic flux was observed (71). The increase of nicotinamide nucleotide transhydrogenase activity in bacteria has also been demonstrated as a successful approach to overcome problems with respect to the redox balance due to a limitation in the NADPH supply (125).

8.5.5 Threonine

Besides lysine, threonine is another member of the aspartate family of amino acids. Like the essential amino acid lysine, threonine is mainly used as a feed additive and its production will thus be described here only briefly. After glutamate and lysine, threonine ranks third in the production volume with about 20,000 tons annually. In contrast to the previous two amino acids, threonine is produced using *E. coli* strains (116). However, studies to improve the application of *C. glutamicum* for threonine production have been reported (117,118). In addition to its commercial significance, threonine is a highly instructive example when reviewing systematic strategies to improve amino acid production. Above and beyond the common features essential for amino acid producing strains, as already discussed for lysine, development of threonine producers is interesting because of two major points. Development of threonine producing strains resembles a straightforward approach in combining classical strain breeding techniques with recombinant DNA technology. It is an example where a broad combination of metabolic changes finally led to the desired result. Among these changes is the introduction of the capacity to use alternate carbon sources as well as the abolishment of amino acid degradation pathways.

In the late 1960s an *E. coli* strain was described which produced threonine because of the presence of a mutant aspartokinase resistant to feedback inhibition by threonine, which was achieved by selection using the threonine analog α-amino-β-hydroxyvaleric acid (119). In the years 1977–1992, a highly productive *E. coli* strain was developed by the group of Debabov (116). The biosynthetic pathway leading to threonine was systematically optimized by several rounds of mutation and selection as well as genetic engineering. In addition to pathway engineering, the production strain was equipped with the capacity to use sucrose as a carbon source, in contrast to wild-type *E. coli* strains which cannot use sucrose. A further significant improvement of threonine production was achieved by reducing threonine degradation. For this purpose, the major threonine degrading enzyme, threonine dehydratase, was inactivated. At the end, a strain producing up to 100 g/L of threonine within 36 h of fermentation was obtained with practically no other products in significant amounts (116).

Threonine is also an example where knowledge on substrate transport in general and on specific excretion systems in particular is available. In *E. coli*, a number of threonine uptake systems are present, the correct contribution of which is not yet understood completely. Interestingly, it has been shown that threonine producer strains have acquired a significantly reduced capacity for threonine uptake in the course of strain construction (74,130). Consequently, expression of the *tdcC* gene encoding an L-threonine uptake system led to decreased threonine production (31). This is another example demonstrating the significance of avoiding product reuptake for effective production strains.

Altogether three genes are assumed to encode for threonine export systems in *E. coli*, namely *rhtA, rhtB* and *rhtC* (42), which all belong to a large family of carrier proteins the function of which has not yet been elucidated. The participation of some of these carriers in threonine export, however, has been questioned (120). Although it seems clear that at least one of these transport proteins contributes to threonine export, the situation does not seem to be fully clear yet (39).

Threonine export has been characterized on the molecular level in the case of *C. glutamicum* (43). Also in this case, the recently identified exporter protein *ThrE* again represents the first member of a new transporter family. In the course of the years, there has been considerable effort to optimize *C. glutamicum* with respect to threonine production also (116,117,118), however, the production capacity of these strains never reached that of good *E. coli* strains, due to a relatively low export capacity, as had been found on the biochemical level before (12,121). In agreement with this explanation, in a recent publication it was shown that both reduction of the activity of the major threonine degradation pathway (serine hydroxymethyltransferase, *glyA*) and overexpression of the threonine exporter *ThrE* led in fact to an increase in threonine productivity (118).

8.5.6 Other Amino Acids

A number of amino acids, which are of significant relevance for the food industry, e.g., L-aspartic acid (besides L-phenylalanine necessary for synthesis of aspartame), cysteine, glycine, and alanine, are still produced by chemical synthesis, by enzymatic methods, or by using immobilized cells (6). In recent years, new developments have been described which may lead to introduction of fermentation procedures for the production of at least some of these amino acids.

A new and promising example in this direction was recently reported for cysteine, an amino acid used as a flour additive, which is produced mainly by extraction or enzymatic methods because of the lack of effective producer strains. Cysteine biosynthesis is in general tightly regulated because of its dependence on sulphur metabolism as well as its potential danger of toxic or unwanted side products. Based on recombinant *E. coli* strains, a process leading to significant cysteine production has recently been developed (122). In the development of a cysteine producing strain, care had to be taken not to simply over express the respective genes encoding cysteine biosynthesis enzymes, but to guarantee a coordinated increase in the flux via this end product, in order to avoid accumulation of intermediates which potentially lead to toxic side products. Interestingly, in the effort to optimize cysteine production in *E. coli* strains, two specific exporters related to cysteine efflux were discovered. First, the gene *ydeD* was identified which after over expression significantly increased the efflux of thiazolidine derivatives of cysteine (45). These derivatives are formed intracellularly by the reaction of cysteine with ketones or aldehydes such as pyruvate or glyoxylate. They can be cleaved again in the external medium. The successful screening strategy was based on the property of genes to augment cysteine production in an industrial producer strain. The same strategy led recently to the identification of a further gene, *yfiK*, the product of which had a similar effect on efflux of cysteine in *E. coli* (46). These two transport proteins are both able to excrete O-acetylserine and cysteine, as well as derivatives of it (*YdeD*). Interestingly, a further, completely different cysteine exporter was recently identified in *E. coli*, obviously related to redox homeostasis during cytochrome biosynthesis (15).

8.6 FUTURE DEVELOPMENTS AND PERSPECTIVES

Classical procedures of strain breeding by mutation combined with selection and screening procedures have proven in the past to be powerful tools for providing efficient amino acid producing strains. With easy access to modern molecular techniques, strain improvement on the basis of detailed biochemical knowledge becomes more and more important. The obvious strategy applied previously was directed toward identifying and overcoming metabolic bottleneck reactions. This strategy, however, was frequently not as successful as

expected, in particular when it was applied to strains which already had a substantial capacity of amino acid production. Production strains which have evolved through many rounds of mutagenesis and selection are already fine tuned in their metabolic setup for increased production to a significant extent. Genetic manipulation that has strong impact on metabolism, as is normally the case when deleting or strongly over expressing particular genes, frequently leads to disruption of the subtle metabolic balance already obtained in these strains.

In the era of rational metabolic design, we need a combination of data and knowledge from many different fields for understanding bacterial metabolism, to design and to further optimize amino acid producing strains effectively. Process optimization needs an increase in systemic knowledge of how a bacterial cell functions in all relevant aspects. This strategy asks for more direct and accurate methods to analyze and monitor the current status of bacterial cells during fermentation. In the following, a variety of tools presently available for analysis and understanding of the complex network of bacterial metabolism will be reviewed.

The availability of a large number of bacterial genomes, including those of biotechnological relevance such as *E. coli* and *C. glutamicum*, fostered the direct application of genomic information for the design of production strains (30). Genome annotation was helpful for defining the inventory of enzymes and pathways with putative biotechnological significance. Post genome approaches, i.e., transcriptome and proteome analysis, are currently applied with increasing frequency. Several examples have been mentioned previously, such as manipulations within the anaplerotic node of reactions in *C. glutamicum*. A recent, very instructive example is represented by the design of a new production strain utilizing a novel procedure, designated "genome breeding" by the authors (31,123). Based on comparative genome analysis of wild-type and production strains, a set of mutations was identified by which these strains differ. Based on physiological and biochemical knowledge, mutations which were supposed to be relevant for amino acid production were selected and introduced step by step into the wild type strain. The response of these manipulations on amino acid excretion finally led to a production strain with high productivity, but a minimal set of known mutations. In the example mentioned (123) the authors succeeded in creating a lysine producing strain carrying single amino acid replacements in just three enzymes, namely aspartokinase, homoserine dehydrogenase, and pyruvate kinase. The strain obtained showed extremely high lysine productivity, and, due to the fact that growth and glucose consumption was almost as fast as in the wild type, the fermentation period was shortened to nearly half of that normally required. Further developments are to be expected with a systematic application of this approach, exploiting the large variety of available useful mutants which have originated during the long history of classical strain breeding. The aim of this strategy is to combine beneficial genetic properties identified in the genomes of various mutants into newly engineered producing strains (30). Future efforts in this direction necessarily need more input from biochemistry, given that the function of a large number of potentially interesting gene products, in particular transport proteins, are presently not known.

The availability of the genome is the basis for analyzing the transcriptome of a cell, i.e., the sum of mRNA synthesized at a given time. The information obtained with DNA array techniques may be extremely relevant in the near future for strain improvement in two respects. It is the basis for identifying regulons and modulons, sets of genes which are regulated in a concerted manner under particular metabolic states or conditions of environmental stress. This information can then be used to understand connections within local and global regulatory networks, which are relevant to the biosynthetic pathway under study. Instructive examples in connection with central carbon metabolism were recently reported.

DNA microarray analysis led to the finding of the reciprocal regulation of two genes encoding two different glyceraldehyde-3-phosphate dehydrogenase enzymes with different cofactor specificity, in dependence on the flux direction through the central metabolic pathways (54). A combination of microarray analysis and transcriptional analysis of specific genes revealed a surprising complexity of the regulon for acetate utilization in *C. glutamicum* (134).

Furthermore, DNA arrays are in principle a promising future tool for direct process monitoring. Efforts are underway in many labs to establish systems in which DNA array techniques and information on metabolic patterns is combined, in order to be able to follow the metabolic state of a cell suspension in a fermentor as closely as possible to an online situation. If this kind of analytic information were available, the performance of a bacterial culture in a fermenter, in particular in a prolonged fermentation mode, could be significantly improved. Fermentation may be run at the edge of the mass transfer capacity of the fermentor given precise monitoring of the physiological state of the cell (72). This is still far from being realistic due to technical reasons, mainly with respect to the time scale between drawing a sample and obtaining the transcriptome pattern, as well as the routine cost. This kind of monitoring system would be highly attractive for the purpose of keeping bacteria constantly at a metabolic state of optimal performance.

Proteome data will certainly be helpful, too, in the future, in particular if they are combined with information on posttranslational modification of the synthesized proteins, e.g., phosphorylation (60). Posttranslational modifications, which are not accessible by DNA array techniques, are potentially of high interest and may play an important role for regulation networks, in particular in central carbon metabolism. So far, the major effort is still directed toward a complete inventory of the proteins synthesized, mainly due to the fact that some classes of proteins, among them membrane proteins and low abundance proteins such as transcription factors, are still not detectable by 2D gel electrophoresis (57–59). The same holds for another developing tool, namely the investigation of protein to protein interactions, which may become a significant help in unravelling regulatory networks based on direct protein crosstalk.

Certainly a tool of utmost relevance will be metabolome analysis, based on gas chromatography (GC)- or liquid chromatography-mass spectrometry (LC-MS) techniques. As a matter of fact, it is not widely recognized that we still do not have an idea of the total inventory of even the major metabolites in any single bacterial cell. It is obvious that this information would be extremely helpful for understanding the differences between certain metabolic conditions, for example, during fermentation, or for identifying metabolic changes in production strains as compared to the wild type. Moreover, metabolome data represents the basis for sophisticated metabolic flux analysis.

Several examples of the value of metabolic flux analysis combined with metabolite balancing have been described in this chapter. With the introduction of NMR and, in particular, MS techniques into this field, a complete analysis of the dynamic situation of cell metabolism (the fluxome) became, in principle, accessible for routine studies. The evaluation of the significance and value of particular changes in the metabolism of bacterial strains under different metabolic situations seems to be an essential basis for a rational metabolic design. Flux analysis is furthermore a prerequisite for understanding the dynamic situation of cell metabolism including all regulatory connections. Last but not least, it is obvious that the information obtained by various levels of analyses mentioned here can be integrated into a systems biology approach only with the help of powerful bioinformatics tools.

Reaching the aim of an increase in the systemic understanding of cell metabolism, however, does not only require global approaches, but certainly depends to a large extent on additional information from biochemistry and physiology. An instructive example mentioned above is the identification and analysis of specific export proteins to be responsible

for amino acid excretion. Furthermore, the architecture of complex regulatory networks cannot be fully elucidated without the help of biochemical techniques.

Although not the topic of this chapter, further development in fermentation techniques is still a major option for improvement of amino acid production, based on detailed knowledge of biochemistry and physiology of the bacterial cell. A potentially promising example concerns the type of fermentation procedure to be used. It has been discussed before that continuous fermentation would in principle provide an interesting method with several advantages, which, however, due to some drawbacks is not yet used for amino acid production. Continuous fermentation needs coupling of growth and amino acid production, which is in fact frequently observed for lysine production by *C. glutamicum*. In a number of procedures, growth and production are artificially uncoupled to some extent, as in for threonine production by *E. coli*. Unfortunately, it is not yet well understood in terms of metabolic, energetic, and regulatory reasons how and to what extent amino acid excretion can be coupled to growth under optimum production conditions.

In the preceding part of this chapter, tools available for future developments in amino acid production have been listed. However, it seems interesting to identify targets for these efforts which seem to be attractive on the basis of current knowledge. To a large extent, this would be *C. glutamicum*, because the wealth of biochemical information available is certainly more impressive for *E. coli*.

In spite of the fact that central and peripheral metabolism in *C. glutamicum* has been studied to a significant extent, this does not hold for sugar metabolism and, in particular, for sugar uptake. Although the flux through glycolysis has been analysed, the regulation of important enzymes, such as fructose bisphosphate kinase, is not yet known. Interestingly, two genes encoding isoenzymes of each the fructose bisphosphate kinase and of the glyceraldehyde-3-phosphate dehydrogenase have been found in the genome of *C. glutamicum* (72). It is well known from *E. coli* that the phospho*enol*pyruvate dependent phosphotransferase systems (PTS) are, besides their significance in sugar uptake, important for regulating other uptake systems and pathways of central carbon metabolism. In several cases, as in for glutamate production, it is not yet known how the cell actually regulates the activity of amino acid excretion systems in dependence of the availability of the carbon and energy supply. It seems to be a plausible hypothesis that sugar uptake via PTS may be involved in this kind of regulation. Moreover, when the carbon flow to amino acid end products in the course of process optimization is further increased, at some point substrate uptake may become limiting in the overall pathway to the product. A further aspect of engineering PTS systems for sugar uptake may be noted here. Efforts have been made to bypass this uptake system in *E. coli* in connection with production of aromatic amino acids, in order to increase the cellular content of phospho*enol*pyruvate, which is both a precursor of aromatic amino acids and the energy donor of the PTS system. In fact, this manipulation resulted in a higher yield of phenylalanine (101), representing another example of transport design, different from that mentioned in connection with reuptake of substrate (tryptophan), as well as in connection with excretion systems.

Certainly a core field of interest in future development will be regulatory networks, including response to stress conditions. Whereas regulation of particular biosynthetic pathways seems to be quite well understood, both in *E. coli* and *C. glutamicum*, this is not true to the same extent for global regulatory mechanism, including the response of the cell to limitation of carbon (carbon control) or nitrogen sources (nitrogen control). Both control systems are well studied in *E. coli* (135), and the latter has also been elucidated in *C. glutamicum* (18,136). Unfortunately, this does not hold for the important network of carbon control in this bacterium. Knowledge on this topic would be furthermore attractive for investigating suspected regulatory interactions between the signal transduction

mechanisms of carbon and nitrogen control, which would certainly be essential for a full understanding of the integration of amino acid metabolism in the cellular network. The wealth of regulatory mechanisms as elucidated in *E. coli* to a significant extent by numerous studies is unfortunately not available in *C. glutamicum*. This refers to the variety of sigma factors, transcription factors, two component systems, attenuation mechanisms, RNA stability, posttranslational modifications, enzyme stability, and degradation. A better knowledge of these mechanisms and their significance for amino acid synthesis would also be the basis for the design of appropriate DNA arrays for controlling the status of fermentation processes.

These regulation networks are also relevant for cellular mechanisms of stress response. Bacterial cells are known to possess sophisticated strategies for stress response (heat, osmotic stress, nutrient limitation, and many others) which involve coordinated regulation on the level of gene expression and protein activity. A well studied example is the sigma B regulon in the Gram-positive *Bacillus subtilis* (127). In case of *C. glutamicum*, only the response to osmotic stress (19,128), nitrogen limitation (18,126), and, to some extent, phosphate limitation (129) have been studied in detail so far. Because enforcement of high yield production in fermentors is certainly a kind of stress in terms of growth limitation, pathway rearrangement, concentration of nutrients, and products, both specific and general stress responses will be active under these conditions and need to be further elucidated.

Another field of significant importance, which is still neglected to some extent, is energy metabolism. This is of particular interest for glutamate production in *C. glutamicum*, which seems to be related to a metabolic overflow situation including mechanisms wasting metabolic energy such as futile cycling (130). Information is available on architecture and organization of the respiratory chain and related redox enzymes in *C. glutamicum* (131–136), whereas the role of the core energy converter ATPase and that of possible futile cycles under conditions of metabolic overflow (glutamate production) is not yet clear. Interesting data have recently been published indicating a close relation of ATPase activity and efficiency of glutamate excretion in *C. glutamicum* (137).

In view of an integrative pattern of reactions being involved in amino acid production (Figure 8.1), the presence, activity and regulation of amino acid excretion systems seems also to be highly relevant. Despite the fact that the importance of active amino acid excretion has been elegantly proven in the case of lysine (14,138), increasing knowledge of these systems and their availability for constructing recombinant producing strains has so far not successfully been integrated into application, with just one exception. The possibility has to be taken into consideration, of course, that, at least in the case of lysine excretion, the activity of the exporter may not be limiting even in producer strains. As has been mentioned above, overexpression of a gene coding for a secondary carrier protein has significantly improved export of cysteine derivatives in engineered *E. coli* strains (45). It has recently been reported that for threonine excretion in a recombinant *C. glutamicum* strain, overexpression of the gene encoding the threonine exporter in fact improved threonine accumulation in the medium. (118). The observed positive effect may be due to the fact that the capacity of the amino acid export systems present, and is very limited in both cases reported, which was in fact shown for threonine in *C. glutamicum* (12,121).

In any case, it would be of utmost interest to identify the export system responsible for excretion of glutamate in *C. glutamicum*, which has so far been characterized only at the biochemical level (87,139). Furthermore, the observation that many more products can, in principle, also be observed to be excreted under particular physiological conditions by *C. glutamicum*, *E. coli* and a number of other bacteria, strongly argues for the presence of many more export systems. Because the discovery of some of these systems has already led to the definition of completely new families of transport proteins, more "surprises" of this kind have to be expected.

A truly special property of *C. glutamicum* is the dependence of amino acid excretion on the integrity of the cell wall or plasma membrane. Although in general only discussed in connection with glutamate export, it is important to note that the excretion of other amino acids, such as lysine and proline is also found to be increased when the cell wall is affected . Several different hypotheses for explaining the contribution of the cell wall to amino acid excretion have already been discussed in section 8.5. If a likely explanation were correct, that of a regulatory connection between activity of cell wall synthesis and enzymes of the central metabolism in *C. glutamicum*, it would add an interesting target for further optimization of amino acid excretion for application of molecular and biochemical techniques. Recent publications indicate significant progress toward an improved understanding of cell wall biosynthesis in *C. glutamicum* (140–142).

Finally, after discussing possible tools and targets for future optimization strategies, it is worth briefly discussing more general aims in amino acid production, other than the specific strategies of increasing metabolic fluxes toward the desired end product. In the case of low price products, such as glutamate, lysine, or threonine, future efforts will concentrate on strategies to increase the yield of amino acid production processes. Current yields (g amino acid / g sugar) are 0.45–0.55 for glutamate, 0.4–0.5 for lysine and threonine, and 0.2–0.25 for phenylalanine (31). It is very difficult to calculate true maximum yields, because some additional factors such as ATP stoichiometry and efficiency of energy metabolism are not exactly known. It is obvious, however, that the enormous heat production by bacterial cultures during industrial fermentation due to the high respiration activity argues for a partially uncoupled energy metabolism. Whether this is an intrinsic property of respiratory chain activity and energy metabolism under conditions of amino acid production, or whether it is due to unknown futile cycles is not clear. Consequently, it may in principle be an interesting future target for improvement of efficiency.

Besides improving already available processes in *C. glutamicum* and *E. coli*, efforts on the design of new products or on new processes for available products are a constant challenge for research in amino acid production. The example of L-cysteine production has been mentioned above, where a new process in *E. coli* characterized by novel aspects of strain construction has been reported recently. It may also be possible and attractive in the future to develop a fermentation process for methionine, the only amino acid which is still chemically produced in racemic form in bulk quantities.

For research in microbial biotechnology, as well as for application in industrial processes, a broad basis of physiological, genetic, and biochemical knowledge would be highly attractive. In spite of all classical and modern tools available, we are still far from a complete understanding even of a single bacterial cell in terms of systems biology. The methods applied so far are increasingly well suited for a descriptive understanding; however, they are clearly not detailed enough to be used for predictive statements. Consequently, the final goal of this multidisciplinary work should aim at the "virtual bacterial cell," an aim which is certainly still far from reality, both in the case of *E. coli* and *C. glutamicum*. Due to the combined effort of many groups working on a multilevel analysis of these microorganisms, however, it seems highly probable that a bacterial cell will be the first cell to be understood on that level.

The introduction of techniques of amino acid production by using microorganisms has led to an enormous increase in the beneficial use of these compounds. The application of the molecular tools available will certainly help to overcome remaining limitations, provided these tools can be applied. In that sense, further improvement of amino acid production in the food industry will only be economically relevant if application of genetically engineered bacterial producer strains will not be restricted to an unnecessary extent.

Biotechnology of Microbial Polysaccharides in Food

Ian W. Sutherland

CONTENTS

9.1 INTRODUCTION

Polysaccharides are incorporated into foods to alter the rheological properties of the water present and thus change the texture of the product. Most of the polysaccharides used are employed because of their ability to thicken substances or to cause gel formation. They are also used to stabilize foams and emulsions, suspend particulate materials and inhibit or decrease syneresis, as well as increase water retention. Advantage is also taken of the ability of some mixtures of polysaccharides to exhibit synergistic gelling — basically for the two polymers to yield a gel at concentrations of each which will not in themselves form gels. Associated with these readily measurable physical properties are others such as "mouth feel," which are more difficult to define but which also show some correlation with physical properties. In addition, polysaccharides are incorporated because of their capacity to control the texture of foods and to prevent or reduce ice crystal formation in frozen foods; they may also influence the appearance, color, and flavor of prepared foodstuffs. It must also be remembered that many foodstuffs already contain animal or plant polysaccharides such as hyaluronic acid, starch, or pectin. Thus addition of any further polysaccharide or polysaccharides will in all probability involve interactions with these components as well as with proteins, lipids, and other food components. Currently the polysaccharides added to food are sourced from bacteria, algae, and plants, and are exemplified by xanthan and gellan, alginate and carrageenan, and pectin and starch respectively.

The use of microbial polysaccharides in food is also governed by a number of factors unrelated to their physical properties. This includes the observation that humans generally do not metabolize microbial polysaccharides. They are nutritionally inert and nontoxic. Currently there is considerable consumer concern over the use of "food additives," including hydrocolloids. Most regulatory bodies review their lists of permitted food additives at regular intervals, when they may amend the regulations. This may also lead to improved or altered specifications. On the other hand, many of the microbial species, which are currently used in food preparations, synthesize and excrete polysaccharides as well as other products.

Very many bacteria, yeasts, and fungi can produce polysaccharides. While much interest in these polymers is due to their role in infection or adhesion, some of these polymers have proved to be useful industrial products. Dextran was the first microbial polysaccharide to be commercialized and to receive approval for food use. Although it is no longer used for this purpose, several other microbial polymers are now commercial products with a variety of uses. Use of these microbial exopolysaccharides (EPS) in foods is more limited. Only two bacterial polysaccharides are currently extensively employed by the food industry, except in Japan where polymers of this type are regarded as natural products. It must also be remembered that although microbial polysaccharides may be incorporated into foods as food additives, many other EPS are integral products of microorganisms which are involved in the preparation of the food. A number of natural foods contain polysaccharide-producing microorganisms and considerable interest has currently been shown in the lactic acid bacteria (LAB) which are widely used in fermented milk products and other fermented foods. This review will consider both microbial polysaccharides as food additives and those EPS which are present as normal products of microorganisms used in fermented foods.

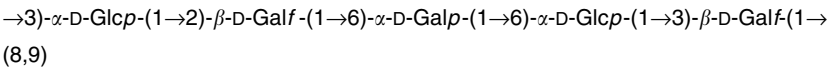
9.2 NATURAL OCCURRENCE OF MICROBIAL POLYSACCHARIDES IN FOODS

9.2.1 Microbial Polysaccharides Present in Food as Products of Microbial Food Components

A number of the microorganisms that are used in the preparation of foodstuffs are capable of synthesizing extracellular polysaccharides. This is especially true of the lactic acid

bacteria (*Streptococcus*, *Lactobacillus* and *Lactococcus* spp.), and a number of structural studies have recently elucidated the nature of some of these polysaccharides. These and other reports can be found in the reviews of De Vuyst and Degeest (1) and Laws et al. (2). Less is yet known about the relationship between structure and physical properties than is the case for Gram-negative bacterial products such as xanthan and gellan (3). As well as the deliberate addition of microbial polysaccharides to food products to obtain specific properties, there are a number of bacterial fermentations in which polysaccharide is produced and is needed to yield a specific type of product. An example of this can be found in certain types of fermented milk product such as yogurts. In some of these, the production of polysaccharide during bacterial growth is claimed to enhance the product, particularly in respect of the body and texture of the product and in its smoothness and mouth feel. This is particularly true of countries such as the Netherlands and France in which the addition of plant or animal stabilizers is prohibited. The polysaccharide from *Streptococcus salivarus thermophilus* is used in this way. Unfortunately, the production of an apparently neutral glycan by these bacteria is unstable and the use of the bacteria tends to lead to a lack of uniformity in the product. Polysaccharide-producing strains of *Lactobacillus delbruekii bulgaricus* are also used for this purpose, strains being available which synthesize from 14 to 400 mg/litre of a culture of viscous polysaccharide in which galactose is the major component. There are also some fermented milk products in which the production of a thick, gel-like texture results from the exopolysaccharide synthesized by the bacteria used. These are traditional products from parts of Finland, which do not have widespread sales elsewhere. Thus, the importance of polysaccharides from mesophilic and thermophilic LAB is recognized in the production and rheological characteristics of fermented milks, but problems have been caused by the instability of products and requirement of many of these bacteria to grow in complex media (4). The textural and other improvements are made by these polysaccharides, even though the actual yields are low. As pointed out by Ruas-Madiedo et al. (5) some of the EPS from LAB may also possess health-promoting effects such as antitumor and immune-modulating activities in addition to possible prebiotic activity and cholesterol-lowering activity (6).

As LAB are recognized food microorganisms, increasing interest has recently been shown in the EPS synthesized by them. It is also accepted that at present EPS derived from these bacteria could not yield significant commercial products (7). Now that a range of polysaccharides from LAB has been studied, it is clear that no common pattern of structures exists, although certain monosaccharides including D-glucose, D-galactose, and L-rhamnose are commonly found (1). While all the heteropolysaccharides are composed of regular repeat units, some carry phosphate groups in addition to their monosaccharide components, while others lack the inorganic residues. Most of the polysaccharides contain the sugars common to other bacterial EPS and as yet few of the rarer monosaccharides have been reported. Among these are galactofuranose found in the pentasaccharide repeat units of the *Lactobacillus rhamnosus* strains C83 EPS (Figure 9.1) (8) and KL37c (9). This monosaccharide is also present in the exopolysaccharide produced by *Streptococcus thermophilus* EU20 (10) as well as *S. thermophilus* strain SY 89 in which it is found together with galactopyranose (Figure 9.2) (11). The majority of EPS from LAB are composed of a small range of common sugars very frequently including D-glucose, D-galactose, and L-rhamnose (2). These are mainly neutral hexoses or methylpentoses, but may also include the corresponding uronic acids and *N*-acetylaminosugars (12). Although L-fucose is common among the EPS of Gram negative bacteria, L-rhamnose is the methylpentose most frequently found in EPS from LAB. Many of the EPS are polyanionic due to the presence of either uronic acids or phosphate groups. The most common uronic acid is D-glucuronic acid, but D-galacturonic acid is also frequently found. The structures are repeat units of 3–7 monosaccharides and although the polymers are essentially linear macromolecules, they



(8,9)

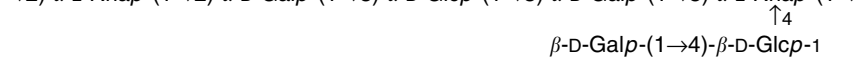
(13)

Figure 9.3 The triply branched repeat unit of the EPS of *Lactobacillus sake* 0-1 (13).

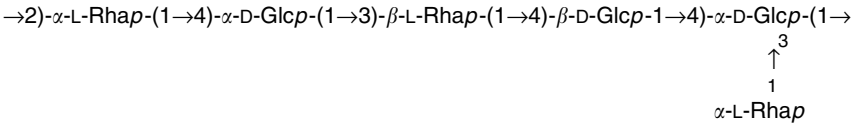


(14)

Figure 9.4 The heptasaccharide repeat of *Lactococcus lactis cremoris* B39 (14).

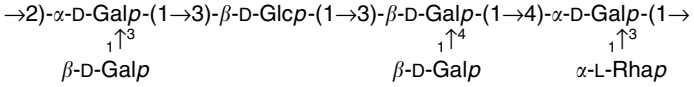
also very commonly carry branches. Examples of this can be seen in the triply branched repeat unit of *Lactobacillus sake* 0-1 (Figure 9.3) (13) or the heptasaccharide repeat of *Lactococcus lactis cremoris* B39 (Figure 9.4) (14). The branches may be on different monosaccharides, or on the same monosaccharide as is the case for the EPS from *Lactobacillus lactis cremoris* SBT 0495 in which a single D-galactose carries both a rhamnose and a galactose-1-phosphate (15). Strains of the same species may yield several different EPS chemotypes. An isolate of *Lactobacillus delbruekii bulgaricus* from kefir grains yielded a polysaccharide with almost equimolar amounts of D-glucose and D-galactose (16), whereas the EPS from another strain of the same subspecies had a very different structure as can be seen in Figure 9.5 (17). Another strain possessed a heptasaccharide repeating unit in which the ratio of D-galactose: D-glucose: L-rhamnose was 5:1:1 with the structure shown in Figure 9.6 (18). Strain 291 differed again in yielding a pentasaccharide repeat unit containing only glucose and galactose (Figure 9.7) (19).

In addition to monosaccharides, bacterial EPS frequently carry other substituents, which may either be organic or inorganic in nature. The most common organic substituents are either *O*-acetyl groups or pyruvate ketals. The pyruvate ketals are most commonly found attached to D-galactose, D-glucose, or D-mannose residues. It is fairly unusual to find both pyruvate and acetate attached to the same monosaccharide residue. As more structures from Gram-positive species are studied, a number of these have been found to contain pyruvate. One such is EPS from *Lactobacillus rhamnosus* RW-959M in which a galactose residue



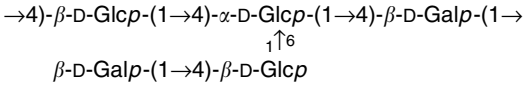
(17).

Figure 9.5 The structure of the EPS from *Lactobacillus delbrueckii bulgaricus* EU23 (17).



(18)

Figure 9.6 The heptasaccharide structure of the EPS from *Lactobacillus delbrueckii bulgaricus* rr (18).

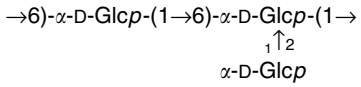


(19)

Figure 9.7 The structure of the EPS from *Lactobacillus delbrueckii bulgaricus* 291 (19).

carried a 4,6-linked ketal (20). In a number of EPS the acyl groups are present in nonstoichiometric amounts. Thus some xanthans contain 0.3 moles of pyruvate per repeat unit. Phosphate groups occur widely among EPS from Gram-positive species including some of the industrially important *Streptococcus* and *Lactobacillus* species, which are employed in the fermentation of milk, yogurt, and cheeses. Quite a few of the extracellular polysaccharides from LAB are neutral polymers as can be seen in Figures 2 and 5. Although some of the LAB can produce homopolymers composed of a single monosaccharide, the majority are heteropolysaccharides. Among the homopolysaccharides synthesized by LAB are glucans and fructans, several of which are produced only when the bacteria are grown in the presence of sucrose. One example is *Lactobacillus reuteri* LB121 which yielded both a fructan and a glucan with masses of 3.5 and 150 kDa respectively (21). Unusually, one strain of *L. lactis lactis* (H414) yielded a galactan. An enzyme from the *L. reuteri* 121 strain was later used to produce a high mass ($>10^7$) fructan with $\beta(2\rightarrow1)$ linkages (22). This was thus the first report of bacterial inulin synthesis in a GRAS listed bacterial species (the only other observation of bacterial inulin formation related to a non-GRAS listed species). The strain was also unusual in being capable of forming a highly branched α-D-glucan (23).

It should also be remembered that a number of bacterial strains might have the capacity to form more than one type of polysaccharide, although it is unusual for two or more EPS to be secreted simultaneously. An example of this was *Streptococcus thermophilus* LY03 which yielded two EPS of the same composition, D-glucose and D-galactose in the same molar ratio of 1:4, but differing in mass (24). In contrast to this, strain S3 formed a polymer composed of D-galactose and L-rhamnose in the ratio 2:1 and was also partially acetylated on a D-galactofuranosyl side chain residue (25). The hexasaccharide repeat unit contained three D-galactopyranosyl residues. One of the simplest structures identified to date is the neutral trisaccharide repeat unit from *Lactobacillus* spp. G-77



(26)

Figure 9.8 The neutral trisaccharide repeat unit from *Lactobacillus* spp. G-77 (26).

(Figure 9.8) (26). This bacterial species was capable of forming two EPS, the other being a 2-substituted (1→3)-*β*-D-glucan, a structure that was also found in the EPS from *Pediococcus damnosus* (27).

Among the most unusual structures determined so far is that for an EPS from *Streptococcus thermophilus* 8S (28). This proved to possess a pentasaccharide repeat unit containing D-galactose: D-glucose: D-ribose: *N*-acetyl-D-galactosamine in the molar ratio 2:1:1:1. In addition an open chain nonionic acid was identified. A substituent of this type has not been reported from other bacterial EPS. Some high mass LAB polymers appear to possess more complex structures with nonstoichiometric amounts of their components. Thus the EPS from *Lactobacillus helveticus* TY1-2 was formed from heptasaccharide repeat units with the molar ratio glucose: galactose: glucosamine 3.0:2.8:0.9 (29). The actual structure was in the form of a trisaccharide backbone with the aminosugar residue carrying both a monosaccharide (a D-galactosyl residue) and a trisaccharide side chain.

9.2.2 Physical Properties

Rheological studies on the EPS from *Propionobacterium acidi-propiionici* DSM4900 revealed shear thinning behavior and suggested that it formed an entangled polymer solution (30), while a polymer from *Streptococcus thermophilus* SY containing rhamnose, glucose, and galactose, was claimed to yield pseudoplastic solutions and have a viscosity higher than xanthan (31). Another LAB EPS, from *L. saké*, had an estimated mass of 4–9 x 10^6 Da and was also claimed to have a higher intrinsic viscosity than xanthan (32). Studies have also been made on the effects of chemical modifications to the EPS from a small number of LAB. Tuinier et al. (33) found that removal of side chain D-galactosyl residues from the EPS of *L. lactis cremoris* polymers increased chain stiffness and thickening efficiency. Deacetylation of the EPS from strain B891 left the chain stiffness unaltered.

In one of the few attempts to model the structure of EPS from *Lactobacillus helveticus*, Faber et al. (34) noted that the EPS from strain 766 exhibited a flexible twisted secondary structure. In their tertiary structure, the polysaccharide chains tended to adopt a random coil conformation.

9.2.3 Production and Synthesis

Yields of most of the EPS from LAB are generally low. However *L. reuteri* LB121 was claimed to form 10g. l^{-1} of two homopolysaccharides (21). Various studies in the laboratory have utilized whey-based media to permit the isolation and characterization of the polysaccharides products from LAB. Thus Ricciardi et al. (31) noted that synthesis of the polymer in *S. thermophilus* was growth associated and obtained yields of 152mg. l^{-1}. Attempts have also been made to improve EPS synthesis through identification and augmentation of key enzymes involved in the earlier stages of carbohydrate metabolism. However this has not always proved successful. In *S. thermophilus*, over expression of *galU* (UDP-glucose pyrophosphorylase) enhanced enzyme activity but not EPS synthesis (35). Only when *galU* and *pgmA* (phosphoglucomutase) were both over expressed were higher yields of EPS obtained. It has also been recognized that in *Lactococcus lactis*, there

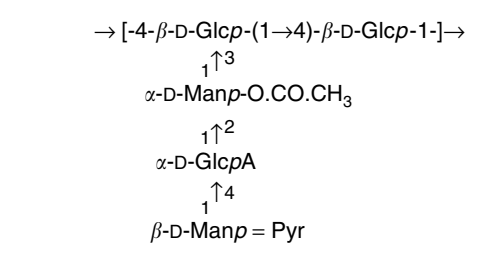
was competition between EPS synthesis and bacterial growth, with glucose-6-phosphate as the key intermediate metabolite (36). This study indicated possible mechanism by which EPS production might be enhanced through genetic manipulation of the EPS biosynthetic and glycolysis pathways. However a later report from the same researchers (37) revealed that although over expression of the *galU* gene greatly increased sugar nucleotide (UDP-glucose and UDP-galactose) levels, EPS production was not significantly different from the wild type.

9.3 MICROBIAL POLYSACCHARIDES INCORPORATED AS FOOD ADDITIVES

In the US, polysaccharides which are to be used as food additives are subject to Generally Regarded As Safe (GRAS) regulations and must be approved by the USDA. Currently only two microbial polysaccharide products have such approval – xanthan and gellan, although curdlan may also be under evaluation. Previously dextran was also an approved food additive, but it is not currently used in food manufacture. In Japan, a wider view is taken and microbial EPS are regarded as natural products. One thus finds the bacterial product curdlan being used in various foodstuffs, while pullulan (from the fungus *Aureobasidium pullulans*) is also acceptable. In the case of pullulan, the polysaccharide also has potential value as a food packaging material, a role which is also strictly controlled.

9.3.1 Xanthan

Xanthan, a product from the plant pathogenic bacterium *Xanthomonas campestris*, is typically produced copiously as an extracellular slime by the various pathovars of *Xanthomonas campestris* as well as by some other *Xanthomonas* species. Acid hydrolysates of xanthan contain D-glucose, D-mannose, and D-glucuronic acid in the molar ratio 2:2:1. Other components have been reported in polysaccharides from bacterial isolates described as *Xanthomonas* species, but the strains involved have generally been poorly characterized. The primary structure of the polysaccharide is a pentasaccharide repeat unit, effectively a cellulose chain to which trisaccharide side chains are attached at the C-3 position on alternate D-glucosyl residues (38,39) (Figure 9.9). The polysaccharides from several other *Xanthomonas* species seem to share the same composition as that from pathovars of *X. campestris*. Depending on the bacterial strain and on the physiological conditions for bacterial growth, the polysaccharide may carry varying amounts of *O*-acetyl groups on the



Typically the internal α-D-mannosyl residue is fully acetylated but only c. 30% of the β-mannosyl termini are ketalated.

(38)

Figure 9.9 The structure of xanthan from *Xanthomonas campestris* (38).

C-6 position of the internal α-D-mannosyl residue and of 4,6-carboxyethylidene (pyruvate ketal) on the side chain terminal β-D-mannosyl residue respectively. Material from some strains (not used for food) carries two acetyl groups on the internal mannosyl residue, and there is some evidence to suggest that certain xanthan preparations may even contain in excess of 2 moles of acetate per repeat unit. However, the material used as a food additive derives from a standard strain (frequently designated NRRL B-1459) and generally contains pyruvate and acetate in approximate molar ratios of 0.3 and 1.0 per pentasaccharide repeat unit.

X. campestris will grow and produce EPS on a wide range of carbon substrates including amino acids, citric acid cycle intermediates, and carbohydrates. Either ammonium salts or amino acids can be used as nitrogen sources. Various ions are needed for bacterial growth and polysaccharide synthesis. Limitation of any of the ions required for substrate uptake or for precursor or polymer synthesis can affect the yield and properties of the EPS. Xanthan formation by *X. campestris* resembles many other bacterial-EPS-producing systems in that polymer production is favored by a high ratio of carbon source/limiting nutrients such as nitrogen. Typically, media for laboratory synthesis of xanthan contain 0.1–0.2% ammonium salt and 2–3% glucose or sucrose. Xanthan can even be produced in fairly good yield when the bacteria are grown in a simple synthetic medium composed of glucose, ammonium sulphate, and salts, but production is improved in the presence of organic nitrogen sources. The quality and the final yield of xanthan may be enhanced by the addition of small amounts of organic acids or of citric acid cycle intermediates such as α-ketoglutaric acid (40). Oxygen is required for growth and for xanthan production, and as the culture viscosity increases as xanthan is formed, oxygen may rapidly become limiting. For satisfactory cultivation in a fermenter, vigorous aeration was essential and fermentation vessels had to be designed to ensure minimal dead space, which would otherwise lead to stagnant areas of culture. The xanthan production process is complicated by mass transfer reactions in the high viscosity broths. Oxygen solubility decreased with increasing xanthan concentration and the diffusion constant of oxygen in dilute solutions of the polysaccharide was reduced relative to water (41). The presence of polysaccharide in the fermentation broth may also affect the availability of carbon substrates such as glucose and sucrose by interaction with these carbohydrates. Consequently, fed-batch culture is usually preferred. Nakajima et al. (42) suggested that in the design of the fermentation vessel, the volume exposed to high shear is of critical importance. The specific rate of xanthan production depended on the volume of the high shear region.

Xanthan is produced throughout growth of *X. campestris* and in the stationary phase. The specific rate of xanthan synthesis was closely related to the bacterial growth rate in batch culture; maximal during exponential growth and minimal during the stationary phase. In this respect, xanthan production resembled the synthesis of several other bacterial exopolysaccharides. Differences could be seen in the viscosity and the acylation of the xanthan synthesized in nutrient limited media during various phases of the growth cycle (43,44). Acetyl CoA and phosphoenolpyruvate may not be readily available during certain stages of growth to permit the complete acylation of the xanthan repeating units. Consequently, the xanthan synthesized in batch culture represents the products of all phases of growth and is possibly a mixture of several molecular types with varying degrees of acylation and varying mass.

9.3.1.1 Industrial Substrates

In the laboratory, pure substrates such as glucose or sucrose are used, whereas in industrial production different substrates are employed. The substrates must be cheap, plentiful carbon sources, which frequently include starch, starch hydrolysates, corn syrup, molasses,

glucose, and sucrose (derived from either sugar beet or from sugar cane). It is imperative that they also be acceptable for food use. Optimal synthesis of xanthan requires a balance between utilizable carbon and nitrogen sources. Care must therefore be taken to obtain consistency in yield and product quality when using substrates which may contain nitrogen in addition to carbohydrate. The nutritional versatility of *X. campestris* is clearly a major factor in favor of its use for commercial xanthan production. However, the quality of the xanthan produced from different substrates may vary considerably — the molecular weight and hence the rheological characteristics of xanthan synthesized from glucose or starch may well differ from that formed when whey or other proteinaceous material is employed. The nitrogen sources used for industrial production of xanthan may include yeast hydrolysates, soybean meal, cottonseed flour, distillers' solubles, or casein hydrolysates. In batch culture for industrial production of the polysaccharide, there must be careful control of pH and of the aeration rate. Adequate oxygen transfer may be difficult to achieve unless the fermentation vessel has been carefully designed to ensure that mixing is optimal. To minimize this problem, fed-batch processes may be used. Even so, the conditions used for production and processing must be carefully standardized to ensure that product yield and quality are consistent. In the laboratory, the polymer can be readily prepared in high yield, and then separated from the bacterial cells by high speed centrifugation or by precipitation with quaternary ammonium compounds. As an industrial product, it is manufactured in stirred tank fermenters on a large scale by batch or fed-batch fermentation by a number of commercial companies; normally fermentation proceeds for 3 days at 30°C. In this respect, Linton (45) has claimed that "exopolysaccharide production is a very efficient process" and calculations have shown that the conversion efficiency of substrate to xanthan is very high. After completion of fermentation, the product is subjected to heat treatment to eliminate viable bacteria and to destroy hydrolytic enzymes such as cellulases, amylases, pectinases, and proteases. This treatment also enhanced the rheological properties of xanthan in solution (46). Recovery of the polysaccharide from industrial cultures requires removal or destruction of the cells followed by precipitation with the polar organic solvent isopropanol. To reduce the cost of the process, the solvents are later recovered for reuse by distillation. The fibrous precipitate is dried, milled, and sieved to give material of different mesh sizes. Bacterial cells are difficult to remove from the highly viscous culture broth, although pasteurization may lead to some autolysis and degradation of cell material as well as improving the subsequent separation of cells from the polymer. Polysaccharide recovery in the presence of polar solvents may be also be increased or accelerated by the addition of electrolytes. Subsequent purification can be achieved by a variety of techniques including fractional precipitation and chromatography. Dilute solutions of xanthan may also be subjected to clarification by filtration. The purified xanthan material can then be subjected to various analytical procedures to verify the composition, and to standard techniques for the determination of polysaccharide structure. The procedures used in the production and recovery of xanthan have been reviewed by Garcia-Ochoa et al. (47) and Galindo (46).

Although it is not degraded in the human or animal body, xanthan is biodegradable. It is a substrate for a range of xanthanases (enzymes with endo-1,4-β-D-glucanase activity cleaving the main chain of the polysaccharide) and xanthan lyases. Most crude enzyme preparations contain at least two different types of enzyme activity, although there may also be associated glycosidases (Figure 9.10). Substrates are randomly cleaved to yield oligosaccharides of different sizes; there is accompanying rapid loss of solution viscosity. Most commercial cellulase preparations lack activity against xanthan unless the polysaccharide is in dilute, ion free solution (48,49). The second type of enzyme found associated with the bacterial preparations is a xanthan lyase (4, 5 transeliminase) which cleaves the β-D-mannosyl-D-glucuronic acid linkage of the trisaccharide side chains (50). The activity of the xanthan

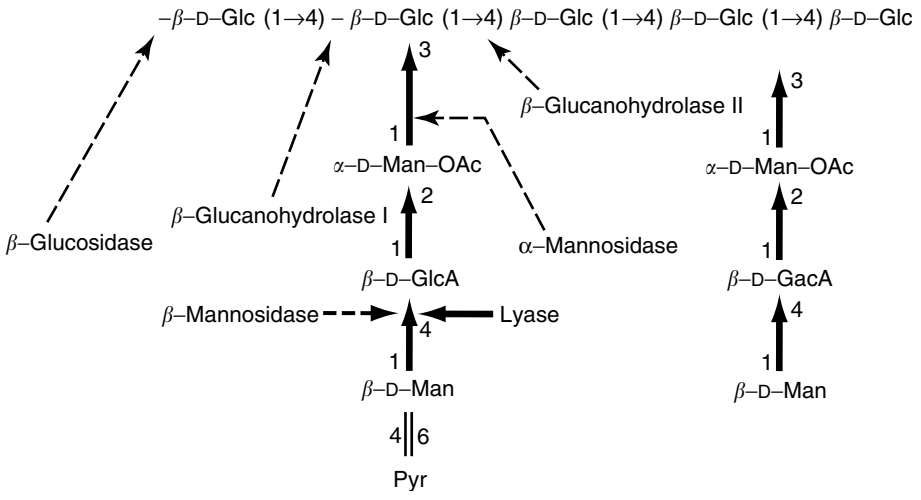


Figure 9.10 Enzymatic degradation of xanthan.

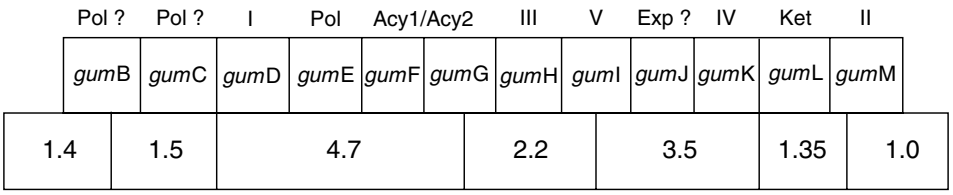
lyase was not greatly influenced by the presence or absence of pyruvate groups on the terminal mannose or of ester-linked acetyl groups on the internal mannose. The enzymes that degrade xanthan are useful laboratory tools for the determination of some of the structurally subtle, acyl modifications found on many xanthan molecules. The fragments generated are more suitable than undegraded polysaccharide for structural studies using fast atom bombardment spectroscopy. They have also proved useful in studies of monoclonal antibody specificity (51). Both the monoclonal antibodies and the enzymes could be used for highly specific quantitation of xanthan in processed foods, as has been suggested recently by Ruijssenaars et al. (52,53), or for the determination of xanthan purity.

9.3.1.2 Biosynthesis of Xanthan

Because of its industrial applications and the very unusual properties of the polysaccharide in aqueous solution, xanthan has been the subject of a large number of structural and physico-chemical studies. These have revealed much information on structure to function relationships in microbial polysaccharides. The biosynthesis of xanthan has also been extensively examined. It shares a common mode of biosynthesis with other bacterial polysaccharides composed of regular repeating units, which are found as cell wall components or extracellular products. Membrane-bound enzymes utilize various activated carbohydrate donors in a tightly regulated sequence to form the polysaccharide on an acceptor molecule. The oligosaccharide repeat units of xanthan are produced by the sequential addition of monosaccharides from the energy rich sugar nucleotides (usually nucleoside diphosphate sugars) to a C_{55} isoprenoid lipid acceptor molecule. At the same time, acyl adornments are added from appropriate activated donors. Thus, the xanthan backbone is formed by the sequential addition of D-glucose-1-phosphate and D-glucose respectively from two moles of UDP-D-glucose. Thereafter, D-mannose and D-glucuronic acid are added from GDP-mannose and UDP-glucuronic acid respectively. Each step requires a specific enzyme and a specific substrate. Absence of the enzyme (or the substrate) inhibits synthesis of the polysaccharide. Depending on the strain used and the physiological conditions under which the bacteria have been grown, and hence on the exact structure of the polymer formed, *O*-acetyl groups are transferred from acetyl CoA to the internal mannose residue, and pyruvate, from phosphoenolpyruvate (PEP), is added to the terminal mannose. This sequence of reactions



The restriction map of *Xanthomonas campestris*. The *Bam*HI restriction map (bottom) indicates the order and the approximate size (in kilobases) of the fragments of the 16 kb of DNA of the xanthan gene cluster. The genetic map (centre) indicates the twelve separate xanthan genes, designated *gum* B to *gum* M. The biochemical functions (top) indicate the enzymic activity identified for each gene: I–V, transferases I–V; Acy, acetylases (1 and 2); Ket, ketalase; Pol, polymerase; Pol?, possible involvement with polymerisation or export; Exp, post-polymerisation processing or export.

Figure 9.11 Genetic map of the genome segment of *X. campestris* involved in polysaccharide production (54,55).

was elegantly demonstrated by Ielpi and his colleagues (54,55) and is indicated in Figure 9.11. After the pentasaccharide repeat unit has been formed, oligomers are produced by transfer to other lipid intermediates, gradually increasing the size of the carbohydrate chain. Although the structure of the repeating unit is determined by the sequential transfer of the different monosaccharides and acyl groups from their respective donors by highly specific sugar *transferases*, the *polymerase* enzyme responsible for polymerization of the pentasaccharides into a macromolecule of $M_r > 10^6$ is now known to be less specific. This is clear from the ability of mutants to form xanthans defective in their trisaccharide side chains. Such a lack of absolute specificity might account for the natural evolution of bacterial exopolysaccharides such as xanthan, and for the existence of families of structurally related but nonidentical microbial polysaccharides. The final stages of exopolysaccharide secretion from the cytoplasmic membrane passage across the periplasm and outer membrane and finally excretion into the extracellular environment — are less well defined than the earlier biosynthetic steps. The process undoubtedly requires an energy source and may well be analogous to the export of lipopolysaccharide to the outer membrane, in which ATP provides the energy. The genetic system controlling xanthan production in *X. campestris was* elucidated by Vanderslice et al. (56,57). A linear sequence of twelve genes responsible for xanthan production was found. This included seven gene products needed for monosaccharide transfer and for acylation at the lipid intermediate level to form the completely acylated repeat unit (Figure 9.11; Table 9.1). Interestingly, two acetyl transferases were found, one of which appears to function when the pyruvate transferase is defective. The region of the chromosome controlling xanthan synthesis comprised 13 kb. However, other genes, responsible for less well defined functions, may yet be identified in *X. campestris.* The later stages of xanthan biosynthesis presumably include features common to those exopolysaccharide-producing bacteria which have been studied in detail. Thus, in *E. coli*, a region of the chromosome extending to 11.6 kb codes for five proteins, expression of which appears to be necessary for exopolysaccharide production. These proteins *may* form part of a multicomponent system responsible for exporting the polymer from the site of polymerization at the cytoplasmic membrane, to the exterior of the bacterial cell. One of the proteins involved appeared to have attributes common to other ATP-utilizing systems and it may be concerned with excretion (58).

Regulation of xanthan synthesis is not yet well defined. Many of the enzymes needed for the formation of precursors not specifically associated with exopolysaccharide production appear to be under separate control. In *X. campestris*, there are no significant

competing demands for substrate as any carbohydrate supplied to the bacteria is metabolized to provide energy, or converted either to essential cell components, wall material, or exopolysaccharide with high efficiency. There are effectively no intracellular storage polymers such as glycogen competing with exopolysaccharide in their synthetic demands on substrate. Xanthan is also the only polysaccharide synthesized by *X. campestris*, unlike several other bacterial species where two or even three extracellular polymers, together with intracellular oligosaccharides, may be produced.

9.3.1.3 Physical Properties of Xanthan

The unusual structure of xanthan as a substituted cellulose confers a number of physical properties to the polymer which are utilized in the food (and other) industries. It is stable at both acid and alkaline pH and forms a pseudoplastic dispersion in water. Relatively low polysaccharide concentrations produce highly viscous solutions and the viscosity does not change greatly on raising the temperature. The solutions are compatible with many other food ingredients and give good flavor release. Currently an estimated 20,000–30,000 metric tons are produced per annum for food and nonfood uses by a number of manufacturers in the US, UK, and elsewhere in the EU, as well as other countries such as China.

The techniques applied to determine the physical attributes of the exopolysaccharide, together with a thorough knowledge of its chemical structure, have enabled the assembly of much information on structure to function relationships pertaining to xanthan and have also provided an excellent model for other microbial exopolysaccharides. Values for the persistence length obtained using techniques such as light scattering and viscometry in dilute solution range from 110–150 nm. A wide range of values proposed for the molecular weight of xanthan has resulted partly from the application of different techniques and also from the tendency of the polysaccharide strands to aggregate in solution. The most consistent results have been obtained using light scattering techniques (Table 9.2). Shatwell (59) noted a range of 0.9–1.6 $\times$ 10^6 Da for four xanthan preparations with differing acyl substitution from different pathovars grown under standard cultural conditions. Other estimated results ranged between the extremes of 1.1 and 47 $\times$ 10^6 Da. Clearly the very high values must be

Molecular Weights of Xanthans obtained by Static Light Scattering Measurements Results of Shatwell et al.(59).

of dubious accuracy. Measurements of contour length similarly produced a wide range of estimates (4–120 $\times$ 10^6). X-ray fiber diffraction studies on xanthan indicated that it formed aligned helices in which there was poor lateral packing. This is consistent with an absence of crystallization and of gelation. The polysaccharide adopted a right handed helical conformation with fivefold symmetry in which the helix pitch was 4.7nm (60). Increase of the temperature of aqueous solutions of xanthan eventually produced a partial melting of the double helix. Xanthan is generally considered to adopt an ordered double helical conformation when in solution at lower temperatures. This conformation causes the apparent stiffness of the polysaccharide at low temperature or in high ionic strength. This stiffness was higher than that estimated for most other macromolecules and is comparable to that of the fungal β-D-glucans which exist as triple helices (61). The conformation was markedly affected by the presence of ions; salt increased the melting temperature. This conformational change, the shift from order to disorder, could be displaced to higher temperatures by the presence of increasing amounts of ions (Figure 9.12) (62). Acyl groups also influence the conformational changes, but light scattering experiments indicated that the inherent stiffness of the polysaccharide molecule is not greatly affected by the pattern of acylation. The presence of acetyl groups on the xanthan structure had a stabilizing effect on the ordered form of the polysaccharide, whereas pyruvate groups had the opposite effect. This could be attributed to intramolecular electrostatic repulsion between pyruvate groups. Conversely, the apolar interactions of the methyl groups of the acetate affected stabilization.

Aqueous solutions of xanthan are highly pseudoplastic whether or not acetyl and ketal substituents are present. The absence of the acyl groups does not normally affect the solubility of xanthans. The viscosity, the degree of pseudoplasticity, and the value for the transition from soft gel to pseudoplastic behavior are all directly related to the polysaccharide concentration. The effects resulting from the addition of salts to the solution also depend on polymer concentration. At ca 0.3% (w/v) xanthan, salts had practically no measurable effect, but at higher polymer concentrations increased viscosity could be observed. This was presumably due to alteration of the macromolecular association. There was probably no significant difference between the viscosity and the degree of acylation. Acetyl and pyruvate contents appeared to have no influence on dilute solution viscosity of xanthan or on the intrinsic viscosity at a given molecular weight. The viscosity of truncated xanthans in which the terminal mannosyl residue is missing was much lower than the wild type material. Surprisingly, the polytrimer, in which the terminal disaccharide is missing, was more viscous than the original xanthan (57,63).

9.3.1.4 Food Usage of Xanthan

Most industrial applications of xanthan derive from its ability to dissolve in hot or cold water to yield high viscosity, pseudoplastic solutions, even at low polysaccharide concentrations. Many of the industrial applications of xanthan were originally in the food industry. It

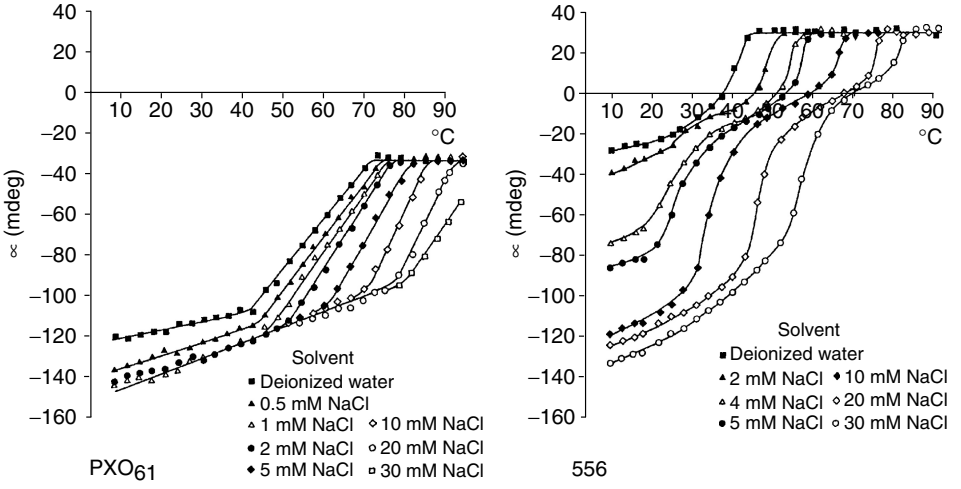

Figure 9.12 Effect of salts on the transition of xanthan from the ordered to the disordered state. Results for two different xanthans (61 - acetylated, non-pyruvylated; 556 - non-acetylated, pyruvylated) monitored by optical rotation measurement. Units mdeg (62).

received approval for food use from the US FDA in 1969 and about 60% of the xanthan currently produced is probably food grade polymer. In many foodstuffs, the useful attributes xanthan include rapid flavor release, good mouth feel and compatibility with other food ingredients including proteins, lipids, and polysaccharides. Salad dressings, relishes, and yogurts to which xanthan is added are of low pH. Xanthan, which is stable over a wide range of pH values, is thus very well suited to such applications. Polysaccharides are added to foods to provide suitable rheological properties during processing and a final appearance which will enhance consumer appeal during purchase and consumption.

Xanthan is incorporated into foods to alter the rheological properties of the water present and thus change the texture of the product. Associated with these readily measurable properties, are others such as mouth feel which are more difficult to define but which also show some correlation with physical properties. Mouth feel has been related to viscosity and, in particular, to nonNewtonian behavior. This also relates to the masking effect of viscosity on the intensity of taste. There is also a specific relationship between the polysaccharide and flavors present in any food. Thus xanthan provides good perception of sweetness and flavor when compared with some nonmicrobial polysaccharides such as gum guar or carboxymethylcellulose. Xanthan is also used for its capacity to control the texture of foods and to prevent or reduce ice crystal formation in frozen foods. As it is compatible with many of the other polysaccharides traditionally used in food, a wide range of textures can be obtained.

Many foods are essentially colloids in which there are complex interactions between the various ingredients. Emulsions of oil in water or water in oil form an important group of food products in which oils or lipids, water, and other ingredients are processed to form sauces, spreads, etc. Some of the emulsion-containing systems are dried and then reconstituted, as in packaged instant soups, desserts, and sauces. Whether used after the initial processing or after reconstitution with water, such emulsions may need to be stabilized with polysaccharides. In this role, xanthan has found many applications in dry mix food products. It can be dispersed in cold or hot water to provide thixotrophic dispersions which can be subsequently heated or refrigerated. The xanthan prevents the constituents from reverting to their original separate phases and ensures the long term stability required for food products.

Some of the foodstuffs into which xanthan is incorporated are of relatively low pH. Xanthan, with its high stability over a wide pH range, is well suited to such applications (64).

Many polysaccharides are employed to provide gelation of foodstuffs. Starch is widely used because of its low cost and its compatibility with many food ingredients, but is not suitable for all food applications. Xanthan on its own only forms very weak gels, but when mixed with various plant galactomannans or glucomannans, and then heated and cooled, it forms thermoreversible gels (*vide infra*).

9.3.1.5 Two Are Better Than One – Synergistic Gels Involving Xanthan

Many food products are formulated using a mixture of two or more polysaccharides to obtain the desired properties after processing (65). The aim may be to reduce the overall content of additive polysaccharides or to form a structured product. Aqueous solutions of xanthan, when mixed with certain plant gluco- or galactomannans, can be induced to form gels, whereas neither component will form a gel on its own. The mixed solution must be heated above the transition temperature of the xanthan in order to denature the xanthan helix and then allowed to cool. X-ray fiber diffraction studies on the mixed gels (66) reveal unique fiber patterns. Previously, gelation of the polymer mixtures had been attributed to the interaction between the helix of the microbial polysaccharide and unsubstituted regions of the plant glucomannan backbone. These results indicated that intermolecular binding could be due to cocrystallization resulting from the stereochemical compatibility between the cellulosic and mannan backbones. Acetyl groups on the xanthan molecules played an important role in inhibiting gelation of the polysaccharide mixtures and increasing the polymer concentrations required (59,62,67).

The most widely used mixture in food manufacture is xanthan and locust bean gum (another widely used food polysaccharide from seeds of the Mediterranean leguminous tree *Ceratonia siliqua*). As pointed out by Copetti et al. (68) concentrated solutions of either xanthan or locust bean gum (LBG) reveal very different properties – xanthan behaves as a weak gel network while LBG represents a hyperentangled macromolecular solution. LBG solutions revealed shear thinning behavior and a Newtonian region at low shear rates, whereas the mixed systems behaved as weak gels. The maximum synergistic effect was observed in a ratio of xanthan: LBG of 1:1. The rheological properties of the mixed gels also depended on the ratio of D-mannose: D-galactose in the LBG (69). LBG with higher mannose–galactose ratios, when mixed with xanthan, showed strongly increased synergism when temperatures were $> 60°C$. The melting points observed also ranged from 40–53°C, again increasing with increased mannose in the LBG. The xanthan-LBG network was formed from xanthan supermolecular strands and was unaffected by the heat treatment or the LBG fraction as addition of LBG failed to influence the xanthan structure. Although these gels are opaque, this is still satisfactory for many food applications where clarity is not required. *Synergistic gels* of this type are employed in a range of foods including spreads and cream cheeses. (Table 9.3).

Mixtures of xanthan with various types of starch have also been examined (70). The pasting peak viscosity of potato starch was reduced in the presence of xanthan, an effect thought to be due to repulsion of the negatively charged bacterial polysaccharide by phosphate groups associated with the starch. The opposite effect, increased viscosity, was seen with xanthan/maize starch mixtures.

9.3.2 Gellan

The polysaccharide (gellan® or gelrite®) was isolated from a bacterial strain initially designated *Auromonas* (*Pseudomonas*) *elodea* but now named *Sphingomonas paucimobilis*

(71,72). It is an intriguing new polysaccharide of microbial origin with a range of potential food applications, and is the only bacterial polysaccharide other than xanthan to be currently GRAS listed. Like xanthan, it is produced by aerobic submerged fermentation. After production is complete, the viscous broth is pasteurized then treated with mild alkali to remove acyl groups. It is then hot filtered to remove bacterial cell debris. This polysaccharide is an excellent gelling agent providing clear, brittle gels at much lower concentration than agar. Recently a mutant yielding enhanced production of gellan has been reported (73). As well as food use,gellan has been widely employed as a gelling agent in plant biotechnology under the trade name of gelrite or phytogel; it can also be used in place of agar in the formulation of bacterial culture media. Other *Sphingomonas* isolates have yielded a family of polysaccharides which are closely related structurally. Although none form gels, they do yield highly viscous aqueous solutions and have been proposed for various industrial, nonfood uses.

9.3.2.1 Structure

The structure of gellan is a repeating linear tetrasaccharide composed of D-glucose, D-glucuronic acid, and L-rhamnose in a ratio of 2:1:1, but devoid of any side chains (74). In the native material, *O*-acetyl and glyceryl residues are present on the D-glucosyl residue adjacent to D-glucuronic acid (75) (Figure 9.13). As a family of polysaccharides with closely similar carbohydrate structures has now been identified, this has permitted examination of the influence of various substituents and side chains on the physical properties of the polysaccharides (76). One polysaccharide is an exact analogue of gellan, in which the L-rhamnosyl residue has been replaced by L-mannose (77). Most of these polymers possess nonstoichiometric amounts of *O*-acetyl groups, the position of which still remains uncertain in some preparations. None have so far been identified as having food applications.

9.3.2.2 Physical Properties

The commercial gellan product has a mass of ~0.5×10^6 Da. The deacylated polysaccharide forms gels with properties common in some respects to those formed with agar, alginate, or carrageenan. Gelation was dependent on ionic strength as well as on the nature of the cation. The gelation temperature increased with increasing polysaccharide concentration (78). In texture, the gels most resembled those formed with agar or κ-carrageenan. In common with agar gels, marked melting/setting hysteresis was observed. The native structure of the gellan

-3-β- D-Glc*p*-(1→4)-β-D-Glc*p*A-(1→4)-β- D-Glc*p*-(1→4)-α- L-Rha*p*-(1-

(74,75)

Figure 9.13 The structure of gellan (74,75).

polymer that contains *O*-glycerate and ~6% acetate formed weak, elastic, thermoreversible gels. From x-ray fiber diffraction studies, a threefold helical structure with an axial repeat of 2.82 nm has been suggested. The glyceryl and acetyl groups inhibited crystallization of localized regions of the gellan chains (79). Rheological data suggested that in solution, the polysaccharide adopted a locally rigid conformation. The changes observed on deacetylation of the native polysaccharide, resulting in both increased crystallinity and gel stiffness, were interpreted as suggesting that longer sections of gellan contribute to the junction zones formed (80). When the polysaccharide was deacylated, extensive intermolecular association occurred and produced strong, brittle gels closely resembling those obtained from agar. In the crystalline structure, the two left handed threefold helical chains are arranged parallel to one another as an intertwined duplex in which interchain hydrogen bonds stabilize the structure (81). Computer models indicate that an almost fully extended polysaccharide chain of 3_2 double helices packs antiparallel, providing good compatibility with measured x-ray intensities (82). A range of gel textures can be produced through control of the degree of acylation of the polymer. The gels also resembled agar in that they were rigid, brittle, and thermoreversible. They could be reautoclaved and were stable to most commercial enzymes. The polymer behaved as a stiff coil when dissolved in dimethyl sulfoxide (DMSO) but preserved its helical secondary structure in aqueous solutions. The difference between melting and setting temperatures was 45–60°C (64), the gelling temperature increasing with the cation concentration. Unlike the more highly charged macromolecules alginate or pectin, there is marked lack of specificity among the alkaline earth cations, and the temperatures at the midpoint of the sigmoidal transitions (T_m) increased only moderately with ionic strength (83). Gelling and melting temperatures increased when either the gellan or the salt concentration was increased within the concentration range 0.3–2.0% (84), but the values were dependent on the cation used. This was ascribed to the increased number of junction zones produced, and decreased rotational freedom, causing higher heat resistance and increased elastic modulus. The mechanical properties of the gel directly related to the ionic selectivity, with monovalent ions in the order K > Na > Li. Grasdalen and Smidsrød (85) also concluded that gelation of the *A. elodea* subsp. *paucimobilis* polysaccharide occurred in two steps — chain ordering and chain association. Increasing the ion or polysaccharide concentration in the medium raised the gelling and melting point of the polysaccharide gels. The presence of the cations increased the number of junction zones and decreased the rotational freedom. The structures were rendered more heat resistant and the elastic modulus of the gel increased (84). It was also suggested that there was a well defined binding site for Ca^{2+} (86). The *O*-acetyl groups on the native polysaccharide had only a weak effect on the aggregation of the gellan molecules, whereas the L-glyceryl residues were detrimental to crystal packing (81). The potassium salt possessed a crystalline structure in which the L-glyceryl groups prevented the coordinated interactions of ions and carboxylate groups which are required for strong gelation (87). Once deacylated, the coordination of calcium between double helices was so strong that molecular aggregation occurred at very low cation concentrations. The backbone conformation of gellan on reexamination proved to comprise two left handed, threefold helical chains organized in parallel. In aqueous solution,

these produced an intertwined duplex in which the chains were displaced half a pitch with respect to each other (88,89).

9.3.2.3 Food Applications

Gellan forms clear, brittle, thermoreversible gels, which give excellent flavor release. The significance of this property in various food applications was indicated by Owen (90). Gellan can also be used in combination with other polysaccharides used by the food industry, although increased concentrations reduced gel strengths. It does, however, induce synergism when blended with gelatine or with gum Arabic, with gel strength increased by 40–60% (64). As pointed out by Gibson (91), blending gellan with other gums or mixtures of gums could produce a wide range of textures ranging from hard and brittle to soft and elastic. The exact texture obtained would depend on the proportion of the different gelling agents. Thus, blending with agar or κ-carrageenan, each of which also form brittle gels, reduced gel strength but retained the brittle texture. The very clear gels formed by low levels of gellan can be expected to have considerable aesthetic as well as practical appeal. Mixtures of gellan and gelatine also provide a range of textures (92). It was suggested that gellan has potential food use where a highly gelled structure or mouth feel was required (Table 9.4) (64).

9.3.3 Curdlan

Different customs exist in different countries. Unlike people in North America and Europe, people in Japan regard microbial polysaccharides as natural products which can be added to food without specific regulatory control. There is thus an upward trend in the use of microbial exopolysaccharides such as curdlan in Japan. Market shortfalls in some of the natural (plant or algal) polymers might lead to increased use of microbial products in their place. This has been exemplified by the fall in the supply of gum arabic in 1985 to 25% of the 1984 level and other shortfalls in the supplies of locust bean gum and guar gum.

Table 9.4
Uses of Gellan

a) Food Application	Function	Concentration Required
Jellies	Gelling agent in desserts.	0.15–0.2%
Jams	In low calorie spreads and fillings	0.12–0.3
Confectionery		0.8–1.0
Processed foods	Gelling in fruit, vegetables, meats	0.2–0.3%
Processed meats	Texture modification	0.1–1%
Icings	Coating agent	0.05–0.12%
Pie fillings	Texturiser	0.25–0.35%
b) Potential Food Applications of Gellan		
Dairy products	Ice cream, milkshakes, yogurts	
Fabricated foods	Fabricated fruits, meats.	
Icings and frostings	Bakery icings, frostings	
Jams and jellies	Low calorie jams, jellies, fillings	
Pie fillings and puddings	Instant desserts, jellies	
Water-based gels	Aspics	
Pet foods	Gelled pet foods, meat chunks	

Gibson (91)

Gels can be formed by several neutral bacterial polysaccharides. These include the linear β-D-glucan homopolymer, curdlan, which is formed by a number of bacterial species related to the Gram negative bacterium *Agrobacterium radiobacter* and *Rhizobium* (93) as well as *Cellulomonas flavigena* (94,95). Curdlan was approved for food use in Japan, Korea, and Taiwan. It is a β-(1→3)-linked D-glucan which is insoluble in water, however, when aqueous solutions are heated it forms a gel. It is unusual in that it may either form a thermoreversible (low set) gel with some similarity to agar or, on heating to higher temperatures (greater than 80°C), yield a high set gel which is not normally thermoreversible (96). In the presence of sugars, salt or starch, the gel strength may be lowered but it is unaffected by freezing and thawing, although syneresis is observed. Curdlan is probably unique among biological gums in that a gel is formed when the polysaccharide suspension is heated, and increased heating may even strengthen the gel. The gel thus formed is stable over a wide pH range and is stable to freezing and thawing. From x-ray crystallographic studies, it has been suggested that curdlan forms a triple helical crystalline structure (97). When added to food as a gelling agent, curdlan yields gels intermediate between the elasticity of gelatine and the brittleness of agar (98). Applications of curdlan in food can be seen in Table 9.5.

The different types of gel formed by curdlan under different conditions vary in their specific properties (99), some showing pseudocrystallinity. Differences in syneresis were also noted. When examined by electron microscopy, considerable differences were revealed (100). Some formed fibril units while in others assemblies of these were seen culminating in net-like structures. Curdlan resembles many microbial homopolysaccharides in that it is biodegradable through the action of specific enzymes such as that from a *Bacillus circulans* strain which yields laminaribiose as the sole hydrolysis product (101). However, some of the gel forms are extremely resistant to most β-D-glucanases.

9.4 EXOPOLYSACCHARIDES AS A SOURCE OF FLAVOR COMPONENTS

As many microbial exopolysaccharides contain appreciable amounts of 6-deoxysugars, it has been suggested that the polymers might be used as sources of these sugars (102). The 6-deoxyhexoses in turn, could then be used as intermediates in the synthesis of furaneol and its derivatives. These compounds can be used as flavoring agents for the food industry. Furaneol yields a powerful caramel-like flavor, but when modified by the addition of various short chain fatty acid esters gives a range of either meat or fruit flavors. Furaneol is fairly expensive (~$1–200/kg), and it has been proposed that this cost could be reduced through the use of polysaccharide derived deoxysugars. If this were to be achieved economically, it would require release of the sugars from the polymers by enzymic treatment.

Table 9.5
Food Applications of Curdlan

Food Application	Function	Concentration Required
Jellies	Gelling agent	1–5%
Processed foods	Gelling agent	1–10%
Processed meats	Texture modification	0.1–1%
Sauces	Improved viscosity	0.2–0.7%
Freeze-dried foods	Improved rehydration	0.5–1%

Nakao (96)

Using immobilized enzymes or cells and microbial polysaccharides containing a high percentage of deoxysugars this might be feasible; however, enzymes capable of degrading the appropriate exopolysaccharides to their component sugars have not as yet been described.

9.5 GAZING INTO THE CRYSTAL BALL: THE FUTURE FOR MICROBIAL POLYSACCHARIDES IN FOOD

In the hope that LAB EPS with improved physical properties can be developed, or that strains can be produced with higher yields of EPS, various groups have recently studied the biosynthesis of these polymers. Normal yields of EPS are usually in the range 100–250mg litre^{-1}. (12) Yields are much lower than those obtained for xanthan or gellan. In *Lactococcus lactis* strain NIZO B40, the genes for EPS synthesis were encoded on a 40kb plasmid (103). A 12 kb region contained 14 genes with products having sequence homologies to other gene products involved in EPS, LPS, and teichoic acid biosynthesis. As with production of xanthan and similar EPS, synthesis involved an isoprenoid lipid carrier and genes responsible for transfer of sugars from sugar nucleotides to this carrier were identified. Comparison of the *eps* gene clusters of *S. thermophilus* and *L. lactis* also revealed considerable homology between genes with similar putative functions (103). It also proved possible to introduce the *eps* gene cluster from *Streptococcus thermophilus* Sfi6 into *Lactococcus lactis* MG1363 to produce an altered polysaccharide (104), while eps-encoding genes carried on plasmids from *L. lactis* could be transferred to other strains of the same bacterial species (105). Portions of the gene clusters in LAB revealed high conservation and some similarity to the genes required for capsular EPS synthesis in other Gram positive Streptococci including *S. pneumoniae* and *S. agalactiae*. It has been suggested that successful genetic engineering and targeting of specific genes leading to alteration of the repeat units might beneficially change the physical properties of the polysaccharides. However, low yields might then present problems as was found with EPS from gram negative bacteria including some xanthan mutants (56,57).

The role of specific enzymes involved in carbohydrate metabolism and EPS synthesis was also studied. In *S. thermophilus*, strain differences were observed in the role of UDP-glucose pyrophosphorylase in polysaccharide production (106). In this bacterial species, the amount of EPS produced in synthetic media depended on the carbohydrate source, with highest yields resulting from a combination of lactose and glucose (24). Attempts have also been made to produce EPS from LAB using defined media but at least for *L. delbruekii bulgaricus* various amino acids and vitamins were necessary for both growth and EPS production (107). As pointed out by Jolly et al. (7), a better understanding of structure function relationships of the EPS from LAB is still required, and this must be allied to studies of the interactions with other components present in the food matrix (108). If after achieving such an understanding, polysaccharide structures can be manipulated to yield specific properties, the question remains whether such products would be legislatively and publicly acceptable.

An alternative approach to alter the physical properties of polysaccharides has made use of glycosidases and other enzymes to remove terminal sugars from side chains. Thus, van Casteren et al. (14) employed an enzyme from *Aspergillus aciduleatus* to remove a terminal β-D-galactosyl residue from the disaccharide side chains in a *L. lactis cremoris* polymer (Figure 9.4). Another possible source of novel EPS may be yeasts, several of which already find applications in food either directly or as sources of pigments and flavors. A few species, including *Rhodotorula glutinis* formed highly viscous polyanionic EPS (109) in good yield. The polysaccharide product from strain KCTC7989 formed

pseudoplastic solutions in water. There is also the possibility that polysaccharides from suitable nonfood microorganism might be designed to provide very specific physical properties. One candidate for this approach might be acetan from *Acetobacter xylinum*. This polysaccharide resembles xanthan both in its cellulosic backbone and in some of its physical properties (110,111). Mutants with altered chemical structure and differing physical properties have been isolated (112).

9.6 LEGISLATIVE ACCEPTABILITY OF MICROBIAL POLYSACCHARIDES

Before new microbial polysaccharides can be permitted for use as food additives, they must be submitted to a process of approval. In addition to the technological justification for the inclusion of the polymer in foodstuffs, evidence has to be provided of the need to use the polysaccharide and of its safety in use. The producer must also demonstrate that the new additive will benefit the consumer. This covers various categories:

1. The presentation of the foodstuff
2. The need to keep the food wholesome until eaten
3. The extension of dietary choice
4. The need for nutritional supplement
5. Convenience of purchasing, packaging, storage, preparation, and use
6. Economic advantage including longer shelf life or reduced price

Not all these factors will be appropriate in the case of microbial polysaccharides. Any company intending to produce or market the polymer must first embark on an extensive research program. In the U.K., evidence is then presented to the Food Advisory Committee in which there are representatives of consumer and enforcement bodies, the food industry, medicine, and academia. This advises the relevant Government Departments (Health; DEFRA). If the Food Advisory Committee considers that the need has been proved, safety is then examined and is assessed by the Committee on Toxicity of Chemicals in Food, Consumer Products, and Environment. Tests include determination of the LD_{50} in rats, feeding trials to animals through two generations of reproduction, and teratology testing. Tests for dust inhalation must also be performed. The costs for a development programm of this type may well be over $10 million and 3–6 years may elapse before approval is given. In addition to official approval, there must be consumer acceptance. A major factor in favor of microbial polysaccharides is their lack of digestion by humans and animals. They can thus be used as constituents of low calorie diets as well as other processed foodstuffs. After the Food Advisory Committee has made its recommendation, the polysaccharide still requires approval from the EU if the foodstuffs in which it will be incorporated will be marketed in other Member Countries of the EU. In the U.K., the schedule of "Emulsifiers and Stabilizers in Food Regulations" is promulgated by DEFRA (previously the Ministry of Agriculture, Fisheries, and Food). The EU has attempted to harmonize food additive regulations within its member countries through a "Directive of the Council of Ministers on Emulsifiers, Stabilizers, Thickeners, and Gelling Agents for Food Use." This provides a list of the agents that are fully accepted for use in member states. The compounds are designated in Annex 1 of the EU Directive 80/597/EEC with an appropriate serial number (E400=alginic acid, E406=agar, E415=xanthan, etc). Further details include the foodstuffs in which the use of the emulsifiers is permitted, together with

criteria for purity and labeling. The attempted standardization of labeling procedures provides details of trade name, manufacture, designated number, etc. In practice many processed foods are clearly labeled with their contents and consumers can see for themselves if xanthan (or gellan) is one of these.

The World Health Organization (WHO) and Food and Agricultural Organization (FAO), joint expert committee on food additives has the responsibility of proposing Acceptable Daily Intakes. Thus an ADI of 0–10mg/kgm body weight has been established for xanthan. The Committee divided food additives into three categories:

1. Fit for use in food
2. Need to be evaluated
3. Should not be used in foods

After evaluation, detailed specifications for the food additives include identity and purity. Typically, WHO provides data on biological aspects such as ingestion, calorific availability, and digestibility, and on toxicology. Toxicological evaluation includes short term and long term evaluation using a range of different animals. A two year study using rats failed to show any carcinogenic or other toxic effects which could be attributed to xanthan. Tests on human volunteers may also be included; again in the case of xanthan no adverse effects were found although this polysaccharide could effect a slow but significant weight loss in individuals suffering from obesity (113). In the USA, xanthan is permitted as a food additive under regulations controlled by the Food and Drug Administration (FDA). It is on the list of substances GRAS list, being approved in the Federal Register for use as a stabilizer, emulsifier, foam enhancer, thickening, suspending, and bodying agent. Use is permitted in sauces, gravies, and coatings applied to meat and poultry products. It may also be added to cheeses and cheese products, certain milk and cream products, food dressings, table syrups, and frozen desserts. A further use, also requiring FDA approval, is as a component of paper and paperboard intended for use in food packaging and likely to be in contact with the food. Although dextran did receive approval for food use, there is apparently no current food usage of this EPS. Curdlan, which might have a number of food applications, is used in Japan as a natural material, but is not currently permitted in the USA. The other microbial exopolysaccharide which is currently GRAS listed as an approved food additive is gellan.

The definition of EPS, for legislative purposes and for patents, is not particularly satisfactory. They are generally identified by the molar ratio or the composition of their carbohydrate and noncarbohydrate components. More detailed information on structure may be provided, together with properties such as optical rotation, viscosity, physical appearance and ash content. Xanthan is currently described in the National Formulary as: "…a high molecular weight polysaccharide gum produced by a pure culture fermentation of a carbohydrate with *X. campestris*, then purified by recovery with isopropyl alcohol, dried, and milled. It contains D-glucose and D-mannose as the dominant hexose units, along with D-glucuronic acid, and is prepared as the sodium, potassium or calcium salt. It yields not less than 4.2% and not more than 5% carbon dioxide, calculated on the dried basis, corresponding to not less than 91% and not more than 108% xanthan gum. When employed as a food additive, xanthan must conform to the definition provided in the National Formulary (UK) of "…a high molecular weight polysaccharide gum produced by a pure culture fermentation of a carbohydrate with *X. campestris*…". "The food grade polysaccharide must also meet the specifications listed in the Food Chemicals Codex (UK). These include absence of *E. coli* and *Salmonella,* and limits on arsenic (<3ppm),

heavy metals (<30 ppm) and isopropanol (<750 ppm). If more exopolysaccharides are proposed for food usage, some may have similar composition and improved methods of definition will be needed. In foods such as yogurt, when addition of xanthan is permitted, it may be difficult using current methodology to distinguish it from polymers synthesized by the LAB present. It is thus surprising that few methods have been developed for the identification and quantification of the EPS once present in food. With the discovery of enzymes specifically acting on the exopolysaccharides, these could well be used to provide highly specific assay procedures for the polymers once they have been incorporated into foods containing other carbohydrate-containing materials. A study by Craston et al. (114) indicated that the gellan lyase from heterologous bacteria (a small pink-pigmented pseudomonad) might prove useful in specific determination of gellan in processed foods. A similar enzyme has been isolated and characterized by Hashimoto et al. (115,116). Their use would have considerable advantages over the tradition assay methods which fail to distinguish between different polysaccharides or carbohydrate-containing material, present in foods. Similarly, pyruvated-mannose-specific xanthan lyase lyases studied by Ruijssenaars et al. (52,53) could be used to quantify xanthan in food as well as determining its quality. Alternatively, techniques based on monoclonal antibodies prepared against xanthan such as those developed by Haaheim and Sutherland (51) could be used. Other enzymes degrading microbial polysaccharides in food, including some of those from LAB, have also been identified but it remains unclear whether they would be as suitable as the xanthan and gellan lyases for quantification of the polymers in foodstuffs (115).

1.10

Genetics of Dairy Starter Cultures

Daniel J. O′ Sullivan

CONTENTS

10.1 INTRODUCTION

Dairy starter cultures have a long history in the production of fermented milk products dating back several thousand years. These cultures consist primarily of several members of the lactic acid bacteria (LAB), a loosely termed group of bacteria that are arguably the most valuable group of bacteria for humans in terms of health and economic impact. Within the dairy industry, the LAB are involved in the production of a myriad of fermented foods, such as yogurts, sour cream, buttermilk, acidophilus milk, kumiss, kefir, and approximately 2000 different types of cheeses. The workhorse of the dairy starter cultures is undoubtedly *Lactococcus lactis* because of its indispensable role in the production of most cheeses and fermented milks. This bacterium was first described by Louis Pasteur during his studies on soured milks in the 1850s, and was the first bacterium to be isolated from a mixed population in pure culture by Joseph Lister (1). It has since achieved quite a

few other firsts among the LAB, being the first one to have genetic tools developed for genetic manipulation, and also the first to have its genome sequenced (2). Currently, genetic tools are available for all pertinent LAB and the genomes of several of them have been deciphered.

While the use of dairy starter cultures dates well before any knowledge of bacteria, knowledge of what microbes are involved is quite recent and is still not known for all dairy starter cultures used. In some cases the old tradition of 'back slopping' some of the previous days product represents the starter culture on a daily basis (3). However, this practice has very limited use in large commercial dairy processing plants today, although undefined starter cultures are still used to a substantial degree. For example, many cheese starter cultures are propagated in milk prior to addition to the cheese vat, but the precise microbial makeup is not known. Interestingly, in the case of cheese starters, the transition from using undefined starters to a defined mix of desirable starter bacteria only occurred to a significant degree over the last 30 years, except in New Zealand, which transitioned decades earlier. Today, most major commercial cheese plants throughout the world now rely on defined starter cultures, as the resulting cheese has a more consistent quality due to the control over the starter bacteria that are present. However, some cheeses still rely heavily on undefined cultures, particularly in Europe, as they can give a better quality product, albeit somewhat inconsistent. Many fermented milks rely totally on undefined starters, such as kefir. Kefir starters are termed kefir grains as the microorganisms are contained in a large grain like mass of protein and carbohydrate, and while the strains are normally undefined, they consist mainly of lactobacilli, lactococci, and yeast (4). Other fermented milk products such as Acidophilus milk, Yakult, and Danone's Actimel or DanActive™ (as marketed in the USA) are sold for the specific strains of LAB they contain.

10.2 TAXONOMY AND IDENTIFICATION OF DAIRY STARTER CULTURES

LAB are the backbone of the dairy culture industry. The main LAB that comprise dairy starters are contained in five genera: *Lactococcus lactis* subsp *lactis* and *cremoris*; *Streptococcus thermophilus*; *Leuconostoc* species *lactis*, *mesenteroides* subsp (*cremoris* and *dextranium*) and *pseudomesenteroides*; *Enterococcus faecalis* and *faecium*; and several species of *Lactobacillus*, most notably, *delbruechii* subsp *bulgaricus*, *casei*, *brevis*, *helveticus, rhamnosus, acidophilus, fermentum*, *curvatus*, *johnsonii,* and *gasseri*. Dairy cultures also contain microorganisms outside the general LAB classification and these include certain bifidobacteria, brevibacteria, propionibacteria, and fungi. These latter three groups of bacteria are from a different taxonomic grouping than the classical LAB, as they have irregular rod shaped cells and a high G + C content in their genome, and group in or close to the *Actinomycetales* branch of high G + C gram positive bacteria, rather than the LAB.

It is essential to be able to accurately and unambiguously identify cultures for their successful application in the diary industry. Previously, identification relied solely on morphological and biochemical profiles, which in some cases can be ambiguous. A 1998 study of commercially available lactobacilli and bifidobacteria showed that many were misclassified at the species level (5). The advent of molecular tools has greatly simplified reliable identification. The most accepted means for typing unknown isolates is by sequence analysis of the16S ribosomal RNA (rRNA). This approach for classifying organisms was first developed by Woese and coworkers (reviewed, 6). The extensive database of rRNA

sequences allows detailed studies to be made on the phylogenetic position of unknown isolates. Technically, the procedure is very feasible, as the polymerase chain reaction (PCR) can be used to directly amplify the 16S rRNA genes using primers, which are directed at universally conserved regions at both ends of the gene. The entire PCR amplicon (~1.5 kb) can be directly sequenced and compared to rRNA databases.

While the use of 16S rRNA sequence analysis has greatly facilitated the accurate identification of dairy cultures, it has a limitation in differentiating closely related species of *Bifidobacterium*. This is an important genus for probiotics and its unambiguous identification is critical for its successful use. Within this genus, the rRNA sequence is highly conserved (7) and makes differentiating between very closely related species, such as *B. longum* and *B. infantis*, challenging. To complement the rRNA sequence approach, analysis of other DNA regions, which are not as conserved as the 16S RNA, have been used. However, not every DNA region can be used for this purpose, as it needs to be universally present in bacteria and should be highly conserved to ensure that sequence changes are less influenced by temporary environmental changes. The region between the 16S and 23S rRNA genes, termed the internal transcribed spacer (ITS), has been used for a more detailed analysis of bifidobacteria (7). This molecule is universally present in bacteria, but is not highly conserved (8), and the different ITS regions within the same bacterial cell can exhibit heterogeneity (9). However, the molecule is technically very feasible to obtain as PCR can be used to amplify the molecule directly, using primers for the universally conserved regions within the bordering 16S and 23S rRNA genes. It has been used for further characterizing bifidobacteria and was much more sensitive than rRNA analysis (7).

Another DNA region that has been used for sensitive species differentiation within the genus *Bifidobacterium* is a short internal segment of the *recA* gene. It possesses the important criteria of being universally present in bacteria and being highly conserved. The *recA* gene encodes the RecA protein, which has a central role in recombination, DNA repair and the SOS response (10). Previous studies had established that meaningful bacterial phylogenetic relationships could be obtained by sequence analysis of the RecA protein (11,12). These studies highlighted the possibility that a segment of the *recA* gene might be a useful molecule for phylogenetic analysis within a particular genus. This concept was applied to the genus *Bifidobacterium*, in a study by Kullen et al. (13). The molecule was obtained from both type and intestinal bifidobacteria isolates using PCR with primers directed to universally conserved regions within the *recA* gene. This approach yielded a fragment of ~300 kb, which was sequenced using a single sequence reaction from either end. The phylogenic relationship obtained by sequence analysis of this short segment of the *recA* gene, compared favorably with the analysis from the complete rRNA gene and provided another means for speciation within this genus.

DNA fingerprinting of dairy starter cultures is becoming more common and cultures can be identified if a DNA fingerprinting database is available. This can be very valuable and useful for DNA fingerprinting techniques that are reliable, reproducible, and can differentiate at the strain level. The use of pulse field gel electrophoresis (PFGE) for DNA fingerprinting is the optimum choice for this purpose, as it is very definitive and unambiguous (reviewed, 14). It is however a technically challenging and long procedure, which limits its widespread use. Furthermore, extensive PFGE DNA fingerprinting databases are not yet widely available. A DNA fingerprinting technique that has gained more popularity in industry is ribotyping, as it is automated and results take less that a day (reviewed, 14). The availability of a fully automated RiboPrinter® is frequently an attractive choice because of its technical simplicity and availability of extensive databases for ribotype DNA fingerprints. It is therefore sometimes used in the diary industry to identify cultures. However, it should be noted that DNA fingerprints obtained using ribotyping are more ambiguous for some groups of bacteria

than PFGE and can result in inaccurate identification. A recent study of enterococci found ribotyping to be unreliable, suggesting that the technique has limitations for bacterial identification within the LAB (15).

10.3 PLASMID BIOLOGY OF DAIRY STARTER CULTURES

While bacterial plasmids were first observed in the early 1960s (16), they were not detected in the dairy LAB until the early 1970s in the laboratory of Larry McKay at the University of Minnesota (17). Dairy starter lactococci had long been known to loose the ability to grow in milk if they were grown for long periods in laboratory media. This instability in phenotypes prompted McKay's group to search for plasmids, which were known to be readily lost from bacteria if they do not contain essential genes for their current growth environment. Subsequent studies by McKay and other groups found that many phenotypes, essential for milk fermentation by *Lactococcus lactis*, were actually encoded on plasmids. These phenotypes include lactose metabolism, proteinase production, oligopeptide uptake, and bacteriophage defense systems. Other phenotypes such as citrate metabolism, polysaccharide production, and bacteriocin production are also plasmid encoded in many cases.

10.3.1 Role of Plasmids in *L. Lactis*

Strains of *L. lactis* that are used in the dairy industry are originally of plant origin, but have evolved for an extended period in a milk fermentation environment. It is therefore intriguing that these lactococci have a heavy reliance on plasmids for metabolic phenotypes that are essential for growth and survival in their environment (18). This is unusual in bacteria as the basic metabolic genes for growth in a natural habitat are usually chromosomally encoded. Plasmid encoded functions are generally not essential for survival except to confer selective advantages under specific environment conditions. One reason for this unusual reliance on plasmids in lactococci may be to increase the expression of phenotypes that are needed to grow in milk. As multiple genes are involved, it less likely that up mutation in the different gene promoters could achieve the same effect while still being competitive in that environment. Clearly, isolates that can metabolize lactose faster, and obtain amino acids from casein more efficiently, would have a selective advantage over time in an exclusive dairy environment. Evidence for the selective evolution of genes in *L. lactis* to be plasmid encoded for increased phenotypic expression comes from the abortive bacteriophage defense system AbiA. This defense system was localized on a plasmid, pTR2030, from the dairy starter culture *L. lactis* ME2 (19,20). Altering the copy number of A*biA* had a dramatic impact on the AbiA phenotype and inserting it in the chromosome reduced the phenotype essentially below detectable levels (21). While there is undoubtedly selective pressure to maintain some gene systems on plasmids for increased gene expression, it is also likely that some are the result of recent horizontal transfer during adaptation to a milk environment. For example, it has been noted that strains in nature are far less fastidious (22), and adaptation to a protein rich environment would eventually select for strains that utilized the milk casein for its amino acids rather than synthesize them *de novo*.

Plasmids in *L. lactis* range in size from about 2–100 kb (23) and most strain contain several plasmids, sometimes more that 10. They encode all the genes necessary for uptake and metabolism of lactose. Interestingly, the uptake of lactose occurs via a phosphoenolpyruvate (PEP) phosphotransferase system, whereby lactose is phosphorylated and metabolized via phospho-β-galactosidase. While *L. lactis* strains do not contain a

β-galactosidase gene (*lacZ*), they do encode a chromosomally located permease gene that permits the uptake of lactose that can be metabolized if a *lacZ* gene is introduced (24). The ability to uptake oligopeptides from the breakdown of milk casein is also plasmid encoded. A cell wall associated proteinase initially degrades milk casein. Seven different proteinases have been detected in *L. lactis,* with different specificities for casein (25). Some strains only contain a single proteinase type, whereas others have more than one. Subsequent oligopeptides of varying lengths are taken up by the cell and metabolized by peptidases, some of which are chromosomally encoded. Bacteriophage resistance mechanisms are also invariably encoded on plasmids, with few exceptions. These systems are essential for successful fermentation in a milk environment as phage are particularly ubiquitous in this environment. Without effective and multiple phage defense systems, *L. lactis* starter cultures invariably succumb to the prevalent phage, causing a prolonged fermentation time and eventually a failed fermentation. This is especially true for the cheese making industry, which could not exist without defenses to counter phage attack. Currently, the most effective approach for combating phage when using defined starter cultures is to include a number of compatible phage defense systems in each of the strains used, which can impede different stages of the phage developmental cycle. Targeting just a single point of the phage developmental cycle can readily lead to resistant phage appearing, whereas, targeting multiple steps makes it much more unlikely for resistant phage to evolve. This is an analogous situation to fighting HIV infection in humans, where before 1995 only a single drug (AZT) was available to fight the infection by inhibiting its reverse transcriptase, which impeded its genome replication. However, HIV resistance eventually arose upon prolonged usage, limiting its effectiveness. However, in 1995 protease inhibitors were developed which impeded HIV replication at a later stage in its developmental cycle, and using both classes of drugs was described as a 'one-two punch' which makes it much more unlikely for resistant viruses to appear. The use of this one-two punch strategy in *L. lactis* starter cultures is effective, but because of the rapid rate of evolution in the microbial world, resistant phage inevitably appear upon prolonged usage. Therefore, a rotation of different defenses in the same starter strain is needed to combat this. This phage defense rotation strategy requires knowledge of the many different defense systems that exist naturally in different strains and has resulted in extensive research of phage defense systems in *L. lactis*. Molecular and phenotypic analysis of lactococcal phage defense systems has revealed four distinct classes: adsorption resistance, whereby the cell produces a polysaccharide material that can block the attachment of phage to the cell; DNA injection blocking, whereby the phage adsorbs to the cell, but is prevented from injecting in its DNA; restriction and modification (R/M) systems, whereby the phage DNA is restricted into segments following injection into the cell; and abortive infection (Abi) systems, whereby the developmental cycle of the phage is prevented at any one of many points following the successful establishment of the phage DNA within the cell (26). It is noteworthy that some strains coevolved combinations of different phage defense systems on a single plasmid highlighting the selective pressure in the milk fermentation environment for the need for multiple defenses to protect *L. lactis* strains. An example of an R/M and Abi system that coevolved together on a native *L. lactis* plasmid, and was characterized in this laboratory (Yang and O'Sullivan, unpublished), is shown in Figure 10.1. This system is the only system uncovered to date, where a methylase gene is required for establishment of both the R/M and Abi systems in a cell, thus intrinsically linking them together. Other plasmid encoding phenotypes in lactococci include uptake and metabolism of citrate (27), which is an essential attribute for effective diacetyl production; resistance to cadmium (28,29); resistance to copper (30); resistance to the bacteriocin nisin (31,32); and production of bacteriocins (33–37).

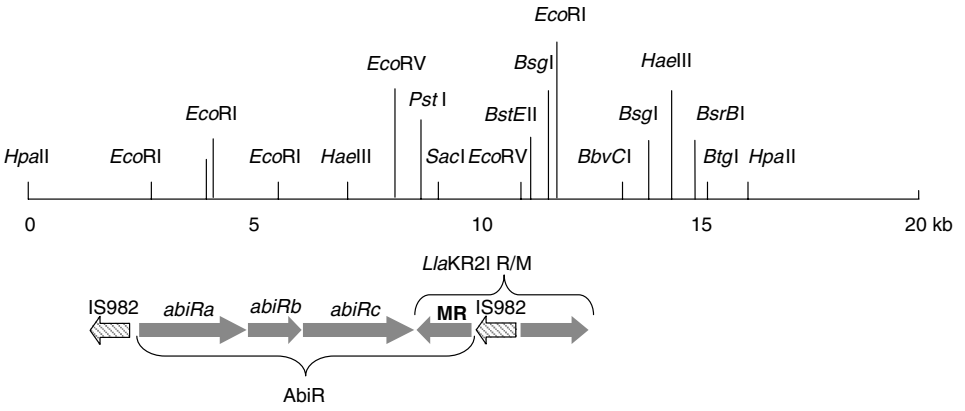

Figure 10.1 Molecular organization of two bacteriophage defense systems, from the native *L. lactis* plasmid pKR223, that are both dependent on a methylase gene for stabilization in *L. lactis*. The methylase protects *L. lactis* from *Lla*KR2I restriction and also from the abortive infection defense system, AbiR.

10.3.2 Role of Plasmids in Other Dairy Starter Cultures

While plasmids play a lesser role in other dairy starter cultures than in *L. lactis*, they do confer a variety of phenotypes in many genera. Many isolates do not contain plasmids and others just contain cryptic plasmids. Plasmids have been detected in some dairy *Leuconostoc* species (38,39). While many *Leuconostoc* do not contain plasmids, and those that do contain mainly cryptic plasmids, some have been shown to encode metabolic phenotypes. Metabolism of lactose via β-galactosidase was linked to a plasmid in *L. mesenteroides* (40) and uptake and metabolism of citrate can also be linked to plasmids (41,42). Recently, diacetyl (acetoin) reductase was located on a plasmid in a dairy *L. pseudomesenteroides* starter culture commonly used for the production cultured buttermilk, sour cream, and ripened cream butter (43).

Dairy enterococci starter cultures are somewhat controversial as many enterococci are pathogenic, including members of the two species relevant to the dairy industry, *E. faecalis* and *E. faecium* (44). However, isolates used by the diary industry are carefully screened for virulence factors. Nevertheless, studies have shown that nonvirulent strains can acquire virulence factors from other enterococci via plasmid transfer (45,46). Indeed, conjugal transfer of tetracycline and vancomycin resistance genes from enterococci to starter *E. faecalis* strains during cheese and sausage fermentations has been demonstrated (47). This illustrates that dairy enterococci have to be carefully monitored for safety purposes. While virulent strains of *E. faecalis* and *E. faecium* can be problematic, members of both these species are prominent in the human large intestine and are considered my many to have probiotic attributes (48). Plasmids are commonly found in both *E. faecalis* and *E. faecium* and while metabolic phenotypes have not been associated with them, they frequently encode bacteriocins (49–53).

Streptococcus thermophilus is the only member of the *Streptococcus* genus used in dairy fermentations. It is a thermophilic starter culture and historically was primarily a yogurt starter culture, but it is increasingly important as a cheese starter. Plasmids are rare in *S. thermophilus*, but are found in some strains and in many cases are cryptic. However, a couple of phenotypes have been associated with *S. thermophilus* plasmids. Some strains have been found to harbor plasmid genes encoding small heat shock proteins (54,55). It is likely that prolonged fermentation pressure at high temperatures provided the selective

pressure for acquiring these plasmid genes encoding heat shock proteins via horizontal gene transfer, or reestablishing them on plasmids as a means of increasing expression of this phenotype that is essential for optimum prolonged existence in high temperature environments. Others have been found to harbor R/M systems encoded on plasmids (56,57). Interestingly, R/M systems are the only phage defense systems found in *S. thermophilus* so far, although possible evidence for an Abi system was suggested previously (58). Heterologous expression of the lactococcal Abi system AbiA has been achieved, but expression could only occur at 30ºC and not at the normal growth temperatures of this thermophilic starter (59). It is intriguing that apparently fewer phage defense systems have evolved in *S. thermophilus*, compared to *L. lactis*. One possibility is that many phage defense systems either do not work, or function poorly, at elevated temperatures, as illustrated in the AbiA example (59). This appears to be an evolutionary response to prolonged existence in a stressed environment, where there is a need for rapid evolution to exist more effectively in the stressed environment. Eliminating barriers to DNA uptake is an effective means for speeding up evolution in a species. The finding of plasmid encoded *hsp* genes in *S. thermophilus*, and not in *L. lactis* even though its plasmids have been extensively analyzed over the last 30 years, supports this hypothesis.

The genus *Lactobacillus* covers an extremely broad range of bacteria and the use of lactobacilli in the dairy industry is also very broad as they are used in nearly all applications, from yogurt production, cheese production, fermented milks, and as probiotics. They are also the most extensively found bacterial genus in other food fermentations, such as vegetable fermentations (pickles, sauerkraut, and fermented olives), meat fermentations (summer sausage, salami, and pepperoni), bread fermentations (sourdough), wine malolactic fermentations (with another LAB, *Oenococcus*), and in many fermented foods indigenous to various countries in the world. While plasmids are frequently found in lactobacilli, they are less common in most dairy lactobacilli. The first evidence for plasmids in *Lactobacillus* was from *L. casei* in 1976 (60). As *Lactobacillus* is a very widely studied genus, numerous plasmids have been characterized and numerous phenotypes have been found. Some plasmids have been linked to the metabolism of sugars, including lactose in some strains of *L. acidophilus* and *L. casei*, galactose in *L. acidophilus* and maltose (reviewed, 61). Citrate utilization has been linked to a plasmid in the plant associated *L. plantarum* (62). Unlike lactococci, phage defense plasmids are not common in lactobacilli. However, an R/M plasmid was found in a *L. helveticus* strain (63), and possible evidence for adsorption resistance and Abi plasmids were reported from a nondairy *L. plantarum* isolate (64). Plasmids have also been linked to exopolysaccharide production in some *L. casei* strains (65,66). A plasmid harboring resistance to hops, the broad spectrum antimicrobial plant additive, prominent in beer especially India Pale Ale type beers, was found in *L. brevis* (67). This is a common beer spoilage organism, and the selective pressure for acquiring hop resistance plasmids was likely due to the presence of hops in its environment. Direct evidence for this, was provided recently by Suzuki et al., who demonstrated that *L.* brevis strains readily lost their hop resistant abilities when cultured in a hop free environment (68). Antibiotic resistance plasmids have also been found in lactobacilli, including chloramphenicol resistance in *L. reuteri* (69,70) and *L. acidophilus* (69), erythromycin resistance in *L. reuteri* (71,72) and *L. fermentum* (73), dalfopristin resistance in *L. fermentum* (73), and tetracycline resistance in *L. fermentum* (74) and *L. plantarum* (75). The selective pressure for the acquisition of these antibiotic resistance genes clearly arose from the presence of these antibiotics in their environments. Most of these species are residents of human and animal intestines and the use of antibiotics in humans and animals evidently provided sufficient selective pressure for their acquisition. The one exception is *L. plantarum*, which is not commonly found in human and animal intestines, but is associated with plants.

However, tetracycline is also used in plant agriculture to prevent bacterial infections in plants (76), thus providing the necessary selective pressure for its acquisition by plant associated microbes. Further evidence is provided by the acquisition of tetracycline resistance by other plant associated microbes, such as *Agrobacterium tumefaciens* (77). Numerous plasmids have been associated with the production of bacteriocins including, acidocin B (78), acidocin 8912 (79) and acidocin A (80) from *L. acidophilus*; brevicin 27 from *L. brevis* (81), Curvacin A from *L. curvatus* (82), plantacin 154 from *L. plantarum* (83), and lacticin F from *L. johnsonii* (84,85). The prominence of bacteriocins in *Lactobacillus* suggests that this is a major characteristic utilized by this genus for competing against other bacteria in their natural environment. The ability to attain dominance in a natural habitat is directly related to the ability to outcompete other bacteria. It is noteworthy that microbes that are dominant in neutral pH environments do not rely on bacteriocins to a large extent for competing against other microbes. An interesting example is *Bifidobacterium*, which is a dairy culture of growing importance because of its probiotic attributes. Bifidobacteria are dominant inhabitants of the large intestine, which is largely a neutral pH environment. However, despite extensive searches by various groups throughout the world, only a few strains of *B. bifidum* were found to produce a bacteriocin (86,87,88). This illustrates that this genus uses alternative means to compete against other microbes in the large intestine. A likely reason for this is that dominant microbes in neutral pH environments rely on suppressing their competitors by scavenging for the limiting supply of iron available in neutral pH environments (89). This occurs because iron is extremely insoluble at neutral pH and therefore becomes a limiting, essential growth factor (90). Recently it was demonstrated that dominant bifidobacteria in the human large intestine inhibit the growth of their competitors in neutral pH environments, by secreting potent iron binding compounds that scavenge the limiting supplies of iron thus preventing the growth of their competitors (14,91). This effective means for inhibiting the growth of competitors in their natural habitat is consistent with the absence of bacteriocin production by most bifidobacteria. Lactobacilli on the other hand reside in habitats that are acidic, and in those environments iron is readily soluble and therefore not a limiting factor for growth. It is therefore not surprising that most lactobacilli have evolved the ability to produce bacteriocins to facilitate their dominance in their environment.

The non-LAB dairy cultures, propionibacteria, brevibacteria, and bifidobacteria have not been researched as extensively as the LAB. In all three groups, plasmids are rare, but have been found in some members. The propionibacteria relevant to the dairy industry include *P. jensenii, P. acidipropionici, P. freudenreichii* (subsp *freudenreichii* and *shermanii*), and *P. theonii.* They are important cultures in many cheese fermentations, especially Swiss cheese. They are also of increasing importance as possible probiotic cultures, because of their ability to survive gastric transport and produce propionic acid, ß-galactosidase, bacteriocins, and vitamin B_{12}, as well as attach to intestinal cells (92,93,94). Plasmids have been reported in some strains of *P. jensenii*, *P. acidipropionici,* and *P. freudenreichii*, and are more commonly found in the latter species. While little research has been conducted on plasmid biology in propionibacteria, most plasmids appear to be small and cryptic. Some do contain useful phenotypes, such as encoding bacteriocin production (95,96).

Brevibacteria belong to the coryneform group of bacteria and are important in the dairy industry particularly for surfaced ripened cheeses, such as Limburger, Brick, Muenster, and some blue cheeses. In contrast to all the other dairy cultures, these bacteria only grow in the presence of oxygen and therefore are only found on the surface of cheeses. *B. linens* is the primary species of importance to the dairy industry and is attracting increasing research attention. Brevibacteria are the only bacteria of dairy significance that produce carotenoides, some of which can be aromatic (97). The metabolic capabilities of

B. linens, which include the production of sulphur compounds and pigments, have a major impact on cheese flavor and appearance (98,99). Plasmids are rare in brevibacteria but are sometimes found in *B. levins* (100,101) and also *B. lactofermentum* (102), which is used commercially for the production of amino acids and enzymes (103). However, to date no phenotypes have been attributed to native plasmids in brevibacteria.

Bifidobacteria are increasingly important cultures in the diary industry because of their prominent role in probiotics. It differs from other dairy cultures in that glucose is metabolized exclusively by the fructose-6-phosphate shunt, which utilizes the enzyme fructose-6-phosphoketolase (F6PPK). This is therefore a frequent diagnostic marker for this group of bacteria. Members of the genus *Bifidobacterium* are dominant flora in the large intestine of humans and also in the GI tracts of many farm animals. Studies throughout the twentieth century have consistently substantiated the association of good intestinal health with high bifidobacteria numbers (reviewed, 14). Because of this, bifidobacteria are important probiotic bacteria for humans (104) and farm animals (105), second only to lactobacilli in commercial dominance. The growing interest in bifidobacteria probiotics has greatly increased the research attention of these intriguing bacteria. The species of *Bifidobacterium* of relevance to the dairy industry include *B. longum*, *B. infantis*, *B. bifidum, B. adolescentis, B. breve,* and *B. lactis.* The latter species is a commonly used probiotic and it is intriguing that it is not a normal human inhabitant. It was first isolated in 1997 from fermented milk by Meile et al. (106) and was noted to have a higher tolerance to oxygen than other bifidobacteria. While it was genetically very close to *B. animalis*, it was deemed to have changed sufficiently during adaptation to fermentation environments to warrant a new species name. While the name *B. lactis* is a much more attractive name for a dairy culture, some studies question the justification for a new species name (107,108). The changes that occurred in *B. lactis* during its adaptation to fermentation conditions make it a very resilient strain that can remain viable during processing and storage, longer than other bifidobacteria. These practical reasons contribute to its popularity, but may limit its probiotic properties in the intestine. Plasmids are only found in some species of *Bifidobacterium*, being most common in *B. longum* followed by *B. breve* (109,110,111). It is interesting that most strains of *B. longum* will harbor plasmids, while *B. infantis,* which is very closely related to *B. longum*, does not harbor any plasmids. Plasmids are generally small ($<$ 10 kb) and cryptic. A number have now being characterized at the sequence level (112,113,114). However, phenotypes outside of normal plasmid functions have not been found on bifidobacteria plasmids. One exception is a report of a plasmid linked to production of the bifidocin B bacteriocin in *B. bifidum* (115). It was interesting that the production of bifidocin B was linked to an ~8.0 kb plasmid, while the immunity did not appear to be correlated with it. As bacteriocin production and immunity genes are inherently linked together in bacteria, this would appear to be an unusual setup. However, sequence analysis of the plasmid will be needed to investigate this further.

10.3.3 Plasmid Replication in Dairy Cultures

The need for molecular understanding and genetic manipulation of starter culture phenotypes has resulted in extensive research into plasmid replication mechanisms in these bacteria. Understanding plasmid replication is essential for the development and application of molecular tools. The type of plasmid replication mechanism can influence many crucial aspects of plasmids, including structural and segregational stability (116). While bacterial plasmids are generally circular entities with the cell, some are present in both prokaryotes and eukaryotes that are linear (reviewed, 117). In the dairy cultures, the plasmids found have been invariably circular except for the report of a 48.5 kb linear plasmid in a *Lactobacillus gasseri* strain (118), which has not yet been characterized. Two modes

of circular plasmid replication predominate in dairy cultures, rolling circle replication (RCR) and theta replication, with the former being much more common.

The primary distinguishing feature of RCR is the presence of single stranded DNA intermediates that accumulate during replication (116). RCR has been observed for all bacterial genera that are relevant to dairy cultures. The replication origins from RCR plasmids are conserved and depend on the presence of a replication initiation gene (*rep*). This gene encodes a Rep protein that initiates plasmid replication by nicking the DNA at the replication origin, which is a double strand origin termed *ori*, thus permitting replication of one plasmid DNA strand to begin, which is referred to as the leading strand. It also has a ligation role during replication and nicking roles during each subsequent round of replication. The single strand intermediates can be readily seen during replication and can be degraded by S1 nuclease, which is the procedure used to confirm RCR replication in these bacteria. The efficient conversion of single strand DNA into double stranded plasmid DNA is critical for the structural and segregational stability of the plasmid. This is initiated at a single strand origin (*sso*) that permits replication of this strand. Single strand origins tend to form extensive secondary structures, and this can influence plasmid stability. While plasmids utilizing RCR are very common among this group on organisms, and are used frequently as vectors for cloning and other molecular applications, they tend not to be very stable, both structurally and also segregationally. It should be noted that not all RCR plasmids suffer these defects to the same degree, as some are more efficient at converting the single strand intermediates into double strand plasmid DNA, via the *sso*, thus improving their stability. The *sso* therefore has a major role on plasmid stability during replication of RCR plasmids.

The other mode of plasmid replication that has been found among dairy cultures is theta replication, so named after the theta appearance of the plasmid during replication. The absence of single stranded intermediates during replication of these plasmids greatly increases their stability over RCR plasmids in general, and they are therefore more useful as cloning vectors. During theta plasmid replication, DNA nicking is not involved, but an RNA primer is synthesized that can initiate replication of both strands following denaturing the two strands around the origin. This opening of the two DNA strands around the origin resembles the theta symbol. While theta replication is very common for plasmids in gram negative bacteria it is much less frequently observed in gram positives. However, plasmids replicating by this mechanism have been observed, by functional analysis or sequence similarities, for many of the dairy related cultures, including *Lactococcus* (119,120), *Lactobacillus* (121), *Enterococcus* (122), *Streptococcus thermophilus* (123), *Leuconostoc* (124), *Brevibacterium* (101), and *Propionibacterium* (125).

10.4 TOOLS FOR GENETIC MANIPULATION OF DAIRY STARTER CULTURES

The development of molecular tools for dairy cultures began thirty years ago in the 1970s, with the study of plasmids and gene transfer in *Lactococcus lactis* (126) and related pathogenic bacteria (127). Since then, tools have been developed for various purposes for all the bacteria of dairy interest, but are much more sophisticated for the LAB, especially *L. lactis*, *Enterococcus,* and *Lactobacillus*. Molecular tools are essential for many purposes, including understanding the roles of specific genes in culture phenotypes, understanding how the expression of culture phenotypes are regulated, deletion of undesirable culture features, improvement of current culture phenotypes or expression of new desirable culture phenotypes. Molecular tools available include general cloning vectors, expression systems, and integrative strategies for DNA insertion or knockout.

10.4.1 Cloning Vectors

There is currently a wide range of cloning vectors available for cloning into all dairy bacteria of interest. As *Lactococcus lactis* has received greater research attention than the other dairy cultures, most of them were developed for this bacterium. However, lactococcal vectors are generally applicable for most other LAB as well. While both RCR and theta replication types have been used for cloning vectors, theta replicons tend to make vectors that are less prone to rearrangements and segregational instability. This is particularly the case for large DNA inserts, as the larger the DNA fragment cloned, the more susceptible it is to rearrangements. RCR plasmids however are much more plentiful and tend to be more promiscuous, allowing them to be introduced into a wider range of bacteria (128). Furthermore, there is a need for many different plasmids whose replication mechanisms are compatible, for many applications in cultures. Table 10.1 lists some of the many cloning vectors that have been developed for various starter cultures. Most of the available vectors were developed for *Lactococcus*, but are generally functional in most of the LAB cultures. These greatly simplified research into these cultures, as a selection of useable vectors was already available. Likewise, many of the original vectors used in *Lactococcus* were originally developed for pathogenic streptococci and enterococci. For example, the streptococcal cloning vector pGB301 (145) was the first vector used to clone DNA into *L. lactis* (146). While RCR plasmids predominate the available vectors for dairy cultures, a good selection of theta replicating plasmids is available for most cultures. An exception is *S. thermophilus*, where currently only RCR vectors are used. However, a theta replicating plasmid for this bacterium was recently described which should facilitate the development of stable theta replicating vectors (147).

The need for food grade markers is quickly growing as the there are many potential genetic manipulations that could greatly enhance current dairy cultures. A safe approach, which has growing acceptance, for genetically modifying food microorganisms, is to only use DNA that comes from food grade microorganisms. A summary of the different food grade markers that have been developed for dairy cultures is listed in Table 10.2.

10.4.2 Expression Systems

The ability to be able to express specific genes in dairy cultures to achieve desirable phenotypes is of great interest. The applications of this technology include over expressing existing phenotypes, expressing new enzymes and inhibitory compounds, and expressing surface antigens for immune stimulation in the GI tract. A summary of the different strategies that have been used for expression systems in dairy cultures is given in Table 10.3. While most strategies have been developed for *Lactococcus*, some strategies have been extended to, or developed for, other LAB. The most commonly used expression system for the LAB is the nisin inducible system, which is dependent on the presence of the *nisRK* genes in the expression host, to enable the signal transduction to occur. However, it should also be noted that the *nisA* promoter can also be induced, in the absence of nisin or the *nisRK* genes, during galactose metabolism by the Leloir pathway in *L. lactis* (165). While sophisticated expression systems have not yet been developed for propionibacteria, brevibacteria, and bifidobacteria, basic shuttle vector expression of genes has been achieved. Heterologous genes have been expressed in propionibacteria (166), brevibacteria (167), and bifidobacteria (168,169,170). The genes expressed in bifidobacteria include several tumor suppressors, as these bacteria are believed to be able to grow in the hypoxic regions of solid tumors (168,171).

10.4.3 Integrative Strategies

The ability to be able to integrate DNA into specific sites within the genome is very useful, as this can be used to stabilize a gene or an expression construct in a culture, and also to

Table 10.1
A selection of general cloning vectors available for dairy cultures

Vector	Replication Type	E. coli Shuttle	Markers	Features	Ref.
Developed for *Lactococcus*					
pGK12	RCR	Yes	Erm^r, Cm^r	single promiscuous *ori* low copy[1]; MI[2]	(129)

pRM2	ND	Yes	Sp^r, Amp^r		(144)

[1] refers to the copy number of the plasmid in *L. lactis*;
[2] MI refers to marker inactivation, the ability to clone DNA within an antibiotic resistance gene;
[3] refers to blue/white screening capability in *E. coli*;
[4] not determined;
[5] hygromycin B resistance

delete undesirable DNA regions. It is also possible to integrate a molecular tag that could serve as a unique signature of a particular strain. This process relies on homologous recombination and has been quite successful in many of the dairy relevant bacterial genera. All strategies rely on identifying the DNA region where the insertion is to occur, as this DNA region forms the basis of the integrative vector. If the objective is to delete a gene, then a 5' region and a 3' region of the gene, or its bordering sequences, is cloned at either side of a selection marker. Typically the cloned regions should be $>$ 500 bp to facilitate homologous recombination. A single crossover is first obtained whereby the inserted construct disrupts

Table 10.2
Food grade selection markers available for dairy cultures

Food Grade Marker	Example Vector	Host(s)	Ref.
Melibiose fermentation	pRAF800	*Lactococcus Pediococcus*	(148)
thyA gene[1]	pBSt1	*thyA* mutants of *S. thermophilus*[2]	(149)
Cadmium resistance[3]	pND919	*S. thermophilus*	(150)
Nisin resistance	pFM011	*Lactococcus*	(151,152)
lacF gene	pNZ2104	*lacF* mutants of *Lactococcus*	(153)
ochre suppressor (*supB*)	pFG1	*pyrF* (ochre) mutants of *Lactococcus*[4, 5]	(154)
amber suppressor (*supD*)	pFG200	*pyrF* (amber) mutants of *Lactococcus*[6]	(155)
heat shock protein[7]	pSt04	*S. thermophilus Lactococcus*	(156)
no selection marker[8]	pVEC	*Lactococcus*	(157)

[1] encodes thymidine synthase;
[2] selection must be in a thymidine free medium;
[3] gene isolated from *L. lactis*;
[4] these are pyrimidine auxotrophs and selection must be in pyrimidine-free media;
[5] unstable in many lactococci as SupB suppresses both ochre and amber stop codons, which account for most stop codons in lactococci;
[6] SupD only suppresses amber stop codons which are $< 10\%$ used in *Lactococcus*;
[7] selection required using elevated temperatures (52ºC for *S. thermophilus* and 42ºC for *L. lactis*)
[8] functions by cointroducing a companion plasmid with an Ermr marker and the same replicon as pVEC except lacking a functional recB gene. Selection for Ermr ensures both plasmids are introduced and the Ermr construct is subsequently cured by omitting Erm, due to replicon incompatibility.

Table 10.3
Strategies used for expression systems in dairy cultures

Strategy Used	Features	Expression Host(s)	Ref.
Strong constitutive promoter	P32 promoter pWV01 *ori*	*L. lactis, B. subtilis, E. coli*	(158)
lactose induced promoter	*lacA* promoter	*Lactococcus*	(159)
A lactose induced	T7 promoter; Lac induced	*Lactococcus*	
T7 RNA polymerase	T7 RNA polymerase gene		(160)
Nisin induced	*nisA* promoter; *nisRK* two-component induction system	*Lactococcus Enterococcus Lactobacillus Leuconostoc*	(161,162)
ϕ31 induced	ϕ31 promoter; ϕ31 *ori* low copy number plasmid[1]	*Lactococcus*	(163)
enterocin induction signal	*entA* promoter; *entRK* two-component induction system[2]	*Enterococcus*	(164)

[1] low copy number plasmid facilitates run away replication following infection by ϕ31, [2]induced by the addition of the enterocin induction peptide

the targeted gene. However, in the low G + C LAB, a double crossover readily follows whereby the original gene can be replaced with the constructed disrupted gene.

To achieve homologous recombination in a cell, the construct must first be introduced into the cell and have no means of replicating unless it integrates into the genome of the cell. Therefore, when the cells grow in the presence of the selection agent, integration will have to occur to allow the selection marker gene to be maintained. One strategy for achieving this is to use a construct that does not have a functional replicon, such that

when introduced into the cell, integration is the only choice when grown on the selection agent. De Vos and Simons have reviewed a number of constructs that used this approach (172). Unfortunately, this forcible homologous recombination approach is directly dependent of the frequency of gene transfer. A high gene transfer is required, and this is not always possible in *Lactococcus*, not to mid other dairy cultures of interest.

Another strategy is to introduce the construct into to the cell on a permissive replicon, and then, following successful introduction into the cell, disable the plasmid replicon, thereby forcing homologous recombination. This is a much more attractive approach as it negates the need for a very high gene transfer frequency. One way to disable a plasmid replicon is to use a replicon that does not function under all environmental conditions. A common example is temperature sensitivity and a number of these have been used for integrative vectors quite successfully. For example, vectors of the pGhost class have temperature sensitive replicons are have been widely used for gene integration in the LAB (173).

10.5 GENOMICS OF DAIRY CULTURES

Prior to this genomic era, it was only possible to understand a limited number of genes involved in different phenotypes. What the genomics era is bringing is the possibility to know the full complement of genes involved in any phenotype of interest. That would greatly help the efficiency when using cultures for specific purposes. Since the first bacterium genome sequence was published in 1995 (174), there has been an explosion in the number of other microbial sequences that followed. Currently there are more that 600 microbial genome projects either completed or in the process. While obtaining the complete genome sequence of organisms can reveal tremendous insights, determining the biochemical and cellular function of each gene is a necessary subsequent step. This daunting task of the functional analysis of genomes has been greatly enhanced by the advent of microarrays. These are small chips, or glass slides, containing probes corresponding to every gene in a genome. The construction of these high density gene chips occurred from advances in the ability of robotics to spot DNA onto chips and was first used for high density gene profiling in 1995 (175). Early gene chips did have limitations as the signal to background noise level of the hybridization results prevented precise profiling of gene expression. However, recent advances, utilizing multiple oligonucleotide probes per gene, have greatly improved the sensitivity of microarrays to accurately profile gene expression. Hybridizing the chips with RNA from the organism allows one to quantify the expression of all the genes being expressed under specific conditions. This is a necessary step in accurately predicting roles for genes (176).

One disadvantage to the genomics era is the cost of obtaining a fully completed genome sequence, although the cost does continue to decrease. Because of this, many genomes sequenced or being sequenced have industry sponsorship and this can significantly delay the release of the sequence information, due to intellectual property issues. This has also been the case with many dairy culture genome projects. One alternative is to get federal funding such that sequence information would not be complicated by intellectual properties. This was the route taken by US scientists, who formed the Lactic Acid Bacteria Genome Consortium (LABGC), consisting of 10 scientists, and formed a collaboration with the Joint Genome Institute (JGI) to sequence 11 genomes of commercially relevant dairy cultures. This partnership was funded by the Department of Energy to enable the genome project to initiate. Currently all 11 genomes have been completed and are in the process of being published. Unlike genome projects with private funding, the genomes sequenced via the JGI/LABGC will be deposited in public databases upon publication.

Currently, there are three complete genomes from dairy cultures that have been sequenced and published. These are for *Lactococcus lactic* IL1403 (177), *Bifidobacterium longum* NCC2705 (178) and *Lactobacillus johnsonii* NCC533 (179). A fourth genome from *L. plantarum* WCFS1 (180) may also be of interest as it is sometimes speculated to be a potential probiotic culture. The *L. lactis* IL1403 genome was the first one published and it provided an exciting glimpse into the makeup of a lactococcal chromosome and the evolution of this organism. Remnants of a once aerobic existence are evident, and a set of genes analogous to the natural competence genes in *Bacillus*. While analysis of the *L. lactis* IL1403 genome does give intriguing information, it does not shed light on many of the commercially significant phenotypes, as these are largely encoded on plasmids, and IL1403 is a plasmid cured laboratory strain. Therefore, as part of the LABGC effort a commercial strain of *L. lactis* subsp *cremoris* with its full plasmid is being sequenced.

The genome sequence of a strain of *Bifidobacterium longum*, which was a recent human isolate and exhibits characteristics consistent with good competitive abilities in the large intestine, is being compiled in this laboratory as part of the LABGC effort. The comparative analysis of this strain with the other sequenced *B. longum* strain is revealing unique insights into how strains within this species evolve. An interesting feature was that even though the two strains displayed very high sequence identity over much of the chromosome, there was very little colinearity, as demonstrated in Figure 10.2. This was unexpected as comparative genomic analysis of other closely related bacteria have revealed a high degree of colinearity (181). It was also noteworthy that the genome of Strain DJO10A was ~130 kb bigger that strain NCC2705 and that both strains contained significant unique regions. The unique regions of both strains were scattered all across their genomes demonstrating the dynamic nature of strain evolution.

10.6 CONCLUSIONS

Dairy starter cultures are a very unique and exciting group of microbes because of what they do and how they impart human life. Optimum application of specific cultures relies on a fundamental understanding of how the relevant phenotypes are expressed. The current and future endeavors of both bioinformatic and functional genomics of dairy culture's genomes will provide a detailed manual of how every component functions. This will permit intricate metabolic engineering whereby a cultures metabolism can be readily optimized for a specific purpose. It will also facilitate a greater understanding of important criteria for probiotic cultures, which would establish optimum criteria for selection and use of cultures for probiotics.

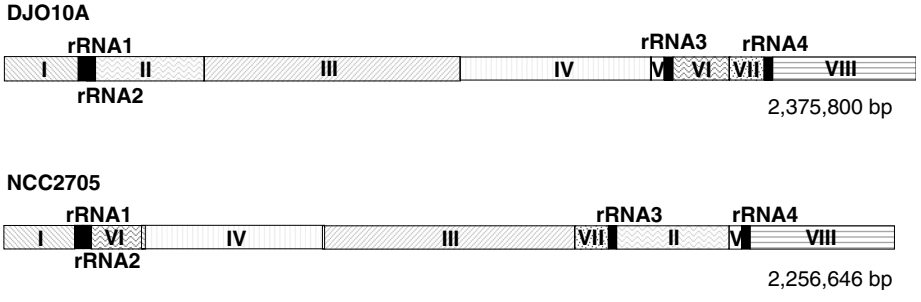

Figure 10.2 Linear maps of the complete genomes of *Bifidobacterium longum* strains DJO10A and NCC2705. Segments I to VIII represent highly identical sequence regions that are not colinear on the genomes.

ADDENDUM

During the publication of this book, the genome sequence of *Bifidobacterium longum* NCC2705, published in 2002, was updated in GenBank. It no longer exhibits the major rearrangements as depicted in Figure 10.2 and discussed in the text. Based on the current deposited sequence for this bacterium, genome rearrangement is not a major factor in *B. Longum* evolution

Genetic Engineering of Baker's Yeast: Challenges and Outlook

Jose Antonio Prieto, Jaime Aguilera, and Francisca Randez-Gil

CONTENTS

11.1 INTRODUCTION

The bread making process is one of the oldest applications of biotechnology. The term bread defines a great variety of baking products, which vary in formulation, ingredients, and processing conditions. For most of them, however, the use of baker's yeast is fundamental to obtaining a high quality product according to the demands of consumers. Baker's yeast contributes substantially to the flavor and crumb structure of bread, but its primary role is the production of CO_2, via the alcoholic fermentation of sugars, which results in dough leavening.

Commercial baker's yeasts are domesticated strains of *S. cerevisiae* that have been selected and optimized for baking applications. Most of them are homothallic, with a high and irregular degree of ploidy and low sporulation ability (1). In addition, they exhibit chromosomal-length polymorphisms and rearranged chromosomes with multiple translocations (2). These special characteristics are the result of natural selection by adaptative evolution together with the successive application of improvement programs. The polymorphism of baker's yeast reflects, at least in part, selection by continuous long term nutrient limitation. In industrial practice, the yeast is grown aerobically under conditions (fed-batch) in which the supply of the carbohydrate feedstock is limited, to avoid ethanol formation. When a yeast population is cultured under this physiological situation, it undergoes a series of adaptative shifts whereby clones that demonstrate better efficiency of nutrient utilization successively replace one another over time (3). The mechanism underlying this response includes random and nonrandom mutations (4) and unequal crossing over, leading to gene amplification, changes in protein structure, and altered expression patterns (5). When compared with laboratory strains of *S. cerevisiae*, baker's yeasts has more copies of the *SUC* gene, which appears to be amplified and translocated to several chromosomes (6,7). This gene encodes for invertase, the enzyme hydrolyzing sucrose, the main carbon source found in beet and cane molasses used for industrial feeding. Thus, amplification of *SUC* genes endows yeast cells with a higher sucrose hydrolyzing ability, overcoming a limiting step for growth and biomass yield (8). A clear example of this evolutive mechanism is the appearance of multiple tandem duplications of high affinity hexose transporters (*HXT* gene family), in a yeast population grown in a continuous glucose-limited environment (9).

The second factor accounting for many of the characteristics of baker's yeast is the repeated use of improvement strategies that provide a high genetic variability. Strain improvement of baker's yeast has traditionally relied on classical genetic techniques, including random mutagenesis, hybridization, and protoplast fusion. The continuous mating and later segregation of meiotic products in baker's yeasts increase the possibilities of chromosomal reorganizations, both in size and number, leading to polymorphism. This phenomenon is enhanced by the presence of many Ty transposable elements and subtelomeric Y´ regions in the baker's yeast genome (7), a key factor for chromosomal rearrangements (10). This feature could have also favored the selection of traits appreciated in baker's yeast, because the *MAL* loci and the *SUC* genes are located at the telomeres of this organism (11). The selection for broad traits, as robustness, growing rate, or fermentative capacity would also have contributed to the genetic constitution of baker's yeast. Although there is a lack of knowledge of the genes responsible for these properties, they are favored by a high ploidy level, as evidenced by much experimental data. For example, industrial yeasts show higher levels of glycolytic enzymes than wild-type strains (12). Dough-leavening ability also correlates with the activity of the *MAL* genes (13,14), which determine the capacity to transport and hydrolyze maltose, the main sugar than sustains dough fermentation. This is certainly not surprising, because duplication of blocks of genes has been a recurring feature of yeast genome evolution (15,16). Increasing the number of chromosomes will increase the

number of favorable genes leading to strains with enhanced fitness, increased maltose utilization capacity, and more vigor (17, 18). Thus, natural adaptation and the selective pressure exerted for decades by producers have led to the transformation, at low cost, of an abundant feedstock to cell biomass of high technological quality.

Nevertheless, there are still important traits in baker's yeast that are far from optimal. Tolerance to various stresses, such as osmosis, freezing, or desiccation, is clearly inadequate. Our limited understanding of the physiological and genetic determinants of these important commercial properties suggests that they are under the control of multiple genes and complex regulatory mechanisms (19, 20). Some of these desired phenotypes could also go against biological design (21). Thus, it is unlikely that classical breeding programs could provide further improvement of these characteristics. Given this scenario, the ability to transform baker's yeast by recombinant DNA technology has opened the possibility to manipulate just a single gene or pathway, without altering other key or valuable genes. Its is also possible to knock out undesirable genes, to engineer the constitutive expression of groups of genes involved in a particular function, or even to switch on or off the transcription of a given gene in a specific technological step. The transfer of heterologous genes to *S. cerevisiae* means that there is now the possibility of using yeast as a cell factory. This has allowed, in the past decade, the development of industrial strains with unsuspected properties, giving a new generation of baker's yeast.

This chapter will collect the available information on the most important advances in the engineering of baker's yeast, from both fundamental and technological aspects. It will also review critically the molecular tools applied for transformation of industrial strains. Information concerning wild *S. cerevisiae* and other industrial yeasts, like brewing or wine strains, will also be considered where it provides knowledge to address unresolved problems or to reveal future perspectives. To date, most of the recombinant approaches have been used for the modification of traits linked to single or a limited number of genes. Thus, the main targets for strain improvement by genetic engineering can be grouped into three categories: (1) extension of substrate range, (2) heterologous enzyme production, and (3) overproduction of essential nutrients.

11.2 MOLECULAR TOOLS

The manipulation of commercial baker's yeast is a difficult task because of the special genetic characteristics of these strains. For instance, the high level of ploidy means that multiple disruption and deletion steps are required to obtain a null mutant. Another consequence of this polyploidy is that most of these strains are prototrophic. Therefore, transformation by complementation of auxotrophic mutations, the most common approach in wild-type *S. cerevisiae*, cannot be employed. On top of this, the molecular tools that could be applied in industrial strains are often limited by legal regulations concerning the commercial exploitation of genetically modified organisms (GMOs). These legal regulations establish, as a criterion of acceptability, the absence of nonessential foreign DNA, and in particular, of vector sequences related to prokaryotic DNAs or antibiotic resistance markers. Additionally, transformants should also (1) keep the same useful properties of the parental strain, (2) have the minimal amount of synthetic DNA linkers, and (3) not express any fusion protein that may arise because of the genomic integration events (22).

11.2.1 Plasmids and Integrative Fragments

The type of cloning vector used for yeast is shuttle plasmids that can also replicate and be selected for, in *E. coli*. They can be grouped into two classes, those that replicate

autonomously and those that integrate into a chromosome (23). From all of them, the 2 μm-based plasmids are probably the most popular. Such multicopy plasmids show high transformation frequency and gene expression, which is useful for preliminary tests. However, gene overproduction can have deleterious effects on fermentation performance. In addition, these plasmids tend to be unstable under the absence of selective pressure (23), which is inappropriate for commercial purposes.

To solve this, integration appears as the best strategy, because it offers high stability. As integrative vectors, it is possible to use integrative plasmids, integrative fragments, or vectors based on Ty elements. Integrative plasmids contain an auxotrophic marker, which complements a host mutation. Integration occurs via homologous recombination between the plasmid-borne marker and the chromosomal allele. Nevertheless, this type of vector is not commonly used for industrial yeast, because the lack of auxotrophic markers in these strains.

In contrast, integrative fragments are widely used. These fragments consist of DNA linear fragments, normally generated by restriction or PCR, containing the expression cassette of one or more genes, flanked at both sides by sequences homologous to a target locus in the genome (Figures 11.2, 11.4). In contrast to integrative plasmids, integrative fragments allow multicopy integrations. For this purpose, the strategy is to target for replacement DNA that is reiterated in the genome that is not essential for growth. The locus most commonly employed is a portion of the rDNA unit (24). To ensure a high number of integrations (100–200 copies per cell), Lopes et al. (25) used a *leu2* defective promoter as selection marker. The transformants were highly stable over 70 generations of nonselective growth. Nevertheless, the mitotic stability, as well as the expression level of heterologous genes targeted to rDNA, depends on the size and the nature of the rDNA fragment required for targeting its integration. Lopes et al (26) reported stable maintenance only when the complete plasmid has a size no larger than that of the rDNA unit (9.1 Kb). Several examples of the use of rDNA-targeted integration in industrial strains have been reported (27, 28).

Other interesting integrative fragments used in industrial strains are those based in the δ-integration system described by Sakai et al. (29). This seems to be the most useful system to allow the sequential insertion of multiple cloned genes in yeast. In this vector, the integration is obtained via homologous recombination between the Ty δ-sequences in the yeast chromosome and those subcloned into nonreplicating plasmids (30). This system is chosen to overproduce recombinant glucoamylase in baker's yeast (31).

11.2.2 Dominant Selection Markers

The prototrophic character of industrial baker's yeast implies that genetic manipulation in these strains is based, almost exclusively, on the use of dominant resistance markers. *Saccharomyces* is sensitive to antibiotics such as geneticine, chloramphenicol, cycloheximide, hygromycin B, nourseothricin, or bialaphos. Heterologous enzymes, most of them from bacteria (32–35), can inactivate these antibiotics. Thus, disruption cassettes containing genes which confer resistance to those antibiotics have been developed and widely employed in laboratory strains of *S. cerevisiae*. However, a copy of the resistance marker remains in the genome after the integration event, making this selection system inadequate for industrial strains (22).

In *S. cerevisiae*, the loss of foreign DNA can be promoted by making use of a natural phenomena named "pop-out" or *in vivo* excision. This is an event of intrachromosomic recombination between two identical or very similar sequences (direct repeats), that results in the excision of a single direct repeat copy together with the DNA fragment placed between both direct repeats. Alani et al. (36), who constructed a disruption module containing direct repeats flanking the *URA3* selection marker, first demonstrated the possibilities

of this approach. Later, dominant disruption cassettes harboring the *E. coli* gene, which confers resistance to geneticine (*kan*^{r}), flanked by direct repeats of KanMX3 modules (34), were constructed and successfully employed for the repeated use of a single marker. KanMX3-based modules containing genes for hygromycin B, nourseothricin, or bialaphos resistance are also available (35). Furthermore, the efficiency of the *in vivo* excision event has been improved by making use of the loxP-Cre system (37). It has been shown that this a useful tool for industrial strains. Puig and co-workers (38) disrupted the two *URA3* alleles of a wine strain by successive transformation with a kanMX3-based disruption cassette and later excision. Recently, a second set of loxP-Cre plasmids was generated, which are ideally suited to genome functional analysis (39).

An inconvenience of these protocols is that after each excision step, a copy of the direct repeat remains in the genome of the yeast. Due to the requirement of heterologous direct repeats, in order to avoid their homologous recombination with the *S. cerevisiae* DNA, sequences of different sources, like *hisG* from *Salmonella* (36), *LEU2* from *Ashbya gossypii* (34), or loxP from the bacteriophage P1 (37, 40) have been employed. However, for commercial purposes, the use of these exogenous DNA is not convenient.

One possibility to solve this problem would be the use of nonrecombinogenic fragments from yeast species closely related to *Saccharomyces*. Following this approach, several research groups (41, 42); Estruch and Prieto, unpublished results) have constructed food safe grade dominant resistance cassettes containing direct repeats from the *MEL1* gene. This gene, which encodes for α-galactosidase, is present in several *Saccharomyces* species, including some strains currently classified as *S. cerevisiae*, but not in baking strains. These cassettes were used to obtain Ura$^-$ (41) and Trp$^-$ (42) (Estruch and Prieto, unpublished results) commercial baker's yeast strains by consecutive disruption of the corresponding wild-type copies.

A different strategy makes use of the Flp FRT (Flp recombinase recognition target) system from the 2 μm endogenous plasmid of *S. cerevisiae* for multiple gene disruption or heterologous gene expression in industrial yeast. The Flp protein is a yeast recombinase that recognizes FRT sequences. A minimal FRT consists of 34-bp, including two 13-bp inverted repeats surrounding an 8-bp core sequence involved in DNA–DNA pairing during strand exchange in the recombination reaction (43). From *in vitro* (44, 45) and *in vivo* (46) characterization of the Flp FRT recombination model, it is known that DNA heterology between the core regions of two FRT site inhibits their ability to engage in recombination. Utilizing this property, Storici and coworkers (47) designed FRT DNA sequences with different core mutations, which were cloned in direct orientation flanking a dominant marker gene, like KanMx4. Thus, the marker can be easily eliminated by *in vivo* recombination between FRT sequences catalyzed by the endogenous 2 μm plasmid-derived Flp protein.

11.2.3 Homologous Dominant Markers

For food and beverages applications, it is desirable to use dominant markers derived from yeast. Several genes from *S. cerevisiae,* conferring resistance to different harmful substances, have been isolated and tested for the selection of recombinant industrial strains.

The toxic effects of heavy metals ions are countered in *S. cerevisiae* by the *CUP1* gene, which encodes for a metal-binding protein. Cooper resistance was the most popular selection method for industrial yeast strains, because the expression of *CUP1* gene has no significant effects on fermentative behavior (48). Sulfometuron methyl (SM) is an herbicide that blocks yeast growth by inhibition of acetolactate synthase, encoded by *ILV2* (49). In *S. cerevisiae*, 10 phenotypically distinct alleles of *ILV2* have been described. *SMR1-410* (50) and *SMR1B* (51) have been used most widely. Both display mutations affecting the

same proline residue, which is required for the binding of SM to the *ILV2* product. In addition, this approach provides a useful site of integration close to the *ILV2* locus, that has been successfully used to generate α-galactosidase- (52) and α-amylase-producing (53) baker's yeast strains. Aureobasidin A (AbA), an antifungal antibiotic produced by *Aureobasidium pullulans*, is highly toxic to fungi, including *S. cerevisiae* and *S. pombe*. Hashida-Okado et al. (54) isolated several dominant mutants to AbA, using the mutated $AUR1^R$ gene from *S. cerevisiae* or the corresponding *AUR1-C* from *S. pombe*. These authors demonstrated the board application of this system for several yeast species and for industrial yeast, including baker's yeast (55). Formaldehyde can also be used as a selecting agent. Indeed, van den Berg and Steensma (56) constructed formaldehyde resistant expression cassettes by placing the gene *SFA1* from *S. cerevisiae*, encoding formaldehyde dehydrogenase (57), under the control of *GPD1* promoter and *CYC1* terminator. This system offers the advantage that formaldehyde is biodegraded to CO_2 during fermentation and therefore its removal during downstream processing is not necessary. The analogue 5,5,5-trifluoro-DL-leucine (TFL), has also been employed in transformation systems. In *S. cerevisiae*, the resistance to this leucine derivative is due to two classes of dominant mutations in the *LEU4* gene (58). Transformation of natural wine yeast strains with linear fragments containing these mutated genes showed a high efficiency, even better than that previously reported for other dominant markers (59). Two *S. cerevisiae* genes, *FZF1-4* and *SSU1,* have been found to exhibit dominant phenotypes useful for selecting transformants in the presence of sulfite. *FZF1-4*, a mutant allele of *FZF1*, a C_2-H_2 zinc finger protein (60), is a positive activator of *SSU1* (61), which encodes for a membrane protein involved in sulfite excretion. An interesting trait of this selection system is the lack of false positives, even at high cell densities (62). This characteristic together with the inexpensive cost of sulfite and its nontoxicity make of this system a good candidate to select transformants from industrial yeast strains.

Recently, a new tool for direct selection of transformants of industrial yeasts, based on the phenotype of multi-drug resistance, has been developed (63, 64). In *S. cerevisiae* this phenotype results from the overexpression of several membrane drug efflux pumps (63, 65). Those genes are under the control of two transcriptional activators Pdr1p and Pdr3p (66, 67). Several dominant point mutations of these effectors enhance its activity (63, 68). Both multicopy and centromeric vectors bearing the mutant *pdr3-9* allele have been used for transformation of laboratory and polyploid industrial strains of baker's yeast (63, 64). Furthermore, *pdr3-9* gene has been also employed as dominant selectable market for natural wine strain transformation (69). These wine strains produce experimental wines of the same quality as their parental natural strain.

11.2.4 Expression Level Promoters

The production of heterologous proteins in *S. cerevisiae* depends on multiple intracellular factors. A fundamental parameter is the level of transcription provided by the promoter (70). The expression of a foreign gene in *Saccharomyces* requires, in most cases, the use of homologous promoters in order to ensure expression and regulation. Thus, strong constitutive promoters are often chosen for efficient protein production (71) The promoters most commonly used are those of the glycolytic genes, phosphoglycerate kinase, *PGK1*, alcohol dehydrogenase and *ADH1*, glyceraldehyde-3-phophate dehydrogenase, *TDH1*, (70) and the promoter of the *ACT1* gene (72). Although those promoters are referred to as constitutive, their transcriptional activity is subjected to regulation, reflecting a particular physiological state of the cell (73, 74). This has been clearly demonstrated in molasses-grown baker's yeast strains by making use of two reporter genes driven by different promoters (75). Expression regulated by the short form of the *ADH1* promoter gave the

highest protein yield for cells cultured in molasses medium or flour and water mixtures. Nevertheless, the *ACT1* promoter appeared as the strongest in cells growing actively with sucrose (75). Similar results were reported by Puig et al. (76) when evaluating the use of phase specific gene promoters for the expression of enological enzymes in an industrial wine yeast strain.

Some times, however, the choice of inducible promoters is more useful, like those of the *GAL* genes, where expression is repressed by glucose and induced by galactose, *PHO5*, repressed by inorganic phosphate, *ADH2*, and repressed by glucose or *SUC2* (70). These tightly regulated promoters allow the production of putatively growth inhibitory proteins, because cells can be grown to high densities before the expression of the foreign gene is induced. This strategy also provides a good system for the optimization of fermentation processes for the utilization of lactose by recombinant baker's yeast strains (27). Thus, the choice of a promoter for heterologous gene expression should reflect the particular condition in which the protein production is and the level of recombinant protein required for a desired technological effect.

In this sense, high throughput technologies, such as DNA microarrays and 2D-electrophoresis, are useful tools to provide information on differential gene expressions and regulatory networks (77, 78). Global gene expression analysis during the shift from fermentation to respiration in *S. cerevisiae* (79), or under different stress conditions, such as salt (80), oxidative stress, or thermal stress (81), has identified target genes induced under those physiological conditions. The promoters of these genes are obvious candidates to drive the production of heterologous proteins in different steps of the yeast propagation and bread making process. For instance, the promoter of a strongly induced gene by heat shock could be useful to express a heterologous protein at the baking stage of the bread dough, whereas an osmotically induced gene could provide an ideal promoter for heterologous expression in high sugar dough.

11.3 EXTENSION OF SUBSTRATE RANGE

A blend of beet and cane molasses is commonly used in the commercial propagation of yeast. Sucrose is the main sugar, accounting for more than 40% by weight. Molasses also provides essential nutrients, such as minerals, vitamins, and some amino acids. This composition has made molasses the most widely extended substrate for baker's yeast production. Nevertheless, molasses is not the ideal culture medium for yeast propagation.

Both cane and beet molasses can contain harmful substances that inhibit yeast growth and baking performance. They also contain a great deal of suspended solids that must be removed, at least in part, before yeast production. This pretreatment increases the cost of the process, reducing the product profit margin. In addition, molasses may vary significantly in quality from batch to batch, especially in terms of sugar content. On top of this, the introduction of modern sucrose extraction procedures has reduced the availability of this carbon source for growth. For these reasons, the expression of heterologous genes in baker's yeast has led to the possibility of using new carbon sources and raw materials other than molasses for yeast propagation.

Many examples of substrate range extension are described in the Literature for *S. cerevisiae*. For biomass production, a feedstock having low cost and availability on a large scale is required (82). Consequently, only a few potential carbon sources can be considered for cost effective yeast propagation processes. The practical application of these nonnatural substrates of baker's yeast will require an extensive evaluation of the traits of the newly engineered strains for properties desired in commercial baking.

11.3.1 Melibiose

In addition to sucrose, beet molasses contains up to 8% (by weight) raffinose, which is hydrolyzed by yeast β-fructosidase (invertase, EC 3.2.1.26), encoded by the *SUC2* gene in fructose and the disaccharide melibiose (glucose–galactose). Baker's yeast can utilize melibiose after its hydrolysis, but lacks α-galactosidase (melibiose, EC 3.2.1.22), which releases the glucose and galactose moieties (Figure 11.1). Thus, the inability of industrial baker's yeast to use melibiose as a carbon source reduces the productivity of the propagation process and increases the organic content of the effluent, which has a high biological demand (BOD).

α-galactosidase is encoded by a *MEL* gene, present in different species of the genus *Saccharomyces*, such as *S. bayanus*, *S. carlsbergensis,* or *S. oleaginosus* (83). Mel^+ strains of *S. cerevisiae* have been also isolated, and eleven genes, *MEL1–MEL11*, have been identified in different natural populations (84, 85). Although an accumulation of the *MEL* genes has been found in some specific *S. cerevisiae* populations, most of the *Saccharomyces* spp. strains carry only one *MEL* locus (83, 86), *MEL1* being the best characterized.

Baking strains with complete raffinose utilizing ability were earlier constructed by hybridization with laboratory strains of *S. bayanus* (87). Higher yeast yields (2–3%) on beet molasses were thus obtained, although these industrial hybrids exhibited poor bread dough leavening ability. Mel^+ baker's yeast strains were further obtained by cloning and expression of the *MEL1* gene from *S. bayanus* (88, 89). This engineered yeast resulted in an increase in the yield in molasses medium and a significant reduction in the BOD from the factory effluent. However, the presence of bacterial sequences into these industrial

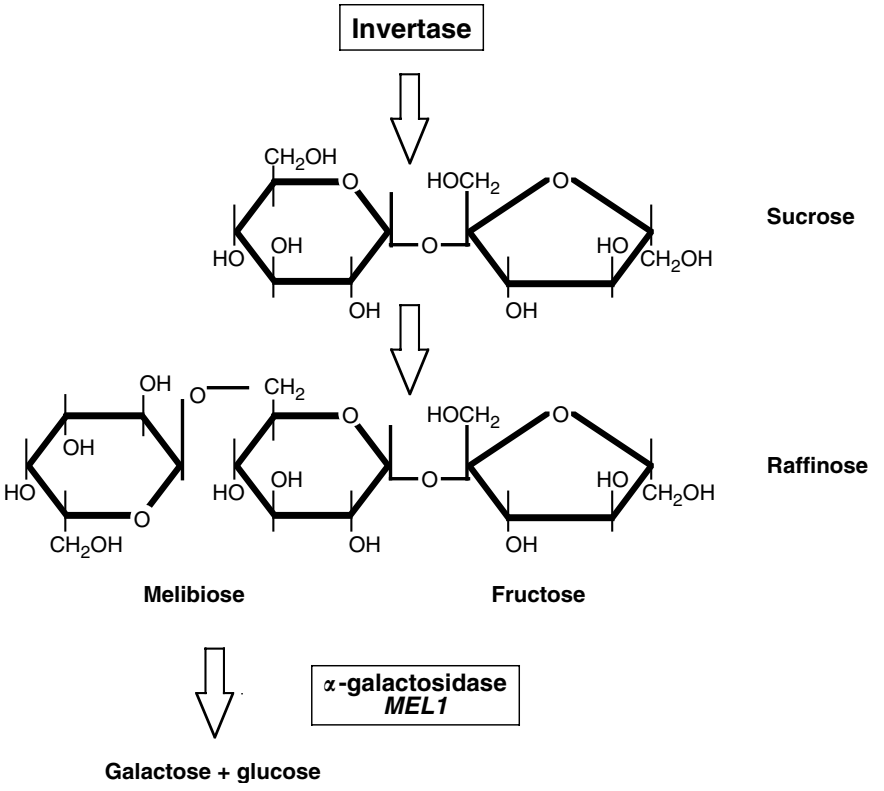

Figure 11.1 Structures of sucrose and raffinose and scheme of their hydrolysis by invertase and α-galactosidase. The main hydrolysis products are shown.

strains resulted in a market resistance to their use. A new approach (52) made use of a one step dominant selection procedure to construct stable integrations of *MEL1* devoid of bacterial plasmid DNA in baker's yeast strains (Figure 11.2). These strains were stable, increased the biomass substrate yield up to 8%, and had growth rates similar to those of the untransformed control strains. In a further study, melibiose-utilizing baker's yeast strains produced by genetic engineering and classical breeding were compared (90). The results showed that the strategies render strains with similar fermentative capacity. However, the strains tested differed in genetic background. In addition, biomass yields on molasses under industrial conditions were not determined.

Aiming to find Mel^+ baker's yeast with optimal performance, Rønnow et al. (91) constructed strains partially relieved of glucose control over galactose metabolism by disruption of *MIG1* and *GAL80*. Mig1p and Gal80p are regulator proteins involved in the glucose repression and galactose induction of the *GAL* genes (92). Overall, these proteins downregulate the synthesis of enzymes involved in the metabolism of galactose and other alternative carbon sources when glucose is present, which means that wild-type strains of baker's yeast consume galactose only when glucose has been exhausted. A simultaneous utilization of both sugars was observed, however, in melibiase-producing *mig1 gal80* mutants (91). Moreover, the recombinant strains showed higher melibiose hydrolysis and galactose uptake rates than the corresponding wild type, resulting in shortened cultivation times on melibiose (93). However, this resulted in a more pronounced respire-fermentative metabolism, with enhanced ethanol yield and less biomass production (91, 93). These

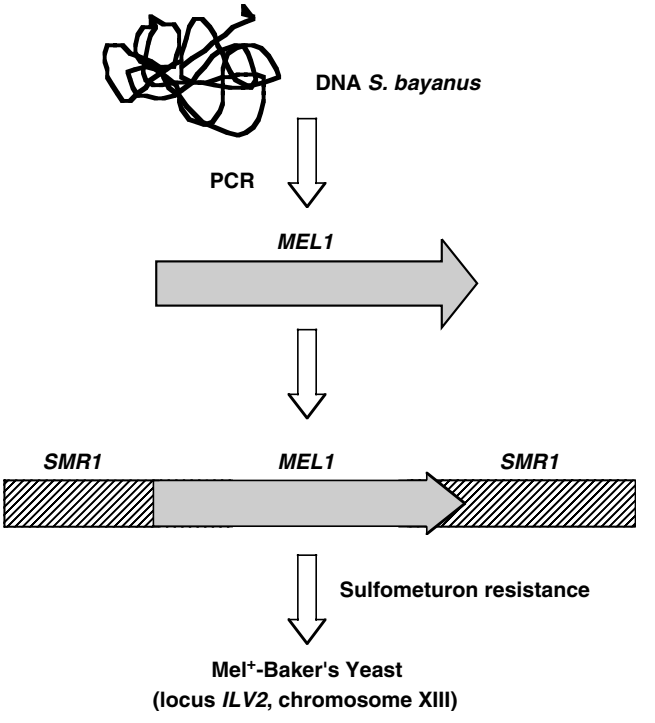

Figure 11.2 Schematic representation of the strategy followed to the selection of stable *MEL1* integrants of baker's yeast strains. Cells were transformed with a PCR-generated DNA fragment containing the *MEL1* gene from *Saccharomyces bayanus* flanked by a *S. cerevisiae SMR1* allele of the *ILV2* gene (chromosome XIII), which confers sulfometuron resistance (50, 52).

derepressed Mel$^+$ strains could be of particular interest in the production of ethanol, a subproduct of the molasses fermentation, although the reduction in biomass yield makes unlikely their application in the propagation of baker's yeast.

11.3.2 Lactose

Whey is the main byproduct of the cheese industry. In 2001, in the USA alone, this manufacturing process generated approximately 3.7 billion Kg of raw whey (USDA). Whey can be processed for a variety of end uses, like animal feed, human food products, and pharmaceuticals (94). Nevertheless, processing procedures are often expensive (95), and the demand for whey derived products is not enough to cover all whey available. As a result, many dairy facilities often rely on land spreading to dispose of this byproduct (96). This common practice has a great pollution potential due to the high BOD of whey, to which lactose is the major contributor. Consequently, the introduction of new biotransformation methods of lactose and whey into useful products is of great interest.

Different microorganisms, including bacteria, fungi, and yeasts, like *Kluyveromyces lactis* or *K. fragilis*, can metabolize lactose (Figure 11.3). Nevertheless, fermentative transformation of lactose by *S. cerevisiae* would be more profitable, because this organism has special properties that represent a higher benefit (97, 98). *S. cerevisiae* lacks, however, β-galactosidase activity, which releases glucose and galactose, and thus is unable to assimilate the disaccharide. Two different strategies have been followed to endow *S. cerevisiae* with the ability to utilize lactose: (1) release or secretion into the medium of recombinant β-galactosidase, and (2) combined production of a specific lactose transport system coupled with an internal β-galactosidase activity.

Fermentation of lactose by yeast cells overproducing the yeast Gal4p and the β-galactosidase (*lacZ*) from *E. coli* was earlier reported by Porro et al. (99). Expression in a high copy number of *GAL4*, the activating factor of the *GAL* genes (92), induces a certain degree of cell lysis with the consequent release of β-galactosidase into the medium. Physiological studies showed than cells were able to grow on media containing whey lactose, but biomass yield was unsatisfactory. A further improvement of this system was achieved by transforming yeast cells with a multicopy vector containing the *lacZ* gene fused in frame with the *S. cerevisiae var. diastaticus STA2* gene (100). This fusion targeted the enzyme to the yeast periplasm, improving the growth rate and biomass productivity.

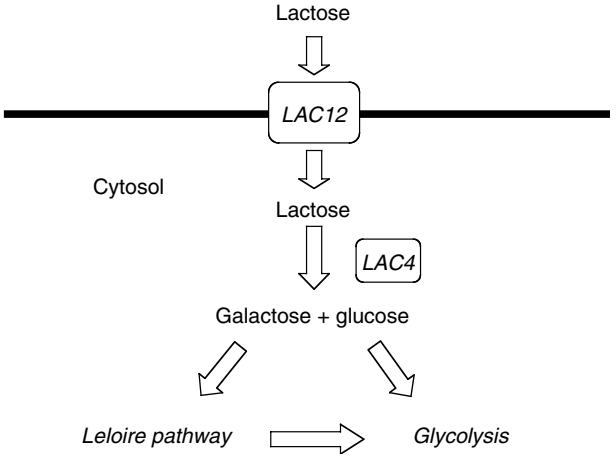

Figure 11.3 Pathway of the transport and catabolism of lactose in *Kluyveromyces*.

Similar results were obtained by expressing an extracellular β-galactosidase, encoded by the *LacA* gene from *A. niger* (101). However, the resulting strains, derived from haploid hosts, showed an unstable Lac^+ phenotype and exhibited a typical diauxic growth (102).

Sreekrishna and Dickson (103) were the first to report the construction of lactose-utilizing strains by transformation of *Saccharomyces* haploid cells with vectors harboring a selectable marker gene, conferring resistance to the antibiotic G418, and the *K. lactis* genes, *LAC4* and *LAC12*, coding for β-galactosidase and lactose permease, respectively (Figure 11.3). Furthermore, they also obtained stable integrative transformants containing both genes and lacking bacterial DNA sequences, as claimed in a U.S. patent (104). This system was later optimized by Rubio-Texeira et al. (105), who reported the construction of a Lac^+ *S. cerevisiae* diploid strain (MRY286), carrying multiple copies of the *K. lactis* genes. In lactose medium, this recombinant strain showed mitotic stability, simultaneous utilization of glucose and galactose, and a respiro-fermentative metabolism characterized by a low ethanol production and a high biomass yield. Following the same strategy, Adam et al. (27) constructed Lac^+ baker's yeast by sequential transformation of a *trp1* auxotrophic recipient strain (106), with linear DNA fragments containing the *LAC12* and *LAC4* genes and flanked by sequences homologous to the rDNA from *Saccharomyces* (Figure 11.4). The resulting strain, L306BY6, was stable under nonselective conditions, and displayed high growth rate in cheese whey with a biomass yield of about 10 g dry weight/liter of culture. Moreover, whey propagated compressed yeast had white color, a characteristic appreciated by bakers, and similar baking properties as molasses-grown commercial baker's yeast. Indeed, measurements of CO_2 production and gassing rate were almost identical for the strains tested (Table 11.1), independently of the culture medium. Bread elaborated with L306BY6 also showed loaf volume and crumb firmness similar to that elaborated with control strains (Table 11.1). Hence, the newly developed strain offers a profitable use for cheese whey and it is a cheap alternative to the traditional procedures of baker's yeast propagation.

11.3.3 Starch

Starch, a cheap raw material of agricultural crops, has been traditionally employed as a source of sugars commonly used in chemical, pharmaceutical, and food industries. The batch hydrolysis of starch into sugar syrups requires its gelatinization by cooking, and two enzymatic steps, liquefaction and saccharification, which involve the use of α-amylase for endo α-1,4 cleavage, and glucoamylase, an exo-acting enzyme able to hydrolyze both,

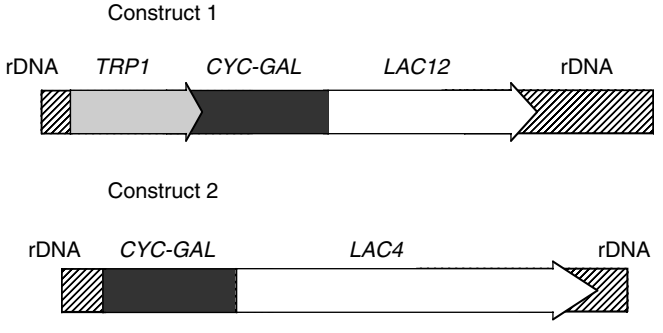

Figure 11.4 DNA arrays (constructs) used in the two sequential yeast transformation steps leading to the construction of the Lac+ baker's strain L306BY6. Source: Taken from Adam, A.C., J.A. α-1,4 and α-1,6 linkages, respectively (107). *Saccharomyces cerevisiae* is unable to hydrolyze starch, but easily ferments its degradation products, glucose and maltose; therefore, the starch-derived sugar syrups can be used as a carbon source for the propagation of baker's yeast. However, because the hydrolysis process requires expensive enzymes, relatively high temperatures (50–80°C), and time-consuming steps, the conversion of starch grains into cell biomass is uneconomic.

Genetically engineered industrial yeast capable of producing starch-degrading enzymes have been constructed, to save some of the cost associated with the traditional methods of starch conversion and to optimize ethanol and single cell protein production. Secretion of α-amylase and glucoamylase activities from *S. cerevisiae* has been done by coexpression of the corresponding genes from amylolytic species, mainly of *Bacillus* and *Aspergillus*, including those from *Schwanniomyces occidentalis* and *Saccharomyces diastaticus* (108–112). These strains perform a single-step hydrolysis of starch with conversion efficiencies greater than 93–95%, although the amylopectin fraction is poorly assimilated. This problem was solved by using a recombinant strain producing α-amlylase, glucoamylase, and pullulanase, a debranching enzyme acting on the α-1,6 linkages (113). The transformed strain showed a high rate of starch hydrolysis and was able to utilize almost 100% of precooked starch. In a different approach, several reports described the development of novel starch-utilizing strains by applying the technique of cell surface engineering. By using the yeast α-agglutinin as an anchor region, Murai et al. (114) were able to target and bind covalently glucoamylase from *Rhizopus oryzae* to the *S. cerevisiae* cell surface. Constructing a laboratory strain that displays glucoamylase and α-amylase on its cell surface yielded a further improvement (115). Although the strain was not evaluated in comparison with other strains expressing secretable enzymes, it is expected that cell-surface engineered cells could maintain the enzyme activity over a longer cultivation period, increasing the efficiency of starch transformation.

Compared to this, the construction of amylolytic baker´s yeast has received less attention, due in part to the difficulty of transforming strains with a polyploid background. Recombinant strains containing the α-amylase gene from *Aspergillus oryzae* or *S. occidentalis* have been generated by employing integrative cassettes targeted to the rDNA or the *ILV2* locus, respectively (28, 53). *Aspergillus oryzae* glucoamylase cDNA has also been expressed in baker's yeast by δ-integration into the Ty1 retrotransposon (31).

However, the ability of these strains to grow on starch as their sole carbon source appears to be quite limited (53), because they lack a complete amylolytic system. Obviously, the most direct approach to this problem would be the coexpression of several amylolytic genes. However, the use of such strains in downstream applications could be problematic, if the high starch-degrading capacity is prolonged during the bread dough fermentation and baking. Excessive starch breakdown results in a moist, sticky, and rubbery breadcrumb and a small volume (22). Nevertheless, this could be solved by an appropriate election of the promoter driving the expression of the heterologous genes. In this way, the application of global expression analysis techniques should help to identify strong promoters showing a differential regulation in the propagation and baking stages.

11.3.4 Lignocellulose

Lignocellulosic wastes are the major potential source of carbon and energy on the earth. Although most of the academic and industrial interest on lignocellulose has been devoted to the bioconversion of this material into fuel (116), improvements regarding pretreatments, enzymatic hydrolysis, fermentation, and process integration should extend its use to the production of different value added commodities. A complex mixture of cellulose, hemicellulose, and lignin are the raw materials of lignocellulose. Total or partial conversion of such complex substrates to yeast fermentable saccharides requires pretreatment to make them capable of enzymatic attack, fractionation into components, and later hydrolysis by a set of several enzymes. Alternatively, lignocellulose hydrolysates can be prepared by strong acid treatment, but this method renders degradation products as hemicellulose-derived acetate and phenolic lignin fragments, which inhibit *S. cerevisiae* growth (117, 118). A detailed description of various pretreatment options, downstream fractionation strategies, and resulting product streams can be found in recent reports (119–123).

Complete enzymatic depolymerization of lignocellulosic materials requires the use of several multicomponent systems, according to the composition and structure of each particular polymer (123, 124). None of these enzymatic complexes is present in *S. cerevisiae*, so far. Consequently, exogenous enzymes must be added to provide a specific conversion of cellulose wastes to sugars. Although these enzymes are commercially available, their high cost has been a major concern in the transformation of lignocellulose to yeast biomass. This can be solved in part by using mixed microbial cultures of *S. cerevisiae* and cellulolytic microorganisms (125, 126), but this strategy is only adequate for ethanol production. Yeast strains genetically engineered for cellulose, hemicellulose, or lignin utilization can overcome most of these problems, rendering them more suitable for industrial fermentation (123, 127). *Saccharomyces cerevisiae* strains able to grow on cellulose and hemicellulose have already emerged. The appearance of lignin-utilizing strains will take longer, because of the complexity of this polymer and because the lignin degradation products are not easily metabolized by *S. cerevisiae*.

11.3.4.1 Cellulose

Cellulose has been traditionally considered the most promising lignocellulosic polymer for yeast cell cultivation, because it consists basically of glucose units, the preferred carbon source for *Saccharomyces*, linked by β-1,4-glycosidic bonds (128). The complete enzymatic degradation of native cellulose requires the synergistic action of cellulases that can be grouped in three main classes, (1) endoglucanases, that release mainly cellooligosaccharides; (2) exoglucanases (cellobiohydrolases), which produce cellobiose from the ends of the cellulose chain; and (3) β-glucosidases, also referred as cellobiose, that hydrolyze the cellobiose disaccharide to D-glucose.

Production of cellulolytic enzymes is common in a large variety of fungi and bacteria, including species from *Trichoderma*, *Aspergillus*, *Penicillium*, *Bacillus,* and *Clostridium* (123, 129). In contrast, *S. cerevisiae* only produces β-1,3-specific glucanases (130), which are unable to degrade cellulose chains. Therefore, recombinant strains of *S. cerevisiae* expressing single genes for heterologous cellulases have been constructed and tested for cellulose bioconversion (127). Although these strains exhibited hydrolytic activity and facilitated the utilization of cellulose wastes, it soon became evident that the effective degradation of cellulose by *Saccharomyces* requires the engineering of a multienzymatic cellulase complex.

With this purpose, van Rensburg et al. (131), obtained a cellulolytic *S. cerevisiae* strain coexpressing the *Phanerochaete chrysosporium* cellobiohydrolase (*CBH1*) and the *Butyrivibrio fibrisolvens* endoglucanase (*END1*) genes. The resulting strain was further improved by incorporating in a multicopy plasmid an expression cassette for *BGL1* and *CEL1*, encoding for cellobiase and cellodextrinase from *Endomyces fibuliger* and *Ruminococcus flavefacies*, respectively (132). The engineered strain was able to degrade efficiently carboxymethylcellulose, laminarin, and barley glucan, and to assimilate cellobiose, but data concerning growth on cellulosic polymers were not provided.

In a similar approach, Cho et al. (133) developed mitotically stable recombinant strains of *S. cerevisiae* producing secretable endo- or exoglucanase and β-glucosidase from *Bacillus*. Expression levels of cellulolytic enzymes were thus significantly increased in comparison with plasmid-based expression systems. Moreover, the resulting transformants showed a significant cell growth on cellulodextrins (133).

Following a different strategy, cell surface engineered yeast strains expressing cell wall anchored β-glucosidase and endoglucanase from *Aspergillus aculeatus* or *Trichoderma reesei* have been successfully constructed (134, 135). This approach tries to mimic the so-called cellulosome structure, a cell surface bound enzymatic complex found in *Clostridium thermocellum* and other species, which promote adhesion to insoluble substrates, degrading efficiently crystalline cellulose (136). Thus, cells of *Saccharomyces* codisplaying cellulolytic enzymes on the cell surface were endowed with the ability to degrade and rapidly assimilate water-soluble cell ooligosaccharides (134) and barley β-glucans (135). Considering the advantages of the cellulosome complex, this system appears to open the possibilities to construct baker's yeast strains able to utilize properly cellulose wastes.

11.3.4.2 Hemicellulose

The hemicellulose fraction of lignocellulosic materials is a complex carbohydrate heteropolymer. Its principal component is xylan, formed by a backbone of β-1,4 linked xylose residues, with L-arabinose and 4-O-methyl-glucuronic acid side chains. Complete degradation of xylan requires the activity of an endo-1,4-β xylanase and a 1,4-β-xylosidase, whereby the monomer xylose is released. In addition, some accessory enzymes breaking down side linkages as α-L-arabinofuranosidases, can act synergistically enhancing the rate and extent of hydrolysis (137). Several genes encoding xylanases and α-L-arabinofuranosidases have been isolated and cloned in *Saccharomyces cerevisiae* laboratory strains with the aim of producing xylan-degrading yeasts (138, 139). Recombinant yeast strains exhibiting both α-L-arabinofuranosidase and β-xylosidase activities have also been constructed (140). Furthermore, the *Aspergillus nidulans* endoxylanase *xlnA*, *xlnB,* and *xlnC* genes, and the *Aspergillus niger* α-L-arabinofuranosidase (*abfB*) gene have been successfully expressed in an industrial baker's yeast strain (141). More recently, La Grange and coworkers (142) have described the construction of a recombinant *S. cerevisiae* strain coexpressing the *A. niger* β-xylosidase (*xlnD*) and the *T. reesei* xylanase II (*xyn2*) genes. Coproduction of these two key enzymes enabled *Saccharomyces* to produce efficiently D-xylose (20 g/liter) from birchwood xylan (50 g/liter), with xylobiose as a minor product.

Despite these advances, the major drawback to converting xylan to cell biomass or other useful products is the inability of *Saccharomyces* to ferment xylose. Numerous efforts have been directed over the last decade toward engineering of *S. cerevisiae* for xylose utilization. In naturally xylose-fermenting yeasts, such as *Pichia stipitis* and *Pachysolen tannophilus*, xylose metabolism begins with its conversion to xylulose in a two step reaction involving xylose reductase, XR, and xylitol dehydrogenase, XDH, encoded by *XYL1* and *XYL2*, respectively. Subsequently, xylulose is phosphorylated by xylulokinase, being further catabolized via the pentose phosphate pathway (Figure 11.5). *S. cerevisiae* displays xylulokinase activity, but lacks the enzymes for xylitol and xylulose formation. For this reason, expression of *P. stipitis XYL1* in *S. cerevisiae* enabled the production of xylitol from xylose, but no growth on this carbon source was observed (143, 144). A significant improvement was obtained by coexpressing *XYL1* and *XYL2* genes from *P. stipitis* (145–147). Indeed, these strains were able to utilize xylose, but the rate of assimilation was poor and took place only in the presence of glucose and under oxygenation conditions. This was attributed to a poor xylose uptake, inefficient xylose to xylulose conversion, starting with an accumulation of xylitol, and the inability of the recombinant strains to route carbon flux trough the pentose phosphate (PP) pathway (145).

Xylose is presumably transported by the same system as glucose, but with a 200-fold lower affinity (148). Consequently, xylose uptake was suggested early as a factor limiting xylose flux in recombinant cells. This appeared to be confirmed by measuring xylose uptake rate in cells of the xylose-utilizing strain TMB3001, cultivated with different xylose–glucose ratios (149). Currently, it is not clear that xylose uptake could have a major impact on xylose utilization. In fact, overexpression of the high affinity glucose transporters of *S. cerevisiae* in the same strain did not result in faster growth on xylose (150).

Xylitol production results in a cofactor imbalance, because xylose reductase uses both NADPH and NADH, while xylitol dehydrogenase utilizes only NAD^+ (Figure 11.5). This was clearly demonstrated by Lidén et al. (151), using a *XYL1*-expressing *S. cerevisiae* mutant unable to produce glycerol. Regenerating NAD^+ could be provided by engineering internal redox sinks, like glycerol (Figure11.5) and succinate synthesis. However, these reactions proceed at the expense of ATP. The redox imbalance could also be overcome by decreasing the XR:XDH activity ratio. Indeed, Walfridsson et al. (152) demonstrated that a strain with much higher specific activity of XDH than of XR metabolized xylose without xylitol formation, but only a small part of the xylose available was consumed. In a different approach, several research groups tried to resolve the redox problem by introducing, instead of the *Pichia* system, bacterial genes for xylose isomerase (XY), an enzyme that transforms xylose into xylulose without a redox cofactor requirement (153). In most of the cases this strategy failed due to the lack of activity of the heterologous protein. Thus, so far only the enzyme from *Thermus thermophilus* has been actively produced in *S. cerevisiae* (154). The recombinant strain displayed ethanol formation from xylose, but no growth was observed. Moreover, xylitol was again the main byproduct. This was ascribed to the presence in *Saccharomyces* of endogenous unspecific aldose reductases. However, deletion of *GRE3*, which encodes the yeast aldose reductase (155), did not improve the xylose metabolism in XY-producing strains (156). Recently, Jeppsson et al. (157) investigated the effects of a flux reduction through the NADPH-producing branch of the PP pathway in a xylose-utilizing strain. Lowering the oxidative PP pathway activity would result in a reduced intracellular level of NADPH, increasing the NADH-dependent reduction of xylose. Although a connection between NADPH levels and xylitol formation was demonstrated, the polyol was still produced. In addition, the recombinant strain showed an 84% lower xylose consumption rate (157).

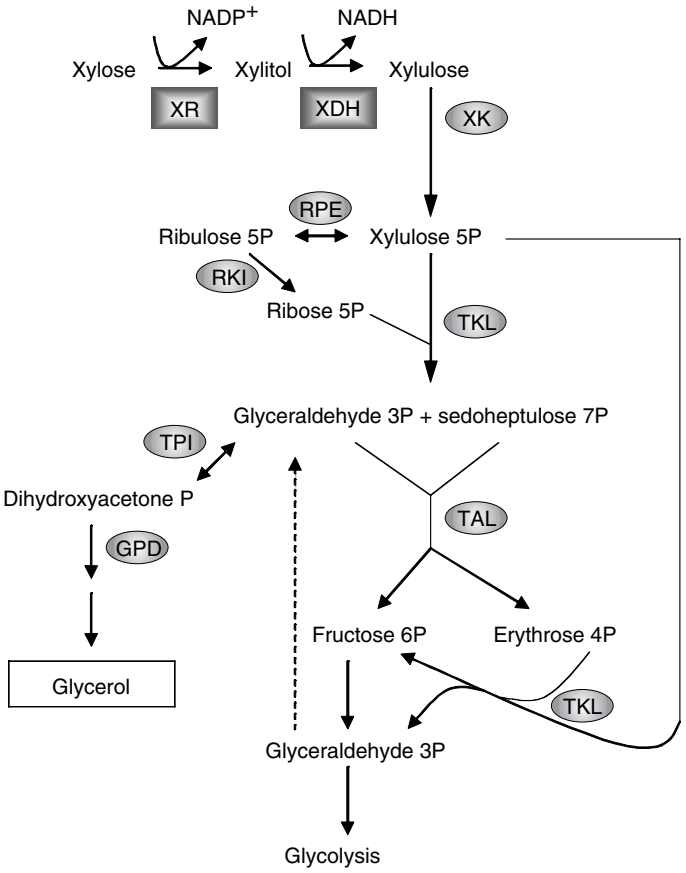

Figure 11.5 Schematic representation of the xylose metabolism through the non-oxidative branch of the pentose phosphate pathway. The main enzymes involved in the pathway, xylulokinase (XK), ribulose-5-phosphate epimerase (RPE), ribose-5-phosphate ketol-isomerase (RKI), transketolase (TKL) and transaldolase (TAL), and related pathways, triosephosphate isomerase (TPI) and glycerol-3-phosphate dehydrogenase (GPD) are shown. The boxes indicate enzymes, xylose reductase (XR) and xylitol dehydrogenase (XDH) that are not present in *S. cerevisiae*.

The capacity of the nonoxidative PP pathway (Figure 11.5) has been traditionally considered as limiting the xylulose consumption in *S. cerevisiae* (158). To investigate this, Walfridsson et al. (159) constructed *XYL1*- and *XYL2*-containing *S. cerevisiae* hosts that overexpress the genes *TKL1* and *TAL1*, encoding transketolase and transaldolase, respectively. These activities catalyze the conversion of two important intermediates of the nonoxidative PP pathway, xylulose-5-phosphate and sedoheptulose-7-phosphate. The study showed that the Tkl1p activity did not control the flux through the PP pathway. Overproduction of Tal1p did enhance growth on xylose, compared with the *XYL1*/*XYL2* control strain, thus improving biomass yield.

The step catalyzed by xylulokinase (*XKS1*), the third enzyme of the xylose pathway (Figure 11.5), has received special attention. Fermentation studies have been conducted in *S. cerevisiae* strains overexpressing the homologous *XKS1* gene along with the *P. stipitis XYL1* and *XYL2* genes (149, 160–163). The results indicated that expression in a high copy number of *XKS1* enhances the specific rate of xylose utilization. In addition, xylose

conversion was achieved on xylose as the sole carbon source (161). A significant fraction of the utilized xylose was still excreted as xylitol with biomass as a minor product (160, 163). Moreover, the overexpression of *XKS1* changed the amount and ratios of xylulose-5-phosphate and sedoheptulose-7-phosphate. Thus, both xylulokinase and enzymes downstream of xylulose-5-phosphate appear to limit the flux through the PP pathway in natural *S. cerevisiae* strains. These results demonstrate that the construction by genetic engineering of efficient xylose-growing recombinant yeasts should take into consideration targets in different branches of the metabolic network.

11.4 HETEROLOGOUS ENZYME PRODUCTION

The use of enzymes in the baking industry is widely extended. They modify the flour components, mainly starch, nonstarch polysaccharides, proteins, and lipids, and as a result, the physicochemical properties of the dough and the bread quality parameters (22).

Regular enzyme application in the dough system is carried out by exogenous addition of commercial preparations. Although substantial amounts of these compounds are obtained from recombinant organisms, mainly fungi and bacteria, all of them contain a cocktail of minor enzymatic activities that may negatively affect bread quality. Moreover, these products may act as allergens, producing a high prevalence of occupational hypersensitivity, in terms of dermal and bronchial (asthma) allergies (164–166). Alternatively, recombinant baker's yeast strains producing a technological enzyme can be employed to obtain the same benefits, avoiding airborne allergen pollution at the workplace (167).

11.4.1 Amylases

The amount of fermentable sugars present in flour is only around 1–2% (168). This is clearly insufficient for the optimum growth and gas production of yeast. The fermentation depends thus on the proper production of maltose from damaged starch by the action of wheat β- and α-amylases (169). Regular nongerminated wheat flour contains good levels of β-amylase but little amount of α-amylases. Because of this, wheat flour is normally supplemented with exogenous α-amylase (170).

The reducing sugars produced by the action of α-amylases not only supply the yeast with the substrate for the proper production of gas, but they serve to improve the aroma and color of bread. Furthermore, the addition of α-amylase enhances bread volume, which results in a softer crumb (169,171).

Baker's yeast strains expressing the α-amylase from *Aspergillus oryzae* have been constructed (172). The α-amylase cDNA was placed under the control of the yeast *ACT1* promoter and the resulting transformant produced a recombinant α-amylase with biochemical and kinetic characteristics similar to the native enzyme (173). Dough produced with this transformant gave bread with greater volume, a softer crumb, and a reduced firming rate (172). In addition, the authors showed that a fraction of the enzyme was somehow protected by the yeast structure, so it could remain active for a little bit longer in the oven, as an encapsulated enzyme, resembling then the action of α-amylases of intermediate thermal stability. Therefore, the action of a particular enzyme on its substrate may be modified just by being expressed by yeast.

11.4.2 Xylanases

Wheat flour contains up to 3% nonstarch polysaccharides (pentosanes or hemicelluloses), which play an important role in water absorption and dough rheology. Enzymatic

modification of these polysaccharides improves both dough properties and bread quality, increasing volume and retarding the process of "staling" during storage (22, 169).

Using the same strategy as previously described, Monfort et al. (141) expressed different xylanolytic enzymes in industrial baker's yeasts. When transformants producing the *A. nidulans* endoxylanase X24 (*xlnB*) were used in regular straight dough, only a discrete increase in bread volume (5%) was observed. However, when this enzyme and the *A. oryzae* α-amylase were coproduced simultaneously (174), a synergistic effect was observed. The bread elaborated with the new transformant showed a larger volume increase (around 30%) and a softer crumb texture than those prepared with either the *xlnB* overproducing transformant or a control strain. Thus, the combination of xylanase and fungal amylase provided a better overall score on dough and bread quality parameters for the combined exogenous addition of these enzymes (175).

11.4.3 Lipases

Lipases (glycerol ester hydrolases EC 3.1.1.3) catalyze the hydrolysis of triacylglycerols to render mono- and diacylglycerides and free fatty acids. The addition of lipases to the dough improves its rheological properties and stability, resulting in breads with larger volume, softer crumb, and longer shelf life (176). These effects depend on the type of flour and the baking formula, being significant in dough systems without added shortening (175). It has been postulated that the lipase activity would form a kind of *in situ* emulsion by producing mono and diglycerides into the dough (176). However, the total amount of lipids in sound wheat flours is low. Besides, the hydrolysis degree by the lipase action in dough systems is limited. Hence, the amount of mono- and diglycerides produced appears not to be sufficient to explain the effect of the lipase properties on breadmaking (175).

Although the expression of lipases of different origins in laboratory strains of *Saccharomyces cerevisiae* is well documented (177–179), the construction of industrial baker's yeast expressing lipases is now emerging. Monfort et al. (180) reported obtaining of lipolytic baker's yeast able to secrete active lipase by transformation with plasmids containing the *LIP2* gene from *Geotrichum* sp. Recombinant lipase-2 protein exhibited biochemical properties similar to those of the natural enzyme (178). Fermented dough prepared with the recombinant strain rendered bread with higher loaf volume and a more uniform crumb structure than that prepared with control yeast. These effects were strengthened by the addition in the bread dough formulas of a preferment enriched in recombinant lipase 2 (180). Following the same approach, Sánchez et al. (181), described the expression of the *lipA* gene from *Bacillus subtillis* in baker's yeast. Unfortunately, the recombinant strain was unable to target the secretion of the heterologous enzyme into the culture media, even when a signal peptide was fused in frame to *lip*A.

11.4.4 Phytases

The low absorption of iron and zinc from cereal based meals has been ascribed to the high content of phytate (myo-inositol hexaphosphate), which forms insoluble complexes with these minerals at physiological pH values (182). Wheat grain contains endogenous 6-phytase (183), a phosphomonoesterase capable of hydrolyzing phytate to free inorganic phosphate and inositol via mono- to pentaphosphates. This phytase is activated during fermentation but not to such an extent that mineral bioavailability is greatly improved. It has been described as a 3-phytase activity characteristic of microorganisms (184), including baker's yeast (185). To reduce the phytate content of the whole wheat bread to a level considered not to affect mineral absorption, addition of phytase has been proposed (186). Furthermore, fungal phytase increases the specific bread volume and improves crumb texture and bread density (187). This improvement in bread making

performance might be associated with the activation of endogenous α-amylase, due to the release of calcium ions from calcium–phytate complexes promoted by phytase activity.

As an alternative to the exogenous addition, phytase (*phyA*) from the fungus *Aspergillus niger* has been biotechnologically expressed in various hosts (188), and a *S. cerevisiae* strain producing an active extracellular phytase is available (189). The baker's yeast secreted phytase was found to be more thermostable than the commercial one, probably due to its high level of glycosylation. According to this, future improvements in commercial baking could be expected from the use of phytase-producing yeasts.

11.4.5 Other Enzymes

Enzyme technology is a major research topic in bread making. The utilization of new enzymes or applications is attracting increasing interest with the possibilities of generating improved products and processes or replacement of chemical substances (emulsifiers and oxidizing agents). In this way, transglutaminases, glucose oxidases, and laccases are a group of interesting enzymes for the baking industry (171, 190–192), because of their ability to oxidize or modify gluten proteins improving dough strength. Transglutaminase is also able to replace emulsifiers (191). This enzyme catalyzes an acyl transfer reaction between lysine and glutamine, stabilizing the gluten structure.

There is a growing interest in the use of some traditional enzymes, like proteases and lipoxygenases (170), because of the possibility of novel applications. For example, the controlled use of proteases with high specificity could increase the level of amino acids and peptides with properties as potential oxidants, taste enhancers, sweeteners, or bitter agents (193). In this scenario, the construction of recombinant strains for new or improved enzymes has started to render promising results. Thus, different pea seed lipoxygenases genes have been characterized and expressed in *S. cerevisiae* (194). Several examples of *S. cerevisiae* producing transglutaminases from different sources have been reported (195). Laccase-encoding cDNA has been isolated from the fungus *Trametes versicolor* and expressed in wild-type *S. cerevisiae* (196) or in recombinant strains overexpressing the protein Sso2p (117), a membrane protein involved in the secretion machinery. The glucose oxidase from *Aspergillus niger* has been also produced in *S. cerevisiae* strains (197).

11.5 OVERPRODUCTION OF ESSENTIAL NUTRIENTS

Human diets are often deficient in amino acids, vitamins, and other substances with high nutritional value. This is especially evident in certain geographic areas and for certain sectors of the population (198). On the other hand, today's lifestyle in developed countries, consumption patterns are evolving dramatically, making it more difficult to maintain a proper diet. In this scenario, bread is considered a good vector to convey effectively the kind of health benefits consumers look for, because it is consumed daily. Thus, several companies are now offering a variety of breads with fiber, ω-3, calcium, vitamins, or prebiotics. Nutritional complements are usually isolated or synthesized by chemical methods, or obtained from high producer organisms, and then purified and employed as additives. As an alternative, metabolic engineering offers us the possibility to convert baker's yeast into a functional ingredient of bread and baked products. Several examples of rerouting metabolic pathways of *S. cerevisiae* for the production of specific compounds are described in the literature (199, 200).

11.5.1 Amino Acids

Cereal flours are deficient in amino acids like threonine, lysine, and triptophan (201). Baker's yeast is also poor in these amino acids (202). In order to palliate this problem, several

attempts have been made to improve the amino acid content of the yeast. In general, amino acid biosynthetic routes are regulated by derepression of the pathway coding genes in the absence of the corresponding amino acid, and by feedback enzyme inhibition and gene repression. Amino acid overproducing strains have been isolated by the use of amino acid homologous. These molecules mimic the feedback inhibitory mechanisms of the pathway, and as a consequence, low or no amino acid is produced, causing growth arrest. By means of this method, mutants overproducing threonine, methionine and lysine have been selected from industrial yeast strains (203, 204). Dough fermented with these baker's yeasts produced bakery products with significant higher contents of essential amino acids Lys, Met, and Thr (205). In addition, their use also provided bread with enhanced taste and aroma.

More focused attempts have been made to characterize the threonine-overproducing mutations, and to engineer biosynthetic pathways for further improvements in the threonine content of yeast cells. In *Saccharomyces cerevisiae*, threonine is synthesized from aspartate, through a five step metabolic route (206) (Figure 11.6). The third intermediate of the pathway, homoserine, also contributes to the methionine synthesis pathway. Threonine is the precursor for the production of other amino acids like isoleucine and valine. Threonine production is regulated both at the genetic and enzymatic levels, being the main regulatory point the first enzyme of the pathway, aspartate kinase (Figure 11.6). This enzyme, encoded by the *HOM3* gene, converts aspartate into β-aspartyl-phosphate, and is strongly inhibited by threonine.

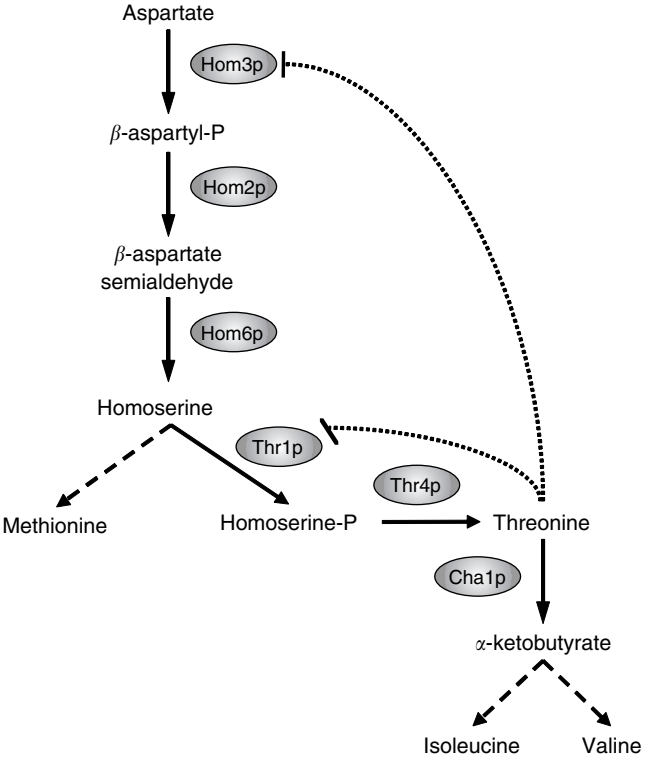

Figure 11.6 Scheme of the threonine biosynthetic pathway. Full arrows indicate direct metabolic steps. Dashed arrows indicate indirect metabolic steps. Dotted, blunt arrows indicate feedback inhibition. Hom3p: aspartate kinase; Hom2p: aspartate-semialdehyde dehydrogenase; Hom6p: homoserine dehydrogenase; Thr1p: homoserine kinase; Thr4p: threonine syntase; Cha1p: threonine deaminase.

The intermediate enzyme homoserine kinase, encoded by *THR1*, also shows threonine inhibition. Thr1p transforms homoserine into homoserine-phosphate, directing homoserine to the synthesis of threonine instead of methionine. Several *HOM3* allelic mutants, impaired in threonine inhibition, have been isolated in laboratory strains (207, 208). All of them overproduce threonine and isoleucine, but not methionine (208), suggesting that only the threonine branch of the pathway is enhanced in these mutants. However, threonine-overproducing yeasts show a growth defect, reaching lower densities that the parental strain (209). This is probably due to interferences between the threonine biosynthetic enzymes and other metabolic routes. To avoid this problem, one of the unrepressible *HOM3* alleles, called *HOM3-R2*, has been expressed under different inducible promoters (209). This approach enabled the authors to induce threonine overproduction using different stimuli. Especially interesting results were obtained with the *GPH1* promoter. This gene, encoding for glycogen phosphorylase, is induced late in the exponential growth phase. Thus, when controlled by *pGPH1*, *HOM3-R2* overexpression only induces threonine production once the exponential growth is over (209), avoiding problems of biomass yield.

Overexpression of other genes involved in threonine synthesis showed good results when combined with the *HOM3-R2* allele, but not by themselves (202). Mutants lacking *CHA1*, which are unable to redirect threonine to the synthesis of isoleucine and valine (Figure 11.6), also showed enhanced threonine content in combination with the *HOM3-R2* mutation (202,209). Therefore, it seems that the inhibitory effect of threonine on the aspartate kinase activity is the key point in the pathway regulation, and threonine cannot be overproduced beyond a threshold value, which is about 350 nmol/mg dry weight (202).

Lysine overproducing yeasts have also been characterized in laboratory strains (210). These mutants are affected in *LYS80*, a general repressor of the genes for the lysine biosynthesis (*LYS* genes), which is upregulated by lysine. Although *LYS80* was first characterized as a specific *LYS* genes repressor, it is actually a general negative regulator of the RAS-cAMP pathway (211). Other lysine overproducing mutants carry altered alleles of the homologous genes *LYS20* and *LYS21*, encoding for the enzymes in the first step of the lysine route (212). On the other hand, the product of the *LYS14* gene is involved in derepression of the *LYS* genes (213). Although there is not a reported work for the moment, *LYS20*, *LYS21*, and *LYS14* genes would be promising targets for the application of genetic engineering techniques, in order to further improve the lysine yeast production in the future.

11.5.2 Vitamins

Deficiencies in one vitamin or another are usual nutritional problems around the world. For example, the risk of deficiency in vitamin A affects up to 2 billion people (198). Although *Saccharomyces cerevisiae* is unable to synthesize this vitamin, heterologous expression of the genes for its synthesis would open new possibilities to produce bread and other baked products enriched in vitamin A. Yamano et al. (214) reported one interesting advance in this direction. These authors engineered *Saccharomyces* to express the whole biosynthetic pathway of the vitamin A precursor, β-carotene, from the Gram-positive bacteria *Erwinia uredovora*. The four genes of this route were situated in a single vector, each one under the control of a different yeast promoter and terminator. The recombinant yeast produced significant amounts of β-carotene. This advance is also relevant because it was the first time that a whole novel secondary metabolic pathway was heterologously expressed in eukaryotic cells.

Other pursued targets for yeast vitamin overproduction is the L-ascorbic acid (L-AA, vitamin C) pathway. Twenty five percent of the worldwide production of L-AA (80,000 tons per year) is used as a food additive (215). This has led to the idea of biotechnologically exploding the microbial production of vitamin C. *Saccharomyces cerevisiae* does not

produce L-AA in natural conditions, but does produce its analogue, D-erythroascorbic acid, D-EAA (216). However, when cells are fed with artificial components, as L-galactonolactone (L-GL) or L-galactose (L-gal), L-AA is accumulated (217, 218). This seems to be due to the versatility of the L-EAA pathway enzymes with nonnatural substrates. L-GL is a byproduct of the sugar industry, and L-Gal is known to be produced in plants. Its biosynthetic enzymes might be transferred to yeast. Although this possibility is a recent one, several research groups are taking steps toward an L-AA overproducing yeast (219).

11.5.3 Production of Novel Lipids

Although the body could synthesize most fats *de novo*, certain fatty acids are required as dietary precursors of the most important functional fatty acids. For instance, linoleic acid is considered essential for growth. Similar to classical vitamins deficiencies, essential fatty acids (EFA) deficiency can be overcome by a small amount in the diet. The two classes of EFA (The ω-6 and ω-3 families) may be present in the diet in different proportions to one another. This unbalancing is thought to be the cause of the increased incidence of many chronic diseases (220). Because of this, improving the ω-3 content in our diet should be considered.

Yeast strains that produce novel lipid compounds are currently available. Indeed, *S. cerevisiae* cells harboring *Brassica napus* fatty acid desaturases genes (*FAD2* and *FAD3*), under the control of the fatty acid inducible yeast *PEX11* promoter have been obtained (221). The combined expression yields a reduction in oleic acid content and the appearance of linoleic (ω-6) and linolenic (ω-3) acids (221). In a similar approach, Peyou-Ndi et al. (222) reported the expression of a Δ^{12} desaturase (*FAT2*) from *Caenorhabditis elegans* in *S. cerevisiae*. The recombinant strain produced high levels of polyunsaturated fatty acids. In addition, physiological studies showed a positive correlation between enhanced production of 16:2 and 18:2 acids and membrane fluidity, and tolerance to ethanol and hydrogen peroxide. Furthermore, baker's yeast strains which accumulate high levels of palmitoleic and linoleic acid, have been recently constructed in our laboratory by heterologous expression of the *FAD2-2* and *FAD2-3* genes from *Heliantum* (Rodriguez-Vargas et al., unpublished results).

11.5.4 Prebiotics

Prebiotic oligosaccharides stimulate the growth and colonization of probiotic bacteria; this is, nonpathogenic microorganisms that when ingested are beneficial to health. Consequently, there is currently a great deal of interest in the use of prebiotic oligosaccharides as functional food ingredients (223, 224). There are many known prebiotic oligosaccharides (225), but the market leaders are fructooligosaccharides and inulin. For instance, inulin-containing bread has been recently introduced in the German market (226).

Two different types of enzymes can catalyze the enzymatic synthesis of oligosaccharides: glycosidases (EC 3.2) and glycosyltransferases (EC 2.4). The first group, also denominated glycosynthases, is an engineered retaining glycosidase that can efficiently synthesize oligosaccharides (its substrate), but is unable to hydrolyze them. Currently cloned reported glycosynthases are β-glucosidase from *Agrobacterium* sp. (227), β-glucanase from *Bacillus licheniformis* (228), cellulase (229), and β-glycosidase from *Sulfolobus solfataricus* (230). New glycosynthases may be obtained by identifying and mutating promising candidate enzymes, or by direct evolution of existing glycosidases (231). Baker's yeast expressing these modified enzymes would be an exciting challenge even for the design of anticancer drugs (232).

Fructosyltransferases have been isolated and cloned from various bacterial, fungal, and plant species. Concretely, the inulin production by *S. cerevisiae* transformants expressing the *SFT* gene from *Aspergillus sydowi* (233) is known, as well as the production of 1-kestose by recombinant yeast carrying the enzyme from *Aspergillus foetidus* (234).

Other fructosyltransferases from *Bacillus subtillis* or *Gluconacetobacter diazotrophicus* have also been cloned and expressed in yeast (235, 236). Production of 1-kestose, nystose, and levan by these recombinant yeasts was achieved. Fructosyltransferases (*1-SST* and *1-FFT* encoding respectively sucrose:sucrose 1-fructosyltransferase and fructan:fructan 1-fructosyltransferase) from several *Asteraceae*, like *Cynara scolymus* (237) or *Helianthus tuberosus* (238) could be also expressed in yeast in order to produce long chain inulin molecules. Thus, a new promising perspective in the engineering of baker's yeast would be the direct production of these healthy oligosaccharides.

11.6 PERSPECTIVES

In the past few years, recombinant DNA technology has led to the appearance of new baker's yeast strains with optimized or novel properties, and it is expected that this tool will produce in the near future a huge spectrum of specialized yeasts of high added value. Their introduction in the manufacturing market will produce a dramatic change in formulation, ingredients, or processing conditions currently used in the baking practice, and will provide new end products with enhanced flavor, textures, and shelf life. Right now, it is possible to construct tailor-made baker's yeast strains able to secrete enzyme cocktails that could satisfy almost any baking requirement. As the potential of recombinant gene expression is better understood, the expression of recombinant enzymes could be targeted further to achieve technological benefits in specific baking steps. This would offer a clear advantage over the traditional use of exogenous enzyme improvers. This aim will be encouraged by the introduction of functional genomics approaches in reengineering baker's yeast, leading to the identification of phase regulated gene promoters.

In the future, the major biotechnological challenge in this area will be the significant improvement of fermentative traits, osmotolerance, and cryoresistance of baker's yeast. There is strong evidence that these commercially relevant traits are under the control of genes and cellular functions (21, 167). Again, genome-wide regulation analysis under industrial conditions is the obvious tool to understand how multiple genes are involved in yeast to accomplish metabolic processes determining the performance of baker's yeast. The knowledge, at the molecular level, of metabolic networks could help us to choose transcriptional regulators as targets to control a specific trait. But, we must bear in mind, as recently described by Lee and his coworkers (239), that eukaryotic cellular functions are highly connected through networks of transcriptional regulators that regulate other transcriptional regulators. Keeping a realistic perspective, improvement of these commercial traits will be a difficult task.

Yeast biotechnology will provide benefits not only to yeast producers and bakers, but also to consumers and the public, offering safe and environmentally sound procedures, and healthy and convenient products. Thus, the utilization for yeast biomass production of new raw materials, such as starch, cellulose wastes, or cheese whey, will result in cheaper, cleaner, and more reliable procedures than those traditionally used for baker's yeast propagation. In addition, this technology offers a profitable use for these resources, some of which have a great pollution potential. The use of enzymes as baking additives gives rise to immunoglobulin mediated sensitization and work related asthma, which causes occupational absenteeism in at least 4–25% of the exposed workers. Although this problem could be reduced by the use of encapsulated enzymes or liquid enzyme preparations, the high cost of these particular additives has made their introduction in the baking market difficult. Thus, the use of engineered strains would provide a cost competitive alternative to avoid hypersensitivity to working area allergens.

Nutraceuticals are the fastest-growing segment of today's food industry. Indeed, the current lifestyle generates in the consumer an increased interest in the role of diet in health and health promotion. In addition, the diet in some countries is deficient in several vitamins or essential compounds. Bread, as a diary product, is one of the best candidates to become a functional food. For these reasons, baker's yeast producing vitamin precursors or essential fatty acids would be welcome. In the near future, baker's yeast strains producing some prebiotics will be also a reality. As the knowledge of the gut microbiota increases, it will probably become increasingly important to match the modulatory effects of prebiotics to the microbiota present at specific population. These approaches will clearly increase the added value of baker's yeast, contributing to the profitability of the baking industry and improving quality of life and welfare of consumers.

Despite remarkable progress during the last years and the possibilities that exist today, no genetically modified baker's yeast is on the market. Public acceptance considerations remain the major obstacle to the commercialization of genetically modified industrial yeast strains. Benefits of GMOs are in most cases not perceptible to end consumers, being only a saving of cost or time to yeast producers and bakers. Public awareness of the potential benefits derived from the use of GMOs will increase if high quality, low cost, and new nutritional, hygienic, or environmental advantages are offered. Clear information is required before a product is introduced in the market. Nevertheless, we believe that is only a matter of time before the public is convinced that the benefits outweigh the potential risks.

1.12

The Biotechnology of Wine Yeast

Linda F. Bisson

CONTENTS

12.1 INTRODUCTION

The production of wine from grapes is one of the world's oldest biotechnological processes. The alcoholic fermentation, that is, the conversion of grape sugars to ethanol, is conducted by yeasts of the genus *Saccharomyces*. In addition to wide-ranging roles in beverage and food processing, *Saccharomyces* is also a premier research organism because of its genetic tractability. Its genome has been sequenced, and an extensive array of molecular technologies has been developed for the genetic manipulation of this organism. In spite of the availability of these molecular tools, genetically engineered yeast strains are not yet in use in the commercial wine industry. Anxiety over consumer acceptance is one reason genetically modified strains are not employed, but there are other concerns as well.

Wine production is unique in many respects. The wine production process is not conducted under sterile conditions, and any modified organism has the potential to become an enduring resident of the winery flora. Further, wine production is both science and art. There is concern that many of the proposed genetic modifications of yeast are designed to correct processing errors or incompetence of the winemaker rather than being useful tools to enhance the artistry of wine making. In spite of these concerns, the efficacy of genetic modification of wine yeast has been demonstrated.

12.1.1 The Winemaking Process

Wine production is a simple process (Figure 12.1). Following harvest, grapes are crushed. The crushed grape aggregate, called must, is used either directly for fermentation (red wines) or pressed to release the juice (white wines). The juice or must is then fermented in wood, stainless steel, or concrete vats, with or without temperature control. Since the

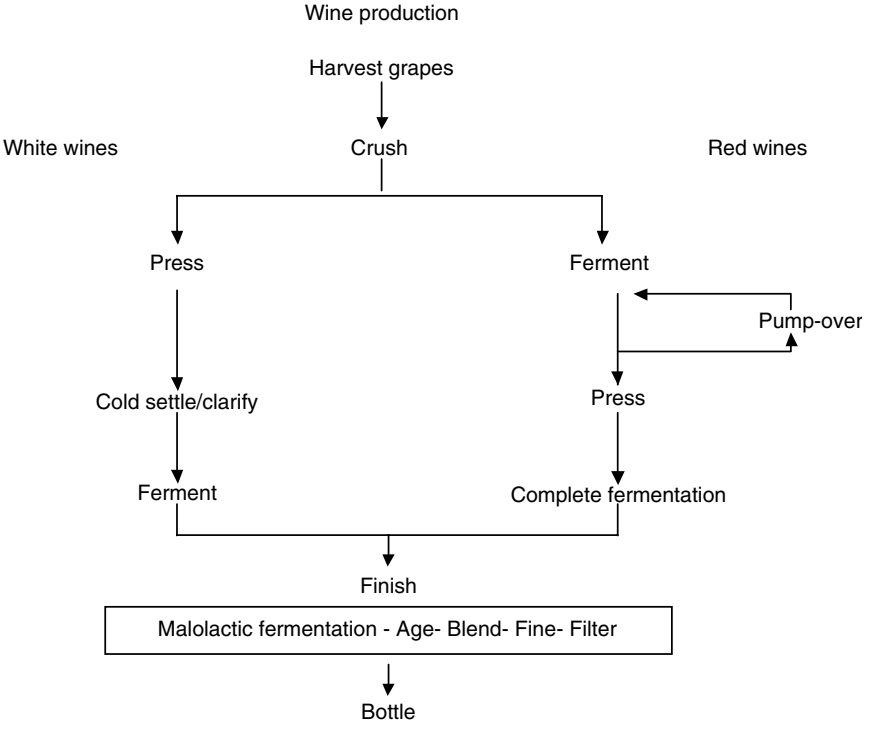

Figure 12.1 Schematic representation of wine production.

red pigments of grape, the anthocyanins, are located in the skin cells, there is a further difference between red wine and white wine production. Red wines are produced from fermentations conducted on the skins to extract the pigments and other materials present in the skin. In contrast, in white wine production the juice is separated from the skins prior to fermentation. In red wine fermentations the grape skins and other insoluble material form a cap on the surface of the wine once fermentation initiates and carbon dioxide is being evolved. In order to extract skin cell components, it is necessary to submerge or bathe the cap, using the partially fermented juice. The accumulating ethanol enhances the extraction of the skin cell components as well as inhibiting the growth of aerobes that may be on the exposed surface of the cap. The cap is either submerged in the tank (a process called "punch down"), or fermenting juice from the bottom of the tank is pumped over the cap on the surface ("pump over"). Although various mixing strategies are used, none are typically performed under sterile or anaerobic conditions in red wine production. The type and frequency of mixing affect oxygen availability for the yeast and the natures and numbers of other microbes present.

The fermentations may be inoculated with selected yeast or left to ferment by the native flora present on the grapes and in the winery. In either case, the fermentation is eventually dominated by *Saccharomyces*. This yeast is a single celled eukaryotic fungus that reproduces by budding. Two species of *Saccharomyces*, *S. cerevisiae* and *S. bayanus*, are commonly found in wine fermentations. It is important to note that there is some confusion in the nomenclature of wine yeast strains, specifically in the designation "*S. bayanus*". True *S. bayanus* (*Saccharomyces bayanus uvarum*) is quite distinct from *S. cerevisiae* (1,2) displaying only 80% sequence identity in coding regions and 62% identity in noncoding regions (1). Many strains used commercially in the wine industry that have been labeled as *S. bayanus* are actually *S. cerevisiae bayanus*. *Saccharomyces cerevisiae cerevisiae*, *S. cerevisiae bayanus* and *S. bayanus uvarum* can all be found in fermenting grape juice or must. Unfortunately, the designation "*S. bayanus*" has been used in the wine literature for both *S. bayanus uvarum* and *S. cerevisiae bayanus*. It is therefore important to understand which organism is actually the subject of the study.

Depending upon the style, the wine either is immediately ready for bottling following completion of fermentation or undergoes postfermentation processing such as aging in wood or stainless steel, a secondary bacterial fermentation, fining to remove undesirable components, or filtration to remove hazes and precipitates. Finally, the wines may be blended to achieve greater complexity and style. The last step in the process is bottling, which may be done under sterile conditions but frequently is not. One of the goals of wine production is to achieve microbial stability of the wine prior to bottling so that sterile conditions are not required for preservation of the wine.

There are several key issues with respect to this process that impact the development of genetically modified strains. First, it is important to reemphasize that it is not a sterile process. It takes advantage of the ability of *Saccharomyces* to dominate a mixed culture fermentation and produce sufficient ethanol to inhibit other microbes. If a genetic modification impacts the competitiveness of the yeast strain, the modified organism will be quickly dominated during the fermentation by unmodified native strains. Thus, any genetic modification will have to have little or no impact on the cell's ability to conduct and dominate a fermentation.

Second, numerous parameters affect the relative numbers and persistence of the wild microbial flora (3,4,5). These factors may be intrinsic to the juice or must (nutrient composition, presence of antimicrobial compounds, length of time the grapes are held postharvest, and nature of the grape bioflora) or extrinsic (length of time juice is in contact with the skins, temperature of contact and of fermentation, nature of the fermenting vat, juice

supplementation practices, inoculation strategies, juice and must processing strategies, use of antimicrobial agents, and winery sanitation practices). The nutritional content of grapes varies from excessive to marginal: by varietal, by vineyard practices, and by growing season. Some of these differences can be mitigated by addition of nutrients to the fermentation. However, a genetically modified strain will have to retain the ability to dominate a fermentation under quite diverse environmental and growing conditions.

Third, there is no one standard practice or recipe for the production of wine, as processing strategies vary by the style and producer, but also within a given winery, as alternate practices may be employed for wines of the same nominal variety and overall style that are targeted to different market segments. If a genetic modification is tailored for one style, the winemaker must make certain that no problems will occur if that strain is present throughout the winery.

Fourth, with a few notable exceptions, there is no consensus among producers internationally or even regionally as to what traits a yeast strain should be engineered to possess. What one region or winemaker may find desirable may be undesired by another. Finally, given the potential of lateral gene transfer (6), any genetic change that would impose a high risk if acquired by the wild flora should not be considered.

12.1.2 Genetic Characteristics of *Saccharomyces*

Saccharomyces cerevisiae cells contain 16 linear chromosomes. The sequence of the genome indicates that approximately 6000 functional genes are present (7). Roughly two thirds of the genes have been assigned a function or putative function, based on the phenotype of mutations or on homology to proteins of known functions (8). There are several gene families, mostly encoding plasma membrane proteins. Systematic mutational analyses have been conducted with null mutations generated for each open reading frame (putative gene) (9). It is known which mutations are lethal. Global screening of this set of mutations is defining the phenotypes of the nonlethal mutations. Within the near future the functional role(s) of every gene will be known. The nature and kinds of protein–protein interactions are also being delineated for each gene product (10,11). The generation of specific genetic modifications and determination of the effect of those modifications on the global biological properties of *Saccharomyces* will be routine.

Saccharomyces can grow vegetatively as haploid or diploid cells. Haploids are able to mate yielding a diploid cell and diploids are able to sporulate yielding haploid spores (Figure 12.2). There are two mating types, designated "a" and "α". Mating type is specified by the information at the mating type or *MAT* locus. Haploid strains may be either *MATa* or *MAT*α. Sporulation of diploid cells leads to the formation of four spores, two of the "a" mating type (inheriting the *MATa* locus) and two of the "α" mating type (inheriting the *MAT*α locus). Spores are formed within a cell or ascus; thus *Saccharomyces* is an ascomycete. Because there are four spores in an ascus, the ascus is called a "tetrad". Tetrads can be dissected, allowing each individual spore to give rise to a colony. The recovery of all four products of a single meiotic division allows sophisticated genetic analyses to be performed.

Yeast strains may be homothallic or heterothallic (12). Homothallic yeast strains are self fertile. An individual haploid cell is able to yield a diploid population. This is because mother cells (cells that have produced at least one bud or daughter) can switch mating type and thus mate with their own daughter cells (Figure 12.3). Heterothallic strains do not have this property, and so stably propagate as haploids, and are only able to mate with a haploid cell of the opposite mating type. Heterothallism is conferred by the loss of a single gene, the *HO* gene that encodes a specific endonuclease required for switching the information at the mating type locus (12).

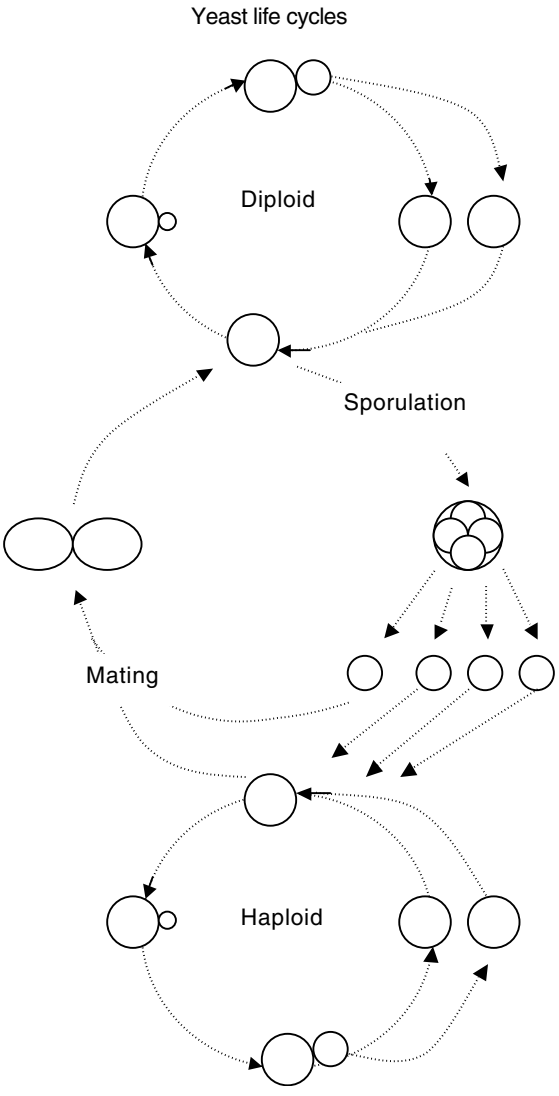

Figure 12.2 The life cycles of *Saccharomyces*. This yeast can grow vegetatively by budding as either a diploid or haploid. Diploids may sporulate or undergo meiotic division to yield four spores that may then grow vegetatively as haploids or mate to form a diploid. Diploids may grow vegetatively as diploids or sporulate.

12.1.2.1 Laboratory, Native and Industrial Strains

Genetic inheritance in *Saccharomyces* has been extensively studied under laboratory conditions. Laboratory strains were selected, however, for their genetic tractability — effectiveness of mutagenesis, stability of mutations, efficiency of sporulation and mating, and predictability of growth under laboratory conditions. To facilitate genetic analysis, most laboratory strains are heterothallic, allowing the researcher to control the genotype of the cells involved in genetic crosses. These strains are genetically stable, displaying low rates of spontaneous mutation. *Saccharomyces* is most commonly found in nature as a minor resident on the surface of grapes (3,4,5,13,14). It can be isolated from other types of rotting fruit and is transferred by insect vectors. *Saccharomyces* is also found as part

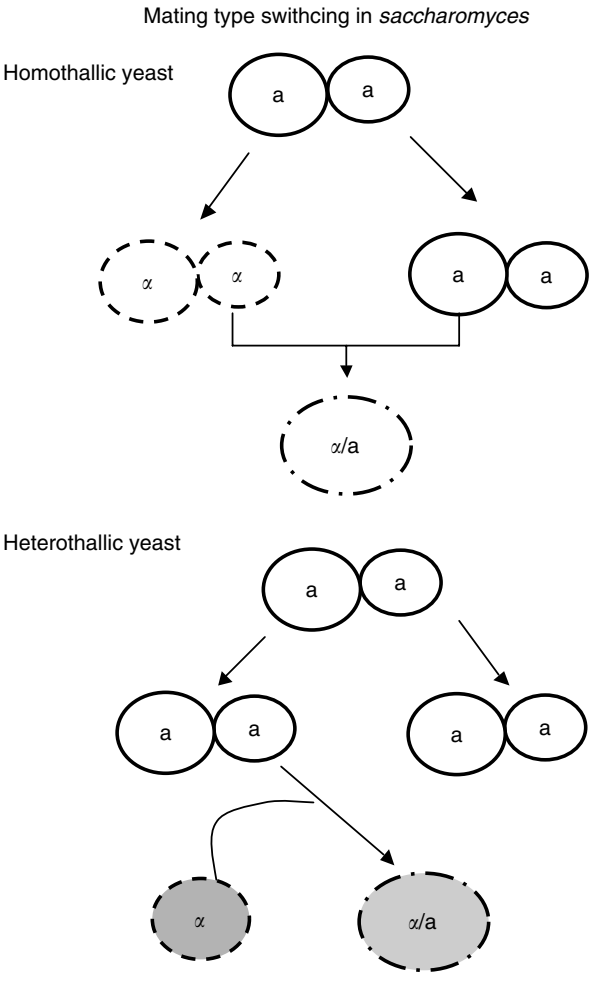

Figure 12.3 Homothallic strains of *Saccharomyces* are able to switch mating type following division. Mother and daughter cells may then mate. Heterothallic yeasts are not able to switch mating type and can only mate when a cell of the opposite mating type is present in the area [reviewed in (12)].

of the bioflora of wineries (3,5). Studies suggest that it is the winery bioflora strains that generally dominate the juice or must fermentation rather than the strains from the vineyard (13). Native isolates of *Saccharomyces* are typically homothallic diploids (15,16). In contrast to laboratory strains, native isolates accumulate mutations during normal growth, displaying higher rates of spontaneous mutation. Sporulation efficiency varies among the native isolates.

Industrial strains are also generally homothallic, but often contain multiple aneuploidies, being monosomic or trisomic for some chromosomes (17,18,19). Industrial strains are defined as those grown under commercial conditions to generate "active dry" inocula. These strains must be able to retain viability following the dehydration–rehydration procedure, and are frequently maintained on media distinct from grape juice. The conditions under which commercial strains are produced are likely responsible for the genomic variation obtained. Chromosome rearrangements are also common in industrial strains. Some commercial strains are not diploid, but display a higher ploidy. The genetic diversity of industrial strains limits sporulation efficiency and spore viability, and poses challenges to

the genetic manipulation of these strains. Although chromosomal rearrangements occur in native strains of *Saccharomyces*, the native isolates are generally all normal diploids. However, these strains have usually accumulated several heterozygosities (20).

12.1.2.2 Genomic Instability of Yeast Strains

Commercial strains of *Saccharomyces* have been obtained following physiological characterization of native isolates from growing regions all over the world. Successful candidates are chosen primarily on the basis of their ability to be produced commercially and secondarily on their winemaking attributes. Genetic analysis of these strains suggests that native isolates from the same region are generally related (21). In one analysis of 13 commercial isolates, sporulation and spore viability varied dramatically (20). Of ten genetic traits analyzed, strains contained from zero to seven heterozygosities. Mitotic recombination and chromosomal rearrangements appear to occur at higher frequencies among the native populations as compared to laboratory strains (17,18,19,20,21). Analysis of a single isolate indicated the existence of mutations affecting global regulatory processes. Transcriptome analysis indicated that approximately 6% of the genes displayed differences in expression patterns in spores obtained from the original isolate (22). Thus, there is considerable genetic divergence among native strains of *Saccharomyces* isolated from vineyards and from wineries that have not employed commercial inocula.

Karyotype analysis has demonstrated significant chromosome polymorphisms that exist in wine yeast strains. Different studies have reached the conclusion that these polymorphisms arise due to recombination events between homologous Ty elements on different chromosomes (23). There is variety in the number and location of these Ty elements across yeast strains (17). Previously these elements were regarded as "junk" DNA, but it is now thought that they play an important role in generating genetic diversity among native populations (23).

12.1.3 Role of Indigenous Yeasts and Bacteria in Wine Production

The flavors and aromas of commercial wines are contributed in part by the grape and by the biological activities of the organisms present. Various yeast and bacterial species (and in some wine styles, filamentous fungi), may be present during grape must and juice fermentation and may impact the final characteristics of the wine (reviewed in (24,25,26)). In addition to *Saccharomyces*, several other genera of yeast are commonly found: *Hanseniaspora* (*Kloeckera*), *Metschnikowia*, *Candida*, and *Pichia.* Various factors affect the presence and persistence of the non-*Saccharomyces* yeasts, such as temperature of fermentation, nutrient addition practices, aeration, skin contact, the nature of the *Saccharomyces* strain used, and inoculation practices. There are other important yeast genera in wine production, the spoilage yeasts: *Brettanomyces*, *Zygosaccharomyces*, and other species of *Candida* and *Pichia.* Under ideal conditions, the yeasts present prior to and during fermentation strip the juice or must of nutrients, limiting the ability of spoilage yeasts to grow.

Several bacterial species are also present. The lactic acid bacteria can persist under wine production conditions and are responsible for the conversion of grape malate to lactate, the "malo-lactic" fermentation. They also impart other characteristics to the wine, such as the buttery note of diacetyl. The principal lactic acid bacterium found in wine is *Oenococcus oeni* (formerly known as *Leuconostoc oenos*) (24,26). *Oenococcus oeni* is able to thrive over the range of low pH values commonly found in grape must and juice (pH 3.2–3.9). Other lactic acid bacteria, members of the genera *Lactobacillus* and *Pediococcus*, can be found in wine if the pH values are greater than 3.5. These bacteria can grow under anaerobic conditions and in the presence of high ethanol. These organisms,

depending upon the spectrum of end products produced and their desirability, may cause bacterial spoilage. *Acetobacter* is also an important spoilage organism. This bacterium produces large quantities of acetic acid and can turn wine into vinegar. It is an obligate aerobe, so its growth is confined to the exposed surface of the wine. It can be easily controlled by limiting the development of a headspace over the surface of the wine.

The skin of the grape teems with other aerobic filamentous fungi and bacteria, but these organisms are quickly eliminated by the anaerobic conditions rapidly established in the must or juice by microbial and enzymatic activity. The role these organisms play in wine fermentation is secondary and is due to impacts on grape composition and on the microflora of the berry.

12.1.4 Historical Aspects of Wine Yeast Biotechnology: Uses of Classical Breeding and Selection

Specific strains of *Saccharomyces* have been selected and used as inocula for decades. The brewing industry was the first to develop pure culture inocula (27). Interestingly, resistance to the use of pure culture inocula persisted in the wine industry for diametrically opposed reasons. Some felt the regional character of the wine was derived from the regional character and diversity of the native flora, whereas others felt that any yeast would do, as the yeast played no role in the final characteristics of the wine. Neither group perceived a need for pure culture inocula. Analysis of the properties of oenological wine strains demonstrated that significant variation existed and showed that some strains produced more off characters or were more prone to fermentation arrest than others. These observations fueled interest in use of known or well characterized strains to assure the commercial acceptability of the wine. In wine production, inocula may be one of two types: native flora, where one tank is inoculated by juice from a tank that has initiated fermentation, or a commercial preparation.

Commercial strains have been selected on the basis of specific attributes: ethanol tolerance, sulfur dioxide tolerance, predictability of fermentation behavior, fermentation to dryness (reduction of sugar below 0.2%), absence of production of spoilage characters (such as hydrogen sulfide), production of specific desirable esters, ability to dominate diverse fermentation conditions, tolerance of other microbes, and neutrality (minimal impact on grape varietal character). These strains are derived from native isolates following evaluation of the physiological characteristics of those isolates. Commercial preparations do not necessarily contain a single strain. Some vary due to spontaneous genomic rearrangements having occurred during production of the strains. Others are deliberate mixtures of different strains to assure that at least one strain will be able to complete the fermentation and to add to the complexity of yeast characters produced during the fermentation.

Several classical genetic techniques have been applied to the improvement of industrial strains of *Saccharomyces*. These include classic breeding of strains relying on genetic crosses between unrelated haploid strains, forced mass matings to detect rare events, and mutation and selection for desired phenotypes (28,29). Protoplast fusion has also been employed. In this case, cell walls of two different strains are digested, the strains are placed in contact under conditions that promote fusion of their plasma membranes, and the hybrid strains isolated (30). Cytoduction has been used to transfer cytoplasmically inherited genetic information between strains. Karyogamy (nuclear fusion) fails in *kar1* mutants of *Saccharomyces* (31,32). Crosses between haploid *kar1* mutants result in failure to form a diploid and in the creation of hybrid nuclei. Each of these techniques has been used to generate strains for use in the brewing, distilling, and baking yeast industries. In contrast, there has been little effort to genetically construct wine yeast strains using classical breeding methods. Instead, the genetic diversity of native isolates has provided ample material from which to select wine yeasts expressing specific traits.

12.2 GENETIC ENGINEERING TECHNOLOGY FOR YEAST

The discovery over two decades ago that yeast could be transformed as easily as bacteria, allowing stable modification of the genome, revolutionized the genetic analysis of *Saccharomyces*. It was then possible to isolate any gene of interest in the test tube and transfer the wild type or mutated allele to yeast. A second important discovery was the ease with which yeast genes could be disrupted, allowing mutations to be made at any known locus. As a consequence, any chromosomal allele could be replaced with any other allele. Combined with the strengths of classical genetic analysis, these technologies allowed unprecedented manipulation of the genome of a eukaryotic organism. Applications of these technologies to the genetic alteration of industrial strains soon followed their development in laboratory yeast.

12.2.1 Molecular Genetic Tools

Several transformation strategies have been developed for *Saccharomyces*, leading to the stable incorporation of introduced DNA into the yeast genome (reviewed in (33)). The first transformation protocol developed for yeast relied on the enzyme glusulase (snail gut enzyme) to digest the vegetative cell wall. This same preparation had been used for years to dissect the ascal wall, allowing isolation of the spores of an individual tetrad. The spheroplasts formed can translocate external DNA. Cells are then maintained under conditions conducive to the regeneration of the cell wall. The uptake of extracellular DNA can also be achieved by the use of salts such as lithium or cesium. This method is technically easy, but differences in permeabilization and sensitivity to the toxic effects of the ions render it challenging to use for some strains. Electroporation, use of an electrical pulse to drive the uptake of DNA, can also be employed with yeast, as can a "gene gun" or biolistic transformation. In our experience, each of these techniques is equally effective in the transformation of native isolates of *Saccharomyces*. Success in the transformation of industrial strains varies, probably as a consequence of their aneuploid nature rather than the specific technique used.

Several different plasmid vectors have been developed for yeast transformation (Table 12.1). These vectors differ in their replications of origin, mode of inheritance, selectable markers, and nature of the cloning site. The two principal modes of inheritance of yeast plasmids are: (1) reliance on the presence of a centromere on the plasmid or of the sites required for replication, and (2) segregation of the yeast 2-micron plasmid. Other plasmids, the integrating vectors, are designed for integration into a yeast chromosome and do not contain a separate inheritance region. Origins of replication may be chromosomal autonomous replication sequence (ARS) sites, or replication origins for the 2-micron plasmid. There are ARS vector plasmids that only contain an ARS sequence but no region of inheritance. These plasmids are transmitted to progeny cells in a passive manner, simply by virtue of being in the right place at the right time of nuclear division. They are the least stable of the yeast vectors.

Recently, a set of interchangeable or "cassette" vectors has been developed (34). A unique restriction site flanks each functional region. In addition to selectable markers, these plasmids also have counter selectable markers, markers that can be selected against, leading to recovery of strains that have lost the plasmid. Cassettes of functional regions are available, allowing easy manipulation of plasmid features.

Linear fragments of DNA can also be efficiently transformed into yeast cells and stabilized by insertion into the yeast genome. If the ends of the linear fragment are homologous to chromosomal sequences, homologous recombination will lead to replacement of the genomic sequence with the one introduced on the fragment (Figure 12.4). Thus, it is possible to replace alleles of any desired gene with another allele, or to simply disrupt the

sequence, creating a null strain for that gene. Multiple replacements of the same locus can occur. The "gamma deletion" method, originally developed by Sikorski and Hieter (35), can be readily replaced by other constructs (36). This method relies on homology introduced by inserted plasmid sequences to direct subsequent recombination events.

Plasmids designed to facilitate exchange or swap of markers have also been developed (37). This allows the researcher to replace markers that have been used in strain construction for other markers while leaving the original null or knock out mutation intact. Double fusion PCR can also be used to create specific unique constructs that can be efficiently transformed into yeast (Figure 12.5) (38). In this technique, a region of interest is fused to flanking regions that can then be used to direct integration of the construct into the genome by homology. Several related adaptamer-mediated PCR methods have been employed in the genetic engineering of *Saccharomyces* (39).

12.2.2 Selectable Markers

Successful DNA transfer is dependent upon the detection of the transformants. Numerous markers have been developed in *Saccharomyces* for the selection of transformants (reviewed in (33)). These markers are used for positive selection, that is, a selection for the marker gene. If the marker is present, then, in theory, sois the rest of the construct, but this should always be independently confirmed. Many of these markers rely on restoration of auxotrophic mutations to prototrophy. Although quite effective in laboratory strains, the

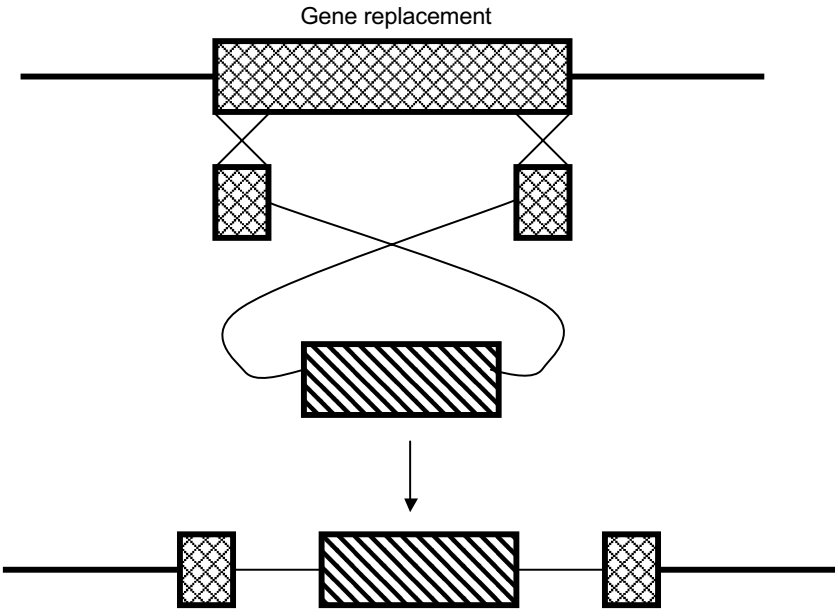

Figure 12.4 Gene replacement in *Saccharomyces*. A linear fragment containing homology to chromosomal sequences on the ends of the fragment will undergo homologous recombination with the chromosomal locus leading to replacement of the information at the locus with that from the fragment [reviewed in (33)].

use of these strategies in the genetic modification of industrial strains is limited by the lack of availability of specific mutations and by the need to maintain the competitive nature of the organism in the natural environment.

Several alternate selectable markers have been developed that are more suitable for wine production. The most commonly used marker is G14 (kanamycin) resistance (40). The *kanMX* marker is a hybrid of the kan^r transposon Tn903 with the promoter and terminator sequences of the *TEF* gene of *Ashbya gossypii* directing expression (41). This gene construct confers resistance to G418 in a variety of fungi. An advantage of this gene is the lack of homology to any sequences within *Saccharomyces* resulting in efficient disruption of the target locus. There are problems with the use of G418 resistance in wild and industrial strains of *Saccharomyces*. Native resistance to this antibiotic varies, and it is important to determine the level of sensitivity of the strain targeted for genetic modification.

The *Aspergillus* blasticidin S deaminase has also been used as a selectable marker in *Saccharomyces* (42). The presence of this gene confers blasticidin resistance. The dehH1 gene from *Moraxella* encodes fluoroacetate dehalogenase and has been used as a selectable marker in *Saccharomyces* (43). Genes conferring resistance to hygromycin B, nourseothricin and bialaphos have also been used as dominant selectable markers in *S. cerevisiae* (44). Other drug resistance markers have also been developed (reviewed in 26). The majority have the same two drawbacks, first that they are encoded by heterologous DNA and second that spontaneous drug resistance appears with varying frequency across the native yeast populations.

Because of a perceived reluctance of acceptance of yeast strains carrying bacterial or other nonyeast DNA in the food supply, researchers have explored the development of alternate selectable markers that would originate solely from yeast. Mutants resistant to the antimicrobial agent sulfur dioxide, which is used in wine production, have been isolated

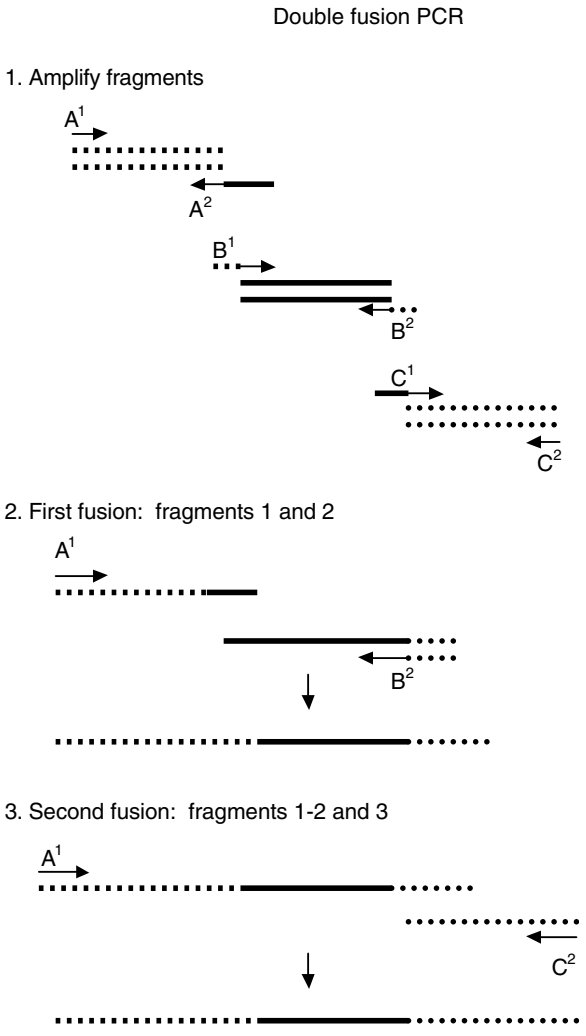

Figure 12.5 Diagram of double fusion PCR (38). Primers are designed that contain regions of homology to the target fusion fragment on one end (Primers A^2, B^1, B^2 and C^1 in the diagram). This results in overlapping homology on the ends of the PCR fragments generated from the primers. A fusion PCR reaction is then done using the flanking primers for each of the two fragments. This can be repeated sequentially to produced double fusion products that can be used for gene replacement in *Saccharomyces*.

and the dominant mutant alleles cloned. These mutant alleles, encoded by the *SSU1* and *FZF1* genes, have been used as selectable markers in *Saccharomyces* transformations (45). The *SFA1* gene of *Saccharomyces,* which encodes formaldehyde dehydrogenase, confers resistance to formaldehyde when over expressed (46). It can also be used as a dominant selectable marker. *CUP1*, encoding metallothionein, can also be used as a selectable marker, as this gene will confer resistance to copper (47). Similarly, mutations of the *PDR3* gene, which is involved in multidrug resistance, can also be used as a dominant selectable marker (48). The *YAP1* gene encodes an AP-1-like transcription factor and is involved in stress adaptation in yeast (49). Over expression of this gene has been shown to lead to resistance to cerulinin, an inhibitor of fatty acid synthesis, and to cyclohexamide, an

inhibitor of protein synthesis. An advantage of these genes as selectable markers is the resistance conferred to more than one drug, facilitating the confirmation that transformation rather than mutation to spontaneous drug resistance has occurred.

Counter selectable markers are also important in strain construction. These are makers that confer a distinct phenotype when lost, one that can be both selected for and easily detected. This is also called a negative selection, as the presence of the gene is being selected against. The availability of such markers allows for the engineering of mutations requiring sequential recombination events. The most common counter selectable markers are based upon resistance to inhibitory analogs of metabolites of nucleic acid or amino acid biosynthesis. Resistance to the inhibitory compound occurs upon loss of the function of a specific gene involved in biosynthesis. If auxotrophic mutations are available, these genes also can be selected for, by restoration of growth in the absence of the specific nucleotide base or amino acid. The most frequently used gene is *URA3*. The *URA3* gene encodes orotodine-5'-monophosphate (OMP) decarboxylase, and this enzyme is required for the conversion of 5 fluro-orotic acid to 5 fluoro-uracil, which is toxic to yeast cells (50). *URA3*, therefore, confers sensitivity to 5 fluoro-orotic acid. A positive selection exists for *URA3*, the conversion of *ura3* mutants to uracil prototrophy, as well as a negative selection, resistance to 5 fluoro-orotic acid, for the conversion of *URA3* strains to *ura3*. The *LYS2* and *MET15* genes can be used similarly. *LYS2* confers sensitivity to α aminoadipic acid (51), and *MET15* to methyl mercury (52). In addition to this counter selectivity, *met15* mutants also become darkly pigmented in the presence of lead ions due to the formation of lead sulfide (53). A colony color screen can therefore also be used to distinguish *MET15* wild type from *met15* mutant cells.

The shortcoming of these counter selectable markers with respect to industrial strains is the need to have auxotrophic mutations in the strain background. Such auxotrophies will likely confer a growth disadvantage to the strain and would have to be corrected subsequent to their use to generate the construct of interest. If needed, the auxotrophic marker would best be introduced by transformation rather than by mutagenesis, to avoid the potential for cryptic background mutations. Once the desired gene has been incorporated into the genome, a second event to replace the mutated gene with a wild type allele will have to occur.

Counter selectable markers not requiring the presence of specific mutations in the strain background have also been developed. The *GIN11* region, which contains part of a subtelomeric region, is growth inhibitory when over expressed. This region has been placed under the control of the *GAL10* promoter (54). In the presence of galactose, the promoter is induced and growth inhibition occurs. The presence of the *GAL10–GIN11* fusion can be selected against by requiring growth in the presence of galactose. Similarly, the *PKA3* gene, which encodes the catalytic subunit of the cAMP-dependent protein kinase, also is growth inhibitory when over expressed. This gene has also been placed under the control of regulatable promoters (34). Counter selection occurs by isolation of those strains able to grow under conditions of induction of the *PKA3* gene. Just about any gene that confers a phenotype of growth arrest when over expressed can be used as a counter selectable marker. However, one shortcoming of these constructs is the absence of a positive selection in the first place. This can be compensated for by having two independent markers on the same construct, one for which a positive selection exists and one for which there is a negative selection. Industrial strain construction strategies will need to involve multiple steps of selection and counter selection if the use of auxotrophic mutations is to be avoided.

12.2.3 Strain Construction Strategies

There are two different goals for the construction of genetically modified wine yeast strains: the alteration of an inherent property of the strain, or the expression of a novel or heterologous activity. The first goal is essentially a swapping of one allele for another,

either a null allele or one mutated to confer a different regulatory or catalytic property. Ideally, genetic modification of an allele should not leave any heterologous DNA as part of the construction, should be stably inherited and not borne on plasmids or other elements that may facilitate lateral gene transfer, should not require the strain be auxotrophic or subjected to mutagenesis, should be readily detectable and identifiable in mixed populations, and should not interfere with any other biological processes that may confer a disadvantage to the organism in its natural environment. Heterologous gene expression should likewise be stably inherited and minimize opportunities for lateral gene transfer.

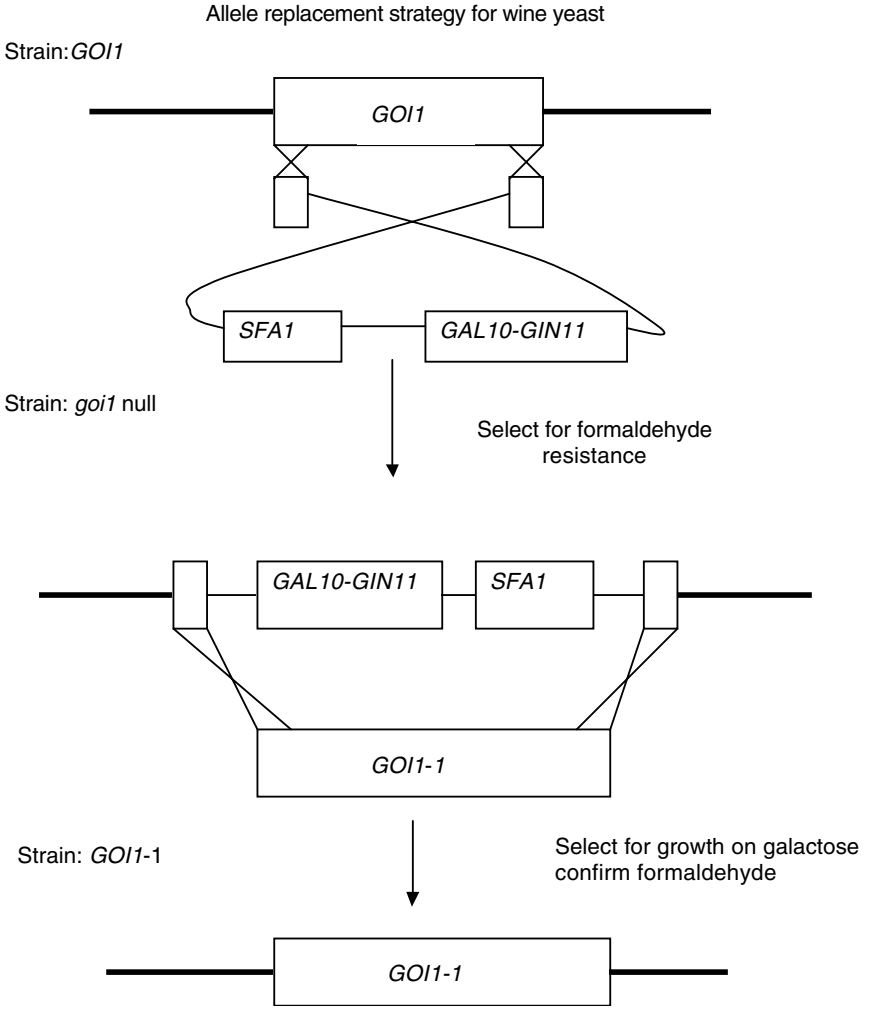

Figure 12.6 A strategy for allele replacement in *Saccharomyces*. A hypothetical gene, *GOI1*, "*G*ene *O*f *I*nterest" is shown. Both selectable and counter-selectable markers must be present. The allele is replaced in a two-step process. First, a null allele is created, in this case by selecting for fomaldehyde resistance. The null construct also contains a counter selectable marker, the *GAL10-GIN11* fusion (54) in this case. The null allele is then replaced with the desired allele, by a second homologous recombination event and selection against the counter-selectable maker, by requiring growth in the presence of galactose. In this example, only *Saccharomyces* markers are used. If double fusion PCR were employed, only *Saccharomyces* DNA sequences need be used throughout.

The amount of foreign DNA should be kept to a minimum, and it is very important that the full impact of the incorporation of the novel trait into the genome be known.

A sample strategy for allele replacement is shown in Figure 12.6. In this case a null mutation of the target gene is first constructed using a fragment containing both a dominant selectable marker and a marker that can be counter selected. Transformants expressing the dominant marker are then isolated and the location of the marker confirmed using PCR, Southern analysis, or another mapping technique. This allele can then be replaced with the altered allele by repeating the transformation and selecting against the counter selectable marker. The location of the construct should be confirmed by PCR analysis followed by DNA sequencing.

Heterologous gene expression requires the presence of efficient promoter and terminator sequences to allow transcription of the gene (Figure 12.7). These promoters may be constitutive or regulated. A series of promoters displaying expression at different times of grape juice fermentation have been identified and can be used to time expression to the desired physiological window (55). Promoters have also been designed that express target genes to varying levels (56) allowing adjustment of the level of expression of a heterologous gene. These genes should be targeted to a nonessential region of the genome. Targeting the heterologous constructs to the *HO* gene resulting in conversion of the strain to heterothallism has been proposed as a benign gene disruption (57). This is not expected to confer any disadvantage during growth and fermentation. However, there is a concern that this may lead to spread of genes through mating with other partners.

The lack of an impact on other metabolic pathways can be confirmed by conducting a functional genomic analysis of the modified strains (59,60). Transcriptome technologies allow display of global gene expression patterns, and the impact of the modification on gene expression can be determined (59,61,62,63,64). Proteome analysis can further demonstrate the absence of an effect on the protein constitution of a cell (60,65).

12.3 IMPROVEMENT OF OENOLOGICAL TRAITS OF YEAST STRAINS

The genetic engineering of wine yeast can be divided into two broad categories: modifications that serve to enhance existing or intrinsic properties of wine strains and those that aim to introduce novel traits (Figure 12.8, Figure 12.9). The modification of existing traits may take the form of (1) the *in vitro* creation of a specific allele, (2) isolation of a specific

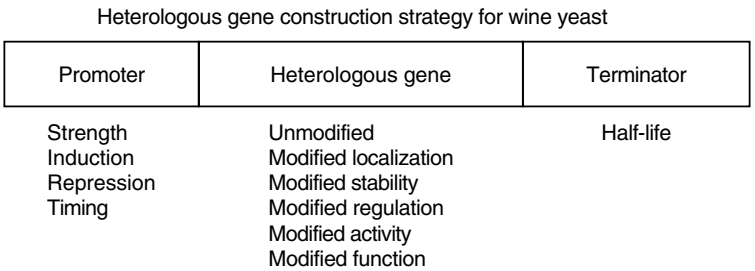

Figure 12.7 Options for the construction of an expression cassette for a heterologous or novel function. The promoter and terminator regions may be selected based on the desired regulation and level of expression (55,56). The heterologous gene may be used unmodified or altered in one or more properties to produce a more effective gene product.

Genetic engineering of intrinsic traits of wine yeast

Fermentation performance	Enhance: Stress tolerance Rate of fermentation Substrate utilization Competitiveness
Off-character production	Reduce: Sulfur volatiles Acetate/acids Aldehydes Higher alcohols Phenolic derivatives
Aroma character production	Increase: Ester formation Glycerol production Lactone production Terpene production S-conjugates release Autolysis flavors production Reduce: Esterase
Production performance	Enhance: Flocculation Sedimentation Hydrolase activity Tannin reduction Mannoprotein release/production
Healthfulness improvement	Decrease: Ethyl carbamate Increase: Vitamin production Pesticide scavenging Metal ion scavenging

Figure 12.8 Proposed intrinsic property targets of genetic modification in wine strains of *Saccharomyces*.

allele from another strain or different species of *Saccharomyces* followed by allele replacement, (3) alteration of promoter or terminator sequences to change the pattern of regulation of the gene or protein, or (4) the construction of a novel hybrid protein that will display altered activity or posttranslational regulation. In some cases a null allele may be desired to eliminate an unwanted activity. Null alleles may impose strong selective pressure for suppression or other compensating alterations of the genome, so the outcome of the presence of these mutations in the genetic background must be clearly understood. Furthermore, our understanding of gene function derives almost exclusively from analysis of laboratory strains, strains that generally are not capable of growth in the natural environment. It is necessary therefore to determine if a given gene, thought to be dispensable for laboratory growth, is dispensable in the natural environment. Alteration of existing traits is largely considered to be a benign genetic modification, and one that does not pose any risks to the

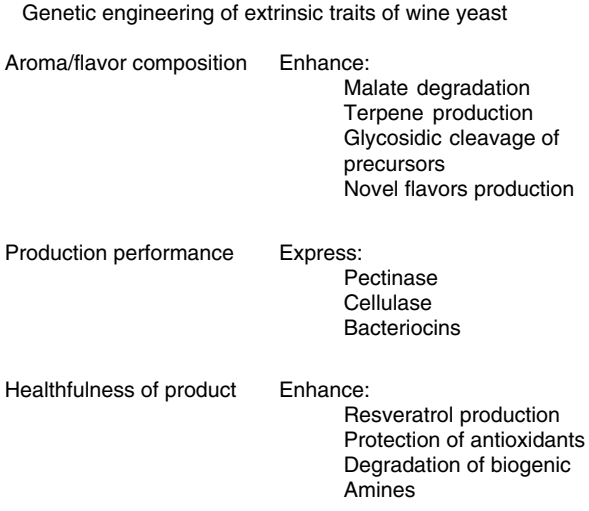

Figure 12.9 Proposed extrinsic or novel properties to be expressed in wine strains of *Saccharomyces*.

food supply. Since these same alterations could occur in the wild population, the threat of negative environmental effects due to lateral gene transfer is minimal.

The creation of recombinant strains, strains expressing DNA elements not normally found in *Saccharomyces* or in yeast in general, causes more concern among consumers and producers. The risks of creation of a strain expressing heterologous traits depend of course upon the trait and the source of the DNA. There is a greater threat to the producer: a modified strain possessing an activity that is not uniformly desired in all fermentations, and the appearance of the strain and the unwanted characters in other wine lots. Cross contamination of wine production lots is the norm, and any organism present in one fermentation has the potential to be present in all fermentations.

12.3.1 Fermentation Performance

There are several existing traits of *Saccharomyces* that it may be desirable to modify by genetic engineering. These fall into four categories: (1) the adjustment of traits associated with fermentative activity and growth, (2) the elimination of the production of negative traits or off characters, (3) the stimulation of the production of positive aroma and flavor characters by the yeast, and (4) the modification of yeast activities that impact grape aroma and flavor or wine stability and processing.

With respect to fermentation performance, the goal is to generate strains that are able to complete the fermentation; that is, consume the available sugar in spite of the appearance of hostile environmental conditions. Yeasts are subjected to numerous stress factors during fermentation of grape juice: the initial high osmolarity (22–26% sugar or more); the generation of high ethanol concentrations (11–17%), the low pH (3.0–3.9), competition from other organisms, the lack of nutrients, extremes of temperature, and the presence of inhibitory compounds such as acetate. These stress factors have two major impacts on yeast biology during wine fermentation. If the strain is not able to adapt to these conditions, fermentation will slow and can be arrested if conditions are severe enough (66). These arrested, or "stuck" fermentations, are notoriously difficult to restart, and lead to losses in production. In addition, the presence of stress in the environment may influence the spectrum of end products produced by the organism, leading to the appearance of negative characters in the wine. As

with stuck fermentations, some of these characters are very difficult to remove or correct. Successful removal is often at the cost of stripping other desirable characters from the wine. Not surprisingly, the objectives for improvement of yeast stress response are to enhance osmotolerance, thermotolerance, tolerance to ethanol, and tolerance to the presence of inhibitory microbial compounds (reviewed in (26)). To define the genes that should be modified, researchers are actively investigating the role of various stress proteins under oenological conditions (reviewed in (67)). Genes identified as being highly expressed under specific stress conditions will be evaluated for their role in stress resistance, and for the effects of altered patterns of regulation of the stress response gene. Once this work is complete, heartier industrial strains will likely be brought to the marketplace.

One of the main causes of fermentation arrest is nutrient deficiencies, particularly of nitrogen. Nitrogen limitation of fermentation can be addressed by nutrient addition, as diammonium phosphate and other nitrogen containing nutrients can be added to the fermentation (25). There are two problems with this practice. First, it may leave excess nutrient levels in the wine, encouraging spoilage organisms and necessitating sterile bottling of the wine. Second, the addition of nitrogen sources will impact the formation of esters derived from amino acid catabolism, which can be important aroma characters in the wine. To address these issues, genetic alteration of nitrogen utilization is being investigated (68,69). Mutants defective in key regulatory factors controlling nitrogen assimilation are being evaluated for their impact on fermentation capacity.

Microarray or transcriptome analyses have been applied to wine strains (64,70,71,72). These studies are identifying genes and pathways important to normal fermentation progression and ethanol stress resistance. There is a remarkable consistency in the transcriptional profiles revealed in spite of the use of different strains, different growth conditions, and different array technologies. These analyses are providing many potential genetic targets of modification to create superior production strains.

The transcriptome array technology can also be used to aid in strain construction and characterization. The DNA complement of a strain can also be analyzed using these arrays. In this case, the array is blotted directly with labeled genomic DNA (73). In the case of oligonucleotide arrays, divergence from the original sequence of the laboratory strain of *S. cerevisiae* can be identified as a failure to hybridize to that particular oligonucleotide, with hybridization to other oligonucleotides still occurring. Allele diversity can then be determined for the strains under investigation. Crosses can be done and this same technique used to define regions of variation or interest that are not represented by a specific oligonucleotide. Once the allele differences have been determined, a hybrid diploid strain containing both of the different alleles can be created and the phenotype of each allele in the same genetic background can then be evaluated using the technique of reciprocal hemizygosity (73). In this technique, each allele is inactivated via a null mutation, leaving only one allele functional. This is done for both alleles, and the biological properties of the two strains compared to each other as well as to the original parent. Any differences in phenotype would be due to the specific allele that is being expressed. This allows the researcher to definitively determine the role of each individual allele in the biological property under investigation, while still retaining the diploid nature of the original strain. This technique can also be used to analyze quantitative traits in *Saccharomyces*. Quantitative traits are those that display a distinct dosage effect phenomenon, meaning that the phenotype is not plus or minus, but a differing degree of expression. In the case of wine strains, hydrogen sulfide production is an example of such a trait. Strains produce varying amounts of this compound in response to identical environmental conditions. In other words, strains are not producing or nonproducing, but are high, moderate, low or nonproducers of hydrogen sulfide. The quantitative nature of the trait is due to the involvement of several different

genes. Expression of yeast aroma compounds is similarly dependent upon multiple genes, the concerted action of which confers the quantitative nature of the phenotype. Use of quantitative trait locus analysis in combination with reciprocal hemizygosity should provide important information on construction strategies for more complex characteristics of wine yeast strains.

12.3.2 Loss of Negative Characters

Another important area of investigation in the construction of improved commercial strains is the elimination of negative characters; that is, those that are undesirable from a sensory perspective, in the finished wine. These undesirable compounds fall into several groups: the sulfur volatiles, volatile acids, higher alcohols, aldehydes, volatile phenol derivatives, and esters. Sulfur volatiles include hydrogen sulfide (H_2S) and other sulfides, thiols, and mercaptans. These compounds derive from the reduction of sulfate for biosynthesis (H_2S) or from the degradation of sulfur containing amino acids as nitrogen sources (25). Inactivation of the gene *MXR1*, which encodes methionine sulfoxide reductase, prevents formation of dimethyl sulfide (74), a compound found in wine that has a rotten clam aroma. The production of these characters could also be eliminated by mutation of the genes responsible for their appearance (75), which would create strains that were methionine or cysteine auxotrophs. It is unlikely such strains would be competitive against non-auxotrophic strains, and supplementation with the sulfur-containing amino acids may lead to the formation of off characters by other non-*Saccharomyces* organisms.

Similar concerns exist for the inhibition of the production of acetate, other acids, and aldehydes. These compounds are likely produced under conditions requiring balancing of the oxidation/reduction status of the cytoplasm. Preventing this balancing will likely impact the competitiveness of the strain in the natural environment. In the case of organic acids, disruption of the tricarboxylic acid (TCA) cycle altered the levels of TCA acids produced by the yeast (76). Mutation of the *FUM1* gene resulted in loss of respiratory ability, but the strains were still able to ferment (76). However, the competitiveness of these strains versus wild type strains was not evaluated.

Volatile phenols may be produced by yeast during fermentation, likely as a means of resistance to the inhibitory effects of specific phenolic compounds. However, these compounds confer negative aroma characters that are not desired in the wine. Strains carrying mutations blocking phenol modification have been isolated (77). Alteration of the ability to eliminate inhibitory compounds would obviously be contraindicated in the presence of these compounds, if the strain were to survive. Thus, while the targets of gene disruption to eliminate off character production are obvious, such genetic modifications would confer a biological disadvantage to the organism. This is one of the challenges of genetically engineering a strain that must retain full competitiveness against wild organisms of the same species.

An alternative, although more time-consuming, strategy is to evaluate the genetic basis of loss or reduction in synthesis of these negative traits that occurs throughout the native yeast populations. The fact that these strains are still competent to complete a fermentation indicates that they have dealt with the loss of the ability to create a negative character in a manner not affecting competitiveness in the native environment.

12.3.3 Enhanced Production of Positive Characters

Just as there are undesirable yeast traits, there are also positive yeast traits some winemakers would like to see enhanced. Yeast esters, derived from amino acid degradation, confer generic fruity and floral characters to a wine as well as some yeast specific notes, such as toasty. Currently these aromas may accompany the production of off characters also

derived from amino acid degradation, so the goal is to increase the concentration of the positive characters without increasing the negative. The level of expression of these compounds must also be controlled. At low levels the esters add to the complexity of a wine, but at high levels they can dominate the overall profile and decrease the perception of complexity. Increased expression of some catabolic amino acid reactions should lead to enhanced ester formation. Over expression of alcohol acetyltransferase (*ATF1*), one of the enzymatic activities responsible for ester formation, increased the production of fruity esters in wine strains (78,79). Ester production was further enhanced by mutative loss of the *IAH1* gene that encodes a yeast esterase (80).

Another character thought to have beneficial sensory effects is glycerol. Glycerol is believed to positively impact mouth feel and to add a certain element of sweetness to the wine. Strains of *Saccharomyces* have been genetically engineered to increase glycerol production (81,82). These strains have other problems — the increase in production of glycerol disturbs the redox balance of the cells such that more acetic acid is produced (81,82). Additional modification is therefore required to reduce or prevent acetic acid production (83,84). These strains have been used in pure culture to generate wines of elevated glycerol content; however, their effectiveness and persistence under industrial conditions is not clear.

The winemaking technique of "sur lies" aging refers to aging the wine for an extended period of time on the yeast lees. During this time, which is on the order of several months, the yeast cells undergo autolysis; that is, they self degrade, due to the release of enzymes from the yeast vacuole. The activity of these enzymes on both wine and yeast components alters the composition of the wine, generating a more "silky" mouth feel and specific sur lies characters. Construction of yeast strains that more quickly or more readily generate these positive characters would be desirable.

Yeast strains that express enzymatic activities enhancing grape flavor and aroma characters are also being developed and tested. These strains express higher levels of innate activities impacting flavor compound production, or contain mutations of native genes leading to the release of metabolic intermediates that possess an aromatic character (78,80,85,86,87). Mutation of the *ERG20* gene, which is involved in sterol biosynthesis, leads to the release of terpenes by yeast (88). Terpenes are responsible for the characteristic odors of Muscat grapes. The use of these strains confers a Muscat note to the wines.

Finally, the role of *Saccharomyces* in the formation of volatile thiols from S-cysteine conjugate precursors has recently been established (29,89). These compounds are important aroma constituents of white wines (90). Classical breeding strategies have been used to develop hybrid strains between *S. cerevisiae* and *S. bayanus uvarum* producing high levels of volatile thiols (29). Once the mechanism by which these strains yield high volatile thiol contents have been elucidated, targeted gene constructions can be conducted to transfer this property to any desired commercial strain.

It is unclear how well accepted these strains will be by the public. There is the concern that such yeasts will compensate for poor harvesting or processing decisions on the part of the winemaker and will modify the regional characteristics of the fruit to the point of obscurity. Many wines are marketed by the special characters imparted to the grapes by virtue of the growing conditions: the interplay of soil, geography, and climate. If this is altered significantly by the yeast strain used, regional wines might not be so highly prized in the marketplace.

12.3.4 Facilitation of Wine Processing and Enhancement of Wine Organoleptic Properties

Many yeast strains are naturally flocculent and will clump during growth in liquid media. Flocculent wine yeasts have been developed to allow better settling of the yeast lees from

the wine. Introduction of enhanced flocculation does not appear to affect fermentation performance or competitiveness with other yeast strains (91). Flocculating yeasts are particularly important in sparkling wine production following the secondary alcoholic fermentation that occurs in the bottle. The process of riddling settles the yeast cake in the tip of the bottle so that it can be removed. If the yeast strain more readily clumps, a more complete reduction of yeast biomass can result.

Researchers are also generating recombinant strains of *Saccharomyces* that can facilitate wine processing or the attainment of wine stability. Proteins present in wine postfermentation can denature, leading to the formation of a visible haze. Yeast strains expressing vacuolar acid protease externally can decrease wine protein content, thereby reducing haze (92). However, certain peptides confer a bitter character, so it is important to assess the bitterness level of protease treated wines. To date, enhanced expression of the *Saccharomyces* native proteases has been attempted. Expression of heterologous proteases can be tricky, as the protease has to remain inactive until release into the external environment so as not to damage the internal constituents of the cell.

Wine tannins are responsible for astringency. Different yeast strains appear to remove tannins from the wine at differing rates and to different extents. Although the mechanism of tannin removal by yeast is not known, once this process becomes better understood, genetic manipulation of yeast may allow alteration of tannin binding activity and permit adjustment of the natural tannin content, and therefore astringency, of a wine.

Yeast mannoproteins, constituents of the yeast cell surface, have been shown to be released during fermentation and to facilitate stabilization of the wine against the appearance of a protein haze (93). Again, the mechanism of action of yeast mannoproteins in haze reduction is not known, but once it is elucidated, strains with enhanced or targeted mannoprotein release may be developed.

Other genetic alterations that are being explored are designed to make wine safer for human consumption or to enrich its nutritional content; for example, efforts to genetically engineer strains that reduce ethyl carbamate levels in the finished wine. Ethyl carbamate is a naturally occurring carcinogen formed in wine and other fermented products spontaneously from the reaction of carbamyl group-containing compounds such as urea and ethanol (94,95,96). The objective of this research is to design strains that do not release carbamyl donors such as urea to the medium during fermentation.

It is also possible to engineer strains that would elevate the nutritional value of wine by increasing the content of micronutrients. This is being explored by the creation of strains that more efficiently sequester vitamins and minerals from the environment and that then release those components upon cell death or autolysis. Construction of vitamin over producing strains is also under consideration. Such strains have been successfully developed for the brewing industry. However, it is important to remember that *Saccharomyces* shares the grape juice fermentation with a host of other organisms, and the excess vitamin may simply feed a neighbor removed along with *Saccharomyces* during filtration and not remain in the wine at the time of bottling.

12.4 NOVEL TRAITS

There are several enzymatic activities that would be of benefit if expressed in wine yeast during the fermentation. These novel activities impact grape flavor and aroma or facilitate the processing or stability of the wine. A relatively recent suggestion is to generate yeast strains that will enhance the antioxidant character or potential of a wine.

12.4.1 Flavor Production

There are three goals of the creation of more flavorful yeast: (1) the use of yeast to enhance the natural grape flavors and aromas, (2) the creation of strains that produce novel flavors not currently found in the grape, and (3) the construction of yeast strains that will carry out some of the important reactions associated with the malolactic fermentation. Many grape aroma compounds are present in the fruit in the form of nonvolatile precursors, or glycosidically bound molecules (reviewed in (79)). The glycoside moiety holds the compound in solution. Only the free compounds (nonglycosidically bound) are aromatic. Unbound or free terpenes impart floral and intense fruity notes to grapes and grape juice. The attachment of a glycoside group prevents volatilization and therefore detection of these compounds. Bound terpenes are hydrolyzed over time thereby maintaining the aroma characteristics of the fruit. The grape glycosidase are inhibited by glucose and are therefore not active in juice or during the early stages of fermentation. Once fermentation has been completed and the sugar content decreased, these enzymes can slowly hydrolyze the precursor compounds over time. Yeast strains expressing a fungal β(1-4) endoglucanase have been generated (98,99,100,101,102). These strains result in the release of more intense fruity character in the wine. However, the use of these strains may impact the long term aging potential of the wine, and lead to the loss of too many characters too quickly.

Malate and tartrate represent the two major acid types found in grapes. In cooler growing regions, malate levels and therefore acidity and sourness may be unacceptably high at the time of harvest. The lactic acid bacteria can metabolize the dicarboxylic acid malate to the monocarboxylic lactate and thereby reduce acidity (25). Yeast and the lactic acid bacteria compete for nutrients during fermentation and produce compounds inhibitory toward the other species, and it can be difficult to obtain both the alcoholic fermentation and malolactic conversion in the same wine. The lactic acid bacteria produce a spectrum of organoleptic characters in addition to the reduction in sourness. Some of these traits, such as the cream and buttery notes, are desired in some wines, while other traits (the mousy and other animal characters) are not.

Several teams of researchers have constructed strains of *Saccharomyces* that will metabolize malate thus reducing acidity without the need for bacterial malolactic fermentation. One early strategy was to express the bacterial malolactic enzyme in yeast (103,104,105).

A different strategy based upon creating strains of *Saccharomyces* capable of metabolizing malate to ethanol has also been pursued (106,107). This strategy takes advantage of the ability of the yeast *Schizosaccharomyces pombe* to degrade malate to ethanol. Malate is first converted to pyruvate, which is subsequently degraded to ethanol and CO_2. Although *S. cerevisiae* possesses the same enzymatic activities, the substrate affinity of the *Saccharomyces* malic enzyme for malate is too low to result in sufficient degradation of malate. Further, *Saccharomyces* does not possess an efficient malate permease. The genes encoding the *S. pombe* malate permease (*mae1*) and the malic enzyme (*mae2*) were both transformed into wine strains of *S. cerevisiae* (106). The recombinant strain efficiently degraded malate to ethanol (107).

12.4.2 Facilitation of the Production Process

Similarly to protein hazes, polysaccharides can form visible cloudiness in wine. Yeast strains possessing enzymatic activities to break down these complex polysaccharides are under development. Similarly, wine filterability is improved by degradation of grape polysaccharides. Strains of *Saccharomyces* with pectinase or cellulase activity have been

constructed that offer an alternative to the use of commercial enzyme preparations (108, 109,110,111,112,113,114,115,116). The advantage of a recombinant wine strain would be the elimination of any potentially undesirable side activity that is present in the commercial preparations. However, an enzyme addition may be easier to control and monitor than an activity produced by a recombinant strain.

Wine strains of *Saccharomyces* producing bacteriocins have also been constructed (117). Bacteriocin production by yeast strains offers many advantages over the current practice of use of sulfur dioxide. Individuals deficient in sulfite oxidase display a strong hypersensitivity to sulfite. In severe cases, exposure can lead to death. The role of sulfite in elimination of unwanted bacteria can be effectively carried out by bacteriocins. In addition, bacteriocins show more selectivity than sulfite and can be used to inhibit specific classes of bacteria, not harming those that are desired in the wine.

12.4.3 Improved Healthfulness of Product

Finally, efforts are underway to generate recombinant yeast strains that will increase the levels of important phytochemicals such as resveratrol (118,119). The reductive environment created by the yeast during fermentation is important in the retention of these compounds in their bioactive form. The aim of this work is to increase the level of bioactive phenolic compounds that have been shown to have positive dietary outcomes in the prevention of disease. Such engineered strains may be of more value to the population as a whole than those leading to subtle differences in wine aroma and flavor or the elimination of economic loss for producers. Also, yeast may be used to remove other compounds in the wine for which there are health concerns such as the biogenic amines (histamine, tyramine and tryptamine), implicated as causative agents of wine headache, that can be produced by lactic acid bacteria (120). It may be possible to produce strains of *S. cerevisiae* that will lead to reduction in the levels of the precursors of these compounds.

12.5 FUTURE PERSPECTIVE

The ability to alter the genetic composition of wine strains of *Saccharomyces* appears limitless. A significant amount of information is accumulating on the physiology of this organism under native environment or grape juice fermentation conditions providing researchers with a fertile database upon which to improve inherent traits or guide the construction of strains expressing novel activities. This review covered some of the current constructions that are underway in several laboratories. Other desirable modifications will emerge as we learn more about the nature of wine flavor and aroma. Genetic engineering of wine yeast poses some unusual challenges, such as the need to maintain strain competitiveness against wild types of the same species and against other organisms, the inability to disturb stress tolerance, and the necessity to sustain patterns of metabolites produced. In essence, the modification needs to have little to no impact on the other biological properties of the organism. Because of this fact, most of the changes to wine yeast are expected to be benign and well characterized, with no risk to the consumer.

In addition to modification of *Saccharomyces*, alteration of other yeasts, those present during the fermentation and those with the potential to spoil the finished wine, can also be explored. Many of these yeasts play important roles in wine aroma and flavor. They also produce off characters that are undesirable. Engineering of strains with enhanced production of positive traits and reduced formation of undesired characters would be beneficial to the wine industry.

Stress Tolerance, Metabolism, and Development: The Many Flavors of Trehalose

Mike A. Singer, Tiago F. Outeiro, and Susan Lindquist

CONTENTS

13.1 INTRODUCTION

Trehalose has a remarkable capacity to protect cells and their component macromolecules against a daunting array of environmental stresses – from extreme heat (1,2) to freezing cold (3), from anoxia (4) to oxidative damage (5), from osmotic stress (6) to withering dehydration (7). The disaccharide is one of a group of unrelated small molecules known alternatively as compatible solutes (osmolytes) or chemical chaperones — the former because even high concentrations do not inhibit enzyme activity (8), and the latter in recognition of their stabilizing effects on proteins (9). Their properties read like the pages of a superhero comic, and indeed harnessing them has long been largely a province of the imagination, making investigation in this area an exciting frontier in food biotechnology.

The discovery of trehalose was itself the product of efforts in food biotechnology. Working in Germany in the early nineteenth century, H.A.L. Wiggers studied ergot, a toxic fungus which contaminates rye and other cereal crops. Wiggers reported among its

constituents a new sugar, later named trehalose. (For further background on the colorful history of trehalose, please see (10) and (11).) Trehalose has since been identified in organisms across an extraordinarily broad spectrum of taxonomy, including bacteria, fungi, plants, insects, and invertebrates (12). We focus here, after a brief review of its structure and proposed mechanisms of function, on the role of trehalose in the budding yeast *Saccharomyces cerevisiae*. In addition to its great commercial importance in baking and brewing, *S. cerevisiae* is a well characterized model system offering convenient and powerful techniques for genetic manipulation. Application of these methods has provided significant insight into complex molecular process even far removed from yeast itself, including cancer (13), aging (14), and neurodegenerative disorders (15–19).

Work by many investigators has revealed that protection from stress is but one aspect of the emerging multifaceted role of trehalose in yeast. Not only synthesis of the sugar, but also its degradation is necessary to optimize survival of extreme heat. Equally intriguing is the finding that the enzymes and products in the trehalose pathway critically influence fundamental cellular metabolism, gene expression, and development. Similar recent discoveries in *Arabidopsis* and *Drosophila* offer the compelling prospect that this link between the mundane and the extreme may be highly conserved, with significant implications for biology and biotechnology.

13.2 STRUCTURE AND PROTECTIVE MECHANISMS

The structure of trehalose is elegantly simple: two monomers of D-glucose joined at their alpha-carbons. This flexible glycosidic bond, together with the absence of internal hydrogen bonds, yields a supple molecule thought to conform readily to the irregular polar groups of proteins (20). While the bond bends, it does not easily break: the 1 kcal/mol linkage is highly resilient, enabling the molecule to withstand a wide range of temperature and pH conditions (21).

Importantly, the bond links the reactive (anomeric) carbon atoms of the two glucose monomers, preventing them from interacting with other molecules and thereby rendering trehalose among the most chemically inert sugars (12,22). One significant advantage is that trehalose consequently does not participate in the Maillard (browning) reaction (23,24). This process is actually a complex series of reactions by which sugars and amino acids are mutually degraded; the end result is multiple products which produce a variety of flavors and aromas. Although desirable in many areas of food biotechnology, the Maillard reaction is an anathema to others, because it is thought to be a key cause of damage to proteins during storage (25).

Early experiments with restriction endonucleases dramatically demonstrated the extraordinary protective capacity of trehalose. In a routine familiar to anyone employing molecular biology techniques, these enzymes are carefully stored in freezers and even when briefly removed for use, are maintained in freezer blocks to preserve their activity. If dried in a trehalose containing solution, however, these normally labile enzymes retained activity upon reconstitution, even after extended storage at room temperature or after being heated to 70°C (8,26,27). In addition to stabilizing native proteins, trehalose has also been found to prevent aggregation of denatured polypeptides, a function previously thought to require molecular chaperones (28) (Figure 13.1).

The protective effects of trehalose shield not only proteins, but other macromolecules as well. Lipid vesicles, which are potentially important tools for drug delivery, fare poorly under storage conditions of freezing or dehydration: rather than crystallize, they aggregate and fuse, resulting in leakage of their contents. If freeze dried in the presence of trehalose,

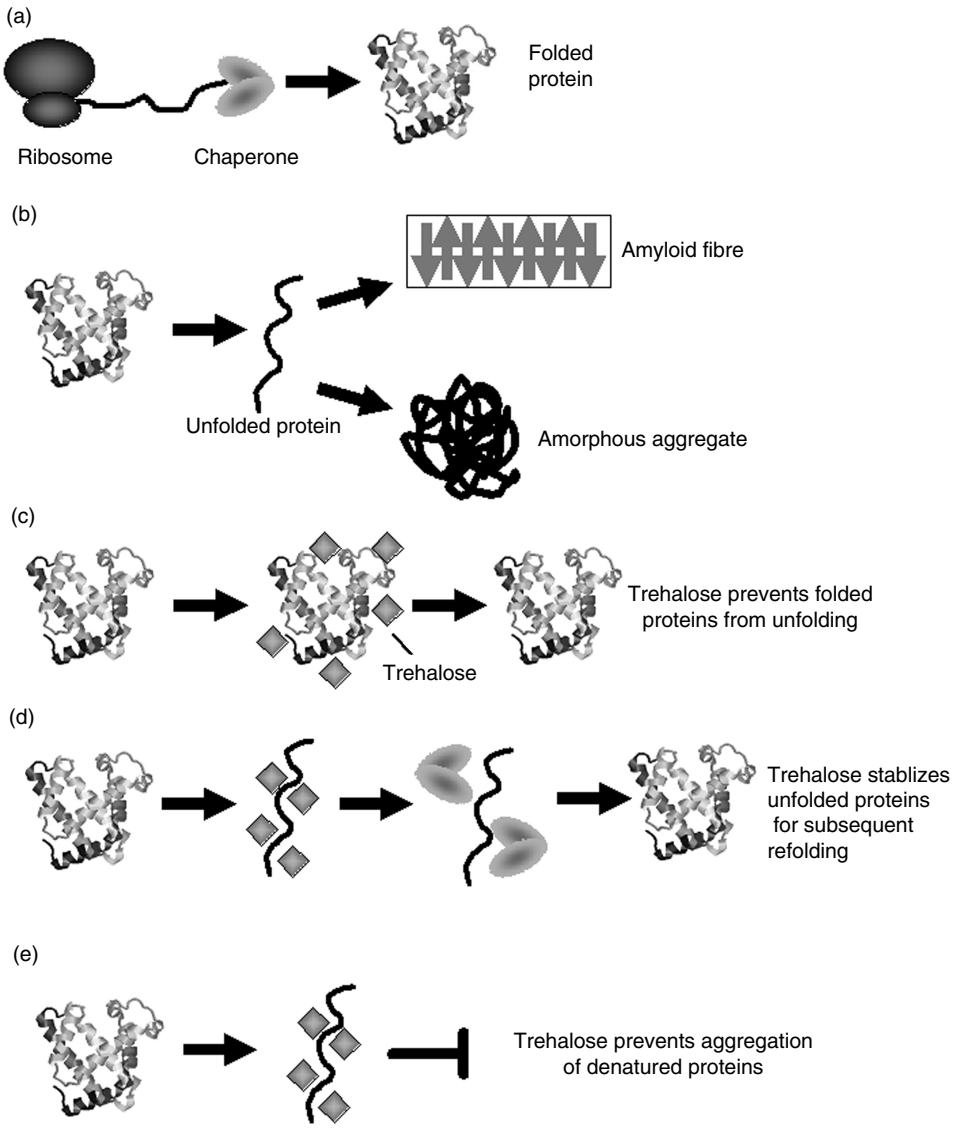

Figure 13.1 Model for trehalose-mediated protein stabilization in cells: (a) Protein folding under normal conditions. (b) Undesirable associations of denatured proteins. (c-e) Roles of trehalose during heat shock.

however, the vesicles remain intact upon rehydration (21). Carbohydrates in the form of starches become disordered during cooking, but may subsequently associate and precipitate, thereby contributing to staling. This undesirable process, termed retrogradation, can be significantly inhibited by trehalose (29). The damaging effects of radiation on DNA are well known, causing structural alterations and strand breaks. These effects, thought to be caused by hydroxide radicals generated by the decomposition of water molecules, are inhibited by trehalose, which may act as a scavenger of those highly reactive species (30).

The mechanisms by which trehalose protects from other forms of damage, however, are less readily apparent. Two general hypotheses have been proposed to explain how trehalose stabilizes macromolecules and prevents their nonproductive associations: water

replacement, and the formation of a glass (20). An important factor is the remarkable concentrations of trehalose which can accumulate, reaching in yeast, for example, up to 0.5 *M*, or 20% of the dry weight of the cells (2).

The water replacement hypothesis emphasizes the role of hydrogen bonding in the protective process. According to this model, macromolecules are stabilized by hydrogen bonds provided by the water that normally surrounds them. During freezing or dehydration, these water molecules are removed. Trehalose may stabilize substrates either by ordering and maintaining the surrounding water, or by interacting with polar regions to substitute as water is removed (20). The finding that trehalose stabilizes denatured proteins suggests that it may also form nonpolar associations, preventing normally buried regions of unfolded proteins from interacting as well (28).

Glass refers a liquid of such high viscosity that it is capable of slowing or even halting chemical reactions (23). Sugars in solution can adopt the glass state (vitrify), holding enclosed macromolecules either in their native state or a conformation which returns to the native form upon rehydration. Consistent with this hypothesis, trehalose readily forms a glass which resists crystallization or separation of phases, and restricts mobility of macromolecules (31,32). Addition of substances such as borate, cations, and glucose may provide increased stabilization; such compounds naturally occurring in cells likely contribute to trehalose mediated stabilization *in vivo* (33,34).

The water replacement and glass transition hypotheses are by no means mutually exclusive, and likely are interrelated. Indeed, studies of dehydration tolerance indicate that both hydrogen bonding and formation of the glass state are necessary (23).

13.3 SYNTHESIS IN *S. CEREVISIAE*

Under normal conditions, trehalose is formed in the cytosol of *S. cerevisiae* through the efforts of a quartet of proteins acting together (2,35,36) (Figure 13.2). The reaction proceeds

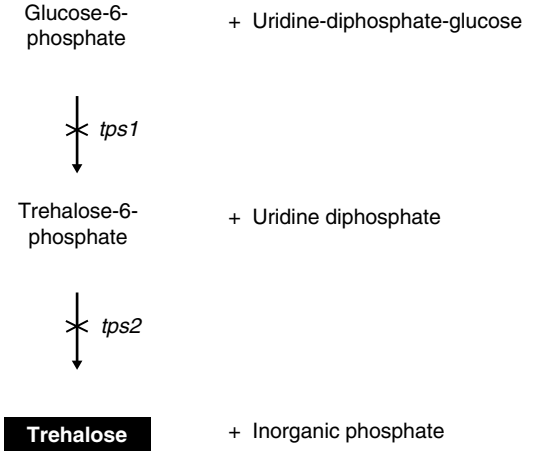

Figure 13.2 Biosynthesis of trehalose: *S. cerevisiae* produces trehalose in the cytosol through the sequential action of the Tps1 and Tps2 proteins. Steps at which trehalose synthesis is blocked in the absence of these proteins are indicated. Tps1 and Tps2 associate physically to form the trehalose-synthase complex, together with Tsl1 and Tps3. The latter components appear to regulate the activity of the complex. (Adapted from Singer, M.A., S. Lindquist, *Trends Biotechnol*. 16:460–468, 1998).

in two steps: UDP-glucose is joined to glucose-6-phosphate (G6P) to form trehalose-6-phosphate (T6P). The phosphate molecule is then cleaved, yielding trehalose (37,38).

The components of the trehalose synthase complex are Tps1, Tps2, Tps3, and Tsl1 (36). Though 35% identical over a length of about 500 amino acids, their functions are distinct (39). Tps1 catalyzes formation of trehalose-6-phosphate (T6P) by uniting the two glucose moieties. The phosphate is then cleaved by Tps2 to yield trehalose and recycle inorganic phosphate. Tps3 and Tsl1 appear to act as regulators, in a manner that remains enigmatic. All members are present constitutively, with expression further induced by heat (40,41), diauxic shift and stationary phase (42), and upon DNA damage (40).Their stoichiometry is not yet known; gel filtration studies estimate the size of the complex as 600–800 kD, indicating that one or more of the subunits is present in multiple copies (36,44).

Tps1 (trehalose phosphate synthase), which facilitates the first step in synthesis, is the smallest subunit (56 kD) (45,46). Mutants lacking Tps1 are unable to produce trehalose, and are severely impaired in thermotolerance (47). Despite their sequence similarity, the other components of the complex cannot substitute for its absence, leading to speculation that the identical regions may instead promote physical association (36).

Upon fractionation of extracts, the other subunits are primarily found in complex, whereas Tps1 is present both as part of the complex and as a free monomer. Free Tps1 is functional, although its catalytic activity is diminished (36). These properties are all the more intriguing given another, as yet unexplained finding: mutants lacking Tps1 are unable to grow on glucose (48,49). We return to this link between trehalose and metabolism more extensively in what follows.

Tps2 (102 kD) carries out the final step in trehalose synthesis, dephosphorylation of trehalose-6-P to yield trehalose (60). In contrast to *tps1* mutants, cells in which *Tps2* is deleted are still able to accumulate trehalose, indicating that one or more other cellular phosphatases are to some extent able to hydrolyze the phosphate group from trehalose-6-P (36).

Tps3 (115 kD) and Tsl1 (the largest subunit, 123 kD) appear to exert a regulatory and stabilizing effect, in a manner that remains poorly understood (40). The former, discovered by sequence homology, is coregulated with Tps1 and Tps2 (35). Deletion of either *Tps3* or *Tsl1* individually destabilizes the complex, yielding more degradation products and free Tps1. In the absence of both genes, no evidence of the complex is found (36). The individual mutants also show diminished trehalose–phosphate synthase and phosphatase activity, an effect that similarly is more pronounced in the absence of both proteins (36).

13.4 DEGRADATION

Like its synthesis, degradation of trehalose in *S. cerevisiae* also poses some puzzling complexities. Hydrolysis is catalyzed by Nth1 (neutral trehalase), an 80 kD cytoplasmic protein which functions as a dimer (45,51,52). Cells lacking this protein grow normally in media containing trehalose, but are unable to degrade intracellular trehalose (53).

Paradoxically, expression of Nth1 is induced by heat, and mutants lacking the enzyme are impaired in their recovery from heat shock (53–56). That is, both synthesis and degradation of trehalose are important for surviving exposure to extreme heat. As the functions of trehalose in thermotolerance, detailed in what follows, have become clear, these seemingly counterintuitive findings can now be explained: trehalose stabilizes native and denatured proteins during stress, but that same process may interfere with the refolding of denatured proteins afterward. Consequently, the continued presence of trehalose may impede return to normal growth.

Nth1 activity is high in log-phase cells, and decreased in stationary phase, circumstances corresponding respectively to low and high levels of intracellular trehalose (52,53). *In vivo*, neutral trehalase is activated by stimuli such as glucose, which triggers germination of spores (52,57). Nth1 is tightly regulated through phosphorylation, particularly by protein kinase A, which activates the enzyme. Nth1 also has a putative calcium binding site, and *in vitro* is stimulated both by calcium and magnesium.

A second gene, *NTH2*, was identified in *S. cerevisiae* by sequence comparison and is 77% identical to *NTH1* (58). Also cytoplasmic and heat inducible, its function is not clear: neither deletion nor overexpression of *NTH2* affects intracellular trehalase activity or trehalose levels, but mutants are impaired in recovery from heat shock, the more so if both *NTH2* and *NTH1* are deleted (59) (Figure 13.3).

A third trehalase enzyme, Ath1 (218 kD) or acid trehalase, is also present in yeast. This heavily glycosylated protein has no homology to Nth1 or Nth2, and does not function in thermotolerance. Instead, it is found in vacuoles, consistent with its optimum pH of 4.5 (53,60). Mutants lacking Ath1 are unable to grow on exogenous trehalose (53). In nature, many fungi utilize trehalose as a carbon source, because it accumulates in insects and microbes and therefore is often present at high levels in decaying soil. Expression and activity of Ath1 is induced by addition of trehalose, and increases in stationary phase (56,61,62). Unlike its cytoplasmic counterparts, Ath1 is activated neither by phosphorylation nor by calcium or magnesium (60,63).

Acid trehalase (Ath1) is thought to be secreted into the periplasm, and then internalized into vacuoles together with exogenous trehalose. Support for this model comes from

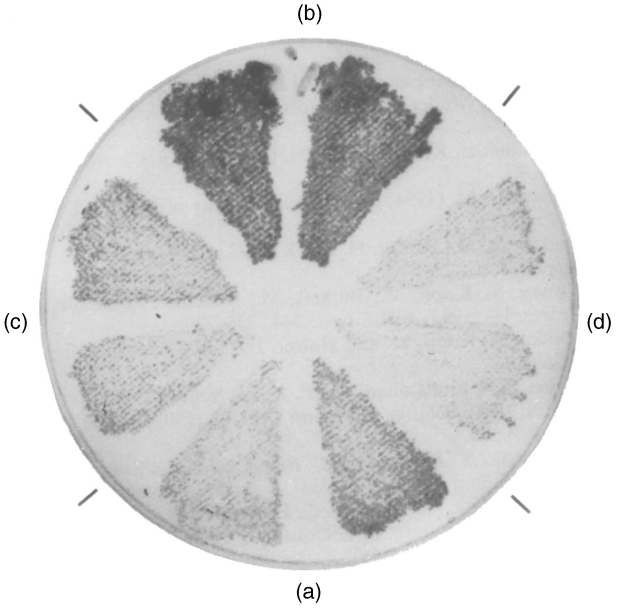

Figure 13.3 Poor growth of the *nth1*, *ath1,* and *nth1ath1* double mutants on glycerol: (a) Two independent *nth1* spores (no neutral trehalase activity), but wild-type for the ATH1 gene. (b) Two independent spores (no acid trehalase activity), but wild-type for NTH1. (c) Two independent spores, wild-type for NTH1 and ATH1. (d) Two independent spores with both *nth1* and *ath1* mutations (neither neutral nor acid trehalase activity). The cells were grown on a YEPD plate for 23 days at 30°C, replica plated onto a YEPGlycerol plate, and then incubated at 30°C for 5 days. (Reproduced from Nwaka, S., B. Mechler, M. Destruelle, H. Holzer, *FEBS Lett*. 360:286–290, 1995).

the finding that Ath1 is present in the periplasm of cells overexpressing the protein, and from the observation that *end1* mutants, in which the endocytosis pathway is impaired, are unable to grow on trehalose (52).

13.5 TREHALOSE AND METABOLISM

As noted earlier, an intriguing aspect of trehalose in *S. cerevisiae* is its relationship to glycolysis, one of the fundamental pathways of cellular metabolism. For reasons that remain elusive, mutants lacking Tps1 cannot regulate the influx of glucose, and become flooded with the sugar. The glucose is rapidly phosphorylated for entry into glycolysis, depleting intracellular phosphate and adenosine triphosphate (ATP) and leading to cell death (48).

Teusnick et al. suggest that this lethal circumstance arises because of the "turbo" architecture of the glycolytic pathway, in which ATP is first invested to promote the breakdown of glucose, and only then are returns obtained by subsequent metabolism. A sudden increase in glucose levels, therefore, can paralyze this process, causing ATP to be depleted faster than it can be replenished (64).

Three models have been proposed to explain the role of the trehalose pathway in glycolysis (49). The first posits that Tps1 regulates glucose influx by production of trehalose-6-phosphate, which in turn inhibits the activity of hexokinases and thereby prevents the uncontrolled phosphorylation of glucose. This hypothesis is based on the finding that regulation of glycolysis and growth on glucose can be restored by mutation of Hxk2, the primary enzyme responsible for phosphorylating intracellular glucose (65). Further support comes from the *in vitro* observation that Hxk2 activity is inhibited by T6P (66,67).

Aside from the genetic finding with Hxk2, results *in vivo* are less straightforward. Expressing the *Escherichia coli* Tps1 homolog otsA restores T6P levels, yet only partially suppresses deregulation of glycolysis (68). Overexpression of Hxk2 in wild–type *S. cerevisiae* does not interfere with growth on glucose (69), and even a broad range of T6P levels had only a limited effect on the accumulation of glucose-6-phosphate in cells (70). In all likelihood, then, Tps1 probably influences glycolysis *in vivo* through multiple mechanisms.

Such mechanisms could include one or both of the other proposed models (49). The second model proposes that by utilizing G6P for synthesis of trehalose, the trehalose pathway enables cells to recover phosphate and regenerate ATP. The absence of a growth defect for *tps2* mutants on glucose may be explained by the ability of nonspecfic phosphatases to compensate in removing the phosphate from T6P. Finally, the Tps1 protein itself may have, in addition to its role in trehalose synthesis, a distinct regulatory function to limit influx of glucose into glycolysis. This latter suggestion is supported by the finding noted earlier, of free Tps1 separate from the trehalose synthase complex (36,49,71).

13.6 TREHALOSE IN HEAT SHOCK

Until recently, it was thought that trehalose, like glycogen, served as a carbohydrate storage reserve for cells under nutrient deprivation. The two compounds indeed have similarities: both are found in high concentrations under conditions when food is scarce, such as stationary phase and in spores, and correspondingly, both are largely absent when it is abundant, as during exponential growth (72–74). Further consideration of the data, however, together with key additional observations, indicated that trehalose functions primarily to help cells withstand not starvation, but stress (1,2).

An energy storage molecule would be expected to be produced when nutrients are abundant, in anticipation of future scarcity. Glycogen is indeed synthesized under such circumstances, during the logarithmic phase of growth. Cells only produce trehalose, however, once they are already entering stationary phase and food is no longer readily available (74).

Similarly, energy stores would normally be consumed after environmental resources are depleted. Cellular glycogen is utilized during maturation of ascospores (72). In contrast, trehalose is not used, and remains present in mature spores. During long term incubation in stationary phase, *S. cerevisiae* first turn to glycogen, and only draw on trehalose after the glycogen has been depleted and cells begin to die of starvation (2,74).

These anomalies became even more compelling in the context of several striking experimental results. Although trehalose was shown *in vitro* to stabilize proteins under adverse conditions, it was not thought to do so *in vivo*, because the concentrations required are much higher than were found in cells. That view changed following the discovery that trehalose in *S. cerevisiae* is present exclusively in the nucleus and cytoplasm and not, for example, in vacuoles, which occupy a large fraction of the intracellular space (54). This key finding indicated that the concentration in those areas was actually on the order of 0.5 M, consistent with levels observed to protect macromolecules *in vitro* (2,8).

Additional *in vivo* support came from the observation that trehalose accumulated in *S. cerevisiae*, as well as in other fungi, prokaryotes, and nematodes, under conditions of environmental stress, such as oxidation, heat, desiccation, and ethanol. Moreover, elevated intracellular levels of trehalose correlated with increased thermotolerance (Figure 13.4) in yeast spores, as well as cells in stationary phase and in certain mutants impaired in the cyclic AMP signaling pathway (1,75).

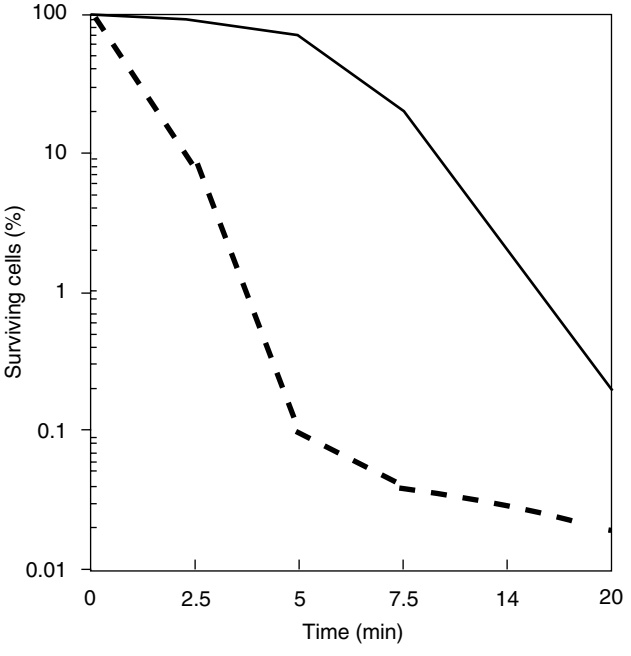

Figure 13.4 Thermotolerance of wild-type and T*ps1 S. cerevisiae* strains in stationary phase: Cultures of wild-type (—) and Tps1 (- -) cells were grown to stationary phase. Thermotolerance was measured as survival following incubation at 54°C for the times indicated. (Adapted from De Virgilio, C., T. Hottiger, J. Dominguez, T. Boller, A. Wiemken, *Eur. J. Biochem.* 219:179–186, 1994).

An important caveat, of course, was that these conditions also stimulate increased synthesis of heat shock proteins (HSPs) (76). Also, trehalose is degraded very rapidly after a stress has passed, unlike HSPs, which are long lived (62,75). The crucial test of this hypothesis could finally be performed once the *Tps1* gene was successfully cloned. Indeed, mutation of the gene resulted in dramatically diminished survival of extreme heat – to an extent similar to that of cells lacking Hsp104, the key HSP mediator of thermotolerance in yeast (47,77,78).

Further experiments established that synthesis of HSPs was unchanged in *Tps1* mutants, confirming that the thermotolerance deficit was due to the absence of trehalose (28). That trehalose exerted its powerful effects through stabilization of proteins *in vivo* was demonstrated using two different heat sensitive reporter proteins. Both showed diminished activity in T*ps1* cells compared to wild–type at elevated temperatures (28).

Two additional, surprising, results emerged from this work. First, trehalose also prevented aggregation of proteins that were already denatured – a function previously thought to be carried out exclusively by HSPs. Second, the continued presence of trehalose impaired reactivation of those denatured proteins (28). Other experiments correspondingly demonstrated that cells unable to degrade trehalose were impaired in recovery from heat shock relative to their wild-type counterparts (53,55,56).

As noted, the current model for trehalose function in stress tolerance resolves these seemingly paradoxical findings: Trehalose stabilizes proteins in their native state and prevents them from denaturing during stress. Together with HSPs, trehalose also keeps those proteins that do unfold from forming nonproductive and potentially toxic aggregates. Trehalose must be rapidly removed, however, because its continued presence may interfere with degradation or chaperone mediated refolding of denatured proteins (11).

13.7 TREHALOSE IN PLANTS AND *DROSOPHILA*

With the exception of the "resurrection plants", *Selaginella lepidophylla* and *Myrothamnus flabellifolius*, which utilize trehalose to survive extreme desiccation, the disaccharide was thought to be largely absent in plants (79). At the same time, however, extending the protective effects of trehalose to plants had been a sought after goal of work in stress tolerance (80,81). A number of exciting recent discoveries have dispelled the notion that trehalose is rare in plants. Equally striking is the discovery that the same basic parameters which characterize trehalose in *S. cerevisiae* are also seen in plants, and now in *Drosophila* as well: trehalose enhances resistance to environmental stress; accumulation of trehalose can be detrimental during growth; and finally, components and intermediates of the trehalose synthesis process are intimately connected to metabolism and gene expression.

The finding that trehalose is widespread in plants was made serendipitously: in the course of efforts to engineer trehalose production in tobacco and potato, the control plants were found to contain trace levels of the sugar (81). Other work demonstrated that treatment of *Arabidopsis* with the trehalase inhibitor validomycin A resulted in significant accumulation of trehalose (79,82). TPS and TPP homologs have since been identified in rice, soybean, and tomato, and more recently, a host of related genes, as well as a putative trehalose, have been found in *Arabidopsis* (71).

The *Arabidopsis* sequences cluster into two groups (71). The first subfamily, members of which most resemble Tps1, contains four genes which are 63–80% identical in sequence. One gene, designated *AtTps1*, restores the ability of *S. cerevisiae tps1* mutants to produce trehalose (67). The *AtTps1* sequence includes a 100 amino acid N-terminal

region not present in yeast Tps1 or the other plant Tps1 homologs. This sequence is homologous to segments of the yeast regulator protein Tsl1 and likewise appears to have a regulatory function: when deleted, activity of the enzyme increases (83). Members of the second subfamily are most similar to Tps2. This group shares 54–83% sequence identity, and all members contain a C-terminal sequence common to phosphatases (71).

Overexpression of yeast and *E. coli* trehalose synthesis enzymes in transgenic plants indeed enhanced resistance to stress (82,84,85). As with *S. cerevisiae nth1* mutants, however, this benefit was not without cost: the transgenic plants displayed altered metabolism and morphological growth defects, such as stunted growth and lancet shaped leaves (82,86).

Studies in *Arabidopsis* revealed that *AtTps1* is expressed at low levels in all tissues examined, and is strongly upregulated during embryo maturation (seed development) (87). Perhaps the most dramatic parallels to yeast were seen in a key study in which the gene was mutated. Although the thermotolerance properties of the mutant have not yet been reported, the effects on development were manifest, resulting in recessive embryonic lethality (87). Development in higher plants such as *Arabidopsis* proceeds in three overlapping stages. Cells first divide and differentiate, establishing the pattern of the embryo. Next, cells expand in size and accumulate storage reserves. Finally, the embryo desiccates and growth halts. The *AtTps1* mutant plants were unable to proceed past the torpedo stage, at the transition between pattern formation and growth (87).

Under normal conditions, sucrose levels rise dramatically in *Arabidopsis* embryos at this juncture, as does expression of AtTps1. The increase is thought to be required both for producing storage reserves and for influencing gene expression to control this developmental transition. The latter suggestion is supported by abnormalities in expression of the seed maturation marker genes *At2S2* and *AtOLEOSN2* seen in the mutant.

As mentioned earlier, *S. cerevisiae tps1* mutants die in the presence of glucose. The sugar enters the cells and is phosphorylated in an unrestricted manner, depleting cellular phosphate and ATP stores. Moreover, Tps1 is also required for carbon catabolites to control gene expression (49). These cells are, however, able to grow on carbon sources such as galactose. As discussed earlier, growth on glucose can be restored by mutating the gene encoding Hxk2, the enzyme primarily responsible for phosphorylating glucose for entry into glycolysis (65). Just as *S. cerevisiae tps1* mutants can be rescued by restricting entry of glucose into glycolysis, *AtTps1* mutants similarly are able to proceed with development *in vitro* if sucrose levels are reduced. Unlike in yeast, growth could not be restored in these cells by targeting Hxk2 (here by antisense methods or treatment with the hexokinase inhibitor glucosamine), nor is *Arabidopsis* Hxk2 inhibited by trehalose-6-phosphate (87). The reason for this failure is not clear, but several explanations have been proposed. The *HXK* gene family in *Arabidopsis* is not well characterized, so another isoform (or perhaps an entirely distinct kinase) may be the critical target. Alternatively, sucrose can enter glycolysis through more than one route in plants, so its catabolism at this developmental stage may proceed by a different pathway, such as that utilizing sucrose synthase, which does not require phosphorylation of glucose (87,88). Finally, it is also possible that AtTps1 acts directly or via trehalose to influence development and gene expression. Based on their finding that the *E. coli* trehalose synthase gene can complement the *AtTps1* mutation, Schluepmann et al. favor the view that the mutant phenotype results from the absence of activity of AtTps1, rather than a regulatory property of the protein (89).

The likelihood that the protean roles of the trehalose pathway are broadly conserved was underscored by exciting work in *Drosophila* paralleling these findings. *Drosophila* is unusually resistant to anoxic injury, a property of considerable medical interest because of its potential to help limit damage to the brain in patients following stroke or cardiac arrest. By overexpressing the *Drosophila Tps1* gene, Chen et al. succeeded in making that organism

even more resistant. Strikingly, deletion of the gene or its overexpression under certain conditions led to developmental abnormalities or death of the developing flies (4).

13.8 APPLICATIONS IN BIOTECHNOLOGY

Efforts to elucidate the role of trehalose in adverse conditions and in growth and metabolism have advanced concurrently with the drive to harness its protective properties in food biotechnology. That work, which has primarily involved genetic engineering and exogenous use of the sugar, also holds outstanding promise broadly in industry and medicine.

Utilization of trehalose as an additive for food preservation or storage has recently become feasible through the development of new techniques enabling economical large scale production from starch (24,29). The sugar's mild sweetness — 45% that of sucrose (29) — and "masking effect" of bitter-tasting compounds, as well as lack of an aftertaste or laxative effect, enhance its versatility as a contributor to the texture and balance of flavors in foods (90). It is not easily degraded during processing, and its resistance to taking up moisture reduces caking in mixtures with other ingredients (29). The protective effects of trehalose prolong the shelf life of starch-containing products by preventing retrogradation, as noted; similarly, the stabilization of proteins and lipids during freezing and drying extends the shelf life of products containing eggs or meat (29).

Genetic methods have successfully been employed to improve the freeze tolerance of frozen dough (91,92). As mentioned earlier, tobacco and potato plants modified to produce trehalose display enhanced tolerance to a diverse range of stresses, including salt, drought, and low temperatures (79). Considerable potential also holds for the use of such methods to promote proper folding and prevent aggregation of recombinant proteins synthesized in *E. coli* or other organisms, for production of foods or pharmaceuticals (11). Trehalose has already been shown to help preserve vaccines and liposomes, as well as organs in preparation for transplant (30,90). The novel finding that disruption of *Tps2* in *Candida* leads to diminished infectivity of that organism suggests that the trehalose pathway may be an attractive target for antibiotics (93,94). The same may also hold true for pesticides: diminished infectivity and pathogenicity was similarly seen for trehalose mutants of the rice blast fungus *Magnaporthe grisea* (95).

Finally, trehalose may be helpful in the treatment and prevention of disorders resulting from misfolding or aggregation of proteins (9,96,97). Expression of α-synuclein, a protein involved in Parkinson's disease, is toxic to yeast. In a genetic screen to identify modulators of this toxicity, Willingham et al. discovered that cells lacking Tsl1 were more susceptible to the deleterious effects of α-synuclein (98). Another recent study, involving a transgenic mouse model of Huntington's disease, demonstrated that mice fed trehalose dosed water developed far fewer polyglutamine aggregates (one of the hallmarks of Huntington's disease pathology) than did untreated controls (99). The trehalose group also lived longer and performed better in coordination tests, suggesting a correlation between the decreased number of aggregates and improvements in the Huntington's-like symptoms.

13.9 PERSPECTIVES

Overall, three general principles are emerging from work on trehalose in *S. cerevisiae* and its striking correlates in plants and *Drosophila*: (1) trehalose has a protective role *in vivo* as well as *in vitro* in stress tolerance; (2) the same properties which can protect macromolecules may also be detrimental as environmental circumstances change; and (3) a critical

but still elusive connection exists between the trehalose pathway and cellular metabolism, gene expression, and development. It is constructive to consider these principles in the broader context of stress tolerance mechanisms, particularly other organic solutes and the heat shock proteins (HSPs).

Regarding the former, trehalose is not unique in its protective effects. Rather, similar properties are shared by a host of other small molecules, such as the amino acids proline and betaine and the sugars sucrose and sorbitol (8,28). The diversity in nature of these "compatible solutes" or "chemical chaperones" is intriguing. It may reflect propensities to stabilize different sensitive structures in different organisms, or perhaps regulatory and metabolic functions (such as the interaction of trehalose with glycolysis) that make certain osmolytes of greater utility in particular organisms. Thus, a vital connection to cell biology and organismal development may exist more generally with compatible solutes, providing another unifying characteristic and potentially powerful tool in food biotechnology.

A paradigm for such an association between fundamental cellular processes and stress tolerance already exists, with the heat shock proteins. While a subgroup are expressed only under adverse environmental conditions, many others, such as the members of the Hsp70 and Hsp40 families, have variants which play essential roles in protein folding and translocation under normal circumstances (100). Even Hsp104, an *S. cerevisiae* heat shock protein initially thought to function exclusively in survival of extreme stress (75,77), subsequently was found to have a key role at normal temperatures for propagation of *[PSI$^+$]*, *[RNQ$^+$]*, and *[URE3]* (101). Also known as yeast prions, these unconventional genetic elements represent alternative but stable conformations of a particular protein, which propagate heritable information through maintenance of a particular conformation (101–03).

This finding and other work in HSPs highlight the subtleties of cellular adaptation to environmental challenges. *Drosophila* utilize Hsp70 as their primary protective mechanism in response to heat shock. In tissue culture cells and embryos, that protein is sequestered into granules with astonishing speed after return to normal conditions. As with trehalose, its removal likely occurs because of interference with protein folding and progress of development (104,105). A similar explanation may underlie the puzzling finding that although *AtTps1* expression has been found in all *Arabidopsis* tissues examined, the disaccharide itself under normal conditions is detectable only at low levels, if at all (88).

As these incongruities continue to inspire further efforts, it is clear that in the nearly two centuries since its discovery, trehalose has indeed come full circle – from a component of the toxin ergot contaminating rye, to a versatile and valuable tool – in a transcendent irony with great promise for food biotechnology.

Production of Pectinases and Utilization in Food Processing

K.S. Venkatesh and S. Umesh-Kumar

CONTENTS

14.1 INTRODUCTION

Raw materials of plant origin are processed in a variety of ways for the production of food. Modern food processing uses enzyme preparations to improve pulp and juice yields from fruits, in wine preparation to increase the color and quality of the wine, in tea manufacture for flavor release, in oil extraction from olives, and in steeping maize for the recovery of sugar. In each of these processes, pectin degradation is an important step.

Pectin is a complex colloidal carbohydrate found in plants. Pectin is found in the middle lamella and primary cell walls of higher plants and is made of anhydrogalacturonic acid units. The carboxyl groups of galacturonic acid in pectin may be partly esterified by methyl groups or partly or totally neutralized by one or more bases. Pectic substances are produced in plants from a water insoluble parent pectic substance called

Protopectin. Pectinic acid is a colloidal polygalacturonic acid containing a methyl ester group.

Under suitable conditions, pectinic acids form gels with sugars and acids. If the methoxyl content is low in pectinic acid, gel formation can also occur with ions. Pectin contains pectinic acids of varying methoxyl ester content. This complex polysaccharide contains "smooth regions" of α-1, 4-linked D-galacturonic acid residues as the backbone, sometimes acetylated at *O*-2 or *O*-3 and methoxylated at *O*-6. In the "hairy regions", a xylogalacturonan consists of a D-xylose substituted galacturonan backbone. Similarly, rhamnogalacturonan and arabinogalacturonan contain rhamnose and arabinose respectively. Certain plant tissues show further complexity in their pectins. Sugar beet and apple pectins contain ferrulic acid as terminal residues attached to *O*-5 of arabinose residues, or *O*-2 of galactose residues. Side chains of rhamnogalacturonan also contain uncommon sugars such as 2-*O*-methoxy-L-fucose and 3-Deoxy-D-manno-2-octulonic acid. These variations in pectin structures are attributes of protective mechanism that the plants have evolved to protect against invading microorganisms.

The presence of such a complex heteropolysaccharide as pectin in the plant world necessitated identification of pectinases useful for food processing. Generally, the enzymes that act on pectic substances can be divided into two categories. The depolymerizing enzymes like polygalacturonase or pectin hydrolase and lyases act by hydrolytic or transeliminating cleavage of glycosydic bonds with endo- or exosplitting action, to break down the pectic acid or pectin. The saponifying enzymes, commonly referred to as pectin methyl esterases, catalyze the deesterification of the methoxyl group of pectin to make the molecule susceptible to hydrolytic enzymes. Several pectinases like rhamnogalacturonase, arabinofuronosidase, and xylogalacturonan hydrolases have found specific applications in food processing industries due to their ability to act on hairy regions of the pectin.

Aspergillus rhamnogalacturonase and xylogalacturonase hydrolytically cleave the main chain of rhamnogalacturonan and xylogalacturonan, respectively. Arabinofuranosidases hydrolyse both α-1,5-and α-1,3-glycosydic bonds of arabinan. The activity of these enzymes is hindered by the presence of acetyl residues in the pectin main chain. Hence, for efficient hydrolysis of sugar backbone, several enzymes called acetyl esterases have been characterized from *Aspergillus* species. All the hydrolyzing enzymes cleave the substrate through an inverting mechanism (1). The characteristics of the enzymes that degrade pectin are described in Table 14.1.

In food processing industries, hydrolases have wide application. In previous years, polygalacturonases and pectin methyl esterases were identified as enzymes that degrade pectin. Because pectin contains methylated polygalacturonic acid, which is not susceptible to polygalacturonase activity, predeesterification of the methyl groups by pectin methyl esterase is important for the activity of the pectin hydrolase and polygalacturonase. Recent advances in the elucidation of the pectin structure, specifically the hairy regions and their resistance to the activity of pectinases, led to the discovery of newer enzymes that found application in food processing. The advent of molecular biological techniques has also resulted in selective production of these enzymes industrially.

14.2 PRODUCTION OF PECTINASES

Though pectinases are produced by bacteria, mold, and yeasts, most of the commercial enzymes are produced from the mold *Aspergillus* (34). Typical commercial preparations of polygalacturonase from *Aspergillus* show different forms of the enzyme that cross react with a single antibody raised against one of the polygalacturonase (Figure 14.1).

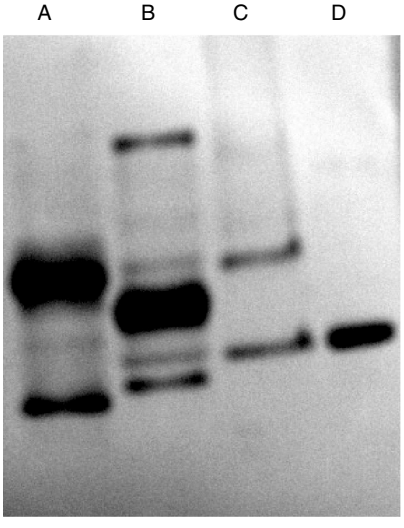

Figure 14.1 Different isoforms of polygalacturonase of *Aspergillus* identified by antibody cross reactivity on western blot reaction. The polygalacturonases of *Aspergillus niger* obtained from two commercial samples [A] & [B] were found to cross react with the antibody raised to a polygalacturonase purified from *A. carbonarius* culture filtrates [D]. Antibody reactivity of another polygalacturonase produced by *A. carbonarius* is also shown [C].

Differences in the molecular mass of polygalacturonases within the *Aspergillus* are also known (34) and it is believed that highly active polygalacturonase is produced by *A. carbonarius* (14). Given that degradation of plant pectin involves activity by several enzymes [Figure 14.2(a), 14.2(b)], commercial preparations generally contain more than one pectinolytic enzyme. Industrially, pectinases are produced by both solid-state fermentation (SSF) and submerged fermentation (SmF) methods using *Aspergillus* sp. Generally, SSF has been considered more suitable for obtaining a particular composition of the enzyme mixture with higher enzyme yields (35,36,37).

14.2.1 Submerged Fermentation

In submerged fermentation using *Aspergillus*, designing of a balanced fermentation medium has been found to be critical. Production of extracellular pectinase by this mold was shown to be induced by the presence of pectic material in the culture medium (38). Pectin is a high molecular weight polysaccharide. Enzyme induction is apparently due to low levels of basal constitutive activity produced by the organism that degrades the polymeric substrate. This results in low molecular weight products that serve as inducers in the cell to promote cell growth and pectinase production (39). General inducers added to the growth medium include sources rich in pectin like beet pulp, citrus peel, or apple pomace (38,40). The medium contains nitrogen, in the form of ammonium salts, corn steep liquor, distillers soluble yeast extract, gelatin, or casein. Mineral supplementation is also provided in the form of inorganic salts to achieve higher growth rates.

In SmF, for the production of pectinase, the type of pectin inducers used influence the pectic enzyme produced by the culture. When an alkali pretreated lemon peel was used, reduced pectin esterase activity was detected in the culture broth (41). In these culture filtrates, at least four times higher endopolygalacturonase activity was estimated. Extensive studies on polygalacturonase production from *A. niger* revealed that the productivity of this enzyme is a function of both temperature and cultivation medium (42). When the fungus was grown in a defined medium containing purified pectin as a carbon source, production of polygalacturonase was most efficient at 18°C and insignificant at 30°C. Higher enzyme activity was also obtained at acidic pH around 3.0 (37,43–49). In *Rhizopus nigricans,* production of endopolygalacturonase was found to be highest at pH 3.0 (50).

Catabolic repression of pectinase production in *A. niger* (44,51) defines a two stage fermentation system for obtaining higher enzyme yields. In such a system, the mycelia are developed using readily metabolizable sugars such as molasses and starch hydrolysates in the first stage. Enzyme synthesis is induced in grown mycelium in the second stage by feeding pectin containing substrate as a carbon source (43).

Mutation of *Aspergillus* spores and selection of mycelium that formed aggregates, such as clumps and pellets, were found to produce a higher concentration of pectinases in SmF (52). The addition of potassium hexocyanoferrate, which affected the morphology of *A. niger* to form small compact pellets with smooth surfaces, was reported to increase enzyme production, reducing viscosity of culture broth and improving the fermentation process for enzyme production (53).

14.2.2 Solid-State Fermentation

Solid-state fermentation (SSF) has been adopted as a fermentation technique for pectinase production, apparently because cellular regulations that affect enzyme production are absent when fungi are grown in solid-state substrates. Low water activity (a_w) in the substrate enhanced enzyme secretion during SSF (54). Reports in literature suggest use of wheat bran, cassava fibrous waste, citrus pulp waste, sugar cane bagasse, coffee pulp, and orange peel as substrates for the production of pectic enzymes using *Aspergillus* (54–60).

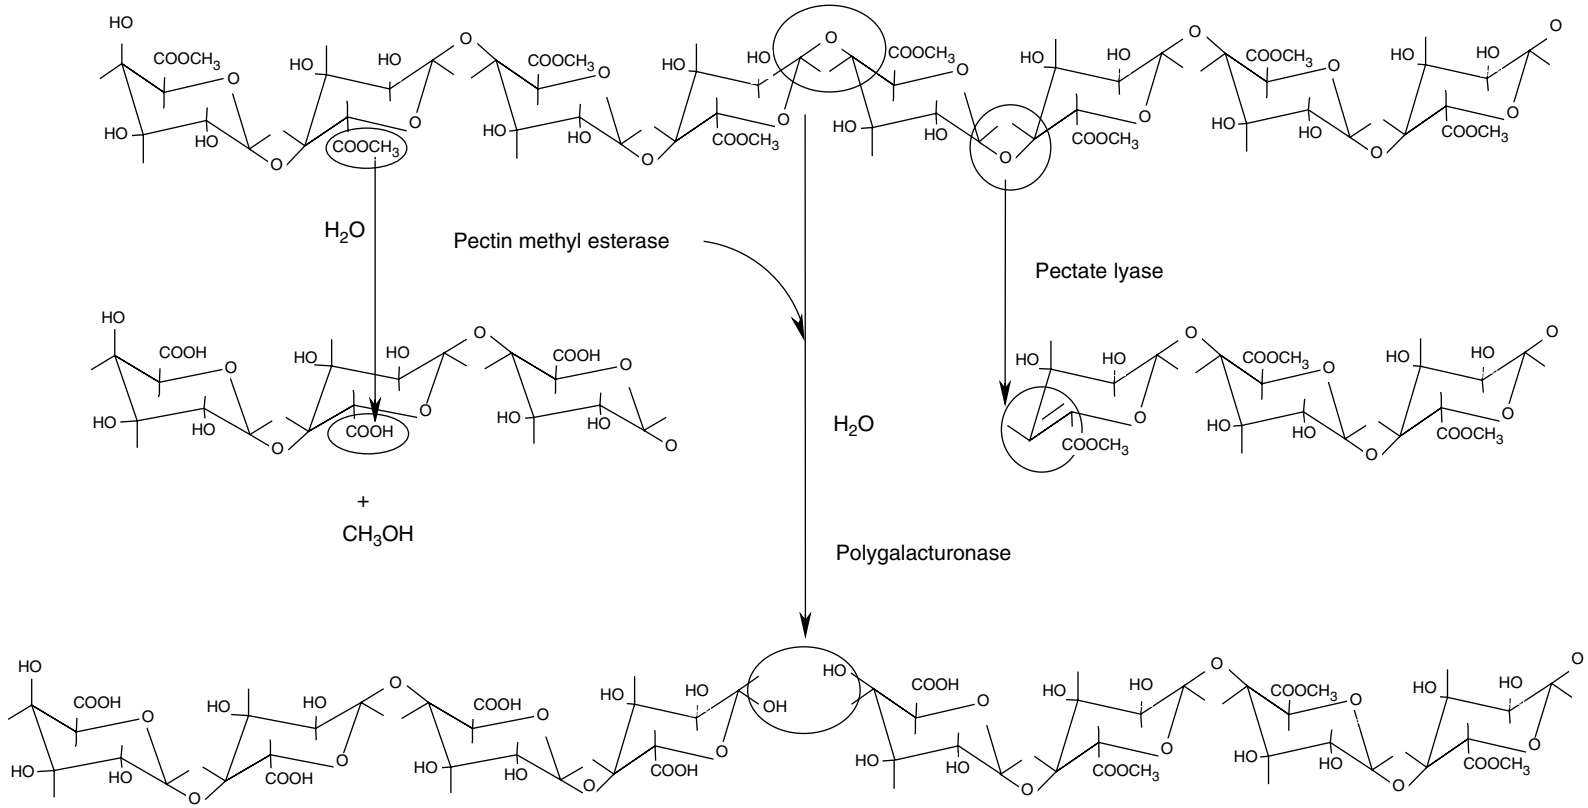

Figure 14.2(a) Pectin main chain structure and enzymes involved in degradation.

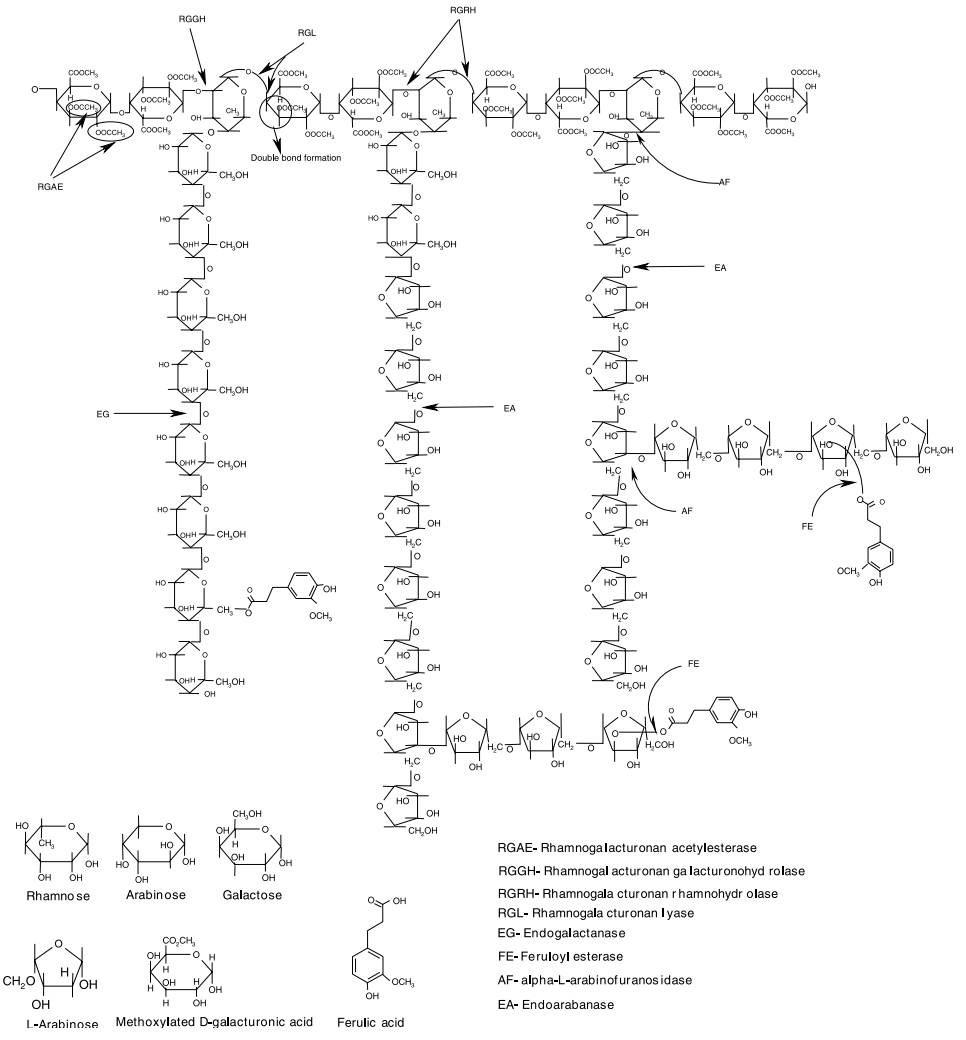

Figure 14.2(b) Structure of hairy region of pectin and pectic enzymes involved in the degradation.

In SSF, an initial acidic pH of the medium increased enzyme yields. In the authors' laboratory, a simple wheat bran based medium has been routinely used for the production of pectinase using *A. carbonarius* by SSF. The bran medium, containing 40% moisture, was acidified with 2N HCl before sterilization. Spores or actively growing mycelia in liquid culture were used to inoculate the substrate. An assay of the enzyme extracted from fermented substrate using 0.1 M of an acetate buffer of pH 4.3 detected maximum pectinases in bran medium after 60–72 h growth.

Glucose catabolic repression has been the major constraint in pectinase production in SmF by a wild-type strain of *Aspergillus* (43). Though in such strains, SSF cultivation gives greater enzyme yields than SmF, mutational selection to avoid regulation by glucose can make SmF an ideal choice of fermentation for pectinase production. This is because the cost inputs are less in SmF, with the added advantage of the absence of an extraction procedure. In SSF, the enzyme is usually dilute, unlike in SmF, due to the involvement of an extraction step using 1:3 to 1:5 ratios of fermented bran and buffer (61). Recently a

strain of *A. carbonarius* that constitutively produced polygalacturonase in SmF was isolated by ultra violet radiation induced mutation by the authors.

14.2.3 Strain Improvement

According to the type of fermentation system adopted for pectinase production using *Aspergillus*, several strain improvement strategies have been described.

In SSF, low a_w and efficient colonization of the substrate apparently dictated yields of pectinase. Hence, *dgr* (2-Deoxy D-glucose resistant) mutants selected for tolerance to low a_w were found to produce higher pectinase when grown in solid-state culture (59). Increased production of pectinase by such mutants was reasoned to be due to modification in the phospholipid fatty acid saturation in the membrane, causing increased permeability of pectinase into culture media.

Observations on differential pectinase production, according to mycelial structure, resulted in the isolation of slow growing mutant strains of *Aspergillus* that formed aggregated mycelia (52). This mutant, when grown in solid-state, produced more pectinase compared to the parent strain.

Inter- and intraspecific fusion of *Aspergillus* protoplasts have been attempted, to obtain strains producing higher pectinase activities during solid-state growth (62,63). Though the results were not encouraging, claims have been made that useful isoforms of polygalacturonases have been produced. One of the reports described fusion of protoplasts of *A. niger* with *A. flaviceps*. A strain isolated by fusion techniques showed increased enzyme production, growth, and specific activity (64).

In SSF, sporulation was identified as a constraint for industrial production of pectinase (55,62). Mutants of *A. carbonarius*, deformed in cell differentiation, were isolated as nonsporulant strains after UV radiation of spores of the parent strain. The nonsporulant mutant showed higher polygalacturonase production by SSF. In fungi, sporulation indicates cessation of growth. Sporulation has several disadvantages in industrial pectinase production by SSF because it contaminates the fermentation section and sometimes causes allergic reactions in the personnel. Absence of sporulation, in addition to improving pectinase production due to vegetative mycelial growth of the fungus, also avoided inherent difficulties of SSF described previously (62).

Cellular regulation of pectinase production by glucose (glucose catabolic repression) was shown to affect pectinase production by *Aspergillus* in SmF (65). In the authors' laboratory, glucose catabolic repression of polygalacturonase production by *A. carbonarius* was overcome by isolating specific mutants of the fungus after inducing mutation with UV radiation. The mutants were isolated by temperature selection at 42°C in a medium containing both pectin and glucose analogue 2-Deoxy-D-glucose, and the pectinase producing mutant was identified using ruthenium red or *O*-toluidine blue (66). The mutants so isolated produced constitutive polygalacturonase with activities about 200-fold higher than the parent strain, in a simple medium containing starch hydrolysates (67). Similar results on hyperendopolygalacturonase-producing mutants of *Aspergillus* strains have been obtained by inducing mutation with N-methyl-N'-nitro-N-nitrosoguanidine (NTG) and the selection of strains resistant to catabolic repression (68).

14.3 GENES OF PECTIN DEGRADING ENZYMES

Promoter deletion analysis of one of the genes (*pga*II) identified the region 5'-TYATTGGTGGA-3' as important for high level gene expression. This region had high similarity to the promoter *pgaA* of *A. niger*. Expression of most of the pectinase genes was reported to be induced by D-galacturonic acid. The induction of several other carbohydrases

like arabinofuronosidase, endoarabinase, β-galactosidase, and α-glucuronidase by galacturonic acid and glucuronic acid suggested a general system of gene expression in these carbohydrases (34). Galacturonic acid did not induce the *pgaB* gene, the promoter of which does not contain the 5'-TYATTGGTGGA-3', and this further augmented the importance of the promoter region in pectinase gene expression (69). A hexanucleotide sequence CCCTGA was identified in the promoters of several pectin lyase-encoding genes. Characterization of several pectinase genes including the gene of polygalacturonase has resulted in cloning and overexpression. These genes are described in Table 14.2.

14.4 PECTINASES OF *ASPERGILLUS*

Several enzymes involved in the degradation of pectin have been purified and their gene sequences obtained. Studies on the expression patterns of the lyase and hydrolase genes of *A. niger* showed differences in the expression patterns (78). The crystal structure of *A. aculeatus* polygalacturonase glycoprotein revealed one *N*- and ten *O*-glycosylation sites. The enzyme folds into a right handed parallel β-helix with the long T_1 loop containing a catalytic tyrosine residue. This residue was significantly different from that found in *A. niger* polygalacturonase. All three of the polygalacturonases analyzed had six subsites. It is hypothesized that the long T_1 loop of *A. niger* polygalacturonases undergos a conformational change upon binding of the substrate to bring the tyrosine residue close to subsite 1 (79).

Polygalacturonase I and II (PG-I and PG-II) were identified as major enzymes produced by *A. niger* (5,34). Probes designed based on the NH_2-terminal sequence of PG-I and PG-II and screening genomic DNA libraries of *A. niger* isolated five new genes. The products of these genes were also detected in *A. nidulans* transformants by western blot analysis, using antibodies raised against PG-I. The sequence of one of the polygalacturonases (*PGC*) identified three introns in the genomic DNA. The product of the gene, a 383 amino acid preproprotein was reportedly cleaved after a pair of basic amino acids. In the upstream region of the *A. niger* polygalacturonase gene, a conserved sequence CCAAT apparently represented a binding site for the regulatory protein (74).

Sequence analysis of *pga*A and *pga*B identified one intron in the former and two introns in the latter. Apparently, these enzymes are also synthesized as preproenzymes with the prosequences cleaved by a KEX2-like dibasic peptidase after the lysine and arginine residues (77). The N-terminal amino acid sequence of several polygalacturonases of

Table 14.2
Cloned genes encoding for pectinases in *Aspergillus*

Organism	Genes	Enzyme	Ref.
A. niger	*pel*A,	Pectin lyase-A	70
	*pel*B	Pectin lyase-B	71
A. niger,	*pga*II	Polygalacturonase-II	72
A. tubigensis			73
A. niger	*pga*I	Polygalacturonase-I	74
A. niger	*pga*C	Polygalacturonase-C	74
A. niger	*pme*	Pectin methyl esterase	75
A. nidulans	*pel*A	Pectin lyase-A	22
A. nidulans	*pel*D	Pectate lyase-D	76
A. niger	*prepro PG*II	Prepropolygalacturonase-II	77

Aspergillus identified three different enzymes. However, polygalacturonase III produced by *A. niger* and *A. oryzae* were similar (79). Sequence analysis of polygalacturonase identified 27 amino acids characteristic of a secretary signal sequence in NH_2-terminal, which is cleaved off in the mature protein (73,80).

A similar processing of rhamnogalacturonan acetyl esterase (RGAE) from *A. aculeatus* was described. The *rha*1 cDNA was also found to encode a signal peptide of 17 amino acids. The amino acid sequence of this enzyme did not show significant similarities with other pectinases, suggesting it as a novel enzyme representing a new family of esterases (33). Analysis of the endoxylogalacturonan hydrolase (xghA) of *A. tubingensis* cDNA revealed the presence of an 18 amino acid signal sequence in the NH_2-terminus. Comparison of the xghA amino acid sequence with sequences in the European Molecular Biology Laboratory (EMBL) data library revealed homology to polygalacturonase sequences of prokaryotes, fungi, and plants and to the *rhg*A and *rhg*B sequences of *A. aculeatus* and *A. niger* (18). The pectin methyl esterase protein of *A. aculeatus* had a molecular mass of 43 kDa as estimated on SDS-PAGE gels. The cDNA gene sequence revealed an apparent signal sequence of 17 amino acids with a typical signal cleave site between Ala-17 and Ala-18 (27).

Three polygalacturonases of molecular mass 61-, 42- and 47-kDa were purified and characterized from *A. carbonarius*. Of these enzymes, the polygalacturonase of molecular mass 42 kDa was highly active on a citrus polygalacturonate substrate with specific activity as high as 7000 U/mg of protein (14). Further studies on this enzyme in the authors' laboratory showed that the N-terminal amino acid sequence Gly-Ser-Cys-Thr-Phe of the protein was identical to the N-terminal sequence of polygalacturonase II of *A. tubingensis* (81), endopolygalacturonase III of *Sclerotinia sclerotiorum* (82,83), and polygalacturonase II of *A. niger* (84). Homology to polygalacturonase of *A. niger* (72) and *A. oryzae* (48) was also found in the four N-terminal amino acids. The polygalacturonases of *A. niger* and *A. oryzae* differed from *A. carbonarius* polygalacturonase in the first N-terminal amino acid. While Asp constituted the N-terminal amino acid in *A. niger* and *A. oryzae,* Gly was the N-terminal amino acid in *A. carbonarius*.

The structure of rhamnogalacturonan hydrolases A and B from *A. niger* predicted the occurrences of three introns at the same positions as identified in *A. aculeatus rhg*A. A high degree of homology was also found between rhamnogalacturonan hydrolase proteins of *A. niger* and *A. aculeatus*. Rhamnogalacturonan hydrolase B showed about 72% identity with rhamnogalacturonan hydrolase A protein of *A. aculeatus* (32).

14.5 CLONING AND EXPRESSION OF PECTINASE ENZYMES

Genomic DNA coding pectinase protein contains introns. Hence, cloning strategies used cDNA in heterologous hosts for expression of various enzymes degrading pectin. The protein expression in homologous hosts was also achieved by cloning genomic DNA of pectic enzymes. Enzyme overproduction using recombinant genes described multicopy expression systems, gene fusions, and expression under the control of strong promoters.

The promoters *pgaA* and *pgaB*, the two constitutively expressed endopolygalacturonases of *A. niger*, were cloned in *A. niger* plasmid pGW635 carrying the *pyr*A gene that encoded orotidine – 5'-phosphate decarboxylase as a selection marker for restoration of uridine prototrophy. The multicopy transformants were used for overproduction of the enzyme. For expression, promoter gene fusions were made in plasmids harboring *pki*A promoter. Standard assays performed indicated overproduction of both the enzymes. Product analysis using polygalacturonate revealed a random cleavage pattern for both the enzymes (8).

The heterologous expression of *A. niger* endopolygalacturonase in *Saccharomyces cerevisiae* yeast has been reported with technological advantages. Endopolygalacturonase cDNA was expressed under the control of the alcohol dehydrogenase (*ADH*I) promoter in yeast — the *Escherichia coli* shuttle vector. Because this yeast secreted only a few of its own proteins in culture fluid, heterologous gene expression yielded polygalacturonase with a high specific activity. It was observed that the enzyme secretion was efficiently directed by the fungal leader sequence and the processing of the enzyme occurred at the same site of yeast as in *Aspergillus*. A shorter version of yeast *ADH*I promoter enhanced the expression level. The yeast *ADH*I promoter is regulated by glucose, and glucose is essential for efficient induction. Hence, the removal of the upstream region of the promoter avoided this regulation. Removal of bacterial sequences from the expression vector increased the plasmid stability and plasmid copy. This led to an increased yield of heterologous protein. The yeast derived enzyme was more glycosylated than that obtained from the mold and showed the same biochemical properties (6).

The cloning strategy and heterologous gene expression of the polygalacturonase gene of *A. awamori* in *S. cerevisiae* involved the preparation of a cDNA probe using the N-terminal amino acid sequence "Ser-Thr-Cys-Thr-Phe-Thr". The gene was isolated from the genomic DNA by Polymerase Chain Reaction (PCR) and identified by southern hybridization. The gene library was prepared by inserting the *Hind* III digested fragment of DNA into pUC118. The transformed *E. coli* DH5α were identified by hybridization and the plasmid extracted from positive clones was used to isolate the polygalacturonase gene. The introns were excised by two step PCR and ligation. The "intron free" polygalacturonase gene was inserted between the phosphoglycerate kinase (*pgk*) promoter and terminator in a yeast expression plasmid containing the *LEU-2* gene as a selection marker. The transformed yeast reportedly secreted the enzyme whose molecular weight (41 kDa) corresponded with the native enzyme. Based on heterologous gene expression studies it was presumed that the glycosylation mechanism in the secretion path of *S. cerevisiae* was similar to that in fungi (81).

The rhamnogalacturonan hydrolase genes (*rghA* and *rghB*) identified in *A. niger* using the genomic rhamnogalacturonan hydrolase gene of *A. aculeatus* as a probe were cloned, and the proteins expressed in *A. niger*. For this study, a genomic library of *A. niger* was screened for the presence of the rhamnogalacturonan hydrolase gene. The expression of the proteins was achieved by putting the genes under the control of the endoxylanase A gene (*exlA*) promoter of *A. awamori*. Despite multicopy insertions, western blot analysis showed very little expression of the two proteins in *A. niger*. Transcription analysis for the mRNAs also showed very little expression. Multicopy integration of the gene in *A. awamori* improved protein expression with yields of 3 and 40 mg of purified rhamnogalacturonan hydrolase A and B, respectively, from one liter of culture fluid (32).

An *Aspergillus tubingensis* expression library constructed in *Kluyveromyces lactis* identified xylogalacturonan hydrolyzing activities in some recombinants that encoded a xylogalacturonan hydrolase containing 406 amino acids. This protein was used to define substrate activity, which appeared to be specific for xylose substituted galacturonic acid backbone (18).

A full length cDNA encoding the pectin methyl esterase isolated from the filamentous fungus *A. aculeatus* was cloned and expressed in *A. oryzae* in fungal expression vector pHD464 for expression of the protein. The expression host, which does not produce endogenous pectin methyl esterase or polygalacturonase, heterologously expressed the pectin methyl esterase of *A. aculeatus*. Though the amino acid sequence of recombinant enzyme showed homology with the authentic enzyme, it was found to be processed differently at the N-terminal by signal peptidase. The authentic enzyme was processed at the

21st amino acid by *A. aculeatus* whereas the heterologous host processed the recombinant enzyme at the 18th amino acid at the N-terminal and it had more glycosylation than the authentic enzyme (27).

A DNA probe constructed based on the N-terminal sequence of rhamnogalacturonan acetylesterase (rha1) of *A. aculeatus* was used to isolate cDNA, encoding the 250 amino acids of precursor protein with a 17 amino acid sequence of signal peptide from the cDNA library. The sequence was expressed in *A. oryzae*, a strain that did not have rhamnogalacturonan acetylesterase activity. Subcloning the cDNA behind the *A. oryzae* α-amylase promoter and expressing the resultant in *A. oryzae* yielded high level production of *rha1* (33).

A heterologously expressed glycoprotein, rhamnogalacturonan acetyl esterase from *A. aculeatus* in *A. oryzae*, was used to elucidate the structure and function of this new family of hydrolase. It was found that the rhamnogalacturonan acetylesterase protein folded into an α/β/α structure, with the active site as an open cleft containing "Ser-His-Asp". The sequence similarities and active site residues suggested that this enzyme, with seven other proteins, formed a new hydrolase family, the SGNH hydrolase family ,which included the carbohydrate esterase family 12 (85,86).

14.6 REGULATION OF PECTINASE PRODUCTION IN *ASPERGILLUS*

Aspergilli that produce pectic enzymes are known to grow over a wide pH range. In *A. kawachi*, it was demonstrated that the pH of the culture broth influenced the type of polygalacturonase produced by the fungus (48). Thus, a role for the pH regulatory protein (PacC) was identified in pectinase gene regulation.

Generally, pH regulation is mediated by *pac* genes, *pac*C, *pad*A, *pal*B, *pal*C, *pal*F, *pal*H, and *pal*I. Mutations that mimic acidity, alkalinity, and neutrality gene expressions have been obtained. This suggested direct involvement of a key transcription factor, which is a product of *pacC*, in the regulation of gene expression by ambient pH. The major arabinofuronosidase gene is reportedly regulated by PacC (87). Evidence suggesting acidic pH induction of polygalacturonase production in *A. carbonarius* (Figure 14.3) was also obtained recently in the authors' laboratory. Hence, regulation of pectinase gene expression apparently is controlled by pH, as in the genes encoding several cell wall degrading enzymes like xylanases and cellulases (88,89).

14.7 APPLICATIONS

Pectinases are enzymes involved in the degradation of the plant cell wall. Hence, these enzymes are applied to provide a good alternative to chemical processing. Figures 14.4, 14.5, and 14.6 describe examples of pectinase applications in industrial processing of fruits. Major applications involve their wide spread use in the beverage industry, due to their ability to improve pressing of fruits and clarification of fruit juices. In wine production, pectinases are used to improve the juice and color yields, enhancing the clarity of the wine. Pectinases, when applied along with other cell wall degrading enzymes, result in increased yields of the oil that can be extracted from lemon peel and olive fruits. Other applications are in the production of carrot puree and neutraceutically important oligouronides, the monosaccharides which are the building blocks of pectin polymer. Arabinose, which is the precursor for α-fructose and L-glucose, released from the pectin polymer arabinogalacturonan (commonly found in apples) can be used as a noncalorific sweetener

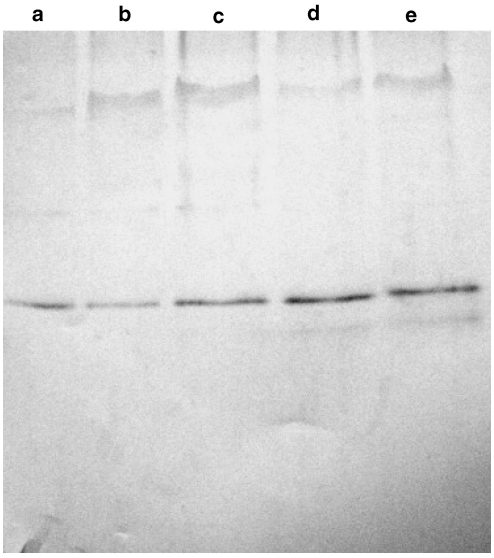

Figure 14.3 Effect of pH on polygalacturonase production in *A. carbonarius*. The fungus was grown at pH 5.0 (a), 4.5 (b), 4.0 (c), 3.5 (d), and 3.0 (e). in a medium buffered to the required pH with 0.25M citrate phosphate buffer. Polygalacturonase was quantitated by the intensity of the reaction in Western Blots after SDS PAGE with identical protein concentrations. Antibody used for this reaction was raised in rabbit using the purified protein (Figure 14.1, column D).

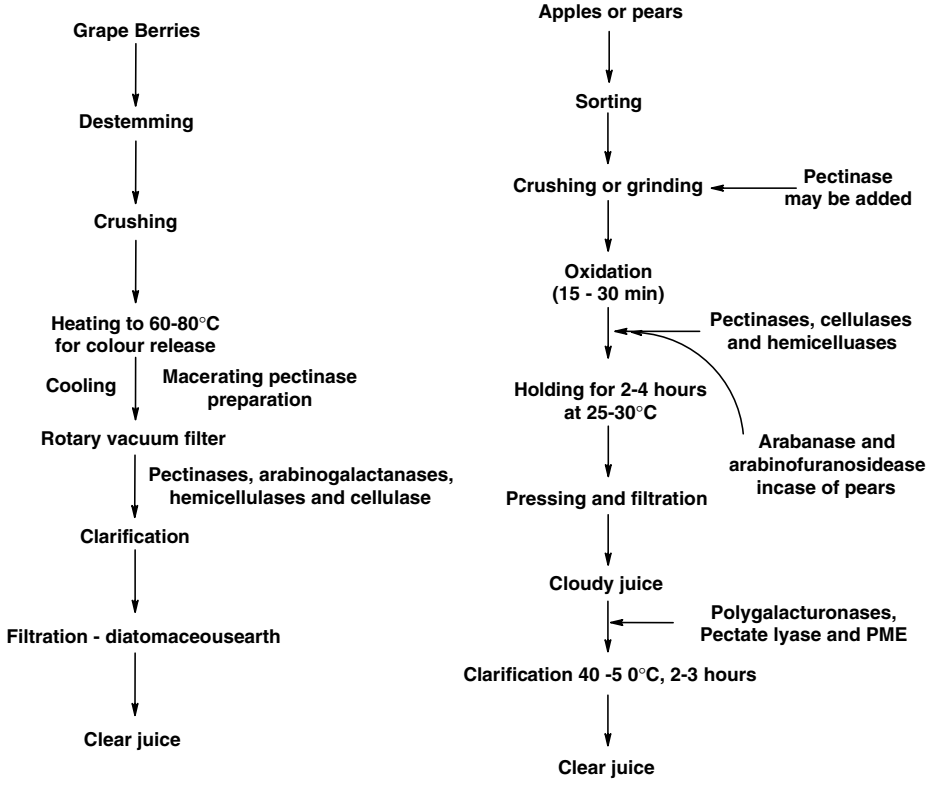

Figure 14.4 Application of pectinases in the processing of fruits for juice production.

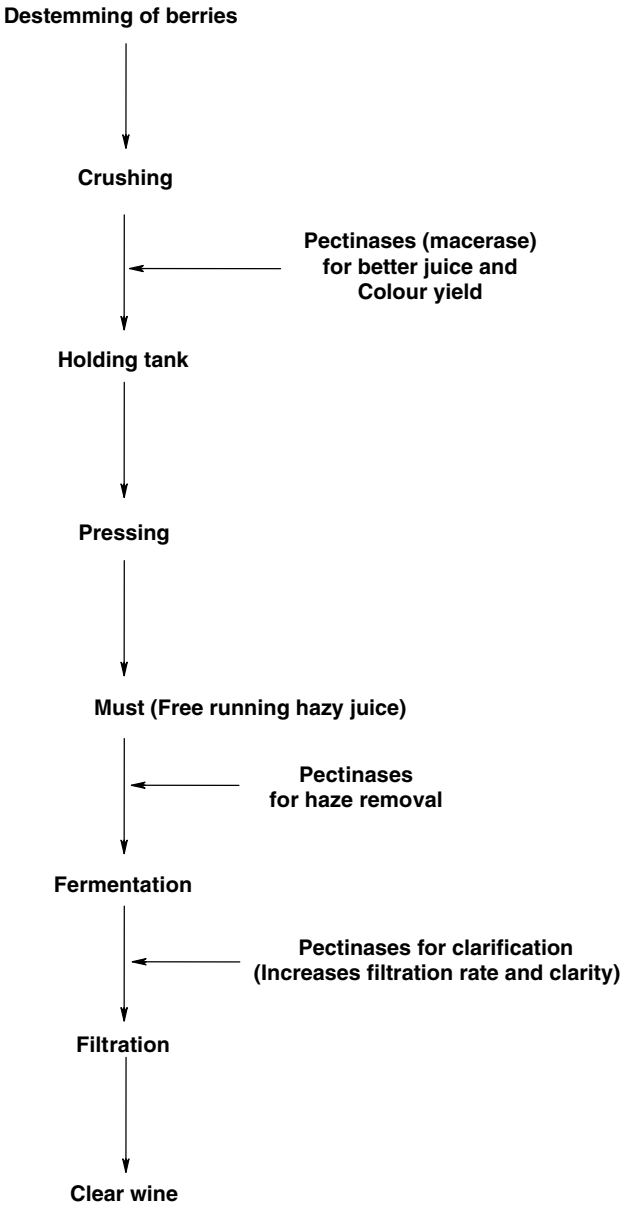

Figure 14.5 Application of pectinases in wine production.

in low calorie foods. 5-Deoxy-L-arabinose has been reported to have anti-Parkinson properties (90). Furaneol can be obtained by transformation of arabinose, the sugar obtained from arabinogalacturonan. Polygalacturonases that produce galacturonic acid make a good substrate for L-ascorbic acid. Galacturonic acid can also be used to produce surface active agents by esterification with fatty acids. Furaneol is used in caramel as fruit flavor (91). Furaneol can be obtained by chemical transformation of rhamnose released from rhamnogalacturonan by rhamnogalacturonan hydrolase. Coffee beans contain pectin in their mucilage coat and pulp. Use of pectinases along with cellulases and hemicellulases accelerate the removal of mucilage coat during coffee processing. Likewise, in the manufacture of tea, the degradation of tea leaf pectin helps in tea fermentation by improving the foam

Figure 14.6 Application of pectinases in oil extraction.

forming property in plant tea powders. Application of pectinases describes processing of plant materials. Recently, *in vivo* modification of plant polysaccharides has been reported using *Aspergillus* enzymes. Transgenic plants containing the *A. aculeatus* endogalacturonase encoding gene have been used to reduce the galactosyl content of rhamnogalacturonan I by 70% (92).

Bioactive food ingredients using pectin are emerging as food products. The oligogalacturonides produced by enzymatic degradation of pectin serve as nondigestible health promoting compounds analogous to the biologically active fructo-oligosaccharide molecules. These oligosaccharides are termed as "prebiotic" because they support the growth of beneficial intestinal bacteria (93).

Pectinases also find application in papermaking; wastewater treatment, especially from citrus processing industries; vetting and degumming of fiber; and for the production of protoplast useful in plant breeding by genetic manipulation.

14.8 PERSPECTIVES

Microbial pectinases have been used to identify variation in pectin polymers of plant tissues. These studies have resulted in the characterization of newer microbial enzymes useful in food processing industries. The structural features of pectinases, the amino acid

sequence of the enzyme protein, and their properties and characteristics are emerging as important contributions. These may predict changes in enzyme functionalities. Research in this direction can decipher the problem of haze and precipitation often encountered by fruit juice industries due to the conversion of the soluble L-arabanan to less soluble (1→5)-L-arabanan by the unwanted enzymes acting on arabanan. Apparently this requires enzymes that have greater activity on (1→5) linkages of arabanan than on (1→3) linkages. A possible solution to this problem is protein engineering, because we now know that the two hydrolytic activities reside in a single enzyme.

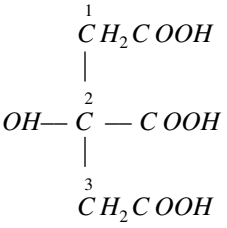
Biotechnology of Citric Acid Production

T. Roukas

CONTENTS

15.1 INTRODUCTION

Citric acid (2-hydroxy-1,2,3-propanetricarboxylic acid), a tricarboxylic acid, has the following structure:



It is naturally found in fruits such as lemon, orange, pineapple, plum, and pear; in the seeds of different vegetables; and in animal bone, muscle, and blood (1,2). Citric acid was first commercially obtained from lemon juice, crystallized in 1784 by Carl Wilhelm Scheele, a Swedish chemist (2,3). Citric acid produced from fruits is known as "natural citric acid," in contrast to that produced by microorganisms (3). Although citric acid is currently being chemically synthesized, there is no chemical method that is superior to microbial fermentation. In 1893 Wehmer investigated citric acid production from sucrose with strains of *Mucor* and *Penicillium* (1). This experiment was not successful and was abandoned in 1903. Difficulties included the selection of proper microorganisms, microbial degeneration, contamination, long fermentation time, high plant construction cost, and an insufficient spread between raw material cost and the price of finished product (4). Wehmer reported that until 1910 no successful citric acid fermentation process was carried out. Until 1920 all commercially produced citric acid came from lemon or lime juice (5). In 1917 Currie described the first production of citric acid with *Aspergillus niger*. He reported that different strains of *A. niger*, grown in low pH medium supplemented with 15% (w/v) sucrose plus nutrients, converted 55% of the sugar to citric acid (4). Citric acid was isolated from the fermentation broth as insoluble calcium citrate by adding calcium hydroxide, followed by regeneration of the acid using sulfuric acid. Citric acid crystallizes into two forms: anhydrous and monohydrous. The anhydrous form is produced at a temperature exceeding 36.6°C while the monohydrate is produced at temperatures of up to 36.0°C (1,5). By 1930 a number of manufacturers used the submerged *A. niger* fermentation process for the production of citric acid from sucrose (5,6). In 1952, America Miles Company (Miles Laboratories, Inc., Elkhart, IN) used the submerged fermentation process in a pilot program on a plant scale to produce citric acid. Little information exists about the processes they used. From the results claimed in their patents, however, it is clear that they used pretreated molasses with a cation exchanger as a substrate deficient in phosphate, iron, and manganese

(3,4). After 1952, many countries used glucose or beet and cane molasses as substrates to produce citric acid. Among the microorganisms producing citric acid, strains of *A. niger* have been used, but more recently, some yeast strains (*Yarrowia, Hansenula, Pichia, Torula*) have also been employed. These strains, which were isolated from soil or plant material, were further improved by mutation (7). Recently, different strains of yeasts have been used instead of *A. niger* for the production of citric acid (8–11). Today, most citric acid used in food and other industries is produced by microbial fermentation.

Two methods are commonly used for the production of citric acid by *A. niger*: surface fermentation and submerged culture fermentation. Beet and cane molasses were for many years the preferred substrates for the production of citric acid. The production of citric acid from n-paraffins by different strains of *Candida* or other yeasts has been developed (8,11–15), but due to production of isocitric acid during fermentation as well as the prohibitive price of petroleum products, this method has proved uneconomical and has never been used commercially (7,10,11).

The current annual world production of citric acid among 35 countries is ~600,000 tons (16). Among these, the two largest manufacturing areas are Western Europe followed by the USA. However, the USA is still a net importer of citric acid, while Western Europe is a net exporter (11). Citric acid is used in the food and beverage industries (70%), in pharmaceuticals (12%), and in other industries and applications (18%) (3,17–19). It is also used for metal cleaning, as an acidulant in soft drinks and confectionary, and can serve as a buffer and pH stabilizer, as well as a fat antioxidant in various food products (2,7). In the food industry it is used as a preservative in that it prevents color and flavor deterioration, inhibits oxidation, protects ascorbic acid from oxidation, inactivates oxidative enzymes, acts as an antioxidant, and is an emulsifier in dairy products. Citric acid is used in the preparation of soft drinks, desserts, jams, jellies, candies, wines, and frozen fruits. It also provides a tart taste in soft drinks. In the pharmaceutical industry, it is used in syrups, astringents, and effervescent tablets and powders. It is also used in blood transfusions. In the chemical industry, its uses include water conditioning, metal pickling, and used as a foam inhibitor for vinyl sheeting and polyester resin. Also, it is used as a nontoxic plasticizer to make plastic film (2). Citric acid can be used to adjust pH levels that are neutral or high, thus permitting its wide application in industry in areas such as electroplating, leather tanning, and reactivation of oil wells where pores of the sand face have become clogged with iron (20). Finally, citric acid is used in the detergent industry to replace phosphates and in the removal of sulfur in stack gases and other industrial facilities (3).

15.2 MICROORGANISMS USED FOR THE PRODUCTION OF CITRIC ACID

15.2.1 Fungi

The selection of a suitable fungus strain is critical to the production of citric acid, because he fungus plays a central role in the process. A strain used in an industrial scale operation should have long term stability, high sporulation, good growth in the substrates, a short fermentation time, resistance to other microorganisms, and produce a high concentration of the acid (70.0–100.0 g/L) in different fermentation systems. Citric acid's production stability is difficult to maintain because of spontaneous mutation and autolysis of the strains during fermentation. These problems can be avoided by periodic reisolation from single spores, storage at low temperature (4.0–7.0°C), and avoidance of "foggy" patches of sterile mycelium (fungal mat lacking spores) when mass transfers are made (6).

Over the years, many microorganisms have been used for the production of citric acid. However, *A. niger* still remains the microorganism of choice in industrial scale production. Other microorganisms, such as yeasts and bacteria, produce potentially large amounts of citric acid (50.0–70.0 g/L), but until recently they have not been used for commercial production (3). There is general agreement that only selected strains of *A. niger* are useful citric acid producers because they can be handled easily, are inexpensive, and give high and consistent yields, thereby making the process economical. Other species of *Aspergillus* which have been found to accumulate citric acid include strains of *A. awamori, A. fenicis, A. fonsecaeus, A. luchensis, A. fumaricus, A. wentii, A. saitoi, A. usami, A. phoenicus, A. lanosus, A. foetidus,* and *A. flavus* as well as some strains of *Penicillium* such as *P. janthinellum, P. simplicissimum,* and *P. restrictum* (3,6,21–24). Fungi that produce citric acid include strains of *Trichoderma viride, Mucor piriformis, Ustulina vulgaris,* and species of *Botrytis, Ascochyta, Absidia, Talaromyces, Acremonium,* and *Eupenicillium* (3,6). The yields of citric acid obtained with these strains are lower than those obtained with strains of *A. niger.* It is generally recognized that *A. niger* consists of a large group of strains that differ from one another in their morphology and biochemical characteristics. The differences reported include: color of spores and mycelium, size and quantity of spores, mycelium size, substrate utilization, fermentation time, and ability to produce citric acid from different substrates (6,25–27). Industrial scale production by fungi has been carried out from chemically defined media or beet and cane molasses using surface or submerged fermentation. Today, almost all citric acid produced by fermentation is manufactured by strains of *A. niger* in submerged culture.

15.2.2 Yeasts

Although *A. niger* is the traditional producer of citric acid, in the past 30 years researchers have been attracted to the use of yeasts as citric acid producers (9). Yeasts have some advantages compared to *A. niger* strains. The fermentation time is short (half the time of *A. niger* fermentation) and thus, productivity is higher. Yeast strains are insensitive to molasses variations and can be used for developing a continuous process (3,5). Also, yeasts are not only more tolerant of contamination, but are capable of metabolizing high initial sugar or n-alkane concentrations (100.0–150.0 or 40.0–60.0 g/L, respectively), with rapid growth resulting in high productivity rates. Moreover, they have a greater tolerance for metal ions, thus allowing the use of less refined substrates. These capabilities can lead to significant reductions in substrate and waste treatment costs and in product recovery costs (10,11). The advantages of using n-alkanes over carbohydrates are potentially lower costs for substrates and higher citric acid concentrations (11). The major disadvantage of using yeasts is the production of isocitric acid during fermentation. The amount of isocitric acid produced depends on the yeast strains used, the chemical composition of the substrates, the fermentation system, and generally the conditions under which fermentation takes place. To overcome this problem, some methods have been developed to reduce the amount of isocitric acid produced. For instance, the utilization of mutants that are sensitive to fluoroacetate results in the production of very small amounts of isocitric acid (5).

The variety of yeasts that produce citric acid belong to the genus *Candida, Saccharomycopsis*, *Hansenula, Pichia, Debaryomyces, Torulopsis, Kloeckera, Trichosporon, Torula, Rhodotorula, Sporobolomyces, Endomyces, Nocardia, Nematospora, Saccharomyces*, and *Zygosaccharomyces* (3). Among these, strains of *Candida* are widely used for the production of citric acid. These strains include *C. lipolytica, C. tropicalis, C. zeylanoides, C. fibrae, C. intermedia, C. parapsilosis, C. petrophilum, C. subtropicalis, C. oleophila, C. hitachinica, C. citrica, C. guilliermondii,* and *C. sucrosa* (3,8–15,28–39). Recently, the production of citric acid by immobilized and mutant strains of *C. lipolytica* has been reported (40–51). The mechanism by which *C. lipolytica* produces a high concentration of

citric acid is unclear. In general, unlimited growth of *C. lipolytica* in a rich medium results in low citric acid production. However, citric acid can be produced in increased amounts if yeast growth is properly restricted during the acid producing phase of fermentation (11). Production by yeasts, carried out in aerobic and agitated fermentation broth and at temperatures of 25–35°C, depended on the yeast strains and equipment used. The medium consisted of either glucose, molasses, n-alkanes, n-paraffins, methanol, butanol, ethanol, $C_{12–16}$ alcohols, acetate, fatty acids, and natural oils, or fats supplemented with nitrogen sources such as $(NH_4)_2SO_4$, NH_4NO_3, or NH_4Cl, KH_2PO_4, $MgSO_4 \bullet 7H_2O$, $CaCO_3$, thiamin hydrochloride, vitamin B complex, and trace elements such as Fe^{2+}, Zn^{2+}, Mn^{2+}, and Cu^{2+} (3,9–14,28–39). The medium was inoculated with 10–12% (v/v) of *C. lipolytica* (culture aged 48 h). Crolla and Kennedy (11) reported that excess inoculum concentration leads to high biomass concentration (20.0 g/L) and lower citric acid production (25.0 g/L), while low amounts of inoculum lead to long fermentation times.

Citric acid production by yeasts in the laboratory employs two phases: (1) a preliminary growth phase on a complete medium, followed by (2) a production phase without nitrogen sources. In some cases the medium is supplemented with limited amounts of nitrogen (1.0 g/L) in order to keep cellular activity at an acceptable level (10). In industrial scale production with *Y. lipolytica*, three steps have been identified: (1) the exponential growth phase, (2) the citrate production lag phase, and (3) the linear production phase. The production phase is connected to a preliminary reduction in intracellular nitrogen content (10). Fermentation runs from 3 to 6 days, with pH controlled at 4.5–6.5. Citric acid concentrations varied from 20 to −60 g/L,, depending on the strain used, the substrate (synthetic or byproduct), the fermentation system (surface culture or submerged fermentation), and the general conditions under which fermentation took place (initial sugar concentration, pH, and temperature). The yeast based process for citric acid production was maintained at neutral pH (5). Thus, the citrate produced was a sodium or calcium salt, which complicated recovery. In order to produce citric acid by yeast in industrial scale, further research is needed in selecting a high citrate producing strain and in optimizing its metabolic pathways as well as in understanding the best operating conditions for minimizing the production of isocitric acid (10).

15.2.3 Bacteria

Little information is available on the production of citrate by bacteria, as most of the references in the literature are to patents (3). Bacteria generally include *Bacillus, Brevibacterium, Arthrobacter, Corynebacterium, Klebsiella, Aerobacter, Pseudomonas,* and *Micrococcus.* Among these, *B. subtilis, B. licheniformis, B. flavum,* and *A. paraffinens* are the most promising (3,52). Kapoor et al. (3) reported that *B. licheniformis* grown in medium containing glucose, urea, calcium carbonate, and ammonium sulfate or glutamate (pH 7.0) produced 42.0 g/L of citric acid. Also, strains of *A. paraffinens, Corynebacterium* sp., and *Bacillus* sp. yielded maximum citric acid concentrations of 28–40 g/L when they were grown in media containing dodecane or a mixture of C_{12}–C_{14} paraffins (3). In all cases the fermentation was aerobic at 30–37°C for 2–5 days, depending on the strain and the composition of medium used. Generally, citric acid production by bacteria was 50–100% lower than that by fungi or yeasts. Nonetheless, these reports have opened a new avenue for the production of citric acid by bacteria.

15.3 BIOSYNTHESIS OF CITRIC ACID

The metabolic pathways by which *A. niger* converts glucose or sucrose to citric acid are outlined in Figure 15.1. Citric acid biosynthesis involves both the Embden–Meyerhof–Parnas

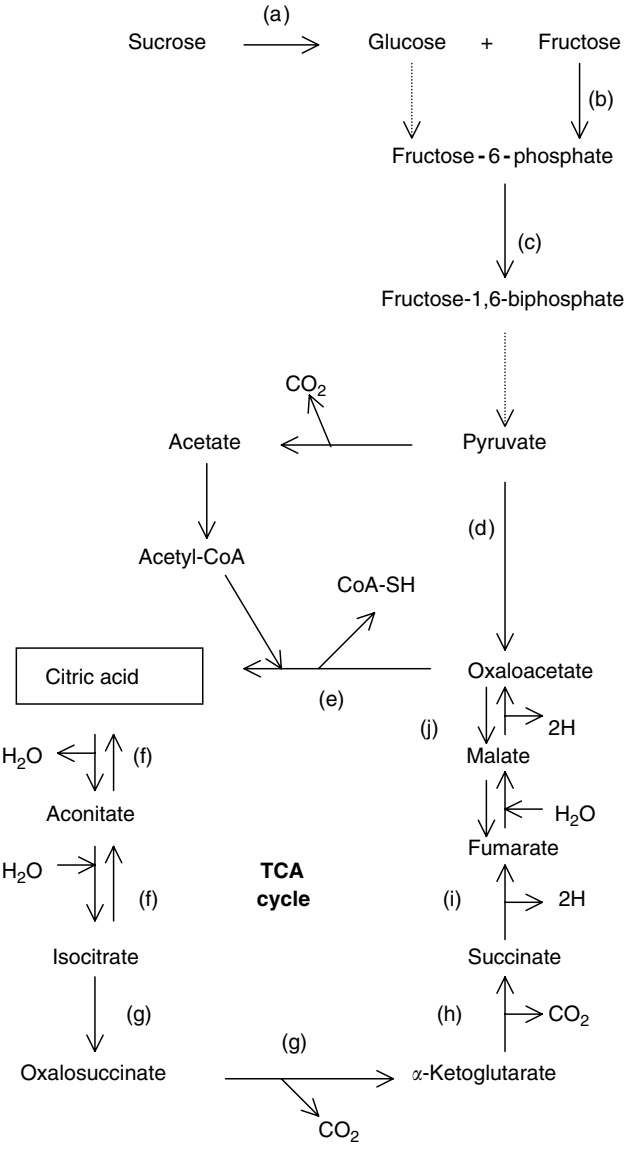


Figure 15.1 Biosynthesis of citric acid from sucrose by *A. niger*. (a) Invertase; (b) hexokinase; (c) phosphofructokinase; (d) pyruvate carboxylase; (e) citrate synthase; (f) aconitase; (g) isocitrate dehydrogenase; (h) α-ketoglutarate dehydrogenase; (i) succinic dehydrogenase; (j) malate dehydrogenase. (From Milsom, P.E., *Food Biotechnology*: 1, King, R.D., P.S.J. Cheetham, eds., London: Elsevier Applied Science, 1987, pp 273–308).

(EMP) pathway and the tricarboxylic acid (TCA) cycle (3,5,7,53–55). Citric acid is formed by condensation of acetyl-coenzyme A with oxaloacetic acid. Experiments with $C^{14}O_2$ indicated that CO_2 was the source of the a-carboxyl group of oxaloacetate (54). Woronick and Johnson (54) and Kapoor et al. (3) reported that *A. niger* contains two different systems for synthesizing C_4 dicarboxylic acids by condensing CO_2 with 3-carbon units. One of these systems seems to be identical to the phosphoenol pyruvate carboxylase kinase system:

$$\text{Phosphoenol pyruvate} + \text{ADP} + CO_2 \rightleftharpoons \text{Oxaloacetate} + \text{ATP} \qquad (15.1)$$

The second system requires pyruvate and ATP to produce oxaloacetate, and the reaction catalyzes by pyruvate carboxylase:

$$\text{Pyruvate} + CO_2 + H_2O + \text{ATP} \rightleftharpoons \text{Oxaloacetate} + \text{ADP} + P_i \qquad (15.2)$$

The major radioactive products were aspartate, malate, and fumarate, and were found to be present in the same ratios (1.6:4.3:1) as in the phosphoenol pyruvate plus ADP system (54). The citrate is metabolized via isocitrate to oxalosuccinate, which loses one CO_2 to yield a-ketoglutarate, which, in turn, loses a further molecule of CO_2 to form succinate. It is further metabolized via fumarate and malate to regenerate oxaloacetate (5). Smith and Anderson (55) studied the activities of the most important enzymes of the EMP and pentose phosphate (PP) pathways and found that the enzyme activities showed both EMP and PP pathways were present and operative at all stages of conidiophore development, but that the relative activities of the pathways differed. The highest activity of the EMP pathway occurred during the initial period of vegetative growth before any signs of morphological change. High EMP activity and high 6-C/1-C ratios were obtained in a medium that did not support conidiophore initiation but allowed vegetative growth (55). Generally, during conidiophore differentiation, PP pathway enzymes were higher in activity (0.35 units/mg protein) than EMP pathway enzymes (0.12 units/mg protein). The direct oxidation of glucose through the PP pathway may be of considerable importance during conidiophore development in *A. niger.*

Because *A. niger* produces both invertase and hexokinase (HXK), which convert sucrose to fructose-6-phosphate, sucrose can be used as a source for the production of citric acid. Verhoff and Spradlin (56) reported that only 10% of the glucose is available for the production of mycelia and CO_2, both of which occur primarily during the growth phase early in fermentation. Thus, practically all the glucose entering into the cell during the citric acid production phase must be converted to citric acid. However, Nowakowska and Sokotowski (57) found that the conversion yield of glucose to citric acid, mycelium, and CO_2 was 79.0%, 10.0%, and 11.0%, respectively. Steinbock et al. (58) reported high HXK activity when *A. niger* was grown in media containing high concentrations of glucose or sucrose (200.0–250.0 g/L). The specific activity of HXK was ~40 and 35 mmol/min/mg protein with glucose and fructose as substrates, respectively. Also, glucose affinity was about tenfold higher than for fructose. Finally, they found that the synthesis of very high HXK activities counteracted citrate inhibition, thereby guaranteeing a high glycolytic flux during citric acid accumulation. The key enzymes that were responsible for the biosynthesis of citric acid from sucrose by *A. niger* were phosphofructokinase (PFK), pyruvate kinase (PKI), pyruvate carboxylase, citrate synthase (CS), aconitase (ACH), and isocitric dehydrogenase (ICDH). Phosphofructokinase is an essential enzyme for the conversion of glucose or fructose to pyruvate. Inhibition of PFK by citrate is nullified by an accumulation of NH_4^+ in the cells. This state results from manganese deficiency, which also adversely affects the synthesis or activity of ACH and ICDH (7). Phosphofructokinase inhibition by citrate produces a measured feedback control over the whole system (5). Phosphofructokinase inhibition was observed in low citric acid producing strains, but was not observed in high yielding strains. Moreover, elevated levels of ammonium ion in the cells relieve the inhibition of PFK by citrate.

Pyruvate carboxylase catalyzes the reaction of pyruvate to oxaloacetate. Smith and McIntosh (59), who studied the effect of dilution rate on PFK and PKI activity, and found that these enzyme activities varied directly with dilution rate under glucose limitation in chemostat culture. Jaklitsch et al. (60) reported that pyruvate carboxylase was found predominantly or exclusively in cytosol. Also, low level activity of this enzyme was present in the mitochondria during the microbial log phase. Hence, intracellular distribution of pyruvate

carboxylase may be influenced by culture conditions. Thus, pyruvate carboxylase is present in both the mitochondrion and the cytosol, with the proportion in the cytosol rising as culture age increases (60). When *A. niger* was cultivated in media containing glucose, sucrose or fructose stimulate citric acid, which also led to increased intracellular levels of fructose 2,6-disphosphate, a potent activator of PFK. Ruijter et al. (61) studied the effect of overexpression of PFK and PKI in citric acid producing *A. niger* and found that PFK or PKI, or both simultaneously, did not significantly increase citric acid production. Data suggest that overexpression of PKI has a negative effect on citric acid production. Increased PFK and PKI did not influence the activities of other enzymes in the pathway, nor did they change intermediary metabolite levels. Strains of *A. niger* produced high concentrations of PFK (0.84 units/mg protein), while the level of fructose 2,6-disphosphate was reduced almost twofold when wild-type *A. niger* was used. Furthermore, a reduction in the fructose 2,6-disphosphate level decreased significantly (30–40%) the specific activity of PFK. Generally, PFK and PKI did not contribute in a major way to flux control in the biosynthetic route involved in the formation of citric acid (61). With use of mutant strains of *A. niger* during increased citric acid production, the activities of HXK and PFK appeared to be twofold higher than with the use of the parental strain. However, improved citric acid production was not due to higher PFK activity but to increased HXK activity (61). In the case of citric acid production by yeasts, the effect of overproduction of PFK, PKI, and a number of other glycolytic enzymes on glycolytic flux was investigated. The results showed that none of the enzymes increased glycolytic flux. One exception was a small increase in glycolytic flux upon overexpression of PFK (61).

Because pyruvate dehydrogenase and CS are present only in the mitochondria, the synthesis of citrate from pyruvate is localized in mitochondrion. Szczodrak (62) studied the activity of selected enzymes of the TCA cycle in *A. niger* mycelium and found that CS activity was maintained at almost the same level or increased slightly until the maximum concentration of citric acid was reached (60.0 g/L). During citrate decomposition, the decrease in CS activity was very high compared to its initial activity. Ruijter et al. (63) reported that overproduction of CS did not increase the rate of citric acid production by *A. niger,* suggesting that CS contributes little to flux control in the pathway involved in citric acid biosynthesis. No significant changes were observed in the activity of other enzymes relevant to citric acid production, such as glycolytic enzymes, pyruvate carboxylase, malate dehydrogenase, and pyruvate dehydrogenase. Furthermore, overproduction of CS did not cause significant changes in the levels of intermediary metabolites (L-malate, oxaloacetate, and ATP). The activities of ACH and both dehydrogenases (NAD-ICDH and NADP-ICDH) decreased significantly with an increase in citric acid concentration (3,5,60,64,65). The activity of ACH was highest in the growth phase of the microorganism. Experiments showed that the activities of the above enzymes never disappeared completely during citric acid production by *A. niger* (62). Decrease in the concentration of citric acid is accompanied by a distinct increase in the activity of the enzymes responsible for the degradation of this acid (ACH and ICDH) as well as a large decrease in CS activity (30–40%). Based on the above observations it was concluded that citric acid production is affected by a larger inhibition of ACH and ICDH activity rather than by an increase in CS activity. Milsom (5) reported that NAD-ICDH was present in the cytosol, and two NADP-specific enzymes (NADP-ICDH and $NADP^+$-specific ICDH) were present in the mitochondria. Generally, mitochondrial enzymes were inhibited by normal concentrations of citric acid (60.0–70.0 g/L) while the cytoplasmic enzyme was not so inhibited (5). Moreover, Legisa and Kidric (66) found that glycerol slowly diffuses out of the cells and possibly into the mitochondria. Because mitochondrial $NADP^+$-ICDH is inhibited by glycerol, citric acid begins to accumulate in the cells. Other workers (67) reported that

$NADP^+$-specific ICDH activity was inhibited by citrate, but was not affected by other metabolites of the TCA cycle. Inhibition of this enzyme was caused by physiological concentrations of citric acid. Experiments showed that a close relationship existed between the citrate production and $NADP^+$-specific ICDH of mitochondria. Thus, $NADP^+$-specific ICDH was one of the key enzymes involved in citric acid production by *A. niger*.

La Nauze (68) and Szczodrak and Ilczuk (69) studied the effect of iron on the activity of ACH and found that a 20-fold increase in the concentration of iron doubled the activity of ACH, while citric acid accumulation was only decreased by 25%. Kubicek and Rohr (70) found that concentrations of Fe^{3+} required to decrease citric acid production were at least 1000-fold higher than those of Mn^{2+}, and it is probable that Mn^{2+} impurities in the Fe^{3+} source caused the actual inhibition. Finally, the results showed that inhibition of ACH was not necessary for the accumulation of citric acid.

Roukas (65) studied the influence of impeller speed on citric acid production and selected enzyme activities of the TCA cycle. The fermentation was carried out in a 12 L stirred tank fermentor (S.K. Fermenters Ltd., Manchester, UK) with a working volume of 9 L and a temperature of 30°C. The fermentor consisted of a glass vessel with stainless steel end plates and had four equally spaced vertical baffles. The aeration rate was 1 vvm (volume of air per volume of substrate per minute) and agitation was provided by a six flat blade turbine operating at 300–600 rpm. The impeller was located 5 cm above the bottom of the vessel. Roukas found that the activity of CS decreased by 80% with an increase of agitation speed from 300 to 600 rpm, while the activity of ACH, NAD-ICDH, and NADP-ICDH increased by 100% with the same increase in agitation speed. The lowest ACH and ICDH activities were obtained at the same time as maximum concentrations of citric acid (20.0–27.0 g/L) were obtained. The above results show that increase in agitation speed resulted in changes in the activity of enzymes, which are connected to citric acid accumulation. This was due to the change of dissolved oxygen concentration, biomass concentration, viscosity, and pH with increases of speed of agitation (65).

Another important enzyme of the TCA cycle is α-ketoglutarate dehydrogenase (AKGDH), which catalyzes the oxidation of α-ketoglutarate to succinate. It was found that the activity of this enzyme is inhibited by NADH, oxaloacetate, succinate, and *cis*-aconitate (71). Monovalent cations including NH_4^+ were inhibitory at high concentrations (>20 mM). The highest enzyme activity (0.065 units/mg protein) was found in mycelia of *A. niger* grown in media supplemented with glucose-NH_4^+ or glucose-peptone. Kubicek and Rohr (72) reported that during the log phase of *A. niger* the activity of almost all the enzymes of TCA cycle, with the exception of 2-oxo acids, was high. During the induction phase of citrate accumulation, malate, fumarate, and isocitrate decreased, whereas pyruvate, oxaloacetate, and citrate increased. The interrelations of the momentary concentration intermediates mainly demonstrate a lack of activity of 2-oxoglutarate dehydrogenase, representing a block in the TCA cycle concomitant with a strongly operating glycolysis as a prerequisite for citrate accumulation. Under conditions of manganese deficiency, it has been observed that the citric acid production stage is characterized by a significant increase in the concentration of pyruvate and oxaloacetate (100%), apparently causing increased activity of citric acid biosynthesis (50–100%) (72). Heinrich and Rehm (73) observed that in a stirred tank fermentor and in a fixed bed reactor, a high concentration of gluconic acid occurred immediately after nitrogen exhaustion during citric acid production by free, and immobilized, *A. niger* cells, respectively. Because manganese is a necessary supplement for glucose oxidase (GOD) formation, manganese from the stainless steel parts of the vessel was responsible for both gluconic acid production and small citric acid yields. After maximum concentration of gluconic acid, the production rate of gluconic acid decreased rapidly at low pH values. This decrease may be explained by the fact that gluconolactone was formed at low pH values.

At pH 5.5 or above, such a decrease was prevented by the activity of lactonase converting gluconolactone to free gluconic acid. High gluconolactone concentrations perhaps lead to feedback inhibition or, by equilibrium, to a decreasing conversion rate (73). Mischak et al. (74) studied the formation and location of GOD during citric acid production by *A. niger* and reported that GOD could be induced *de novo* by a shift in pH from 1.7 to 5.5. Induction required the intracellular presence of either glucose or glucose-6-phosphate. Glucose oxydase produced was rapidly secreted into the fermentation broth.

The role of intracellular cyclic AMP in the control of citric acid production by *A. niger* has been investigated (75). It was found that citric acid accumulation was only observed in media containing high sugar concentrations and low manganese concentrations. When sucrose was substituted by other monosaccharides or disaccharides, similar intracellular concentrations of cyclic AMP were observed. However, citric acid accumulation was only significant with sucrose, glucose, and fructose. Thus, it is clear that the intracellular level of cyclic AMP is not related to the accumulation of citric acid by *A. niger* and is not affected by manganese deficiency. Also, the addition of cyclic AMP to the medium resulted in a drastic alteration in the morphology of *A. niger*, from filamentous to pellet growth (75).

Another two enzymes (the cytosolic $NADP^+$-specific glycerol dehydrogenase and a mitochondrial $NADP^+$-specific glycerol dehydrogenase) were detected in *A. niger* mycelium (76). It was found that these enzymes were regulated by bicarbonate or CO_2. A change in carbohydrate metabolism from PP pathway to glycolytic flux was detected during the early stages of the growth of *A. niger.* The decrease of PP metabolism was shown to be due to inhibition of 6-phosphogluconate dehydrogenase (6-PGDH) by intracellular citrate (77). The excretion of citric acid by *A. niger* in the early stages of fermentation is connected with glycerol accumulation from the intermediates stages of the PP pathway. Glycerol inhibits mitochondrial $NADP^+$-specific ICDH, causing citrate accumulation. Citrate, by inhibiting 6-PGDH, stops glucose degradation via the PP pathway, which, in turn, results in cessation of glycerol synthesis. When glycerol disappears there is already enough citrate present in the cells to keep the mitochondrial $NADP^+$-specific ICDH blocked. For rapid citric acid accumulation, uninhibited glycolytic flux is required. This process is dependent on 6-PFK activity, but the mechanism of its activation still remains unexplained (77). Other researchers (78) found that *A. niger* accumulates a considerable amount of polyols during citric acid production. Moreover, these authors reported that during the first phase of citric acid accumulation, more sugar is taken up than is used in the production of biomass, CO_2, and citric acid. In contrast, during later phases of fermentation more citric acid, CO_2, and biomass are formed than sugar uptake. Accumulation of polyols as byproducts of citric acid fermentation has also been observed with yeast, but in this case mannitol and arabitol were the main accumulated polyols (78).

Recently, studies by Torres (79,80) showed that the most important step controlling the glycolytic flux occurs prior to formation glucose 6-phosphate such as during glucose uptake or glucose phosphorylation. In addition, *A. niger* contains a single hexokinase enzyme which shares a significant part in the control of the rate of citric acid accumulation. Several studies have been carried out on glycolysis regulation and the stimulation of its flux rate. The presence of high concentrations of glucose or sucrose ($\geq$50 g/L) causes a rise in the intracellular concentration of Fru-2,6-P_2, a strong activator of glycolysis. This may be explained by the fact that poor regulation of 6-phosphofructo-2-kinase (PFK2) in *A. niger* mycelium is carried out, which suggests that the metabolic steps prior to PFK1 and PFK2 are of major importance for glycolytic flux and citric acid accumulation (81). Moreover, Torres et al. (81) found that *A. niger* contains a single, high affinity glucose transporter when grown in low glucose concentrations (1% w/v), but forms an additional low affinity transporter when grown in high glucose concentrations (15% w/v). Both glucose transporters exhibit decreased activities at

low pH values, and are inhibited by citric acid. However, the activity of the low affinity transporter is much less affected by these conditions. The results showed that the low affinity glucose transporter has a major function in glucose catabolism under conditions of excess extracellular glucose, because it was specifically formed only under these conditions. However, the fact that this carrier was also less sensitive to a low pH, and that the inhibition by extracellular citric acid was not strong enough to significantly reduce its activity, suggested a role in citric acid accumulation (81). Hence, despite the importance of the low affinity glucose transporter for the rate of glycolysis and citric acid accumulation, hexokinase activity appears to contribute most significantly to the control of the glycolytic flux to citric acid. Finally, Torres et al. (81) concluded that the low affinity glucose transporter takes part in the mechanism by which *A. niger* responds to high extracellular glucose concentrations that lead to citric acid accumulation.

Other workers (82) investigated the relationship between specific glucose uptake rate and glucose concentration during citric acid production by *A. niger.* In shake flask cultures, airlift bioreactors, and stirred tank fermentors, they found a simple relationship between glucose concentration and specific uptake rate which is independent of fermentation parameters. However, in a glucostat sfermentation system (the concentration of glucose is kept constant while the other fermentations parameters are not controlled), no significant relationship between the specific glucose uptake rate and glucose concentration was observed. Finally, Wayman and Mattey (82) found a simple diffusion model that fit all of the observed data and explained the relationship between specific uptake rate and glucose concentration, which should not exist under carrier saturated conditions. It also reflected the known effects of trehalose-6-phosphate on the flux through glycolysis that produced citric acid, as the values obtained for the diffusive flux constant were lower than expected, with glucose concentrations >400 mM. Because simple diffusion is an inevitable physical process, it is not capable of being regulated directly by the microorganism. This fact may, in itself, account for the dramatic overproduction of citric acid under the conditions of this process. The simple nature of this mechanism also explains the similarity of the uptake relationships from different sources despite the use of different strains and growing conditions (82).

Alvarez-Vasquez et al. (83) studied the metabolism of citric acid production by *A. niger* and found that when the total enzyme concentration was increased two times higher than the basal value, the citric acid production rate was capable of being increased by more than 12-fold, and even larger values were attainable if the total enzyme concentration was allowed to increase even more (up to 50-fold when the total enzyme concentration rose up to tenfold the basal value). Also, Alvarez-Vasquez et al. (83) investigated the metabolic optimization of a model of *A. niger* metabolism under conditions of citric acid production. The results showed that a minimum of 13 enzymes responsible for the biosynthesis of citric acid were needed to increase significantly the production of the acid.

Recently, Guebel and Torres (84) studied optimization of citric acid production by *A. niger* through a metabolic flux balance model and suggested three strategies to increase citric acid production: (1) increasing the glucose uptake rate; (2) decreasing the biosynthesis rate of byproducts (i.e., polyols); and (3) decreasing fluxes diverting mass from the pathway leading to citrate precursors, namely, the biomass synthesis and the TCA cycle. However, the results showed that the synthesis of citric acid described not only a carbon consuming process but also an energy consuming one. Consequently, the biosynthesis of the citric acid would be improved either by a higher ATP (3.7 mmol/g/h) availability from oxidative phosphorylation, or by a diminished activity of H^+/ATPases (1.8 mmol/g/h). The influence of both glucose uptake rate and polyol excretion has already been discussed in relation to carbon availability. Also, the results showed that the TCA cycle would have a

dual effect: a larger and positive effect as a source of FADH and ATP, and a quantitatively less important but negative effect because of carbon loss through production of CO_2 (84). During citric acid production by *A. niger*, a significant amount of CO_2 is produced. It can be generated by the hexose monophosphate (HMP) cycle, the TCA cycle, and the 4-amino-butirate cycle. The results of Guebel and Torres (84) showed that increases in mitochondrial phosphate carrier activity enhance citric acid rates of production. The main factor underlying this effect is the enhancement of ATP availability. Thus, while the activity of cytoplasmatic H^+-ATPase is diminished, the mitochondrial H^+- ATPase is more active. Because the mitochondrial pump is energetically most efficient, a net ATP saving can be expected. Other perturbations, based on the blocking of some diverting fluxes (the HMP pathway or the excretion polyols, mainly glycerol and arabitol), have been shown to have no effect on citric acid production. Finally, Guebel and Torres (84) concluded that the HMP pathway accounts for 16% of the glucose input, the TCA cycle for 13%, and citric acid biosynthesis for the remaining 71%. This profile implies an operative glycerol-P shuttle. It recycles 93% of the cytosolic glycerol-P to cytosolic dihydroxy acetone phosphate (DHAP), thus coupling the transformation of cytosolic NADH to mitochondrial FADH. The GABA cycle and NH^+_4/NH_3 are not significant during citric acid production by *A. niger.* Specific citric acid productivity can be increased by 45% if glucose influx is duplicated.

Kapoor et al. (3) reported a hypothetical pathway for the production of citric acid from n-alkanes by yeasts (Figure 15.2). n-Alkanes are converted to propionyl-CoA and acetyl-CoA through β-oxidation. Propionyl-Coa condenses with oxaloacetate to form methyl citrate. This is isomerized to methyl isocitrate which is further cleaved to succinate and pyruvate. Succinate is oxidized via the TCA cycle to oxaloacetate, which is then recycled. Finally, carboxylation of pyruvate to oxaloacetate and condensation with acetyl-CoA forms citric acid. Moreover, acetyl-CoA through the glyoxylate cycle converts to oxaloacetate, which condenses with acetyl-CoA again to yield citric acid. The most important problem during citric acid production by yeasts is the production of isocitric acid. Thus, the activities of NAD-ICDH and NADP-ICDH play a significant role in the biosynthesis of citrate by yeasts. Media supplemented with low concentrations of potassium ferrocyanide or quinaldinic acid, or media that are deficient in thiamin, decrease the activity of isocitrate dehydrogenase and increase the accumulation of citric acid (3,12). When n-alkanes are used as substrates for the production of citric acid by *Yarrowia lipolytica,* citric and isocitric acid are generated at the end of the exponential growth phase when nitrogen in the fermentation broth becomes limited (12–14). Simultaneously, the activities of AMP, ADP, and NAD-ICDH decrease significantly. This prevents the oxidation of citrate to isocitrate, while the activity of isocitrate lyase is not inhibited. During the growth phase, CO_2 production and oxygen consumption rates increase, approximately in parallel with the cell production rate. They then decrease with a decline in cell concentration and reach constant values during the production phase (12). Aiba and Matsuoka (13) studied the production of citric acid from n-alkanes by *Yarrowia lipolytica* in nitrogen limited chemostat culture and found that the ratio of citrate to isocitrate remained virtually unchanged (about 1.2). This signifies that ACH must have an appreciable activity to establish a dynamic equilibrium between intracellular pools of citrate and isocitrate. The results showed that there was a relatively high specific activity of ACH comparable to that of CS. Also, a large increase in the ratio of citrate to isocitrate was achieved with an ACH leaky mutant of *Yarrowia lipolytica.* Aiba and Matsuoka (13) found that the specific activity of isocitrate lyase (ICL) decreased from 184.0 to 64.6 μmoles/min with the decrease in specific growth rate from 0.073 to 0,012 h^{-1} , while the specific activities of CS, NAD-ICDH, and NADP-ICDH were not affected. In addition, the activity of CS was always higher than the activities of NAD-ICDH and NADP-ICDH, and ICL controlled the production of citric

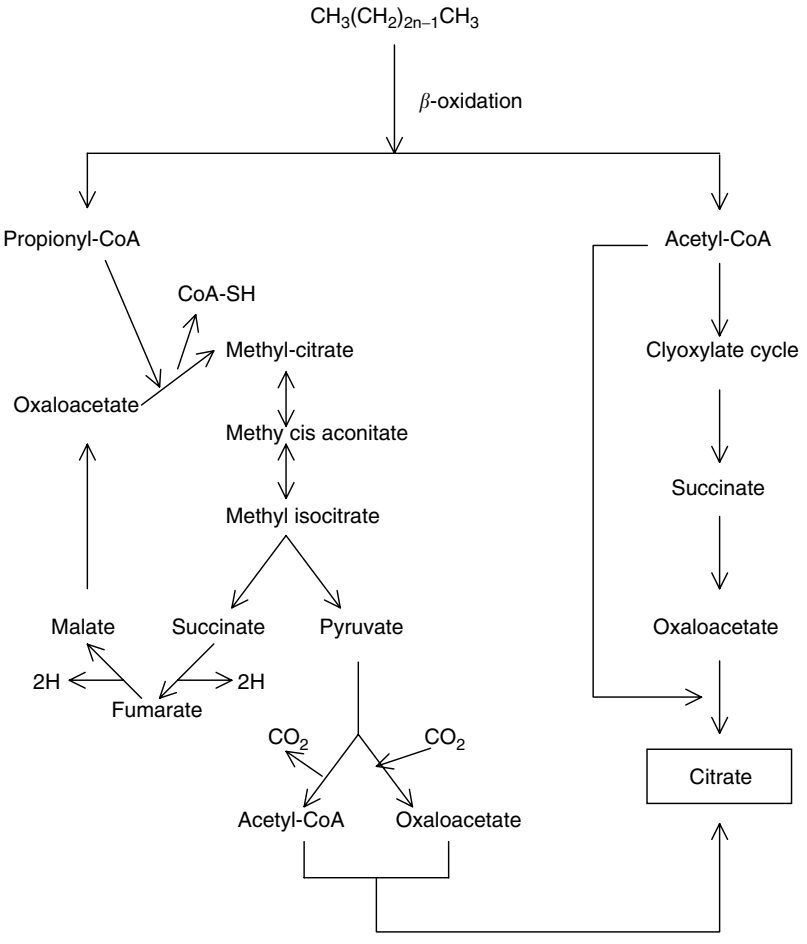

Figure 15.2 Biosynthesis of citric acid from n-alkanes by yeasts. (From Kapoor, K.K., K. Chaudhary, P. Tauro, *Prescott and Dunn`s Industrial Microbiology*, Reed, G., ed.. UK: MacMillan Publishers Ltd, 1983, pp 709–747).

and isocitric acid. Finally, Kapoor et al. (3) concluded that excretion of citric and isocitric acids probably occurred due to other physiological changes such as alteration of cell permeability in relation to these acids**.**

15.4 FACTORS AFFECTING CITRIC ACID PRODUCTION

15.4.1 Nutrients

The composition of the media used for the production of citric acid by *A. niger* depends on the strain of the microorganism used and the type of process. Generally, strains that can use one carbon source efficiently fail to show good acid production when cultured in a medium containing another (3). *Aspergillus niger* grows well in media containing carbohydrates (sucrose, glucose, fructose, maltose, mannose, and starch), nitrogen (as ammonium or nitrate ions), phosphate, low amounts of potassium, magnesium, sulfate, and trace metals such as iron, manganese, zinc, and copper. It has been found that citric acid yields are much higher

when *A. niger* strains are grown in simple synthetic media rather than in complex media. The initial sugar concentration plays an important role. The highest citric acid concentrations were observed in cultures grown at high initial sugar concentrations (15–20% w/v) (3,27,85,86). Further increase of sugar concentration (i.e., 250 g/L)) resulted in a decrease of acid concentration by 15%. The decreased concentration of acid encountered with the highest concentration treatment was probably due to osmotic effects. It has been reported that above a critical substrate concentration (150 g/L), decreased water activity and the onset of plasmolysis combine to cause a decrease in the rates of fermentation and product concentration (27,86). Also, initial sugar concentration (>20%) leads to low sugar utilization, making the process uneconomical, while a low concentration of sugar (<5%) leads to low yields of citric acid and a high accumulation of oxalic acid (3,27,86). Precultivation of *A. niger* at 1% (w/v) sucrose and transference to a 14% concentration of various other sugars (sucrose, maltose, glucose, mannose, and fructose) induced citric acid accumulation. This accumulation can be blocked by the addition of cyclohexamide, an inhibitor of *de novo* protein synthesis. However, precultivation of *A. niger* at high sucrose concentration (14%) and subsequent transfer to the same concentrations of various other carbohydrates led to the formation of citrate. These results indicate that high concentrations of certain carbon sources are required for high citric acid yields (60–70%) because they induce the appropriate metabolic imbalance required for acidogenesis (85).

In addition to sugar concentration, the source of carbohydrate has been shown to have a marked effect on citric acid production by *A. niger.* Xu et al. (85) found that sucrose and maltose were better carbon sources for citric acid production by *A. niger* than glucose and fructose. Hossain et al. (87) studied the effect of the sugar source on citric acid production by *A. niger* and found that sucrose was the most favorable source, followed by glucose and fructose, and then lactose. They also observed that while the fungus grew in medium containing galactose as the carbon source, no citric acid was produced. Strong relationships were observed between citric acid production and the activities of enzymes that were responsible for the biosynthesis of the acid.

When sucrose, glucose, or fructose was the sugar source pyruvate carboxylase activity was high (1050, 600, and 500 μmole/min/mg protein, respectively), while 2-oxoglutarate dehydrogenase activity was not detected. However, when galactose was the sugar source, pyruvate carboxylase activity was low (20 μmole/min/mg protein), but 2-oxoglutarate dehydrogenase activity was high (45 μmole/min/mg protein). The activities of ACH showed a strong relationship with the citric acid production rates during fermentation. The activity was highest (2200 μmole/min/mg protein) when sucrose was the sugar source and lowest (150 μmole/min/mg protein) with galactose. The activity of the enzyme decreased during fermentation except in the presence of galactose, where activity increased. Similar effects were seen with both NAD-ICDH and NADP-ICDH. In conclusion, the results demonstrate that the nature of the sugar source has a strong effect on citric acid production. These findings can be related to the activities of certain enzymes. The 2-oxoglutarate dehydrogenase appears to be the key enzyme for the accumulation of citric acid, and it is repressed during growth on glucose and fructose, but not on galactose (87).

In addition to carbohydrates, nitrogen and the phosphate concentrations have a strong influence on citric acid production. Generally, a nitrogen or phosphate concentration less than 0.2% (w/v) in the medium appears to be adequate. High concentrations of nitrogen (>0.8 g/L) resulted in a reduction by 100% in citric acid production (3–6,88–92). Kristiansen and Sinclair (88) studied production of citric acid in continuous submerged culture and reported that citric acid is produced by cells that accumulate carbon under nitrogen limitation. The nitrogen in the feed is accounted for by the new cells growing at the hyphal tip. The older cells suffer nitrogen limitation and consequently store carbon and

produce citric acid. The transformation of basic cells into storage cells is probably brought about by the streaming of cytoplasm. In general, the effect of nitrogen on citric acid production by *A. niger* can be described as follows (88). The number of cells formed increases with nitrogen concentration and streaming increases with the number of cells formed. Thus, at low nitrogen concentration few cells are formed and with little or no streaming citric acid production is low. When nitrogen concentration increases, the rate of formation of storage cells increases and more citric acid is produced. The production of citric acid is carried out in the mitochondria, which may be carried along toward the nonproducing tip of hyphae not suffering nitrogen limitation if the streaming becomes too pronounced, thereby causing citric acid concentration to drop. This process offers a possible explanation for the drastic reduction in citric acid production at high nitrogen levels. Experiments performed in batch fermentation under phosphate limited growth conditions showed that citric acid yield was inversely related to excessive nitrogen concentration in the medium (89). Results from chemostat culture confirmed a negative relationship between citric acid production and both specific growth rate and nitrogen consumption rate. Dawson and Maddox (89) concluded that under phosphate limited growth conditions, citric acid production by *A. niger* is possibly subject to nitrogen catabolite repression. Also, a fed batch fermentation process operated under nitrogen and phosphate limitation is efficient and economical. Moreover, Choe and Yoo (90) studied the production of citric acid using batch and fed batch culture, and found that citric acid biosynthesis increased more significantly in the fed batch system (40 g/L) than in the batch culture (21 g/L). Other workers (91) reported that not only the timing of the addition of ammonium ions is important, but the concentration of nitrogen must be considered. Optimum addition time of $(NH_4)_2SO_4$ was in the range of 40 and 75 h, and concentrations of the above nitrogen source between 0.25 and 0.5 g/L yielded a 12% increase in maximum citric acid concentration relative to standard fermentation. The concentration of phosphate in the medium is very important to the growth of *A. niger* and the biosynthesis of citric acid (92). A high concentration of phosphate ($>$2.0 g/L) promotes more growth of the microorganism and less acid production. As in the case of nitrogen, the production of citric acid starts after exhaustion of phosphorus compounds (3). Finally, the maintenance of low levels of phosphorus ($<$1.0 g/L) also becomes a key factor, at least in cultures developed on natural carbohydrate sources, an effect that has been related to the presence of trace metals in the medium. In addition to the above nutrients, *A. niger* needs amino acids and vitamins for growth and for production of citric acid. Lal and Srivastava (93) studied the effect of amino acids on citric acid production by *A. niger.* They found that the presence of glutamic acid and aspartic acid stimulated citric acid production to the extent of 79.6% and 76.7%, respectively. Lysine was effective in increasing yield by 62%. However, serine could not influence the yield (50.4%) to a greater extent, while the effect of cysteine was found to be detrimental. Hamissa et al. (34), however, found that the addition of certain amino acids to the medium completely inhibited citric acid biosynthesis by *C. lipolytica* Y 1095. When the medium was supplied with vitamins such as thiamine, nicotinic acid, and nicotinamide, concentration of citric acid increased. The optimum concentration of thiamine favoring the yield was 6.0 mg/L.

Trace elements play a significant role. High concentrations of trace metals (5.0 mg/L) decrease concentration of citric acid while low concentrations (1.0 mg/L) improve production of the acid (3–6,23,34,94–102). Clark et al. (94,95) studied the effect of potassium ferrocyanide on the chemical composition of molasses used for the production of citric acid. They found that the removal of trace metals (Fe^{2+}, Mn^{2+}, Zn^{2+}, Cu^{2+}, Ca^{2+}, Mg^{2+}) from molasses resulted in a significant increase in citric acid production. Banik (96) studied the effect of minerals on citric acid production by *A. niger* and observed that K_2HPO_4

and $MgSO_4 \cdot 7H_2O$ were required at concentrations of 0.1 and 0.02%, respectively. The optimum level of each of the trace elements Fe^{2+}, Mn^{2+}, and Zn^{2+} was 1.0 mg/L , whereas NaCl and $CaCl_2$ at lower concentrations had no effect. Other trace elements such as Cu^{2+}, Co^{2+}, and Mo^{2+} had an adverse effect, while Ni and V were without effect. Kubicek and Rohr (97) reported that a comparison of citric acid fermentations in manganese deficient and manganese containing media showed that manganese strongly influenced idiophase metabolism. In the presence of manganese, cell growth increases, sugar consumption is diminished, and acidogenesis decreases drastically. An investigation of the key enzymes of glycolysis, the PP pathway, the TCA cycle, nitrogen metabolism, and gluconeogenesis indicated that manganese deficiency was accompanied by a repression of anabolic and TCA cycle enzymes, with the exception of citrate synthase. In general, manganese deficiency mainly affects the operation of biosynthetic reactions in *A. niger,* thus leading to an overflow of citric acid. Production of citric acid from molasses by *A. niger* in surface and submerged fermentation is highly sensitive to the concentration of trace metals in the molasses. However, studies on citric acid production from wheat bran in solid-state fermentation showed no such influence despite high concentrations of minerals in the wheat bran. In contrast, when the medium was supplemented with iron, manganese, copper, zinc, magnesium, and phosphorus, the concentration of citric acid was increased by 100% (99). When the mineral ions were used individually at optimum levels the concentration of citric acid increased by 1.4–1.9 times. However, only iron, copper, and zinc were effective in combination. These results indicate that the advantage of solid-state fermentation in tolerating high concentrations of elements in the production of citric acid is probably due to concentration gradients and impaired transport of the metal ions in conditions of limited water availability (99). Addition of 0.5 g/L $CaCl_2$ to the fermentation medium decreased the biomass dry weight by 35% whereas the uptake rates of phosphate and sucrose and the concentration of citric acid increased by 15, 35, and 50%, respectively (100). Tsekova et al. (101) found that copper and cadmium inhibited the growth of *A. niger* and the production of citric acid. The activity of ACH and both NAD-ICDH and NADP-ICDH was strongly inhibited by copper. The contents of DNA and proteins in the cells decreased, but the contents of lipids and polysaccharides increased considerably in the presence of both heavy metals. However, Haq et al. (102) reported that the addition of 2.0×10^{-5} M $CuSO_4$ to the molasses solution increased concentration of citric acid (92.0 g/L) by *A. niger* GCB-47. This means that the effect of heavy metals on citric acid production depends on the strain used and the composition of the medium. Finally, Hamissa et al. (34) studied the effect of micronutrients such as $FeSO_4 \cdot 7H_2O$, $PbSO_4$, $CuSO_4 \cdot 5H_2O$, $MnSO_4 \cdot 4H_2O$, $ZnSO_4 \cdot 7H_2O$, $CoCl_2 \cdot H_2O$, and $(NH_4)_6 \cdot Mo_7O_{24} \cdot 4H_2O$ on citric acid production by *C. lipolytica* Y 1095. They found that $FeSO_4 \cdot 7H_2O$ and $MnSO_4 \cdot 4H_2O$ were more suitable than the other micronutrients for citric acid production. Generally, the tolerance of different strains to trace elements varies so widely that it is necessary to determine the optimum concentrations of such ions in order to avoid the inhibitory effects caused when these cations are present in toxic concentrations (103).

15.4.2 Inhibitors and Stimulants

When certain inhibitors are added to the medium, more specific product may be produced or a metabolic intermediate that is normally metabolized is accumulated instead. In most cases the inhibitor is effective in increasing the concentration of the desired product and reducing the yield of undesired related products. Inhibitors have also been used to affect the structure of the cell wall and increase its permeability for release of metabolites (104).

Stimulants are chemical substances that increase the concentration of the product when added to the medium. The most important stimulants used for improving citric acid yield by

A. niger are methanol and ethanol (3–6,27,86,103,105–111). These chemicals have been found to retard growth, delay sporulation, and increase (by 30–50%) citric acid production.

Roukas and Liakopoulou-Kyriakides (27), Roukas (86), and Roukas and Kotzekidou (103,105) studied the effect of methanol on citric acid production from fig extract, carob pod extract, brewery wastes, and date syrup in surface fermentation by *A. niger* and found that the addition of 4% (v/v) methanol in the above media increased the concentration of citric acid by 50%, 41%, 17%, and 60%, respectively. Moreover, Roukas (106,107) studied the production of citric acid from carob pod and fig by *A. niger* in solid-state fermentation and found that the addition of 6% (w/w) methanol into the media increased the concentration of citric acid by 62% and 50%, respectively. In all cases methanol was added on the third day of fermentation. The observed increases in citric acid concentration show that methanol has a profound effect on the metabolism of sugars by *A. niger*. It was reported that the effect of methanol is at the cell permeability level; it allows citrate to be excreted from the cell. The cell then responds by increasing its citrate production via repression of 2-oxoglutarate dehydrogenase in an attempt to maintain an adequate intracellular level of the metabolite (86,108). In addition, the high stimulation effect of methanol can be attributed to inhibition of spore formation and an increase of microorganism tolerance to high levels of minerals contained in the media (105).

Other workers (111) reported that the addition of methanol to the production medium remarkably depressed cellular protein synthesis without inhibiting nitrogen uptake, thus causing an increase of amino acids, peptides, and low molecular mass protein pooled in the mycelium, especially at the early stage of cultivation. It was also found that addition of methanol to the medium affected the activity of some enzymes of the TCA cycle. Saha et al. (109) studied the effect of methanol and ethanol on citric acid production by *A. niger* using a magnetic rotating biological drum contactor. They found that ethanol promoted citric acid production as well as productivity. Jianlong and Ping (111) reported that the addition of ethanol resulted in a twofold increase in CS activity, and a 75% decrease in ACH activity. The activities of other TCA cycle enzymes increased slightly (5–10%). Increase in citric acid accumulation with the addition of ethanol might be due to the slow degradation of citric acid consequent to reduction in aconitase activity. Both continuous and repeated batch fermentations could be easily carried out using a magnetic drum contactor. In continuous fermentation, methanol and ethanol increased citric acid concentration by 82% and 85%, respectively, in comparison to 49% when no ethanol was used. The highest citric acid concentration and productivity in the continuous culture was attained when ethanol was added during fermentation.

Other stimulants such as fats and oils significantly increased the production of citric acid. It was reported that fats and oils act as carbon sources and are broken down to glycerol and fatty acids. The latter enter the TCA cycle via glycolysis, whereas the former enter directly by the formation of acetyl-CoA (111). Roukas and Kotzekidou (103) found that the addition of sodium monofluoroacetate to brewery wastes resulted in decreased citric acid yield. This chemical is toxic to the mold and does not stimulate citric acid (111).

Addition of some inhibitors such as calcium fluoride, sodium fluoride, potassium fluoride, hydrogen peroxide, naphthaquinone, methylene blue, sodium malonate, potassium ferricyanide, iodoacetate, sodium azide, and sodium arsenate to the different media increased (by 30–40%) citric acid concentration (111,112). Hossain et al. (113) observed that the presence of galactose caused inhibition of citric acid production and also reduced the rate of glucose utilization. Enzyme analyses using mycelial cell free extracts indicated that galactose interfered with glucose repression of the key enzyme 2-oxoglutarate dehydrogenase. Legisa and Mattey (114) studied the production of citric acid by *A. niger* and found that the production of 1% glycerol at the early stage of fermentation caused inhibition of

the $NADP^+$-specific ICDH, which led to the accumulation of citric acid. Also, citric acid concentration increased when the medium was supplemented with cyclic AMP at a concentration of $\geq 10^{-6}$ M. Adenosine, ATP, or cGMP stimulate citric acid production at a concentration of 10^{-3} M, while ADP strongly inhibits citric acid accumulation. Addition of thiophylline along with cAMP increases the effect of cAMP. It is suggested that citric acid production in fungi perhaps results from an abnormal cAMP metabolism (3). Kirimura et al. (115) reported that in *A. niger,* a cyanide (CN)- and antimycin A insensitive and salicylhydroxamic acid (SHAM) sensitive respiratory pathway exists beside the cytochrome pathway and is catalyzed by the alternative oxidase (AOX). When *A. niger* WU-2223L was cultivated with antimycin A or methanol, both citric acid concentration and productivity increased with an increase of both the activity of AOX and the rate of CN insensitive and SHAM sensitive respiration. However, when *A. niger* WU-2223L was cultivated with SHAM, an inhibitor of AOX, CN insensitive and SHAM sensitive respiration were not detected; citric acid concentration and productivity drastically decreased, although mycelia growth was not affected. These results clearly indicate that CN insensitive and SHAM sensitive respiration, catalyzed by AOX and localized in the mitochondria, contributed to citric acid production by *A. niger* (115).

Recently, Jianlong and Ping (111) reported a new stimulator that increased citric acid production by *A. niger* to about 1.1- to 1.7-fold. They observed that the addition of sodium phytate to the fermentation medium at a concentration of 1% increased citric acid production and substrate utilization and slightly inhibited the growth of the microorganism. Several key enzymes involved in the TCA cycle were affected by addition of phytate to the medium (for instance, sodium phytate depressed the activity of NADP-ICDH and activated pyruvate carboxylase, hence favoring the accumulation of citric acid).

15.4.3 Inoculum

To prepare inoculum, *A. niger* is grown in standard media for molds. It is usually cultivated on potato dextrose agar (PDA) slants or in petri dishes at 28–30°C for 3–5 days. The spores obtained are suspended in sterile water containing 0.1% Tween 80. Inoculation is carried out using spores of *A. niger* or pregrown mycelia. When mycelia pellets are used, they are grown in submerged fermentation for 2–3 days in medium that has the same composition as the production medium. The production medium is then inoculated at a concentration of 5–10% (v/v). When spores are used as inoculum, the substrate is inoculated with 0.5–1.0% (v/v) of the inoculum to give a final concentration of ~1.0×10^6 spores/mL (3,27,86). In solid-state fermentation, the medium is inoculated with 5% (v/w) of the inoculum containing 1.0×10^8 spores/mL to give a concentration of 0.5×10^7 spores/g wet substrate (106,107).

15.4.4 Fermentation Time

The optimum time for the maximum production of citric acid depends on the strain used, the chemical composition of the medium, the fermentation system, and generally, the conditions under which fermentation takes place. In the surface culture, fermentation time is usually completed in 10–20 days, while in the submerged culture incubation time is much shorter (5–10 days). In solid-state fermentation the fermentation time depends strongly on the amount of inoculum used, the moisture content of the substrate, the initial pH, the temperature, and the particle size of the medium (e.g., carob pod or fig) (106,107). In this case, the maximum citric acid concentration is between 10 and 15 days.

15.4.5 Temperature

Asperillus niger and other fungi used in the production of citric acid from synthetic media or molasses in submerged fermentation have an optimum temperature between 25 and

30°C (3,116). However, Roukas (86) studied the effect of temperature on citric acid production from carob pod extract by *A. niger* and found no significant differences between cultures grown at 25 and 40°C in terms of citric acid concentration (67.7 and 70.0 g/L, respectively) and citric acid productivity (3.22 and 3.33 g/L/h, respectively). Also, no significant differences were noted in biomass yield, specific biomass production rate, and specific sugar uptake rate among cultures grown at 25 and 30°C. Increasing the fermentation temperature from 25 to 40°C significantly affected specific citric acid production rate (0.157 to 0.111 g citric acid/g biomass dry weight/d) and biomass dry weight (20.5 to 30.0 g/L). Other kinetic parameters, namely, biomass dry weight, biomass yield, specific biomass production rate, and fermentation efficiency, were at their maximum at 40°C (86). In addition, this author studied the effect of temperature on citric acid production from carob pods and figs in solid state fermentation and observed that the maximum citric acid concentration (176 and 64 g/kg dry carob pod or fig, respectively) was achieved at 30°C. Very similar results were obtained by Szewczyk and Myszka (117) who found that the optimum temperature for growth of *A. niger* in solid-state fermentation was 26–34°C. At temperatures >34°C, the maintenance coefficient decreases as the temperature increases. This reflects a deactivation effect of temperature on endogenous metabolism. Perlman and Sih (6) reported that a two stage process, where *A. niger* was incubated at 28–30°C for 2–3 days and then for a week at 20°C, resulted in higher yields than when the temperature was maintained at 28–30°C.

15.4.6 pH

One important factor that affects the biosynthesis of citric acid is the initial pH of the medium. When *A. niger* is used for the production of citric acid, the initial pH is dependent on the medium employed. In synthetic media the initial pH of the medium is usually adjusted to 2.5–3.5, while in the case of molasses the initial pH must be neutral or slightly acidic in order for germination and growth of the microorganism to occur. The pH of the medium is adjusted with HCl, H_2SO_4, or NaOH. The pH of the substrate decreases during fermentation (from 7.0 to 2.0) due to the production of citric acid and other acids generated in the TCA cycle (27,86,106,107). Roukas and Alichanidis (118) studied the effect of initial pH on citric acid production from molasses using surface fermentation. They found that the best results were obtained using an initial pH of 6.5 without control during fermentation. Adjustments of pH of the fermentation medium at appropriate times have also been made to affect the change from the growth to the production phase (2). In this process the initial pH of the substrate was within the range 4–6. After the desired amount of mycelial growth was obtained, the pH was lowered to stimulate citric acid production. When yeasts are used for the production of citric acid, the pH is often adjusted to 6.0–7.0 by addition of lime, calcium carbonate, or sodium hydroxide.

15.4.7 Aeration and Agitation

Aspergillus niger is an aerobic microorganism and therefore requires oxygen. Aerating and agitating the fermentation broth normally satisfies the oxygen demand of a fermentation process. The effect of agitation and aeration on citric acid production in submerged fermentation is extremely important for the fermentation's successful progress. Agitation is important for adequate mixing, mass transfer, and heat transfer. It not only assists mass transfer between the different phases present in the culture, but also maintains homogeneous chemical and physical conditions in the culture by continuous mixing. Agitation creates shear forces, which affect microorganisms in several ways, causing morphological changes, variation in their growth and product formation, and also damage to cell structures.

Aeration can be beneficial to growth and performance of microbial cells by improving mass transfer characteristics with respect to substrate, product and byproduct, and oxygen. The morphology of the microorganism strongly influences product formation, because it affects broth rheology and consequently the mass and heat transfer capabilities of the fermentation broth (119). Three techniques are used for the aeration of the substrate during citric acid production: (1) the shake flask culture, where Erlenmeyer flasks are placed on reciprocating or rotary shakers (200–250 rpm); (2) surface culture, where oxygen diffuses through the surface, which is maintained in a static condition; and (3) submerged culture, in which filter sterile air or oxygen is pumped into the medium from the bottom of the reactor. Industrial production of various metabolites by filamentous fungi is susceptible to regulation by the dissolved oxygen tension (DOT) of the medium (120). In this case, the critical DOT for growth and DOT for product formation are distinct parameters; in general, the latter is higher by 25–30%. Kubicek et al. (120) conclude that citric acid accumulation is favored by increasing the DOT of the fermentation broth (40–150 mbar). Furthermore, this demonstrates that oxygen acts as a direct regulator of citric acid accumulation because a response was obtained within only minutes after altering the oxygen supply. These changes in citric acid production were accompanied by changes in the oxygen uptake rate, whereas carbon dioxide formation remained relatively unaffected, which suggests that there is a regulatory linkage between respiration and citric acid accumulation. However, the lack of coordination in the behavior of adenine nucleotides and citric acid synthesis makes it probable that the oxygen effect is not exerted via the adenine nucleotides (120). Also, these authors reported a critical DOT of 9–10% of air saturation and 12–13% of air saturation for growth and production phases, respectively, during citric acid production by *A. niger*. Moreover, they found that the concentration of citric acid steadily increased between DOT values of 20% and 75% of saturation. Dawson et al. (121) studied the effect of interruptions to the air supply on citric acid production by *A. niger*. Interruptions were carried out by treating the cultures with nitrogen gas or by stopping the air supply and impeller speed. Provided that the measured DOT of the culture did not fall below 20% saturation, no gross effect was obtained on the performance of the culture. In contrast, when the DOT fell to zero, both mycelial growth and citric acid production were inhibited.

Roukas (65) studied the influence of impeller speed on citric acid production and found that the highest citric acid concentration (28.0 g/L) was obtained in culture agitated at lower speed (300 rpm). The concentration of dissolved oxygen increased with the increase of speed of agitation. In the cultures agitated at 300, 400, 500, and 600 rpm the concentration of dissolved oxygen from the second to the 12th day remained at ~22%, 30%, 40%, and 50% of the initial saturation level, respectively. It fell rapidly during the first 2 days of fermentation after which it increased more slowly due to the rapid increase of biomass concentration (6.0–9.0 g/L) observed at the same time.

Because of significant oxygen requirements during citric acid production and the relatively low solubility of oxygen in water, Jianlong (17) studied the production of citric acid by *A. niger* using n-dodecane as an oxygen vector. The advantage of using the oxygen vector in fermentation is that it increases the oxygen transfer rate from the gas phase to the cells of the microorganism without the need for an extra energy supply. In addition, oxygen vectors can act as surface active agents to lower the surface tension of water and increase the gaseous specific interfacial area. Jianlong (17) found that the addition of 5% (v/v) n-dodecane to the medium enhanced citric acid accumulation by 40%, significantly increased the volumetric oxygen transfer coefficient ($K_L a$) (130 h^{-1}), reduced the residual sugar concentration by 15–100%, stimulated mycelial growth (25–90%), and did not affect the activity of citrate synthase. Generally, the use of n-dodecane as an oxygen vector is of great potential interest for a number of fermentation processes, particularly those that

depend strongly on oxygen concentration. It is biologically inert, has no toxicity, is readily available commercially, is inexpensive, and can be reused (17).

15.5 MORPHOLOGY OF *ASPERGILLUS NIGER* AND RHEOLOGICAL PROPERTIES OF THE FERMENTATION BROTH DURING CITRIC ACID PRODUCTION

The *A. niger* group consists, among others, of the fungi we commonly call black mold. *Aspergillus niger* grown on Czapek agar at 25°C forms colonies attaining a diameter of 4–5 cm within 7 days. They consist of a compact white or yellow basal felt with a dense layer of dark brown to black conidiophores (122). Conidial heads are globose, radiate, or (as they grow) split into several columns of conidial chains. Conidiophore stipes are smooth walled and hyaline, but often brown in color. They arise from the substratum, varying from 200 μm to several millimeters in length, and 10–20 μm in diameter. Vesicles are globose to subglobose, colorless to yellowish brown, and fertile over the whole surface. Phialides are borne on metulae that are 7.0–9.5 × 3–4 μm in size. Metulae are hyaline to brown, often septate, and 15–25 μm long by 4.5–6.0 μm wide. Conidia are globose to subglobose, 3.5–5.0 μm in diameter, brown, and ornamented with irregular warts, spines, and ridges (122). In submerged culture, the morphological characteristics of *A. niger* have been correlated with high yields of citric acid. The most desired morphological characteristics are as follows: abnormally short, stubby, forked, bulbous mycelium; numerous swollen, oval to spherical shaped cells well distributed throughout the mycelial structure; mycelial structures showing granulation and numerous vacuoles or refractile bodies; an absence of normal reproductive bodies; and formations of compact aggregates or colonies having gross granular appearance, with cross sections under 0.5 mm and averaging about 0.1 mm. The individual pellets are 0.2–0.5 mm in diameter, with precipitated matter enmeshed in the pellet; the lateral hyphae are short, thickened, vacuolated, and granular, with short club like branches (6).

Jernejc et al. (123) studied the composition of the mycelium of *A. niger* and found that the total lipids in mycelia grown in the presence of manganese were up to two times higher than in conditions favoring citric acid accumulation. The concentrations of phospholipids and neutral lipids were lower under manganese deficiency. Regarding phospholipid composition, phosphatidylethanolamine and diphosphatidylglycerol prevailed under citric acid accumulating conditions, whereas under restricted citric acid biosynthesis, phosphatidylcholine was present in larger amounts. Among the fatty acids contained in mycelium, unsaturated acids predominated in mycelia of *A. niger.* The ratio of saturated (palmitic and stearic) to unsaturated (oleic and linoleic) acids was always lower in accumulating conditions of citric acid. In this case, the amount of linoleic acid was higher compared to the amount of palmitic and stearic acid. Moreover, trace levels of myristic and palmitoleic acid, and an odd chain marguaric acid were detected during fermentation (123).

In another work (124), it was reported that phosphatidylcholine and sterols play an important role in membrane permeability. *Aspergillus niger* mycelia grown in conditions hindering citric acid accumulation contained higher amounts of sterols, with ergosterol as the main component and six other sterols representing minor components. In submerged fermentation, *A. niger* forms pellets or mycelium during fermentation, depending on the type of inoculum used. Inoculating the production medium with spores or preculture of pellets causes *A. niger* to form filamentous suspension or pellets, respectively. The most important advantage afforded by a pellet suspension is a significant decrease in viscosity compared with a filamentous suspension, which considerably enhances the desirable mixing and mass

transfer properties of the suspension. However, in the case of pellets, growth of microorganism and acidity decrease due to limited diffusion of oxygen and other nutrients into the interior of the pellets (125). Citric acid production requires high dissolved oxygen concentration (30–40% saturated) which may adversely affect the fermentative capacity of hyphae and pellet formations. In general, it is accepted that pellet formation commences through aggregation of conidia during germination and that development progresses at low stirrer speeds and high growth rates (125).

Gomez et al. (125) studied the effect of inoculation methods and aeration conditions on the morphology of *A. niger.* They found that inoculation of the production medium with spores gave rise to cultures with a filamentous morphology at low agitation speeds (450 rpm) and either long filaments or a mixture of filaments with a small proportion of fluffy, loose pellets at high impeller speeds (1000 rpm). In contrast, inoculation with a preculture of pellets gave rise to cultures of small, compact, smooth pellets of uniform size. Culture morphology was either uniform, consisting solely of such pellets, or else the pellets were mixed with larger, gelatinous pellets at high or low impeller speeds, respectively, during the first two days of fermentation. These results suggest that the morphology of *A. niger* is sensitive to aeration conditions employed in the initial phase of fermentation. Generally, slow agitation speed during germination and the beginnings of vegetative growth of the spores and high agitation speed during the exponential growth phase of the microorganism favor the formation of small, compact, and smooth pellets (125). A relationship between culture morphology and citric acid production was observed during fermentation. In general, the cultures of standard pellets yielded higher levels of citric acid than did the cultures consisting of filaments (125). However, Paul et al. (126) reported that citric acid titer was higher when the morphology was filamentous or pelleted culture. Moreover, these authors reported that the citric acid titer obtained from a culture with small pellets was higher than that obtained from a culture containing large pellets with extensive filamentous annular regions.

Papagianni et al. (127–130) studied the morphology of *A. niger* in batch and fed batch culture using a stirred tank fermentor or a tubular loop bioreactor. They reported that the most important factors influencing the morphology of *A. niger* in submerged fermentation are size of inoculum, type and concentration of carbon source, nitrogen and phosphate limitation, trace metals, pH, dissolved oxygen tension, aeration, and agitation. The following morphological parameters were measured using an image analysis method: mean perimeter of clumps (P1), mean perimeter of the core of clumps (P2), mean length of filaments (L), and mean diameter of filaments (d). In batch culture, during the first phase of fermentation, the length of filaments decreased with a decrease of initial glucose concentration. The mean length and specific growth rate was found to increase for the first 2 days of fermentation with decreasing initial glucose concentrations, indicating a link between specific growth rate and branching frequency. Also, the perimeter of the core of clumps changed with initial glucose concentration. The shape of clumps changed because at the end of the fermentation, the ratio P1/P2 increased as the concentration of glucose decreased. The reduction of clumps at low glucose concentrations could be explained by the observation that the filaments became highly vacuolated and fragmentation occurred, keeping the size of the filaments small (129). In fed batch culture, the main observations on morphology of the microorganism were similar with those of batch culture. In this fermentation system, the mean length of filaments decreased with decreasing glucose levels. Comparing the mean values of P1 and L from batch and fed batch culture, it was found that mean values were smaller in fed batch culture than in batch culture. Finally, Papagianni et al. (129) concluded that the morphology of *A. niger*, as determined by clump perimeter and hyphal length, was found to be related to specific growth rate and thus was indirectly linked to sugar concentration. The large clumps with long filaments increased

viscosity of the broth to the point at which oxygen became a limiting nutrient. A small increase in phosphate concentration in the medium caused a drastic change in morphology. The clumps lost their compact structure and the length of filaments increased during fermentation. However, at lower phosphate concentrations, after early growth phase, the length of the filaments remained the same until the end of fermentation.

Among trace metals, only the effect of manganese concentration has been shown to influence the morphology of *A. niger.* Paul et al. (126) reported that manganese deficiency in the medium influenced the development of pellet morphologies of *A. niger* in submerged culture. Addition of manganese to the medium caused an undesirable change in the morphology from a pellet like form to a filamentous form (126). Other morphological changes such as prevention of clumping, absence of swollen cells, and reduced diameter of filaments took place during incubation. In spore inoculated fermentations a high initial spore concentration usually tended to produce dispersed growth while a low one favored pellet formation. However, evidence has been presented that pellets can arise even at high spore concentrations due to spore agglomeration during the early stages of germination (126). The perimeter of the clumps, the core perimeter of the clumps, and the length of filaments increase by 90%, 15%, and 50%, respectively, with increases of pH from 2.1 to 4.5. No unidirectional response takes place for the diameter of filaments. In addition to the small size of clumps and small length of filaments at low pH values, an unusually high number of swollen cells and tips occurs in the mycelium (126,127).

Paul, et al. (126) studied the effect of agitation speed on the morphology of *A. niger* and found that with low agitation (300 rpm) the pellets of an initial mean equivalent diameter of 1.4 mm grew larger with fermentation time, until the agitation was increased, at 96 h, to a very high level of 800 rpm. The pellets then fragmented rapidly from 3.2 to 1.6 mm in diameter. In that case, both citric acid yield (0.49 g/g glucose) and cell growth were very low. The glucose uptake rate, oxygen uptake rate, and carbon dioxide production rate were also low compared to nonpelleted fermentation, although all showed a sharp rise after fragmentation of the pellets. The high agitation speed of the second pelleted fermentation (500–800 rpm) retarded continued pellet size increases. The mean equivalent diameter at inoculation was 1.4 mm and rose to only 1.5 mm toward the end of fermentation. Both citric acid yield and cell growth were higher than those obtained from fermentation with large pellets but were still lower than in the dispersed morphology case.

Papagianni, et al. (127,128) studied the relationship between *A. niger* morphology and citric acid production in two reactor systems with different configurations, a tubular loop bioreactor and a stirred tank fermentor. They found that in both reactors citric acid production and morphology were dependent on agitation speed. The length of the filaments was shown to be the most important parameter related to citric acid production in both bioreactors. However, for the same concentration of citric acid produced, the morphology of the microorganism grown in the tubular loop reactor differed significantly from that grown in the stirred tank fermentor. The perimeter of the clumps decreased as circulation frequency through the pump increased in the loop bioreactor and as agitation speed increased in the stirred tank fermentor. In the loop bioreactor, citric acid production appeared to increase sharply with hyphal diameter, while in the stirred tank reactor this relationship was not as clear. Intensive agitation conditions transformed the filaments from long, thin, and almost unbranched to short and thick, with many branches. At high agitation intensity, fragmentation of the mycelia was carried out in both reactors and resulted in the presence of free filaments in the fermentation broth. These free filaments formed new and smaller clumps. This cycle of fragmentation and regrowth kept the average size of clumps small (127).

Roukas (65) studied the effect of agitation speed on *A. niger* morphology and found that at agitator speeds $\geq$300 rpm, pellets were formed within 24 to 48 h of inoculation,

which crushed later into pieces of mycelia in which the hyphae formed a homogeneous suspension dispersed through the fermentation broth. The biomass concentration increased by 25% with an increase in speed of agitation (300–600 rpm). This was due to the crushing of the pellets into small pieces of mycelium, resulting in the surface of the mycelium having much better contact with nutrients and oxygen. In another work, Papagianni, et al. (130) observed that under intensive agitation conditions and during early fermentation stages, the characteristics observed were increased specific growth rates and hyphal branching, along with low vacuolation levels. These were followed by fragmentation of the highly vacuolated parts of filaments and regrowth at later stages of the fermentation, a process that did not increase biosynthetic activity. In fed batch culture, increased vacuolation (162.5 μm) and low specific production rates were observed at low glucose levels (17.0 g/L). The results indicate that vacuolation weakened the hyphae, and low glucose levels created conditions that favored fragmentation and made the mycelium more susceptible to it when exposed to increased agitation. Generally, Papagianni, et al. (128) reported a close link between morphology and productivity, with both dependent on "relative mixing time," whether in a stirred tank or a tubular loop bioreactor.

Other workers (131) studied the effect of cAMP on the morphology of *A. niger* and the production of citric acid. They found that high levels of intracellular and extracellular cAMP in the later stages of fermentation were associated with those treatments that yielded pellets of intermediate size and the highest citric acid concentration. It was suggested that cAMP stimulates conidial aggregation under certain conditions in *A. niger,* and that such conidial aggregation may influence pellet formation. It is perhaps not surprising that intermediate sized pellets have a higher cAMP content than larger pellets, because the center of large pellets is hollow or contains physiologically inactive mycelium. It is possible that the intermediate pellet size is optimal for a range of physiological activities, not just citric acid production, and that the high rate of citric acid production obtained is a result of an optimum metabolic state in the mycelium which exhibits this morphological form (131). The morphology of *A. niger* influences the activity of enzymes that are responsible for biosynthesis of citric acid. Thus, glyoxylate and several intermediates of the TCA cycle also promoted conidiation in the presence of ammonium. The activities of two glutamate dehydrogenases (NAD-GDH and NADP-specific GDH) and of aspartate and alanine aminotransferases varied during growth as a function of the stage of the life cycle and of the growth medium (132). It was also found that the activities of key enzymes of EMP and PP pathways were present and operative at all stages of conidiophore development, but that the relative activities of the pathways differed. The highest activity of the EMP pathway occurred during the initial period of vegetative growth before any signs of morphological change. High EMP activity and high 6-C:1-C ratios were obtained in a medium that did not support conidiophore initiation but allowed vegetative growth to occur. In contrast, high activity of the PP pathway and very low 6-C:1-C ratios accompanied each stage of conidiophore development (133).

During citric acid production, the fermentation broth consists of liquid medium, biomass, citric acid, and any product produced by the microorganism. Thus, the rheology of fermentation broth is affected by the composition of the original medium, the morphology of biomass, the concentration of microbial products, the mixing qualities (impeller speed and working volume), and the dissolved oxygen concentration (134,135). The morphology of *A. niger* in submerged culture varies between the pelleted and the filamentous form, depending on strain and culture conditions (130,136–138). Fungal morphology affects the rheological properties of the fermentation broth and has a strong effect on bioreactor transport phenomena relating to problems of mass transfer, heat transport, and energy consumption. The rheological behavior of fermentation broth is also of great importance for the

design, scale up, and operation of reactors (134). In the filamentous form, the hyphae are dispersed throughout the medium, thus rheological behavior is highly nonnewtonian and extremely viscous, so that agitation and aeration become difficult. The pellet growth form consists of branched hyphae intertwined to a stable aggregate, and this growth form causes less viscous fluids than the filamentous form (136,137). The main disadvantage of the pelleted form, however, is that the center of the pellet is subject to autolysis, due to oxygen limitation, and does not participate in product synthesis (130).

Among the factors affecting the morphology of *A. niger,* agitation has been studied extensively and shown to account for significant changes in morphology and productivity of citric acid. Roukas (65) studied the effect of impeller speed on shear dependent viscosity and found that shear dependent viscosity decreased by 25% with increase in speed of agitation from 300 to 600 rpm. This may be explained by the fact that filamentous pellets were crushed into smaller pieces by increased agitation speeds (600 rpm) as a result of shear stress between the fermentation broth and the impeller. In general, the reduction in viscosity with increasing stirred speed indicated that culture morphology is the major determinant of rheological properties of the fermentation broth (65).

Berovic, et al. (138) studied the rheological properties of fermentation broth during citric acid production by *A. niger* in a stirred tank fermentor. They observed that during the first period of fermentation (36 h after inoculation), the fermentation broth was characterized by nearly newtonian behavior, showing a high power law index (n = 1.0–0.95), a low consistency index (K = 5–10 mPas^n), and a high volumetric oxygen transfer coefficient (K_{la} = 156 h^{-1}). During the second fermentation period the change in *A. niger* morphology to spherical pellets and the increase in biomass (18.5 g/L) changed the rheological behavior of the fermentation broth to a pseudoplastic one, reducing the power law index (n = 0.45) and the volumetric oxygen transfer coefficient (K_{la} = 28 h^{-1}) and increasing the consistency index (K = 130 mPas^n). The power law index and the consistency index were evaluated from a log-log plot of the equation $n_a = K\gamma^{n-1}$ where n_a is the apparent viscosity and γ is the shear rate. The equation can be written as $\log n_a = \log K + (n-1)\log \gamma$. In the curve formed by plotting the data $\log n_a - \log \gamma$, the intercept is $\log K$ and the slope is equal to $n-1$ (138). Generally, it was observed that a submerged citric acid fermentation broth shows nonnewtonian rheological behavior. The most significant changes in rheological behavior occurred during the period of maximal citric acid production at the time of exponential increase in biomass. It seems that the pellet growth form represents resistance to shear stress in the system, causing pseudoplastic rheology and significantly reducing the volumetric oxygen transfer coefficient (138).

15.6 FERMENTATION PROCESSES FOR CITRIC ACID PRODUCTION BY FREE AND IMMOBILIZED MICROBIAL CELLS

15.6.1 Surface Fermentation

Surface fermentation was the first fermentation system used for the production of citric acid on an industrial scale. Nowadays fermentation in deep tanks, the so called submerged process, is also employed. Only 20% of world production of citric acid is through use of the surface fermentation process using molasses as raw material. In this process, *A. niger* forms a mycelium layer on the liquid surface of the aluminum or stainless steel trays. These trays are stacked in fermentation rooms supplied with filtered air which serves both to supply oxygen and to control the temperature of fermentation (5,7). The air supply for the chambers

is sterilized by passage through a 2 in. thick cotton filter impregnated with salicylic acid, then passed through a water spray and heaters to bring it to 40% humidity at 30°C. The air supply is 0.25 vvm (4). The trays are 2 × 2.5 m in size and 12 cm deep. They are sterilized and filled to a depth of 8 cm with the medium, inoculated with spores of *A. niger*, and incubated 9–12 days at 28–30°C. After the maximum concentration of citric acid is reached, the mycelium is separated from the fermentation broth by filtration. The biomass is washed with water to remove citric acid and the washings are added to the main liquor. The citric acid contained in the solution is precipitated as calcium citrate. The fermentation chambers are sterilized by washing with 1% NaOH, then with water, then with 6% formaldehyde. Finally, sulfur dioxide is blown into the chambers with the airstream (4).

In recent years, several methods for citric acid production have been proposed, and various continuous or multistage processes have been patented. Despite various advances in process development, surface and submerged batch culture techniques are still being used. However, in the batch technique, a significant amount of productive biomass is discarded each time. Cell recycling techniques have advantages over batch techniques because the biomass is conserved, batch downtime is mostly eliminated, and productivity is often increased. These techniques make use of the fact that citric acid production occurs in cells not in the active stage of growth (139).

Roukas and Alichanidis (139) studied the production of citric acid from beet molasses at a varying pH profile using cell recycling of *A. niger.* Fermentation was carried out in Erlenmeyer conical flasks containing 100 mL of molasses solution (initial sugar concentration of 14%). For the first cycle, the pH of the medium was adjusted to 6.5. The flasks were incubated at 30°C, as in surface fermentation. When the maximum concentration of citric acid (65.0 g/L) was achieved, the original medium was aseptically withdrawn from each flask and aseptically replaced with 100 mL of fresh sterile medium, with an initial pH of 6.5, 4.5, or 3.0.This cycle was repeated until the productivity of citric acid was decreased (six cycles). The experiments showed that best results in terms of citric acid concentration (75.0 g/L), yield (0.62 g citric acid/g sugar utilized), productivity (0.3 g/L/h), and specific citric acid productivity (0.0071 g citric acid/g biomass dry weight/h) were obtained with a substrate pH of 3.0. Moreover, the authors concluded that the most significant advantages for citric acid production from beet molasses, at pH 3.0, using cell recycle surface fermentation techniques, are as follows: (1) increases in citric acid production and productivity; (2) energy savings from washing and resterilization of equipment; and (3) possible cost savings from repeated use (up to six times) of the culture.

In another relevant work, Roukas (140) studied the production of citric acid from carob pod extract by cell recycling of *A. niger.* It was found that citric acid concentration (85.5 g/L) and productivity (0.16 g/L/h) remained constant for 42 and 60 days, respectively.

15.6.2 Submerged Fermentation

In submerged fermentation, the microorganism is grown in the fermentation broth. Fermentation is carried out in shake flasks, aerated stainless steel tanks, agitated reactors, sparged towers, a loop bioreactor, a bubble column, a tower fermentor, a disk fermentor, and a rotating disk contactor or trickle flow fermentor (141–149). Among these fermentors, the tower fermentor is the most economical. This fermentor, having a proportion from 1:4 to 1:6 (diameter:height), was found to be especially suitable. Air is supplied from the bottom of the column via a distribution system. Oxygen transfer by rising air bubbles also ensures a thorough mixing in the fermentor. Thus, an agitator, which needs additional energy and makes the fermentor system much more complicated, is not necessary (1). The use of oxygen instead of air to improve oxygen transfer has been applied in unagitated vessels. Foaming of the broth is counteracted by mechanical or chemical foam breakers (7).

Some cell recycle reactors consist of a mechanical device that separates the cells from the liquid, returning the cells to the fermentor. A hollow fiber filter is connected to the fermentor by silicon tubing and a peristaltic pump. Such reactors conserve substrate, because cell mass is conserved. They allow continuous operation and increased productivity by eliminating batch downtime and allow high cell densities. Enzminger and Asenjo (37) studied the production of citric acid from glucose using an aerobic continuous stirred tank bioreactor with cell recycling of *S. lipolytica.* They observed that in batch fermentation, under nitrogen limited conditions, stability of citric acid biosynthesis (75.0 g/L) and excretion was constant over a period of 700 h. In addition, cell concentration (26.0 g/L) and citric acid productivity (1.16 g/L/h) were constant over 200 h of operation under conditions of cell recycling.

Tongwen and Weihua (150) studied the effect of cell configurations on energy consumption and the electroacidification parameters in citric acid production by bipolar membrane electrodialysis. Three basic cell arrangements, type I: A (anion membrane)-C (cation membrane)-BP (bipolar membrane)-A-C, type II: C-BP-C, and type III: BP-A-C-BP, were used. Type I generated acid citrate by acidification with acid sulfate produced from the dissociation of sodium sulfate, and type II produced acid citrate by replacing Na^+ with H^+ generated at bipolar membrane electrodialysis. Type III generated acid citrate by directly splitting sodium citrate. From energy consumption, current efficiency, and concentration of the produced acid citrate, it was suggested that type II seems to be a favorable cell configuration for the production of citric acid. Other workers (141,147) studied the production of citric acid from synthetic medium by *S. lipolytica* and *A. niger* using a stirred tank reactor and a disk fermentor. They found that maximum citric acid concentration was 95.0 and 80.0 g/L, respectively.

15.6.3 Comparison of Surface Fermentation and Submerged Fermentation

Surface fermentation is easy to control and to implement. It needs no aeration or agitation of the fermentation broth, so it needs no instrumentation for aeration and agitation. The separation of citric acid from the mycelium is easy because the microorganism is not dispersing into the medium (151). Only the temperature and humidity of the fermentation chamber need controlling. It can be used easily in small plants as well as in third world countries. With surface fermentation, the fermentation broth is concentrated due to a high evaporation rate during fermentation. Thus, expenses and losses during recovery and purification are low (152). However, surface fermentation has the following disadvantages: Building investment costs are high. Personnel expenses are high in developed industrial countries with extremely high wages. Fermentation time is long and therefore productivity is low (152).

Submerged fermentation is favored over surface fermentation for the following reasons: lower total investment costs; higher yields of citric acid; improved process control; reduced fermentation time; reduced floor space requirements; lower labor costs; simpler operations; and easier maintenance of aseptic conditions on an industrial scale (1,4,152). However, submerged fermentation has some disadvantages compared to surface fermentation: expenses for equipment are higher; consumption of electrical energy is higher; and the process is very sensitive to short interruptions or breakdowns in aeration and vulnerable to infections, which result not only in losses of yield, but also in a total breakdown of respective batches.

Shierholt (152) concludes that surface fermentation is theoretically superior to submerged fermentation. Some essential criteria for industrial management of these two processes are ground requirements as well as the number of and costs for assistants to be employed.

15.6.4 Continuous Culture

In continuous culture the substrate is fed to the fermentor at a constant rate, and the culture is harvested at the same rate, so that the culture volume remains constant. Continuous culture is superior to batch culture in productivity, uniformity of operation, and ease of automation but is more susceptible to contamination (104). Very little published information is available on the production of citric acid by free cells of *A. niger* in continuous culture (59,88,153,154). Kristiansen and Sinclair (88) investigated the production of citric acid from synthetic medium by *A. niger* in single stage continuous culture operated under nitrogen limiting conditions at dilution rates between 0.04 to 0.21 h^{-1}. Citric acid concentration increased rapidly as the dilution rate decreased and appears to be critically dependent on the pH of the fermentation broth and the nitrogen concentration in the feed. The maximum citric acid productivity (0.43 g/L/h) was observed at a dilution rate of ~0.075 h^{-1}. The biomass dry weight, which was independent of pH in this range, did not increase significantly until the dilution rate fell below 0.1 h^{-1}. The optimum pH range for the maximum citric acid productivity was ~3.4. The growth rate was not affected by dissolved oxygen concentration at a dilution rate between 0.07 and 0.3 h^{-1}. The production of citric acid is strongly dependent on culture conditions, especially pH. It appears that pH affects the enzymes that are active in degrading the substrate or the permeability of the cell membrane to substrate and product. The pH does not appear to directly influence the biosynthesis of citric acid (88). Dawson et al. (154) studied the production of citric acid from synthetic medium in continuous culture and found that maximum citric acid yield and production rates were observed at low dilution rates (0.017 h^{-1}) and high dissolved oxygen tension values (90% of saturation). Roukas and Harvey (153) studied the effect of pH on production of citric and gluconic acid from beet molasses using continuous culture and found that at pH values >2.5 gluconic acid was the major product, while at low pH values (1.8–2.0), citric acid was the predominant product. The optimum specific activities of CS, ACH, NAD-ICDH, and NADP-ICDH occurred at pH 4.0 and of glucose oxidase at pH 5.0.

15.6.5 Fed Batch Culture

Fed batch culture is a batch culture fed continuously or sequentially with substrate without the removal of fermentation broth. Compared to conventional batch culture, fed batch culture has several advantages including a very low concentration of residual sugars, higher dissolved oxygen in the medium, decreased fermentation time, higher productivity, and reduced toxic effects of the medium components that occur at high concentrations (155).

Dawson et al. (154) studied the production of citric acid by *A. niger* in batch, chemostat, and fed batch cultures. They found that in fed batch culture, the maintenance of active growth resulted in improved citric acid yield and production rates when compared with batch culture. However, the specific citric acid production rate in fed batch culture was still less than the rate observed in chemostat culture. This was probably due to a higher dissolved oxygen tension value or a higher dilution rate used in the chemostat. To obtain high dissolved oxygen tension values in fed batch culture, where biomass concentration is high, it may be necessary to use pure oxygen rather than air or provide significantly greater power input. Finally, the authors found that in fed batch culture, citric acid productivity was two times higher than that of a conventional batch culture. These results agree with those of Dawson, et al. (89) and Choe and Yoo (90). In addition, Dawson, et al. (89) observed that a fed batch fermentation process operated under nitrogen and phosphate limitation is an efficient and economic process for citric acid production.

15.6.6 Solid-State Fermentation

Solid-state fermentation (SSF) is generally defined by the growth of the microorganism in a low water activity environment on an insoluble material that acts both as a physical support and a source of nutrients (156,157). However, it is not necessary to combine the role of support and substrate, but rather to reproduce the conditions of low water activity and high oxygen transference by using a nutritionally inert material soaked with a nutrient solution (156). In recent years, SSF technology has gained more attention. Solid-state fermentation offers numerous advantages for the production of microbial products. It requires less economic investment, an important aspect when methods for waste treatment are being encouraged (156). It has lower energy requirements and produces less wastewater than submerged fermentation (19,157). In addition, increasing environmental concerns regarding the disposal of solid wastes and their use as substrates for the commercial production of microbial metabolites is becoming an attractive proposition (157). Generally, SSF for citrate production is equal or superior to surface or submerged fermentation. Given the above advantages of this technology, use of this fermentation system is expected to increase (158).

For commercial implementation of SSF, the tray reactor is currently the most popular technology. It is simple but has some disadvantages such as a poor air supply. It also requires a large area and thus poses serious handling problems on a commercial scale (18,157). Moreover, in tray bioreactors the transport of heat and mass is limited by convection, conduction, and diffusion, and the gradients quickly become steep, placing a low limit on the design thickness of the solid substrate bed (18). Thus, other types of reactors are being investigated, including the packed bed reactor (18,157,159,160). A packed bed reactor consist of a glass column of 700 mm in length and 48 cm in diameter (157). Dry air from a cylinder is passed through a rotameter, a cotton wool filter, and then a solution of 20% (w/v) Na0H to remove carbon dioxide. It is then adjusted to 29–30°C and 95–100% RH as it passes through the humidifier. The moist air enters the reactor at the top to prevent lifting of the substrate, which can cause serious blockage in the reactor during the later period of operation. The air exiting the substrates bed is passed through a condenser (0°C) and then a water trap to strip its moisture (157). The substrate is inoculated prior to installation in the sterile reactor by mixing with a spore suspension at a rate of 2.5×10^{-4} spores/g wet weight of substrate. The most important fermentation parameters influencing the production of citric acid by *A. niger* in SSF are inoculum size, moisture, pH, temperature, particle size, aeration rate, and bed height (18,106,107,161).

Lu et al. (157,159) studied the production of citric acid from kumara, a starch containing root crop, by *A. niger* in SSF using a single layer and multilayer packed bed reactor. They found that maximum citric acid productivity to be 0.82 g citrate kg^{-1} wet weight kumara h^{-1}. This amount was twice that observed in flask culture. In this respect, the results in the packed bed reactor were superior to those of flask culture, probably because of improved aeration. In addition, the multilayer packed bed reactor yielded a marked increase in citric acid concentration compared to the single layer reactor, presumably because of improved mass transfer.

Other workers (18,160) studied the production of citric acid from apple pomace by *A. niger* in a packed bed reactor. It was found that the maximum citric acid concentration was124–130 g of citric acid per kilogram of dry apple pomace. This amount of citric acid was obtained at an aeration rate of 0.8 L/min, a bed height of 10 cm, particle sizes of 0.6–2.33 mm, and a moisture content of 78% (w/w) (18).

Pintado et al. (156) studied the production of citric acid from mussel processing effluents by different strains of *A. niger* in SSF using polyurethane foam particles soaked

with the culture medium. The results showed that in comparison with submerged fermentation, the strains with requirements of N and P seemed to be disfavored in SSF. The ones with low requirements were favored and showed a bigger tolerance to a surplus of both nutrients. The maximum citric acid concentration (46.5 g/L) was obtained in culture grown in SSF. Another relevant work (162) examined the possibility of monitoring citric acid production by *A. niger* in SSF on sugarcane bagasse. This study was conducted by measuring CO_2 and O_2 concentration in exhaust gases using an automatic sampler connected to a gas chromatograph and a data acquisition system. A relationship between citric acid accumulation and a decrease in CO_2 production was reported. Other workers (163) examined the production of citric acid at high glucose concentration (400 g/L) by *A. niger* in SSF on Amberlite as an inert support. They observed that maximum citric acid concentration (94.5 g/L) and maximum productivity (1.3 g/L/h) were obtained without inhibition related to the presence of heavy metals at high concentrations.

15.6.7 Immobilized Cells

In the past few years, immobilization of microbial cells has been studied with greater interest, and immobilized cells have been used for the production of organic acids, amino acids, antibiotics, enzymes, and other compounds. The production of citric acid by immobilized *A. niger* or yeasts cells compared with free cell systems has several advantages. The cells can be reused for long periods and transferred simply by draining the supernatant and replacing with fresh medium. The fermentation process can be controlled more easily. A less expensive fermentor design is required. Continuous fermentation takes place at a high dilution rate without washout and with higher product yield. Working at dilution rates greater than the growth rate of contaminating microorganisms also helps to overcome infection problems. Immobilized microbial cells are more stable than free cells. In the case of *A. niger,* the immobilization process generally leads to a consistent decrease in medium viscosity, thus enhancing nutrient and oxygen transfers which makes repeated batch and continuous processes possible (164–167). However, immobilized cell systems have some problems such as possible metabolic changes, a need to ensure diffusion of substrates and products, contamination of the medium with free cells, the cost of the immobilization matrix, and, in the case of *A. niger*, a layer of the mycelium forms outside of beads, which prevents the diffusion of substrate and air into the beads (164,165).

Fermentation systems used for the production of citric acid by immobilized microbial cells are the batch and repeated batch culture systems, and the continuous culture system. Fermentation is usually carried out in a bubble column reactor, where high cell concentrations and thus productivity values can be attained. Furthermore, the construction cost of the bioreactor is low, and these reactors can be readily used in continuous flow mode. Consequently, they can be maintained for long periods of time (44). In recent years, citric acid has been produced on a laboratory scale with *A. niger* or yeast cells immobilized in calcium alginate beads (5,41,43,164,166,168–176), k-carrageenan (5,41,168), polyacrylamide gel (40,177), polyurethane foam (41,167,178), cellulose microfibrils (179), and sawdust (44). When the media contains large amounts of nitrogen compounds, the production of citric acid by immobilized *A. niger* cells in calcium alginate gels is carried out in two phases. In the first phase, gel bead immobilized spores or hyphae are precultivated in medium containing 200 mg/L NH_4NO_3. In this case, a peripheral layer of the mycelium is grown on the gel bead. In the second phase, the growth medium is replaced with the production medium, which is supplemented with a limited concentration of NH_4NO_3 (150 mg/L). This limitation of the nitrogen source induces a higher mycelium growth in the center of the beads (169). Eikmeier and Rehm (169) reported that in the case of immobilized *A. niger* cells the development of the mycelium layer near the gel bead surface becomes overloaded at high NH_4NO_3

concentrations (>400.0 mg/L), and free cells occur in the medium. Moreover, these densely packed and actively metabolizing peripheral mycelia build up a critical diffusion resistance which may overcome the normal diffusional limitation of the alginate bead. This might explain the enormous decrease of acid production of the immobilized *A. niger* cells at high nitrogen concentrations (169). In fermentation systems with nitrogen limitations, the immobilized *A. niger* cells produce more citric acid than the free pellets, perhaps due to the fact that the immobilized microorganisms grow from a large amount of spores, whereby the formation of free pellets depends on a limited spore inoculum. Given this fact, immobilized mycelia are characterized by thin or just germinated young hyphae which have a higher metabolic activity than submerged cultivated free cells (169). Using an air lift fermentor, Eikmeier and Rehm (169) found that the outgrowth of free mycelia into the medium could be provided by increasing the particle volume:medium volume ratio, by which means the productivity increased twofold, over that obtained in shaking culture. In general, high nitrogen concentrations (400.0 mg/L) cause a peripheral development of the fungus and outgrowing of the cells, whereas at low concentrations of NH_4NO_3 (200.0 mg/L), *A. niger* forms thin mycelia which grow through the whole interior of the particles, with no outgrowing cells. The immobilization system with low nitrogen concentrations and fungal growth inside the particles seems to be favorable for fermentation of hydrophilic substrates such as molasses and sucrose, without contamination of the media by free cells (168).

Honecker et al. (174) studied the influence of sucrose concentration and phosphate limitation on citric acid production by immobilized cells of *A. niger.* They found that immobilized cells of *A. niger* needed a lower initial sucrose concentration (120.0 g/L) than free cells in order to obtain maximal yields of citric acid (50.0 g/L). However, high sucrose concentrations (240.0 g/L) led to reduced yields (40.0 g/L) and increased polyol formation (glycerol, erythritol, arabitol). These results agree with those of Bisping, et al. (175) who studied the formation of citric acid and polyols by immobilized cells of *A. niger.* Continuous culture with media containing low sugar concentrations prevented the formation of polyols. The change from nitrogen limited to phosphate limited precultivation of immobilized spores significantly increased the productivity of citric acid. Bayraktar and Mehmetoglu (166) found that immobilized cells of *A. niger* require a 2-day preactivation period at a 0.05 g/L NH_4NO_3 concentration. Maximum citric acid concentration was obtained with medium containing 0.01 g/L of NH_4NO_3.

The rate of citric acid production in the nitrogenous medium was 33% higher when oxygen was used instead of air during the production phase. In the nonnitrogenous production medium, citric acid production was not significantly influenced when oxygen was used instead of air. Similar results were observed by Vaija and Linko (170) who studied the production of citric acid by *A. niger* cells entrapped in calcium alginate beads in continuous culture. They observed that oxygen transport was the limiting factor when air was used as the oxygen source. The effectiveness factor (n) was estimated to be between 0.1 and 0.2 with air and 0.6 and 0.95 with pure oxygen. The use of pure oxygen appeared to be the only effective way to reduce oxygen transport limitations. The average volumetric productivity under optimal conditions was 0.3–0.5 g/L/h, while the specific productivity at the beginning of the process was about 0.025 g/g/h, decreasing slowly to about 0.01 g/g/h after 33 days of fermentation.

In another similar work (166), citric acid production was tested in a packed bed bioreactor, and an increase in productivity by a factor of 22 was achieved compared to the batch system. Other workers (173) studied the production of citric acid by immobilized *A. niger* cells in calcium alginate beads using semicontinuous and continuous culture. They reported that citric acid production could better be prolonged by semicontinuous cultivation with medium exchange every 7 or 14 days, respectively. After 32 days, the remaining activity in

semicontinuous culture was 1.4-fold higher than in comparable batch experiments. Similar improvements were obtained with a continuous process at a dilution rate of 0.125 h^{-1}, whereby medium efflux kept completely free of detaching mycelia.

Tsay and To (171) examined the production of citric acid from synthetic medium by *A. niger* cells entrapped in calcium alginate gels using batch and repeated batch fermentation. They found that maximum citric acid concentration (77.0 g/L) was obtained at an initial sucrose concentration of 14%, an initial pH of 3.3–4.8, and a temperature of 35°C. The final pH was maintained lower than 2.0; such a low pH value is advantageous in that high yields of citric acid are favored, oxalic acid formation is suppressed, and the danger of contaminations is minimized. Under the same conditions with a batch wise culture, immobilized cells of *A. niger* retained the ability to produce citric acid up to 31 days without marked activity loss when the microorganism was grown on chemically defined medium in surface fermentation. In contrast, free cells maintained a shorter acid producing phase (17 days). This indicated that immobilized cells could retain enzyme activities for long periods, which may be due to a change of the chemical composition of cells (proteins, lipids, DNA, RNA, inorganic substances, saccharides) and the activity of some key enzymes (164). Gupta and Sharma (176) studied the production of citric acid from sugarcane molasses using a combination of submerged calcium alginate immobilized and surface stabilized culture (free cells) of *A. niger* in a continuous flow horizontal bioreactor. They observed that citric acid productivity depended on the dilution rate, with an optimum value of 0.015 h^{-1}. Presaturation of fermentation medium with sterile air, in addition to surface aeration, before feeding to the bioreactor enhanced citric acid productivity. The highest citric acid concentration, productivity, and yield was 110.0 g/L, 1.7 g/L/h, and 91.0%, respectively. The fermentation system was continuously used for 30 days without any apparent loss in citric acid productivity.

Roukas (164) immobilized cells of *A. niger* in calcium alginate beads and studied the production of citric acid from beet molasses in a shake flask and glass bioreactor. It was found that the production of citric acid from molasses by immobilized *A. niger* cells presented the problem of outgrowing of free cells in the medium, which was due to large amounts of nitrogen compounds contained in molasses. To remove the nitrogen compounds, the molasses solution containing 14% initial sugars was treated with a cation and an anion exchange resin. The pH of the solution was adjusted to 3.0, and this substrate (production medium) was used for the production of citric acid. Fermentation was carried out in two phases: immobilized *A. niger* spores were grown on molasses medium, pH 6.5, containing 20 g/L sucrose and 0.6 g/L nitrogen compounds, and the above growth medium was replaced by production medium. In one experiment, 20 g of calcium alginate gel beads entrapping the fungi spores were added in 500 mL Erlenmeyer flasks containing 100 mL of growth medium. The flasks were shaken on a rotary shaker at 250 rpm for 4 days at 30°C. Thus, immobilized growing cells were obtained. The gel beads were then washed with sterile physiological salt solution and 100 mL of production medium was added to the flasks. When a maximum citric acid concentration was achieved, the original production medium was removed, the gel beads were washed twice with sterile distilled water, and fresh production medium was added to the flasks. The above batch fermentation was repeated four times. In a second experiment, calcium alginate gel beads were packed in a glass bioreactor containing the production medium. (The gel beads were incubated in growth medium as described above prior to being added to the bioreactor.) Incubation was carried out under aeration at rates of 0.5, 1.5, and 2.5 vvm at 30°C. The results showed that for the production of citric acid, shaking culture was a better fermentation system than the bioreactor. Maximum citric acid concentration (35.0 g/L) was observed from immobilized *A. niger* cells in shake flasks after 28 days of fermentation. In repeated batch fermentations,

A. niger cells entrapped in calcium alginate gel beads retained their ability to produce citric acid for up to 84 days. In the glass bioreactor, citric acid concentration increased with increased aeration rate, from 0.5 to 2.5 vvm, but was not significantly increased when aeration rate increased beyond 1.5 vvm. This may be explained by the fact that the higher the aeration rate, the better the growth of cells into the beads, and when the aeration rate increased, the diffusion coefficient of substrate into the beads increased. At an aeration rate of 0.5, 1.5, and 2.5 vvm, the maximum concentration of citric acid was 6.0, 22.0, and 27.0 g/L, respectively, after 28 days of incubation.

Horitsu et al. (177) immobilized *A. niger* cells in polyacrylamide gels and studied the effect of aeration volume, oxygen tension, and shape of immobilized cells on citric acid production from sucrose in a glass bioreactor. They observed that in the case of immobilized cells, the rate of citric acid production was ~2.4 times higher than of free cells. This fact indicates that immobilized *A. niger* cells retained their activity to produce citric acid for a long period of time, whereas in the case of free cells their activities are difficult to retain because autolysis occurs under conditions where they are supplied minimum nutrients. Increasing the aeration rate from 0.7 vvm to 2.8 vvm increased the concentration of citric acid 1.4-fold, and then a falloff occurred. The rate of citric acid production using only oxygen was ~1.7 times higher than that of air. This means that immobilized cells require more oxygen tension for citric acid production. The effect of shape of immobilized cells on citric acid production showed that the rate of production with the $4 \times 4 \times 1$ mm slice was ~1.4 times higher than that of the 4 mm^3 cube. In this case, the rate of citric acid production with slices aerated at 1.4 vvm of O_2 was ~2.1 times higher than that of a cube at 1.4 vvm of air. The above results show that the higher the oxygen tension, the more citric acid is produced; and the greater the surface of immobilized particle, the more citric acid is produced because the surface grown mycelia have much better contact with the nutrient and oxygen supply. In a glass bioreactor, the maximum rate of citric acid was 39.1 mg/h per 40 g gels, and the period of half life was found to be 105 days. However, in a tower fermentor the maximum rate of citric acid and the period of half life were 96.6 mg/h per 80 g gels and 96 h, respectively.

Other workers (178) immobilized *A. niger* cells on polyurethane foam and examined the production of citric acid from synthetic medium in a bubble column. They reported that most of the adsorbed cells remained on the support and, as a result, high oxygen tension was maintained during the reactor operation. However, uncontrolled growth of the pellets made continuous reactor operation difficult. The maximum citric acid productivity (0.135 g/L/h) was observed from 15% foam particle concentration. This productivity of immobilized cells was almost the same as that of free cells. The oxygen level dropped to half saturation in 5 days in the immobilized cell culture, in contrast to 2 days in the free cell culture. Jianlong (167) used a rotating biological contactor (RBC) to produce citric acid by immobilized *A. niger* cells on polyurethane foam (PUF). The reactor was a 2.0 L fermentor with 1.0 L working volume. The reactor contained five plastic disks (120 cm^2/disk). Polyurethane foam, 60 cm^2 per side, was attached to both sides of each disk. The disks, with a total surface area of 600 cm^2, were connected to a single stainless steel shaft, which had bearings at both ends and was rotated by a variable speed motor using a reducing gear. The disks were placed in the fermentor containing growth medium. Mycelial fungi showed a strong tendency to grow on PUF to form the biofilm and immobilized on the surface of PUF. During fermentation, air was flowed into and out of the upper portion of air space at an air flow rate of 1.2 vvm. The disks were rotated and the biofilms were exposed alternately to the fermentative medium and the air space. The reactor was operated in a batch mode. During incubation, with slow rotation of the plastic disks (10 rpm), the germinated spores with hyphae became attached to the surface of PUF upon contact. They grew on and

around the disks, eventually covering the entire surface of the PUF, and formed a mycelial biofilm. During fermentation, the disks were rotated at 20 rpm, slightly faster than during the microbial growth phase. The slower rotational speed used during the biofilm formation phase was to allow the mycelia to attach to the surface of PUF without much friction. The results showed that maximum citric acid concentration (86.0 g/L) was obtained from an initial average glucose of 120 g/L, which is a higher concentration than that in the stirred tank fermentor. Fermentation time was 4 days, which is much shorter than that in the stirred tank fermentor. The productivity of citric acid obtained with the RBC-PUF system (0.896 g/L/h) was almost three times higher than that obtained with a stirred tank fermentor (0.33 g/L/h). The immobilized biofilm was active for over 8 cycle periods of citric acid production with repetitive use without loss of bioactivity. In general, the most significant advantage of the RBC-PUF system for citric acid production is an increase of volumetric productivity and the reusability of fungal mycelia.

Sankpal et al. (179) immobilized *A. niger* cells by adsorption onto cellulose microfibrils of a porous fabric and used them in batch, fed batch, and continuous production of citric acid. The support used for immobilization of *A. niger* and the mode of fermentation have played important roles in enhancing productivity of citric acid due to the different morphology achieved under conditions of submerged and surface modes of fermentations. In submerged fermentation, the mycelia form a thick mat of microfibrils whereas in the surface mode, a protruding mycelial structure was seen in a cobweblike network of free filaments between the microfibrils of fabric. These microfibrils also show lumens, which may play an important role in medium flow and interfacial interactions during medium movement. Immobilized cells showed a great variability in morphology, which is an important consideration in heat and mass transfer. Interface interaction and metabolite excretion are the major advantages in immobilization techniques. Highly improved interface interaction between mycelia and oxygen, as well as substrate, improves the diffusion of substrate; continuous removal of the metabolite formed also contributes to improved productivity. In the fed batch mode using a recycle reactor, the dissolved oxygen concentration of the system was maintained at 20 mg/L using oxygen enriched air. This improved volumetric productivity to 1.85 g/L/h of citric acid, representing a 15-fold increase over results obtained simultaneously using a shake flask and a 1.6-fold increase over a conventional aerated batch reactor. An overall specific production rate of citric acid of 0.147 and 0.208 g/g/h was achieved using cane juice and sucrose, respectively. In continuous culture, a medium containing 50 g/L of sucrose was allowed to drip through the fabric support at a residence time of 20 h. As a result of interface interaction, a citric acid productivity of 2.08 g/L/h was achieved for 26 days without any significant loss of productivity.

Several workers have investigated the production of citric acid by entrapped yeast cells in different matrixes. Maddox and Kingston (40) immobilized *Y. lipolytica* cells in polyacrylamide gel to produce citric acid from glucose. It was found that the production rate was 50 mg/L/h. In comparison with free cells in a stirred tank fermentor, this production rate of citric acid was low. Nonetheless, the immobilized cells of the yeast retained their activity to produce citric acid for 45 days, and the gel particles were able to be stored at 4°C for 14 days without loss of activity. Kautola et al. (41) studied the production of citric acid by immobilized *Y. lipolytica* cells in calcium alginate beads, k-carrageenan, polyurethane gel, nylon web, and polyurethane foam using repeated batch culture. The highest citric acid productivity (155 mg/L/h) was observed with calcium alginate beads in the first batch. A decrease in bead diameter from 5 to 6 mm to 2 to 3 mm increased volumetric citric acid productivity threefold. In an air lift bioreactor the highest citric acid productivity of 120 mg/L/h with a product concentration of 16.4 g/L obtained from cells entrapped in k-carrageenan gel. Rymowicz et al. (43) investigated the production of citric

acid by *Y. lipolytica* cells entrapped in calcium alginate beads in a repeated batch and continuous air lift bioreactor. The highest citric acid concentration (39 g/L) was obtained in medium containing 150 g/l glucose, 0.105 g/l potassium dihydrogen phosphate, 0.84 g/l magnesium sulphate, and 21 mg/l copper sulphate. The production of citric acid was further improved by hardening the alginate carrier beads with glutaraldehyde, and by activation of the immobilized biocatalyst in a nutrient solution. In continuous air lift bioreactor with a height to diameter ratio of 3.0, the highest citric acid productivity (350 mg/L/h) was achieved at a dilution rate of 0.023 h^{-1}.

Tisnadjaja et al. (44) immobilized *C. guilliermondii* cells by adsorption onto sawdust and used in a bubble column reactor for the continuous production of citric acid. The results showed that at a dilution rate of 0.21 h^{-1} in a nitrogen limited medium containing glucose, a productivity of 0.24 g/l/h has been achieved which is twice that observed in a batch fermentor culture using free cells. The corresponding specific production rate of citric acid was 0.024 g/g biomass/h , while the yield was 0.1 g/g glucose utilized. These latter values were lower than those observed using free cells. In conclusion, the technique of immobilization of the yeast cells onto sawdust is cheap, simple to operate, and allows reactor productivities comparable to those reported using other immobilization techniques.

15.7 SUBSTRATES USED FOR THE PRODUCTION OF CITRIC ACID

15.7.1 Chemically Defined Media

Chemically defined media consist of (g/L) sucrose 100–140; NH_4NO_3 1.5–2.5 ; KH_2PO_4 0.25–1.0; $MgSO_4.7H_2O$ 0.25; $CuSO_4.5H_2O$ 40.0 mg/L, and $K_4Fe(CN)_6$ 6.0 mg/L (180,181). The pH of the medium is adjusted to 2.5–5.0. It was found that the maximum citric acid concentration was 110.0 g/L when *A. niger* was grown in synthetic medium in shake flask culture (180). Qazi et al. (181) studied the production of citric acid from synthetic medium in a pilot study (500 L and 2.6 m^3 stirred tank fermentor) and found a maximum concentration of citric acid of 60.0 and 80.0 g/L, respectively. Maddox et al. (182) studied the production of citric acid from glucose, mannose, galactose, xylose, arabinose, or a mixture of the above substances by *A. niger* or *S. lipolytica* and found that the maximum concentration of citric acid ranged between 5.0 and 27.0 g/L. Also, they reported that *S. lipolytica* failed to assimilate xylose, arabinose, and galactose, while *A. niger* did not metabolize galactose. Asenjo, et al. (35) investigated the production of citric acid (6.0 g/L) from cellulose hydrolysate by *C. guilliermondii.* Kirimura et al. (183) studied the production of citric acid from xylan and xylan hydrolysate by *A. niger* Yang no. 2 strain. The microorganism produced 72.4, 52.6, 51.6, and 39.6 g/L of citric acid from xylose, arabinose, xylan hydrolysate, and xylan, respectively. Drysdale and McKay (184) studied the production of citric acid from inulin in surface fermentation and found that citric acid yields can be improved by airflow over the surface of the fermentation, but yields from inulin were 20–30% lower than from sucrose, the traditional commercial substrate.

15.7.2 Molasses

Molasses is a byproduct of the sugar industry and readily available at relatively low cost. It contains water, sugars (sucrose, invert sugar, ~50% w/w), nitrogen compounds (betaine, glutamine, asparagine, leucine, isoleucine, alanine, valine, glycine, and nitrogen as nitrates and nitrites), organic acids, and heavy metals such as iron, zinc, copper, manganese, magnesium, and calcium (185). High heavy metal concentrations in molasses solution cause a

critical problem during fermentation as they inhibit the growth of microorganisms, influence substrate pH, and are involved in the inactivation of enzymes associated with product biosynthesis. To overcome this problem, molasses solution containing 14% (w/w) initial sugars is treated with cation exchange resin, sulfuric acid, tricalcium phosphate, potassium ferrocyanide, or EDTA. Among these chemical methods, potassium ferrocyanide treatment is the most common used. The maximum concentration of citric acid produced from molasses by *A. niger* in surface and submerged culture ranged between 60.0 and 110.0 g/L (186–190). Hamissa and Radwan (191) and Qazi et al. (181) studied the production of citric acid from cane molasses by *A. niger* in a pilot study using surface or submerged fermentation and found a maximum concentration of citric acid of 60.8 and 67.0 g/L, respectively. Garg and Sharma (192) examined the production of citric acid from cane molasses by cell recycling of *A. niger* in surface fermentation. It was observed that the rate of citric acid production was doubled, reducing fermentation time in half compared to the normal single cycle batch submerged or surface fermentation process. About 80% of the sugar was converted to citric acid in 5 days of batch fermentation, and three batches were carried out with the same fungal mat without any significant loss of productivity. Jianlong et al. (193) developed a novel method of citric acid production from beet molasses in which an anion exchange resin packed column was connected to a fermentor for separation of citric acid from fermentation broth. The results indicated that, as compared with a conventional batch, the new fermentation technique increased citric acid productivity and sugar conversion from 0.338 g/L/h and 82.2% to 0.543 g/L/h and 94.8%, respectively.

Jianlong (194) improved the production of citric acid from beet molasses by *A. niger* with the addition of phytate to the medium. Phytate is an important plant constituent and can be found in the seeds of cereals and legumes. The effect of phytate addition was found to be dependent on concentration and the stage of fermentation at which phytate was added. When added at the beginning of incubation, the optimal concentration of phytate in the medium for citric acid production was 10.0 g/L, which resulted in a ~3.1-fold increase in citric acid accumulation. Addition of 16.0 g/L phytate to the medium, after 3 days incubation, gave the maximal citric acid concentration, which was ~2.4-fold higher than the control experiment.

Adham (195) reported that natural oils (almond, caster, maize, nigella, olive, peanut, soybean, sunflower) added at concentrations of 2 and 4% (v/v) to beet molasses medium caused a considerable increase in citric acid yield by *A. niger.* Among these natural oils, best citric acid yields were obtained with olive, sunflower, and maize oils at 4% doses. Maximum citric acid concentration (72.8 g/L) was achieved in the medium supplemented with 4% olive oil after 12 days of incubation using surface fermentation.

15.7.3 Cereal Constituents

Starch is the main constituent of cereals. The production of citric acid from different sources of starch (corn, potato, cassava, yam bean) has been reported (196–200). Generally, in the starch medium, the critical factors of citric acid production are the aeration efficiency of the medium and the amylase formation of the strain (196). Mourya and Jauhri (197) tested 17 strains of *A. niger* for their capacity to produce citric acid using starch hydrolysate as a substrate. The most efficient strain, *A. niger* ITCC-605, was selected for further improvement in citric acid content by mutation. In this case, the maximum citric acid concentration was 64.7 g/kg of glucose consumed. Bolach et al. (198) reported that liquefied starch (DE <25) was a better substrate for the production of citric acid than saccharified starch (DE >80). Tan, et al. (199) found that a typical medium containing 2% cassava starch yielded 5.4 g/L biomass dry weight and 74.8 g/L organic acids (citric, malic, gluconic, succinic, fumaric). Sarangbin and Watanapokasin (200) investigated the

production of citric acid from yam bean starch by a protease negative mutant strain of *A. niger*. They found a maximum citric acid concentration of 106.0 g/L, whereas the parental strain produced 58.0 g/L from 140.0 g/L of soluble starch in semisolid culture after 5 days of fermentation. Esuoso et al. (201) reported the production of citric acid from imumu *Cyperus esculentus* and maize *Zea mays* by *A. niger*. Imumu, although a weed, has a tuber rich in carbohydrate. It is widely distributed and constitutes one of the world's worst weeds. Proximate analysis reveals a high percentage of starch, with pockets of sugar, protein, and lipids. It was observed that the maximum citric acid concentration (14.3 g/L) was obtained in unagitated and defatted cultures compared to agitated and undefatted cultures, respectively. Hang and Woodams (202,203) studied the production of citric acid from corncobs and corn husks by *A. niger*. Corncobs and corn husks are important byproducts of the sweet corn processing industry that have been either used as animal feed or are returned to the harvested field. Methanol had a significant effect on the production of citric acid from corncobs. Of the four cultures examined, *A. niger* NRRL 2001 was found to produce the highest amount of citric acid (250 g/kg dry corncobs) after 72 h of incubation at 30°C in the presence of 3% methanol. The yield of citric acid was over 50% based on the amount of sugar consumed. Combined treatments of corn husks with dilute NaOH and Rapidase Pomaliq (a commercial apple juice processing enzyme preparation) significantly enhanced the yield of citric acid. Under favorable conditions (pretreated with 0.5 M NaOH, followed by 120 h fermentation at 30°C in the presence of Rapidase Pomaliq and 3% methanol), the yield of citric acid was 260.0 g/kg of dry matter of corn husks. Yuguo et al. (204) investigated citric acid production from dried sweet potato mash with its dregs by *A. niger* in an external loop airlift bioreactor and in a stirred tank fermentor. They found that an average of 10.6 g/L of citric acid was obtained in the external loop airlift bioreactor under an airflow rate of 1.3 vvm and liquid volume of 8.5 L as compared to 9.6 g/L of citric acid in the 10 L stirred tank fermentor at an agitation rate of 200 rpm, airflow rate at 1.0 vvm, and liquid volume of 6.5 L.

Khare et al. (205) reported the production of citric acid from okara (soy residue) in SSF using a cellulolytic *A. terreus* and citric acid producing *A. niger*. Okara or soy residue is generated as a byproduct from soy milk and tofu production. The medium supplemented with ammonium sulfate (0.1% N) when fermented by *A. niger* with simultaneous saccharification using *A. terreus* at pH 8.3 and incubation temperature of 30°C resulted in the production of 5.1 g citric acid/100 g dry solids.

Other workers (158) produced citric acid from kumara (*Ipomoea batatas*), taro (*Colacasia esculenta*), and potato (*Solanum tuberosum*) by *A. niger* in SSF. Raw tubers were peeled, heated at 121°C for 30 min, and blended into a paste. The fermentation was carried out in 250 mL conical flasks containing 40 g of paste, inoculated with 10^8 spores per flask and incubated at 30°C as surface fermentation. The results showed that kumara and taro were excellent substrates for citric acid production, while potato was a poor medium, although it supported profuse fungal growth. The maximum citric acid concentrations were 69.0, 66.0, and 3.0 g/kg wet weight of the substrate from kumara, taro, and potato, respectively, after 6 days of fermentation. The optimum moisture content of the kumara for citrate production was ≥65% (w/w), while metal ions were shown not to be inhibitory to the process.

15.7.4 Fruit Extracts

In past years, a considerable interest has been shown in using agricultural products such as dates, carob pods, and figs for the production of citric acid by *A. niger* (27,86,105–107,206,207). Date syrup is produced from dates by boiling the dates in water, filtering the solution, and concentrating the filtrate under vacuum. The extract of the date syrup

contains large amounts of heavy metals which are removed by treatment of syrup with cation exchange resin, sulfuric acid, tricalcium phosphate, potassium ferrocyanide, and EDTA (105,206,207). Al-Obaidi and Berry (207) applied a filtration technique to produce citric acid from date syrup. In this process the medium was exchanged using an external filtration loop in which only a small percentage of the medium passing through the upper chamber of the filter was removed at any one pass. In this way cells were maintained suspended in the growth medium throughout the filtration process. Using this technique, the maximum citric acid concentration and the yield were 102.0 g/L and 72.2%, respectively. Roukas and Kotzekidou (105) studied the production of citric acid from date syrup and found that the maximum citric acid concentration (55.0 g/L), citric acid yield (50.0%), and sugar utilization (73.0%) were obtained in medium treated with 2% tricalcium phosphate. The optimum pH for citric acid production was 6.5. The addition of 4% (v/v) methanol in the date syrup solution increased the concentration of citric acid by 63.5%. Roukas (86,106) investigated the production of citric acid from carob pod extract and carob pod using surface culture and SSF, respectively. After removing the seeds, carob pod residue, or kibble, was chopped into small particles which were mixed with water at a ratio of solid to liquid of 1:4. The mixture was shaken on a rotary shaker incubator at 250 rpm for 2 h at 70°C in order to extract the sugars from the kibble. The extract was centrifuged at 4000 $\times$ g for 15 min, and the supernatant (production medium) was used for the production of citric acid. In the case of SSF, the kibble was chopped into small particles and pulverized in a Waring Blendor at high speed. The pulverized particles were oven dried overnight at 70°C and passed through sieves with a pore size of 0.5, 1.2, 2.5, and 5.0 mm. The medium was moistened with the appropriate amount of distilled water to contain 55, 60, 65, and 70% moisture. The results showed that the maximum citric acid concentration (85.5 g/L) was achieved at an initial sugar concentration of 200 g/L, pH of 6.5, and a temperature of 30°C. In solid-state fermentation, the highest citric acid concentration (176.0 g/kg dry pod) was obtained at a particle size of 0.5 mm, moisture level of 65%, pH of 6.5, and temperature of 30°C. The external addition of 6% (w/w) methanol into the substrate increased the concentration of citric acid by 50%. In other relevant studies, Roukas (27,107) reported the production of citric acid from figs by *A. niger* in surface and SSF. Figs were chopped into small particles which were mixed with distilled water (solid/liquid ratio 1:2), and the mixture was maintained at room temperature for 24 h in order to extract the sugars from the figs. In SSF, the particles of figs were moistened with an appropriate amount of distilled water to contain 60, 65, 70, 75, or 80% moisture. The maximum citric acid concentration was 20.5 g/L in the surface culture, whereas in the SSF the highest citric acid concentration (64.0 g/kg dry figs) was obtained at a moisture level of 75%, initial pH 7.0, temperature 30°C, and fermentation time 15 days.

15.7.5 Hydrocarbons

The production of citric acid from hydrocarbons (n-paraffins, n-alkanes, a-olefins) by the yeast *Y. lipolytica* has been described (8,11–15,29–31,36). Paraffins used for the production of citric acid were usually composed of 12–19 carbon atoms. The medium containing n-paraffins (50.0 g/L) was supplemented with (g/L) the following: NH_4NO_3 5.0; KH_2PO_4 4.0; $MgSO{\bullet}7H_2O$ 2.0; $FeSO_4{\bullet}7H_2O$ 0.4; $MnSO_4{\bullet}7H_2O$ 0.05; and thiamine•HCl 0.0005. The n-paraffins mixture had the following composition (in %): C_{12} 0.10; C_{13} 3.50; C_{14} 21.50; C_{15} 28.70; C_{16} 25.30; C_{17} 18.20; C_{18} 2.30; C_{19} 0.15; isoparaffins 0.25; and aromatics 0.01 (12). The disadvantage of citric acid production from hydrocarbons by yeasts is the formation of isocitric acid during fermentation. Aiba and Matsuoka (13) suggested that the production of the above acids is controlled by the enzyme isocitrate lyase (ICL). Treton, et al. (29) gave several explanations for the nonconsumption of isocitric acid observed in

the presence of citric acid: (1) If the same permease mediates the uptake of both citric and isocitric acids, one could expect that phenomena of competitive inhibitions would occur to the prejudice of isocitric acid uptake. Actually, citric acid is always in excess over isocitric acid. (2) There is also the possibility that the carriers might be different, as has already been shown with different microorganisms. Citric acid could act as a repressor or an inhibitor of the transport system specific for isocitric acid. The maximum concentration of citric and isocitric acid produced from n-paraffins by *Y. lipolytica* ranged between 55.0 and 65.0 and 30.0 and 35.0 g/L, respectively (12,29). Terasawa et al. (31) studied the production of citric acid from *l*-tetradecane and *n*-tetradecane and found that the amount of total citrates (citrate and isocitrate) was 40.0 and 48.0 g/L, respectively. Crolla and Kennedy (11) studied the optimization of citric acid production from n-paraffin by *C. lipolytica.* They concluded that the optimal initial concentrations of inoculum, n-paraffin, and ferric nitrate for maximum citric acid production were 10–12%, 10–15%, and 10 mg/L, respectively, at temperatures of 26–30°C. Furukawa and Ogino (15) investigated the production of citric acid from n-paraffins by *S. lipolytica* using a semicontinuous cell recycle system in order to prolong the effective production phase, to minimize product inhibition, and to shorten the lag phase preceding the production phase. They found that the lag phase was shortened and the overall productivity of citric acid was maintained at a higher rate (0.92 g/L/h) than that with the batch culture (0.58 g/L/h), although productivity during the effective phase decreased gradually.

15.7.6 Agricultural Wastes

Recently, research has been directed to finding ways of utilizing agricultural wastes for the production of citric acid. Hang and Woodams (25,208–210) studied the production of citric acid from apple and grape pomace by *A. niger* in SSF. Apple pomace is the residue left from juice extraction and constitutes about 25% of the weight of fresh fruit. Disposal is by trucking to farms for soil application. This procedure is very costly and also poses a serious environmental problem. Grape pomace is rich in carbohydrates, but its nitrogen and phosphorus contents are low. It is dumped despite increasing disposal problems and efforts at byproduct utilization. It was found that maximum citric acid concentrations were 300 g/kg dry apple pomace at moisture content of 65–75% and 90 g/kg grape pomace in the presence of 3% methanol. In another study, Hang et al. (211) described the production of citric acid from kiwifruit peel by *A. niger.* Kiwifruit peel is a byproduct resulting from the manufacture of kiwifruit into nectars or slices and represents nearly 10–16% of the weight of the original fruit, depending on the peeling method used. Its current disposal poses considerable economic and environmental problems. The highest citric acid concentration (100 g/kg dry kiwifruit peel) was obtained in the presence of 2% methanol at 30°C in 4 days. Potvin et al. (38) studied the production of citric acid from kraft black liquor by *C. tropicalis.* Kraft black liquor is the residual liquor from the kraft pulping process. It also contains significant amounts of acetic, formic, lactic, and other carboxylic acids. The maximum concentration of citric acid was 8.0 g/L. The utilization of immobilized cells improved the process parameter and enhanced fermentation capabilities. Kumagai et al. (212) produced citric acid from mandarin orange waste in SSF. It was found that maximum citric acid concentration was obtained in medium containing 6% (w/v) of mandarin orange peel and 11 mL of citrus molasses (14% total sugars content). The average yield of citric acid after 3 days of fermentation was 55–65%. Tran and Mitchell (213) and Usami and Fukutomi (214) studied the production of citric acid from pineapple waste by *A. niger* using SSF. It was found that the highest concentration of citric acid was 160.0 g/kg dry pineapple waste with a moisture content of 70% in the presence of 3% methanol. This represents a yield of 62.4% based on the sugar consumed (213). Kiel et al. (215) examined

the production of citric acid in two stage fermentations. However, mycelium obtained from surface cultures in cotton waste medium yielded more citric acid when transferred to sucrose containing media than when directly inoculated to sucrose containing media. It was concluded that cotton waste can be used for the growth of the microorganism and for increasing yields of citric acid fermentation by *A. niger.* Hossain and Brooks (216) studied the production of citric acid from whey permeate by a mutant strain of *A. niger.* In this case, a maximum citric acid concentration of 8.3 g/L was observed. Supplementation of the permeate with lactose to a final concentration of 140 g/L increased the production of citric acid to 14.8 g/L. The addition of methanol at a concentration of 3% (v/v) increased the production of citric acid to 25 g/L. The natural pH of the whey permeate (pH 4.5) was the most suitable for the process, and pH control during fermentation was unnecessary. Hang et al. (21,217) and Roukas and Kotzekidou (26,103) investigated the production of citric acid from brewery wastes by *A. niger.* Spent grain liquor is the liquor resulting from the spent grain recovery process in a brewing plant. It contains total reducing sugars as glucose, 25.7 g/L, and has a pH of 6.0. Lager tank sediment is the sludge obtained after wort fermentation and lagering of beer. It is centrifuged at 4,500 X *g* for 15 min and the supernatant is used as fermentation medium. The liquor contains total reducing sugars as glucose, 31.5 g/L, and has a pH of 4.4. The highest concentrations of citric acid produced from spent grain liquor and lager tank sediment were 19.0 and 11.5 g/L, respectively. Vandenberghe et al. (19) reported the production of citric acid from three different agroindustrial wastes, sugar cane bagasse, coffee husk, and cassava bagasse by *A. niger* in SSF. The results showed that cassava bagasse gave the highest yield of citric acid among the tested substrates. Citric acid production reached a maximum (88.0 g/kg dry matter) when fermentation was carried out with cassava bagasse having an initial moisture of 62% at 26°C for 120 h.

15.8 GENETIC ENGINEERING OF MICROORGANISMS USED FOR THE PRODUCTION OF CITRIC ACID

There is little information about mutagenic techniques applied to the improvement of microorganisms used for the production of citric acid. The main techniques are old and involve the treatment of microorganisms with UV, gamma rays, nitrogen mustard, UV nitrous acid, UV ethyleneamine, UV nitrosoguanidine, and UV N-nitroso-N-methyl urea (3,197,200,218–232). Mutations were carried out in some strains of *A. niger* and *Y. lipolytica.* The irradiation facility used was Cobalt-60 gamma chamber 4000 A. Spore suspensions were exposed to 2.0–3.0 KGy at ambient temperature. In the case of UV irradiation, fresh conidia of *A. niger* are subjected to shortwave UV irradiation for 15 min. The conidial suspension is inoculated in substrate containing 30.0 g /L of glucose and 5.0 g/L of 2-deoxyglucose (MMG5DG medium) and cultivated aerobically by shaking. After 48 h, the liquid is filtered on a sintered glass filter with a pore size of 20–30 μm to remove ungerminated conidia. The washed mycelia are resuspended in distilled water and then spread on MMG5DG agar medium. After cultivation for 2 days, growing colonies are transferred onto Koji-extract agar (KEA) medium. The conidia are inoculated on MMG5DG agar plates and growing colonies are picked up and maintained on KEA slants. Conidia of these strains are inoculated on medium containing 30 g/L glucose and 30 g/L cellobiose (MMC medium) and cultivated for 9 days. Colonies showing good growth on MMG5DG and MMC are selected and evaluated for citric acid production (220). The mutant strains of *A. niger* have some advantages over the parent strains: (1) They produce higher concentrations of citric acid. (2) Fermentation time is shorter. (3) They increase

metabolic flux through the pathway leading to citric acid formation. (4) There is a direct increase of the flux through the main pathway (i.e., by overproduction of the enzymes involved in the production of the acid). (5) Finally, they tolerate high concentrations of heavy metals and produce large amounts of citric acid when they are grown in molasses solution (3).

Mutant strains of *A. niger* have some disadvantages as well. During the screening of mutants for high citric acid concentration producers, there is a lack of a precise and quick method by which citrate producing strains can be easily selected. The variability of the strains is decreased after repeated mutagen treatments (237). Mourya and Jauhri (197) studied the production of citric acid from starch hydrolysate by a mutant strain of *A. niger*. It was found that it produced 130 times more citric acid than the parent. For further increases in citric acid production, the medium contained 15% (glucose equivalent) supplemented with NH_4NO_3 0.25%; KH_2PO_4 0.15%; nicotinic acid 0.0001%; and had an initial pH of 2.0. In this case, the mutant strain produced 490 g of citric acid/kg of glucose consumed at 30°C in 8 days of fermentation. Sarangbin and Watanapokasin (200) reported the production of citric acid from yam bean starch using a protease negative mutant strain of *A. niger.* These strains were obtained by UV irradiation of the parent strain. Using a haloselection medium, the authors selected a number of mutants with decreased extracellular protease activity. In addition, when 17 g per plate of rod shaped yam bean was used instead of soluble starch, the protease negative mutant strain produced 490 g/L of citric acid, which is ~1.5 times higher than the parent strain and showed enhanced extracellular glucoamylase production. An investigation was undertaken by Das (218) where parasexual crosses were made between strains of *A. niger.* The mutagenic treatment was carried out with UV irradiation (2537 A) and 1% N-nitroso-N-methyl urea (NMU). A heterozygous diploid was derived from the two auxotrophic mutants and produced segregants, including parental haploids and a recombinant. Kirimura et al. (219) and Sarangbin et al. (220) studied the production of citric acid by 2-deoxyglucose-resistant mutant strains of *A. niger.* It was found that the mutant strain showed faster glucose consumption and growth rate, and fermentation time was shortened from 9 to 6 days. Moreover, in semisolid culture, when the mutant strain was grown in medium containing cellobiose it produced 1.6 times more citric acid than the parent and showed enhanced β-glucosidase production. These results indicate that mutant strains are insensitive to catabolite repression. A study was made of the effects of various lipids on citric acid production by an *A. niger* mutant strain (221). Fatty acids with <15 carbon atoms inhibited growth and no citric acid was produced. Natural oils with a high content of unsaturated fatty acids, when added at 2% (v/v) to suitable media, increased citric acid yield ~20%. This may be explained by the fact that unsaturated lipids act as alternative hydrogen acceptors to oxygen during fermentation and thus improve the production of citric acid (221). Schreferl, et al. (222) reported that mutant strains of *A. niger* with reduced citrate control of carbohydrate catabolism (cic mutants) grow faster than the parent strain on media containing 5% (w/v) citrate. The mutant tolerated a higher intracellular citrate concentration (114.0 g/L) than the parent strain (85.0 g/L). Also, one mutant (cic-7/3) contained phosphofructokinase activity significantly less sensitive toward citrate than the enzyme from the parent strain. When this mutant was grown under citrate accumulating conditions, acidogenesis was far less sensitive to inhibition by Mn^{2+} than in the parent strain. Some cic mutants showed altered citrate inhibition of NADP-specific isocitrate dehydrogenase. Ghosh and Banik (224) studied the effect of chemical nutrients on aconitase activity during citric acid fermentation by a mutant strain of *A. niger.* The results showed that Fe^{2+} stimulated aconitase activity while Co^{2+} (up to 5.0 mg/L) and Ni^{2+} (10 mg/L) strongly depressed enzyme activity. Boric acid (0.5 mg/L) had a very good stimulatory response toward citric acid production. Steinbock, et al. (226)

investigated the properties of a single hexokinase from citric acid accumulating *A. niger.* They isolated mutant strains of *A. niger* by UV irradiation, which tolerated 5.0 g/L of 2-deoxyglucose in the presence of an equal concentration of fructose. These strains showed decreased growth rate and activity of hexokinase during growth on glucose. It was concluded that the synthesis of very high hexokinase activities may counteract citrate inhibition, thereby guaranteeing a high glycolytic flux during citric acid accumulation.

Islam, et al. (227) produced citric acid from cane molasses by gamma ray induced mutants of *A. niger.* Molasses contains many organic and inorganic metallic ions that inhibit the growth of microorganism and citric acid production. These are usually removed by chemical treatment before fermentation. It was found that two mutant strains of *A. niger* showed a good ability to produce citric acid without pretreatment of molasses. Thus, other workers (228–230) studied the production of citric acid from different carbohydrate media by gamma ray induced mutants of *A. niger* and by the parasexual cycle. The results indicated that improved reproducibility of a citric acid producing *A. niger* strain can be obtained after mutagen treatment or diploidization (228). Citric acid yield was found to be sevenfold higher compared to the parent strain (229). A natural isolate of *A. niger,* and two of its second step mutants, grown on sucrose medium gave maximum citric acid yields of 34.0, 70.0, and 126.0 g/L, respectively. A combination of two sugars, at 50% each, improved citric acid yield for sucrose:glucose, glucose:sorbitol, glucose:xylose, and xylose:sorbitol combinations with the mutant strains. Inclusion of galactose in combinations decreased citric acid yield (230).

Chaudhary et al. (231) and Roy and Das (232) studied the production of citric acid by nitrosoguanidine induced (NTG) mutants of *A. niger.* Lower concentrations of NTG (0.5 g/L) were more effective in producing high citric acid yielding mutants. Of 100 mutants selected for preliminary screening, 12 were found to be high citric acid producers. Mutant strains gave 1.5–2.0 times higher citric acid yield than parent strains. Promper et al. (233), however, found that a mutant strain of *A. niger* accumulated much more citric acid intracellularly; it excreted less citrate than the parental strain. Under growth conditions that led to uncontrolled catabolic flux through glycolysis, a dramatic catabolic overflow occurred in the mutant strain. The parent strain, under these conditions, excreted large amounts of citrate to moderate the intracellular catabolic overflow.

Watanabe, et al. (234) investigated the production of citric acid from cellulose hydrolysate by a 2-deoxyglucose resistant mutant strain of *A. niger.* The hydrolysate prepared in acetate buffer was concentrated to contain 150.0 g/L of reducing sugars and was used as a medium for fermentation. Parent and mutant strains produced 77.9 and 98.7 g/L of citric acid, respectively, in 9 days of incubation. When the hydrolysate was prepared in citrate buffer and used as a medium, parent and mutant strains produced 92.2 and 102.3 g/L of citric acid, respectively, after 3 days of fermentation.

Yeasts, particularly the strains of the genus *Yarrowia,* are used for the production of citric acid from different substrates. In these fermentations, a mixture of citric and isocitric acid is produced. The development of mutant strains that accumulate only citric acid has been attempted. Good et al. (45) examined the production of citric acid from canola oil by a mutant strain of *S. lipolytica.* It was isolated after mutagenesis of the parent strain with NTG and had an improved citric to isocitric acid ratio. The maximum citric and isocitric acid concentration was 152.3 and 38.5 g/L, respectively. Ermakova, et al. (46) and Finogenova, et al. (47) studied the properties of *C. lipolytica* mutants with the modified glyoxylate cycle and their ability to produce citric and isocitric acid. They found that the key enzyme citrate synthase had the highest activity in both parent and mutant strains grown on glucose or hexadecane. NAD-dependent isocitrate dehydrogenase had the minimum activity. The mutant strain had actively functioning enzymes for both anaplerotic

pathways—pyruvate carboxylase, isocitrate lyase, and malate synthase. The low activities of both isocitrate lyase and pyruvate carboxylase in the mutant strain showed that this strain has an additional pathway for oxalacetic acid synthesis during the assimilation of n-alkane. The mutant with high isocitrate lyase and low aconitate hydratase activities was shown to synthesize citric acid almost exclusively when grown on glucose, glycerol, hexadecane, acetate, or ethanol. However, the mutant with low isocitrate lyase and high aconitate hydratase activities produced primarily isocitric acid in media with n-alkanes. Tani, et al. (48) produced citric acid from methanol by a fluoroacetate resistant mutant of *Candida* sp. Y-1. This mutant strain had lower aconitase activity than the wild strain and produced 4.6 g/L citric acid from methanol after 4 days of incubation. Four commercial strains and two mutants of the yeast *Y. lipolytica* were screened using batch fermentation (49). The mutant strain induced with UV irradiation was found to be the most suitable for citric acid production from glucose hydrol (39.9% glucose and 2.1% other sugars), a byproduct of glucose production from potato starch. In this case, the highest citric acid concentration (100.0 g/L) was obtained after 80 h of fermentation.

Finogenova et al. (50) studied the biosynthesis of citric and isocitric acids by the wild-type and mutant strains of *C. lipolytica.* They found that when the mutant strains cultivated in media containing acetate, ethanol, glycerol, glucose, or hexadecane, supersynthesis of the acids started after complete consumption of the nitrogen source and resulted in a delay of culture growth. In another relevant work (51), it was observed that comparisons of enzyme activities among parent and mutant strains showed that mutant strains possess higher citrate synthase activity and lower aconitate hydratase activity than the parent, implying that the altered activities may favorably affect citric acid production of mutant strains.

Other workers (225,235,236) studied the production of citric acid by a diploid strain of *A. niger.* The parent strain was treated with UV irradiation which produced auxotrophic mutants. These mutants were less productive than the parent. All possible crosses in pairwise combinations were carried out between these auxotrophs, and three heterokaryons. Finally, one heterozygous diploid was isolated from each. These heterokaryons and diploids showed improved productivity when compared with their corresponding parents, except for one diploid. The citric acid concentration of the diploid strain was 1.2–1.5 times higher than the parent strain.

Martinkova et al. (237) reported that the disadvantages of mutagenesis and parasexual hybridization (low frequency of hybrid formation and incompatibility of the strains) could be avoided when using protoplast fusion. Auxotrophic strains of *A. niger* were obtained from citric acid producing strains of the fungus after UV irradiation. Protoplasts were isolated from young hyphae of auxotrophic strains after treatment with snail enzyme and then treated with polyethylene glycol (30%, w/v) in a Ca^{2+} solution (10 mmol/L) at pH 9.0 The frequency of the heterokaryons was 0.67%. Prototrophic heterozygous spores were isolated from a heterokaryon with the frequency of 1.2×10^{-6}. Citric acid production in the best heterozygous strains was about 15% higher than that of the parent strain.

Production of citric acid by *A. niger* depends on a high flux through glycolysis. Arisan-Atac et al. (238) investigated the possibility of flux control by trehalose 6-phosphate synthase A (T6PSA), an inhibitor of hexokinase. In order to study the relevance of T6PSA inhibition of hexokinase on the glycolytic flux and citric acid accumulation, they used a recombinant strain of *A. niger* carrying multiple copies of *ggsA* by cotransformation. The results showed that these strains produced citric acid with similar yields on 1.0 or 2.5% (w/v) sucrose. At 5–14% sucrose, the *ggsA* disrupted strain initiated citric acid accumulation earlier, whereas the multicopy strain showed the reverse effect. This means that while the disruption of the *ggsA* gene did not increase the product yield, it reproducibly decreased

the time required to reach maximum citric acid concentration. These results demonstrate for the first time the possibility of improving citric acid fermentation by a recombinant method. Previous attempts to amplify genes encoding glycolytic enzymes have been unsuccessful. This can be explained by the fact that glycolytic flow is subject to tight control by several metabolites that antagonize the effect of gene amplifications (238).

Verdoes, et al. (239) reported the cloning of the *nicB* gene of *A. niger.* They describe an improved gene cloning strategy by complementation of mutant alleles in *A. niger*. The strategy was based on the use of a fungal autonomously replicating vector, pAB4-ARp1. This vector was constructed by the introduction of a sequence involved in autonomous replication of an apical membrane antigen 1 (AMA1) into a *pyrG* integrative vector, pAB4-1. With vector pAB4-ARpl, a 10- to 100-fold increase in transformation frequency was obtained, as compared to pAB4-1. The use of pAB4-ARp1 in gene cloning was demonstrated by the complementation of two linkage group VII-specif *A. niger* mutants. Complementation of a lysF mutant was achieved by cotransformation of pAB4-ARp1 with total genomic *A. niger* DNA (instant banK). A nicB-deficient *A. niger* was complemented by cotransformation with pAB4-ARp1 and an *A. niger* cosmid library. The complementing DNA was re-isolated from a Nic^+ transformant by transforming *E. coli* with total genomic DNA of this transformant. A complementary DNA (cDNA) fragment encoding the mitochondrial alternative oxidase, the enzyme responsible for cyanide insensitive and salicylhydroxamic acid sensitive respiration, from the citric acid producing fungus *A. niger* was cloned and expressed in *E. coli* as a host strain (240). Synthetic primers were designed from the conserved nucleotide sequences of the alternative oxidase genes from higher plants and a yeast. The 210-bp DNA fragment was amplified by PCR with these primers using chromosomal DNA of *A. niger* as a template, and was employed to screen a cDNA library of the culture. One full length cDNA clone of 1.2 kb was obtained and was sequenced to reveal that the clone contained an open reading frame (ORF-AOX1) encoding a polypeptide of 351 amino acids. In the 5'-terminus region of the ORF-AOX1, a mitochondrial targeting motif was found. The whole ORF-AOX1 was ligated to plasmid pkk223-3 to construct the expression vector pkAOX1 and showed that cyanide insensitive and SHAM sensitive respiration, and expression were increased approximately twofold by the addition of isopropyl-beta-D-thiogalactopyranside (IPTG). These results indicated that the ORF-AOX1 encodes an alternative oxidase of *A. niger* (240).

15.9 RECOVERY OF CITRIC ACID

The fermentation broth obtained either from surface or submerged fermentation is filtered to remove mycelia or cells and other suspended impurities. Citric acid is precipitated from the filtrate as calcium citrate by the addition of lime slurry at 95°C for 1 h or 50°C for 20 min (3). The precipitate is washed to remove soluble impurities and treated with sulfuric acid to precipitate calcium sulfate and regenerate the citric acid. The solution is then filtered to remove $CaSO_4$. The liquid is decolorized with charcoal and ion exchangers. The purified solution is concentrated by evaporation and run into low temperature crystallizers. Finally, the crystals are removed by centrifugation. Citric acid is marketed as an anhydrous crystalline chemical, as a monohydrate or as a crystalline sodium salt (241). A general flow sheet for the production and purification of citric acid from molasses by *A. niger* is given in Figure 15.3.

Citric acid may be extracted from the fermentation broth using solvent extraction methods. Solvents employed include 2-butanol, tributyl phosphate, secondary or tertiary amines or a mixture of n-octyl alcohol, synthetic isoparaffinic petroleum hydrocarbons,

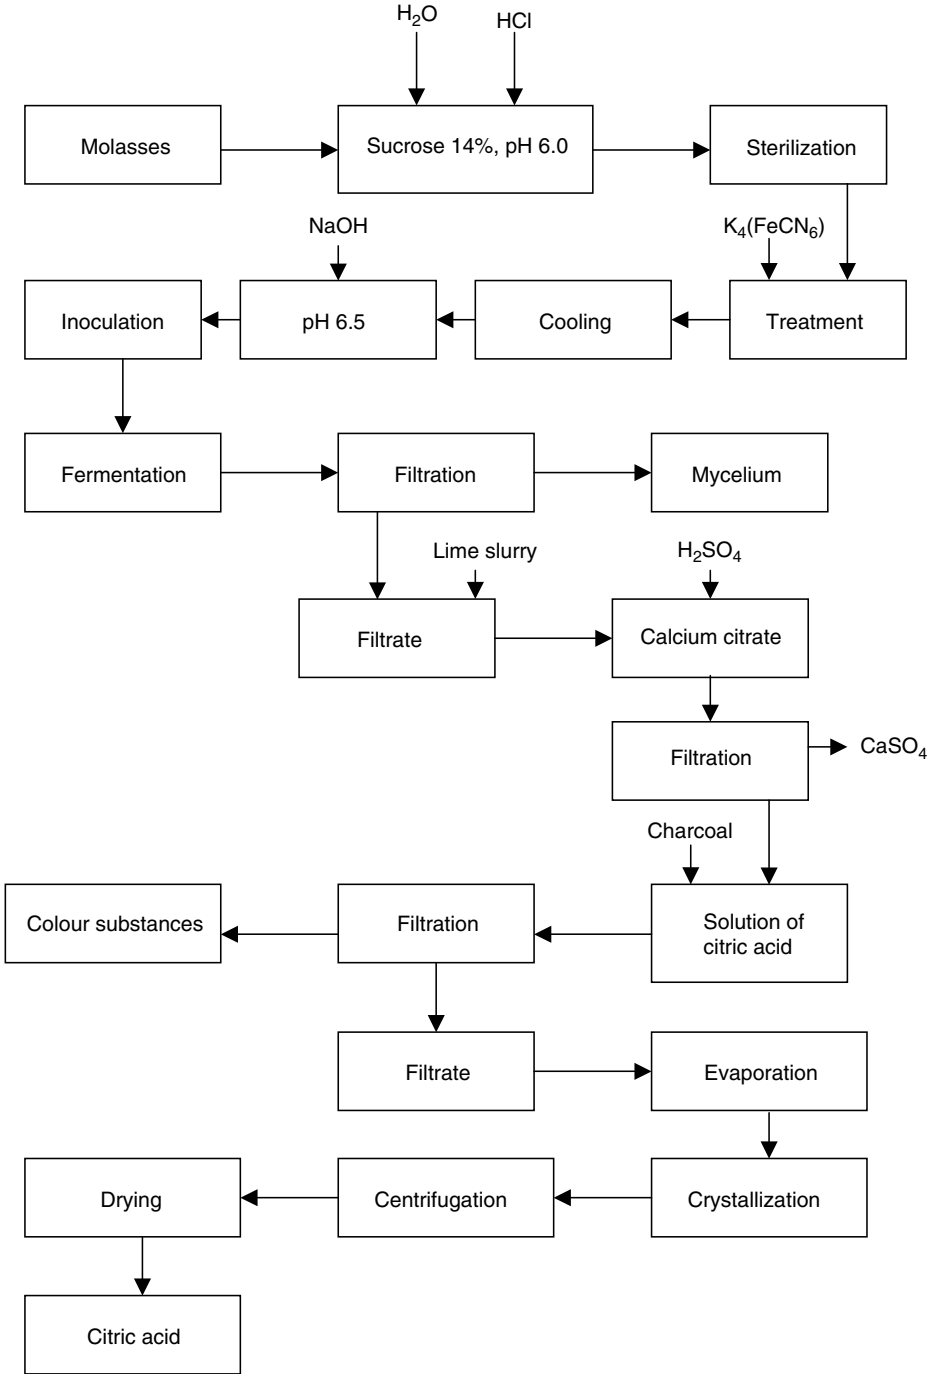

Figure 15.3 Schematic diagram of the production and purification of citric acid from molasses by *A. niger* (From Atkinson, B., F. Mavituna. *Biochemical Engineering and Biotechnology Handbook*. Hong Kong: The Nature Press, 1985, pp 1033–1036).

and tridodecylamine (3,5,7). The citric acid is extracted into the solvent at a low temperature and reextracted into water at a higher temperature. The solution containing the

acid is then concentrated and crystallized. Kapoor et al. (3) reported a process in which citric acid is extracted from the fermentation broth by two phase extraction using tridecylamine or triisononylamine and ester, ketone, or ethanol. Citric acid salts are precipitated by extracting the mixed solvent extracts with aqueous solutions of ammonia, alkalihydroxides, carbonates, or bicarbonates. Kilic et al. (16) investigated a method for the extraction of citric acid in the presence of corn oil and Hostarex A327 in oleyl alcohol. The addition of corn oil reduced solvent toxicity. These authors combined the extraction method with the effect of potassium ferrocyanide on citric acid production. They found that citric acid concentration increased with increasing $K_4Fe(CN)_6$ concentration. Using the response surface methodology, they found that 0.02–0.10% (w/v) potassium ferrocyanide, the ratio of organic phase volume to the aqueous phase volume (V_{or} /V_{aq} = 0.5–1.5), 0–20% (v/v) of corn oil concentration, and 10–50% (v/v) of Hostarex A327 content in oleyl alcohol were the critical components. Optimum citric acid concentration was predicted under these optimum extraction conditions: $K_4Fe(CN)_6$ of 0.06% (w/v), V_{or}/V_{aq} of 1.25, corn oil concentration of 13.7% (v/v), and Hostarex A327 content in oleyl alcohol of 33% (v/v). Citric acid production by extractive fermentation was increased ~40% with respect to the control run.

15.10 CONCLUSIONS

Citric acid, a tricarboxylic acid, is used in the food and beverage industries, in pharmaceuticals, and in other industrial applications. It is produced by fungi, yeasts, and bacteria. *Aspergillus niger* strains dominate other microorganisms producing citric acid on an industrial scale. They can be handled easily, are resistant to fermentation conditions, grow in various raw materials and agricultural wastes, and give high and consistent yields of citric acid by utilization of inexpensive substrates, thereby making the fermentation process economical. Citric acid production takes place during exponential and stationary growth phases. The strains used for citric acid production need major elements such as carbon, nitrogen, phosphorus, and sulfur in addition to various trace elements and stimulants. Also, fermentation parameters such as fermentation time, initial sugar concentration, pH, temperature, agitation, and aeration play a profound role in yield. The fermentation systems used for citric acid production are surface fermentation, submerged fermentation, continuous culture, fed batch culture, solid-state fermentation, and immobilized microbial cells. Among these systems only surface and submerged fermentation are used on an industrial scale. The substrates used include chemically defined media, molasses, agricultural wastes from the food and beverage industry, hydrocarbons, and oils. Currently, molasses is the superior medium for the production of citric acid on a pilot plant scale. Understanding of basic biochemical pathways and genetic mechanisms in microorganisms is useful for improving the organisms used for citric acid production. Thus, recent research has been focused on immobilized microbial cells and genetically improved microorganisms. These new methods aim to improve citric acid production by obtaining shorter fermentation time, by using raw materials without any pretreatment, and by finding strains that will produce high citric acid yields. The discovery of yeasts that produce higher amounts of citric acid than fungi in shorter fermentation time has been accompanied by the disadvantage of the production of isocitric acid. Mutant strains of the yeasts producing low amounts of isocitric acid have been evaluated in bench and pilot studies. Generally, while the new methods are promising, they are far from adequate, and further studies are required before a commercial process can be envisaged.

1.16

Microbial Biotechnology of Food Flavor Production

G. Feron and Y. Waché

CONTENTS

16.1 INTRODUCTION

Traditional fermentations use the ability of microorganisms to transform raw materials in complex food products. This process of biotransformation involves a wide range of biochemical reactions that depend on both the microorganism used and its direct environment. Since the 1980s, biotechnologists have tended to exploit this biological capacity in order to produce high value added products, especially aroma or flavor compounds. During the last twenty years, a large number of reviews and contributions discussing the possible industrial applications of microbial volatiles have been published (1–13). In spite of many advances in cell biology, enzymology, genetic engineering, and process control, and considering the high demand and commercial value of natural flavors, to date about 15% of natural flavoring molecules are produced as pure compounds by biotechnological means. This is principally explained by economic constraints that limit the industrial scaling up of many laboratory processes. However, the recent development of genetic engineering tools as well as new investigations on the direct control of the biocatalyst environment via redox potential or hydrophobicity and polarity opens novel and innovating developments in this field. Such developments may help to overcome the limits encountered and widen the spectrum of biotechnologically accessible flavor compounds.

16.2 MARKET OF FLAVOR: COST AND LEGACY CONSIDERATON

Perfumes and flavors appeared in early Egyptian times via plant extracts and derivatives. However, authors believe the foundation of the modern flavor industry was established in 1843 with the synthesis of methyl salicylate, followed by cinnamic aldehyde in 1856, and benzaldehyde in 1863. Then came the pioneering explosion for the flavor industry: the synthesis of vanillin, still the key ingredient in flavor creativity, in 1872.

How large is this industry? The total global market is worth 10.9 billion euros (€) and grows by 4–5% per year. There are approximately 1800 registered global flavor houses but there are probably an additional 1500 flavor companies spread over China and India as well as a few other countries. However, there are 10 international companies that command 90% of the whole market of perfumes and flavors, and they are principally split between the USA and Europe.

About 10,000 volatiles have been mentioned in food products (6) that are representative of the complexity of the investigations in this field. To date, 2000 synthetic flavors are available on the market and about 400 natural flavors. It is generally considered that about 15–20% of these flavors may be produced by biotechnological means (13).

Beverages and cooked products represent around 70% of the total use of flavor additives. However, if we consider only natural flavors, up to 90% are used in beverages and only 20% in sweets and candies. This can be explained by the cost of flavoring but also the consumer target.

The use of natural or synthetic flavors depends partly on the legislation applied in the different countries, principally in the US and in Europe, which are both considered the principal producers and users of flavors in manufactured products. To summarize briefly, in the USA, the system that has been adopted since 1965 is the positive list. The flavoring substances are evaluated and classified as GRAS (generally recognized as safe) on the basis of long usage without toxicity or by undertaking the safety evaluation of novel flavoring ingredients. The only alternative designations for the consumers are "natural flavor" and "artificial flavor," the latter being avoided wherever possible. The term "natural flavor" or

"natural flavoring" is defined in Title 21 of the Code of Federal Regulations (14). In contrast, in Europe, the system is a combination of positive and negative lists and is now being changed to a total positive list. Three designations are possible: "natural 'X' flavor" if the amount of the flavoring substance is greater than 90% from 'X' ('X' referring to the named source); "natural flavor" if the flavoring component consists of exclusively natural flavoring substances, including "bioflavoring"; "'X' flavor" or "'X' flavor(s)" if nature identical flavoring or artificial substances are used alone or in combinations.

If we consider the cost ratio between natural and artificial flavor (Table 16.1), one can see that, depending on the flavor family, the price of natural flavoring substances is from 10 to 100 times more than the corresponding synthetic flavor. As an example, synthetic vanilla is sold at about 15 €/kg whereas vanilla extract is ~4000 €/kg. These cost considerations help explain the preferential use of nature identical flavor in the European Food Industry.

16.3 TRADITIONAL FERMENTATIONS AND *DE NOVO* SYNTHESIS OF FLAVOR

The origins of fermented food go back many thousands of years with evidence of consumption of fermented products in China 6000 years ago. In terms of total production and consumption, the three major groups of fermented foods are beverages (primarily wine and beer), dairy foods, and cereals (15), but many other raw materials such as meat, fish, legumes, and fruits are used in fermentation processes.

Fermented foods are those foods which have been subjected to the action of microorganisms or enzymes so that desirable biochemical changes of the raw materials cause significant modifications to the food. The biogenesis of flavor is one of the main modifications that appear during the fermentation process and that contributes largely to the organoleptic characteristics of the corresponding food. The development of flavor during fermentation involves a variety of biochemical pathways using the main three classes of raw materials: glucoside or carbons, lipids, and proteins.

16.3.1 Metabolism

16.3.1.1 Carbon Metabolism

During fermentation, the source of carbon is essentially used for the growth of the microflora that are naturally present in the raw material or that have been added for the improvement of

Table 16.1
Cost ratio between different chemical classes of natural flavoring substances and their natural identical correspondence (G. Feron, personal data, 2003).

Class of Aroma	Cost Ratio : Natural/ Natural Identical
Lactones	20 – 25
Esters	10 – 20
Acids	10
Alcohols	25 – 30
Aldehydes	100 or more

the process. For this reason the diversity of flavor directly resulting from glucose catabolism is not very broad. Glucose is oxidized to pyruvate via the Emden-Meyerhof pathway of glycolysis. As summarized in Figure 16.1, pyruvate can be metabolized to some major flavor compounds such as diacetyl, acetoine, 2-3 butanediol, ethanol and acetaldehyde. Diacetyl, acetoine, and 2-3 butanediol contribute principally to the butter odor characteristic of many dairy products, but in this case they come from the metabolism of lactose and citrate present in milk. Diacetyl is also an important flavor compound in fermented beverages, especially beer and wine. Ethanol is principally synthesized during anaerobic fermentation and significantly contributes to the organoleptic properties of alcoholic beverages. Ethanol is synthesized from acetaldehyde, which when diluted possesses an apple like flavor, but at higher concentrations gives a characteristic pungent and penetrating odor that is not well appreciated in the fermented foods.

16.3.1.2 Lipid Metabolism

Unlike glucose metabolism, the oxidation and/or hydrolysis of lipids can lead to an important source of flavors (Figure 16.2).

Through the lipolysis of triglycerides, a broad variety of fatty acids can be released. Short chain fatty acids contribute directly to the flavoring of fermented products with aromatic notes such as vinegar (acetic acid), goat (4-ethyloctanoic acid), or rancid (butyric, octanoic, and decanoic acid).

After lipolysis, free medium and long chain fatty acids can be oxidized leading to different groups of flavors: methyl ketones, lactones, aldehydes, and alcohols. Methyl ketones are responsible for the fruity, musty, and blue cheese notes of cheeses, other dairy products, and fermented meats such as dried sausage. Methyl ketones are synthesized through the β-oxidation pathway of medium or short chain fatty acids (16) (Figure 16.3). After the third step of β-oxidation, β-acetoacyl-CoA is released from the cycle. This acyl-CoA is hydrolyzed with a thiolase and then decarboxylated, leading to methyl ketone characteristically possessing an odd number of carbon atoms. Some microorganisms such as

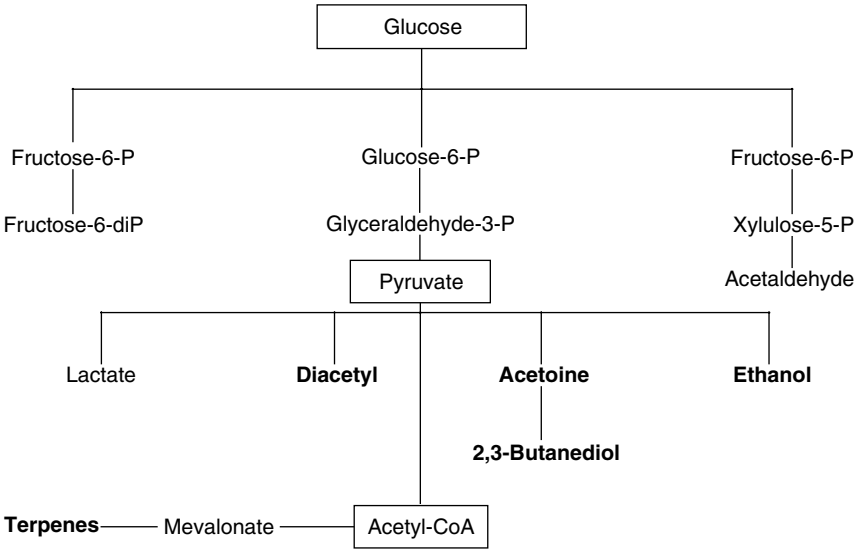

Figure 16.1 Formation of flavor compounds from glucose/carbon metabolism.

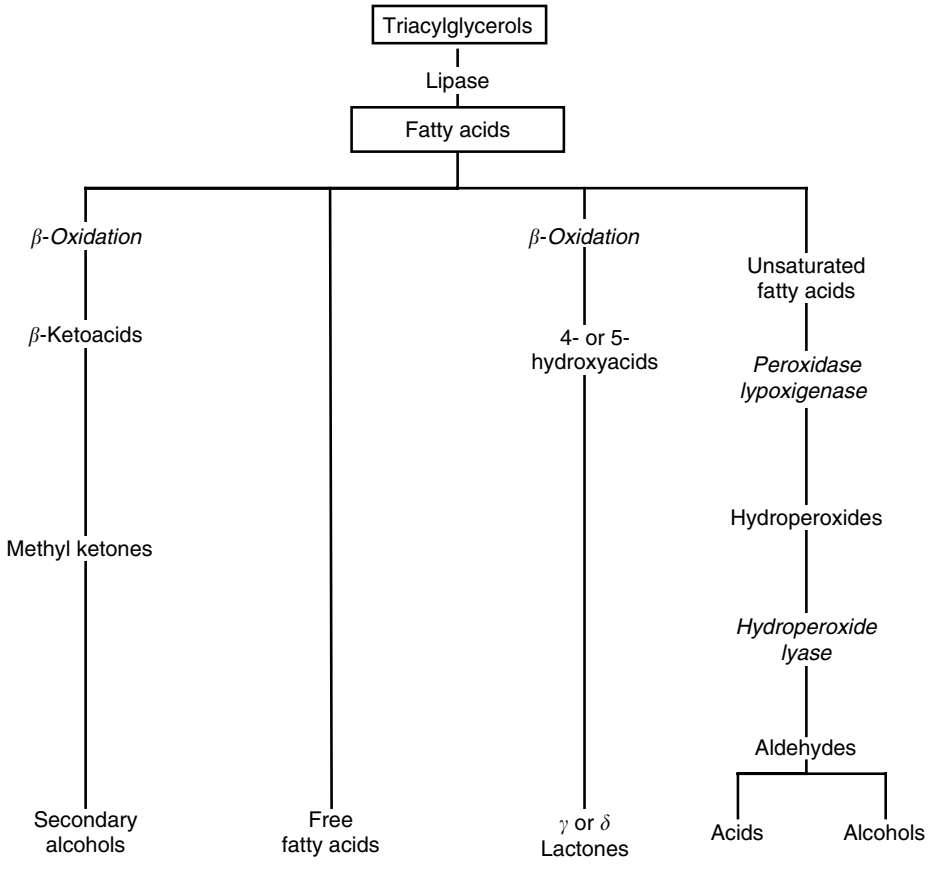

Figure 16.2 Formation of flavor compounds from lipid metabolism (adapted from Molimard, P., H.E. Spinnler, *J. Dairy Sci*. 79:169–184, 1996).

Penicillium camemberti use this metabolic pathway in order to detoxify the medium against high concentrations of lipids. This pathway is interesting because of the use of one CoA instead of two for a complete degradation of the fatty acids. β-oxidation is particularly important in the fermentation of raw material rich in fats and lipids; in some cases 60% of the carbonyl compounds produced are methyl ketones (17). Methyl ketones can be further reduced leading to the formation of different alcohols such as 2-pentanol, 2-heptanol, or 2-nonanol.

Even lactones come principally from the β-oxidation of hydroxy fatty acids. Hydroxy fatty acids can be naturally present in triglycerides or can be generated from the oxidation of polyunsaturated fatty acids by the action of lipoxygenases or hydratases. They are characterized by very pronounced fruity notes such as peach, apricot, and coconut. They are present in many products and are particularly appreciated in beverages. As an example, 21 different lactones have been identified in white wine (18,19). The metabolic pathway for odd lactones is not well understood in spite of their flavoring importance. Because odd fatty acids are not present naturally in high quantity and diversity, the corresponding lactones cannot come from β-oxidation. However, in 1978, Tressl (20) proposed another oxidative pathway for the synthesis of γ-nonalactone during beer fermentation (Figure 16.4).

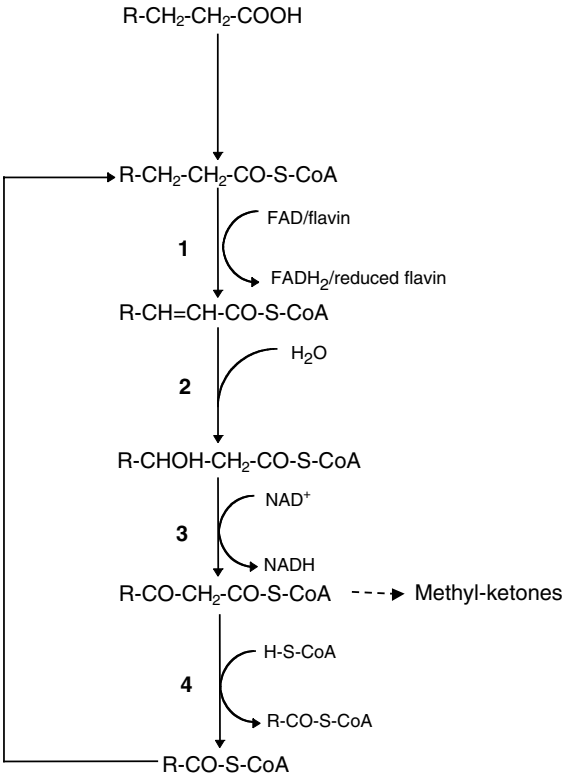

Figure 16.3 β-Oxidation cycle and methyl-ketone synthesis. Individual enzyme reactions: (a) fatty acyl-CoA dehydrogenase (mitochondria) or oxidase (peroxisomes); (b) 2,3-enoyl-CoA hydratase; (c) 3-hydroxyacyl-CoA dehydrogenase; (d) 3-oxoacyl-CoA thiolase. [FAD : Flavin Adenine Dinucleotide, NAD(H) : Nicotinamide Adenine Dinucleotide (reduced form), R= $CH_3(CH_2)_n$].

The intrachain oxidation of fatty acids can also lead to the synthesis of different alcohols and aldehydes. In particular, linoleic and linolenic acids are precursors of eight carbon aroma compounds, particularly 3,1-octenol (mushroom), 2,1-octenol, 1,5-octa-3-dienol, and 1,5-octa-1-dienol. This oxidation is catalyzed by lipoxygenases and hydroperoxide lyases with different specificities (Figure 16.2).

16.3.1.3 Amino Acid Metabolism

Proteolytic activities lead to the formation of peptides that are degraded by aminopeptidase and carboxypeptidase activities. Amino acids coming from this degradation are subjected to transamination, dehydrogenation, decarboxylation, and reduction reactions that directly contribute to the flavoring of fermented foods (17,21) (Figure 16.5).

Different classes of aroma compounds are synthesized in amino acid metabolism, such as alcohols, sulfur compounds, amines, and some organic acids. Recent work showed that, in dairy products as well as in fermented meat products, the synthesis of such compounds depends on lactic bacterial transaminases activities showing different substrate specificities (22–26). Two transaminases have been isolated and cloned. One is active on branched chain fatty acids and after a series of decarboxylation or dehydrogenation reactions leads to the formation of alcohols such as 2/3-methylbutanol, 2-methylpropanol, and the corresponding aldehydes, which are globally characterized by fruity and malty flavors.

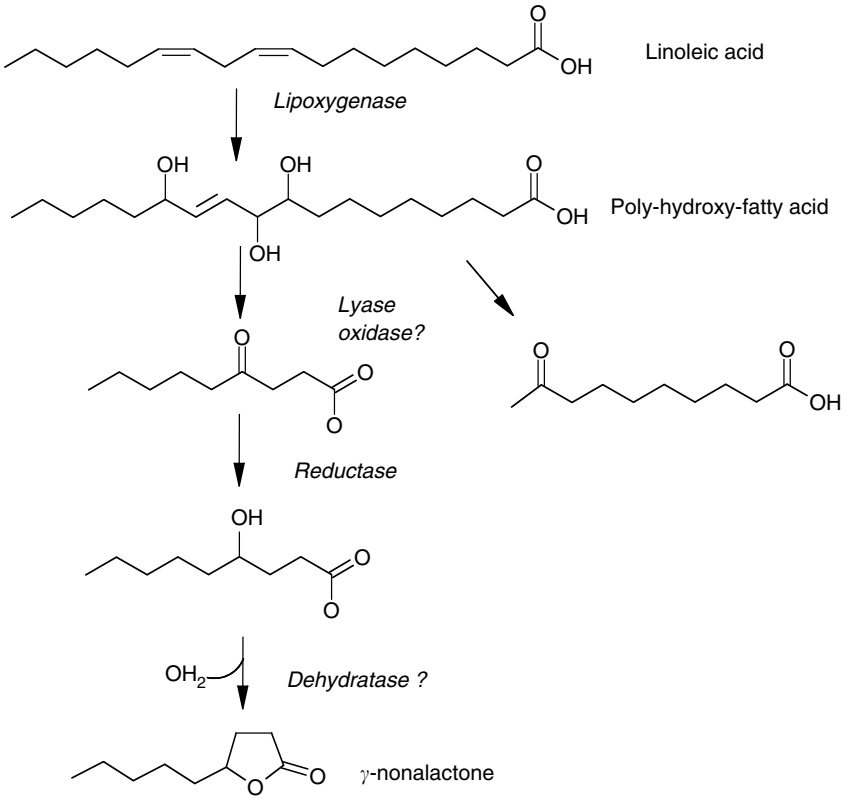

Figure 16.4 Proposed metabolic pathway for the synthesis of γ-nonalactone from lipid oxidation (adapted from Tressl, R., M. Apetz, R. Arrieta, K.-G. Grünewald, *Flavor of Foods and Beverages*, London: Academic Press, 1978, pp 145–168).

Further steps of oxidation can generate short chain fatty acids (isovaleric, 2-methyl butyric, and isobutyric acids) that are responsible for rancid, fecal, putrid, and sweaty flavors (17).

The second transaminase is active mainly on aromatic amino acids such as phenylalanine, tyrosine, and tryptophan leading to the formation of floral notes. For example, the degradation of phenylalanine can generate a broad variety of flavor compounds such as benzaldehyde (almond), cinnamaldehyde (cinnamon), veratraldehyde (woody, vanilla like), or phenyl ethanol (rose) (Figure 16.6) (7).

The degradation of methionine is directly responsible of the synthesis of sulfur compounds in fermented food products such as cheese and beer (Figure 16.7) (27,28). Sulfur compounds are flavors of major importance. They can be found in many different products in very low quantity (mainly at a ppb level). However, their detection threshold is also very low (from 0.004 ppb for isopentenylmercaptan to 1.2 ppm for methionol). Some of the main compounds described in the literature are dimethylsulfide, dimethyldisulfide, dimethyltrisulfide, methional, methionol and methanethiol. Their odors are often described as onion, garlic, radish, and cabbage, but also as excrement or putrefaction. For this reason, sulfur compounds play an important role in consumer preferences and choices.

Pyrazines are synthesized from threonine through a series of biochemical reactions (reduction, decarboxylation, and hydration) (29). Pyrazines are typical aroma components of heated foodstuffs, with a characteristic roasty nutty flavor or Maillard flavor. They are particularly found in beverages such as wine and beer, but also in meat products.

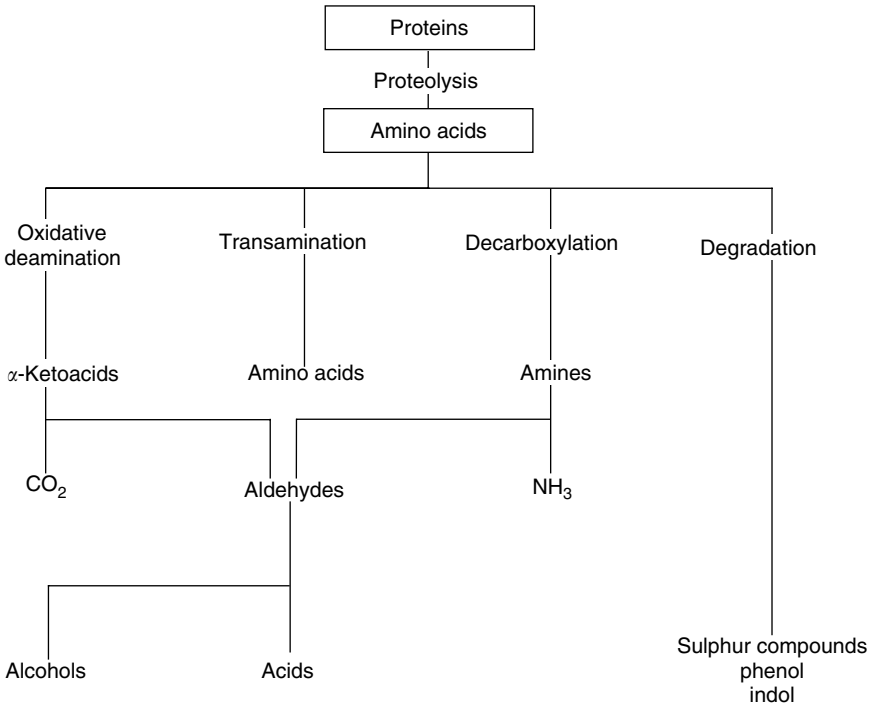

Figure 16.5 Formation of flavor compounds from protein and amino acid metabolisms (adapted from Molimard, P., H.E. Spinnler, *J. Dairy Sci*. 79:169–184, 1996).

16.3.1.4 Cometabolism

Esterification reactions occur between the different alcohols and acids synthesized from lipids and carbon metabolism enabling the formation of a large diversity of ester compounds. Esters are very important flavors in all types of fermented food. There is a great diversity of ester compounds. The most common are the acetates formed from an alcohol and acetyl-CoA. The esterification reactions can be catalyzed by carboxylesterases, characterized by a wide range of substrates, and arylesterases. The aromatic notes used to characterize esters are fruity [pineapple (ethylacetate, ethylpropanoate and ethylbutanoate), banana (isoamylacetate), apricot (isoamylpropanoate, ethyloctanoate), and pear (isoamylacetate)], floral [rose (2-phenylethylacetate)], honey (phenylethylbutyrate) or wine (ethyloctanoate) (17,21).

16.3.1.5 Conclusion

All of the aspects of microbial metabolism previously cited contribute to the flavoring of fermented foods. The large variety of such products observed all around the world depends principally on the characteristics of the raw material, the biocatalysts, the conditions and processes of fermentation and the conditions of storage. Hence, the results typically come from the combination of many different metabolic activities. As an example, Table 16.2 shows the different flavors found in dry sausage. The entire metabolism of the different microorganisms present or added to the meat is expressed and, except for the flavor coming from the spices added to the meat, all classes of compounds described in the previous chapter have been identified in dried sausage (30).

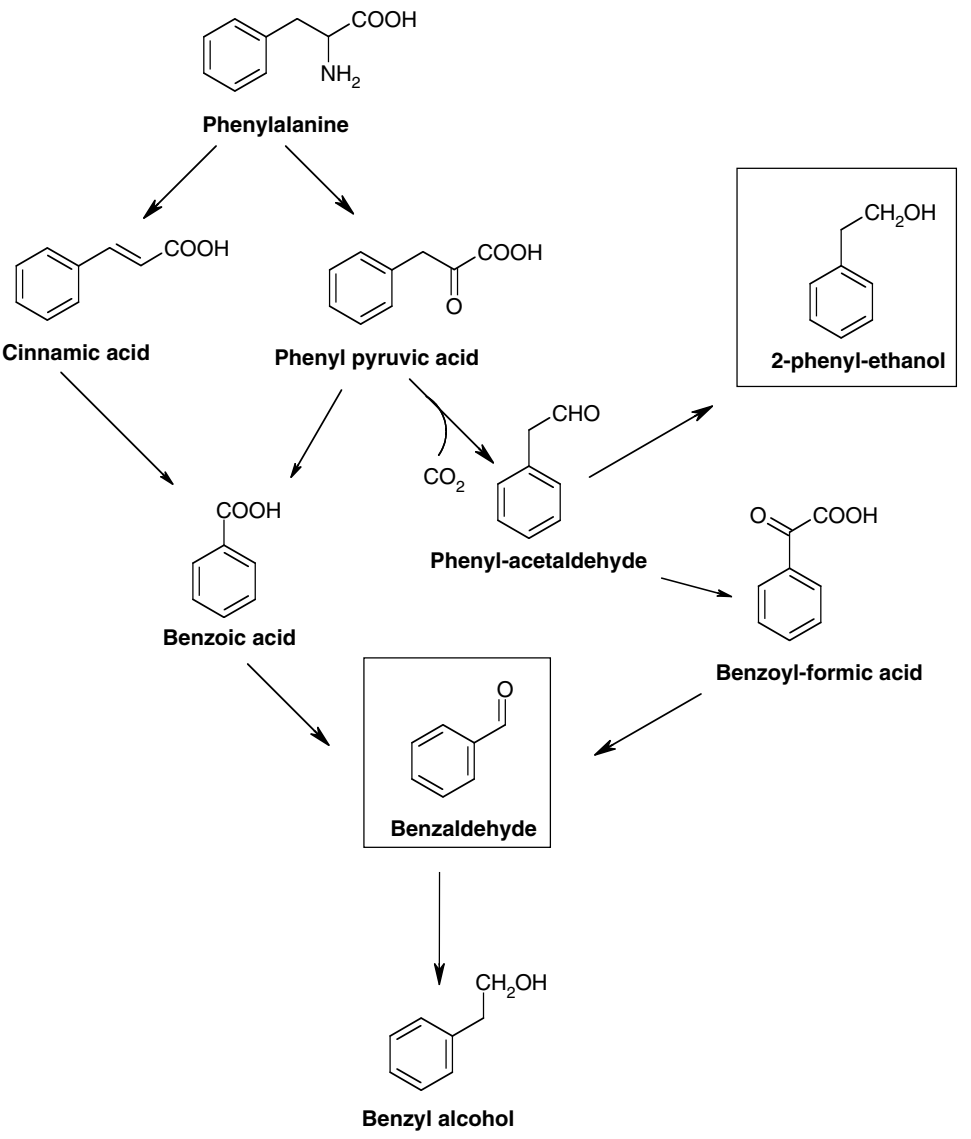

Figure 16.6 Proposed metabolic pathways for the biotechnological synthesis of benzaldehyde and *β*-phenethylalcohol (adapted from Feron, G., P. Bonnarme, A. Durand, *Trends Food Sci. Technol.* 7:285–293, 1996).

In parallel to traditional fermentations, many microorganisms not commonly used for the elaboration of food are able to produce many different flavor compounds *de novo*. These microorganisms can be also used by the industry for the production of pure natural flavor compounds. This is the purpose of the following sections.

16.3.2 *De Novo* Synthesis of Flavors

It has been known for a long time that some microorganisms can generate pleasant odors (31). Odor description has therefore been used for many years as a parameter of taxonomic classification for some microorganisms, especially wood destroying fungi (32). In 1992, an

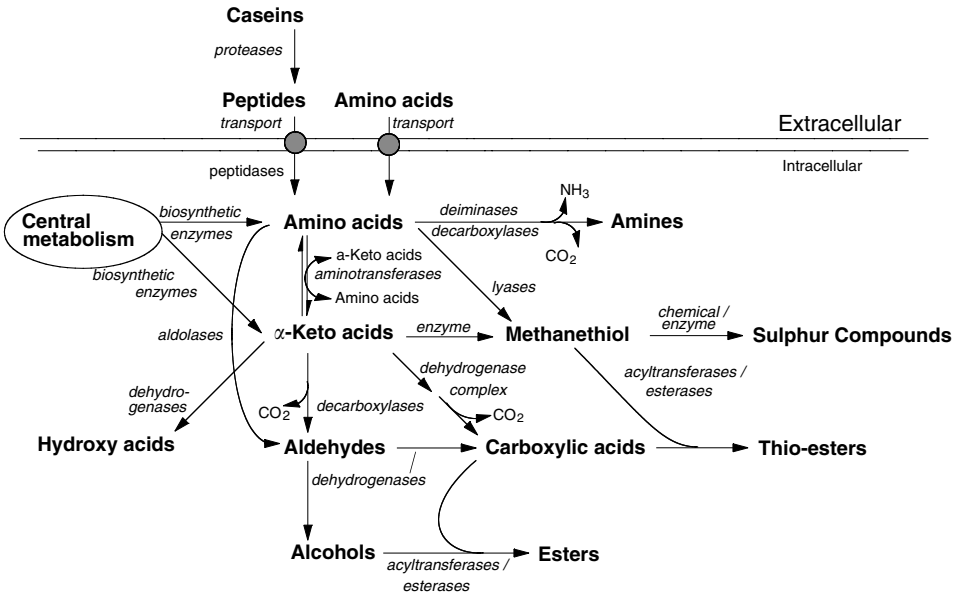

Figure 16.7 Potential routes for conversion of amino acids during cheese ripening (after Engels, W., E. Floris, R. van Kranenburg, J. van Hylckama Vlieg, W. Noordman, G. Smit. *Proceedings of the 10th Weurman Flavor Research Symposium*, Beaune, 2002, pp 326–331).

excellent review listing the flavor producing microorganisms was published by Janssens (4). A total of 130 microorganisms were cited in this paper (Table 16.3) and concerned mainly mold and fungi (72 genera and species described). This is principally due to the large biodiversity that occurs among the world of filamentous fungi and especially in the ascomycetes and basidiomycetes orders. As an example the latter can produce a wide variety of phenolic compounds such as benzaldehyde, anisaldehyde or veratraldehyde (6) (Table 16.4), as well as lactone compounds, from the γ-butyrolactone (C4) to the γ-dodecalactone (C12) (33); and also a large variety of terpenes. Moreover, this diversity can be enhanced by modifying simple constituents of the culture medium as carbon or nitrogen source. An example can be found in the genus *Ceratocystis* which is able to produce a high diversity of aroma compounds (34–36). Depending on the composition of the culture medium, we can enlarge the variety of accessible flavor compounds such as fruity or banana flavor (isoamyl acetate), weak potato (unknown compound) or peach flavor (γ-decalactone) (37).

Yeasts are also able to produce *de novo* flavors. One of the well known examples is *Sporidiobolus salmonicolor* which produces a high variety of lactones (38) such as γ-decalactone or delta lactones. Other species such as *Kluyveromyces lactis* or *Williopsis saturnus* are also capable of synthesizing large amounts of terpenes or fruity ester flavors (39).

Because of their limited genome, bacteria do not show the same biodiversity for the production of flavor. However one particular example can be found in recent works (40) showing that strains of *Bacillus cereus* were able to produce different pyrazines such as 2,5-dimethylpyrazine, 2,6-dimethylpyrazine or trimethylpyrazine. This production depended on the bacteria strains, the temperature, and the culture medium. The concentrations did not reach more than 4 mg/l of medium.

De novo synthesis of flavor can be considered as a good indication of the flavors that could be potentially accessible by biological means. However the production levels are

Table 16.2
Chemical classes of volatile constituents of dry sausage, odor descriptions and metabolic origins (adapted from Berdague, J.L., P. Monteil, M.C. Montel, R. Talon, *Meat Sci*. 35:275–287, 1993).

Volatile Compounds	Fragrant Descriptors	Metabolic Origin
Alcanes- Alcenes		
Pentane, heptane, 2-octene	None	Lipid oxidation
Terpenes		
Limonene, b-pinene	Fruity, lemon	Pepper
Aldehydes		
Pentanal, hexanal, heptanal, methylated aldehydes, benzaldehyde	Grassy, fatty, rancid, fruity, roasty, bitter almond	Lipid oxidation and amino acid metabolism
Alcohols		
Ethanol, methyl-propanol, butanediol, hexanol, 1-octen-3-ol	Piquant, ethereal, fatty, buttery, fruity, mushroom, flowery	Sugar fermentation, lipid oxidation, amino acid metabolism
Ketones		
Methyl-pentanone, pentanone, heptanone, octanone, nonanone, pentanedione, butanedione	Grassy, fruity, blue cheese, buttery, fatty, milky	Lipid oxidation, sugar fermentation
Carboxylics acids		
Acetic acid, methyl-buta/ propanoic acids, buta/penta/ hexanoic acids	Vinegar, "feet", "dirty socket", rancid, acid, blue cheese	Sugar fermentation, lipid oxidation, amino acid metabolism
Esters		
Methyl/ethyl-acetate, ethyl-butanoate, ethyl-propanoate, ethyl-3/2-methylbutanoate	Soft, ethereal, fruity, "green", banana, pine-apple, acide	Sugar fermentation, lipid oxidation, amino acid metabolism

very poor, and thus constitute a limit for industrial exploitation. For this reason, biotechnologists have focused on bioconversion processes that offer more economic advantages.

16.4 BIOCONVERSION

Starting from specific substrates, microorganisms are able to catalyze many different reactions such as oxidations, reductions, dehydrations, hydrolytic reactions, and other metabolic reactions in order to produce food flavors. In contrast to *de novo* synthesis, the concentrations of molecules produced are high enough to permit industrial exploitation of the bioproduction process. This potential to exploit the diversity of life for the production of added value compounds has led to a strong interest, even if the applications have not been as numerous as we have expected.

Price is one of the major obstacles for the development of bioflavors, because cost is strongly related to production volume, which is generally low. From the 400 compounds of bioorigin available, a substantial part are produced in very small quantities (less than 10 kg/year) as impact molecules. It is generally admitted that an average consumption of 100 kg/year of an additive seems to be the minimum necessary to expect to find a market for a bioflavor.

Table 16.3
Synthetic survey of flavor, de novo produced from microorganisms (summarized from Janssens, L., H.L.D. Pooter, N.M. Schamp, E.J. Vandamme, *Proc. Biochem.* 27:195–215, 1992). Numbers in () correspond to the number of different strains in a class or in a genus cited in the review.

Mould (72)	**Class of Aroma**
Aspergillus (3)	Acids, alcools, terpenes
Cerastocystis (9)	Terpenes, esters, alcohols
Fusarium (2)	Terpenes, lactones
Geotrichum (3)	Esters, lactones
Trichoderma (5)	Terpenes, esters, lactones
Levures (36)	
Dipodascus (3)	Esters, alcools
Hansenula (4)	Esters, alcools
Kluyveromyces (3)	Terpenes, esters, alcohols
Sporobolomyces (2)	Lactones
Saccharomyces (8)	Terpenes, lactones, esters, alcohols.
Bacteria (22)	
Clostridium (2)	Esters, alcohols, acids
Corynebacterium (2)	Pyrazines
Pseudomonas (6)	Esters, pyrazines
Streptomyces (4)	Terpenes, pyrazines

Table 16.5 summarizes the production cost evaluation as proposed by Delest in 1995 (41), and is based on a combination of production size, concentrations and duration. The first part of this table presents a high precursor cost with a low production size for the bioflavor. Considering the different parameters that must be taken into account, the finding of cheap raw material is one of the main limits encountered when a process for the bioproduction of flavor is investigated.

In spite of the different technical and economical constraints encountered, different processes have been described the last twenty years, as shown in Table 16.6. Some of them have led to commercially available natural flavors. Because of the industrial confidentiality commonly observed in this field, this table is not exhaustive. In fact about 80–100 flavor compounds coming from biotechnology are considered to be on the market (13).

16.4.1 Vanillin

Vanillin is considered the most widely used flavoring agent in food products with a market of 12000 t/yr for artificial vanillin (15 €/kg) and 50 t/yr for vanilla extracts (4,000 €/kg) (42). Between these two sources of aroma, a third possibility was envisaged given that the development of biotechnology permits the access to a biovanillin with an estimated market of 5,000 t/yr and an average price of 800–1,000 €/kg.

Biovanillin has long been considered as the Holy Grail of biotechnologists and flavoring companies with an impressive quantity of processes, papers, reviews and patents published on the subject (43). Figure 16.8 summarizes briefly the most important routes investigated in this field.

Table 16. 4
Volatile aromatics compounds produced by filamentous fungi (adapted from Berger, R.G., Berlin: Springer-Verlag, 1995, and Lapadatescu, C., PhD dissertation, Université de Bourgogne, France, Dijon, 1999).

Mould	Aroma
Agaricus bisporus	benzaldehyde, phenyl acetaldehyde
Ascoidea hylecoeti	2-phenyl ethanol
Bjerkandera adusta	anisaldehyde, veratraldehyde
Camarophyllus virgineus	anisaldehyde
Hebeloma saccariolens	2-amino benzaldehyde
Hyanellum suaueolens	coumarine
Inocybe sp.	methylcinnamate
Ischnoderma benzoinum	benzaldehyde, anisaldehyde
Lentinus sp.	benzyl acetate, methyl anisate, methyl cinnamate
Hycoacia vda	methyl acetophenone, alcool methyl benzylique, *p*-tolualdehyde
Nidula sp.	Cinnamic acid derivatives, raspberry
Phanerochaete chrysosporium	veratraldehyde
Phellinus sp.	methylbenzoate, salicylate
Pleurotus euosmus	coumarine
Poria sp.	Cinnamic and anthranilic acid derivatives
Pycnoporus cinnabarinus	methylanthranilate, vanilline
Sirodesmium diversum	*p*-hydroxybenzaldehyde
Stereum subpilatum	methylcoumarate
Trametes sp.	anisaldehyde, methylphenylacetate
Tyromyces sambuceus	benzaldehyde, ethylbenzoate

Table 16.5
Production cost evaluation of biotechnological compounds (adapted from Delest, P., Paris: INRA, 1995, pp. 13–19.)

Raw Materials (€/kg)	120	15	1.5
Fermentation/Bioconversion (€/kg)	280	80	4
Recovery/purification (€/kg)	80	30	2.5
Total (€/kg)	460	120	8
Assumptions Concentrations (g/l)	10	60	50
Duration (Days)	2	1	2
Reactor Size (m3)	1	5	100

The first involves the transformation of natural stilbene as isorhapontin to vanillin via an oxidation reaction catalyzed by a stilbene dioxygenase. This process has led to numerous patents (5).

The most promising route may be the transformation of eugenol, via coniferaldehyde or ferulic acid, to vanillin, because eugenol is an inexpensive and commercially available natural raw material. However, production is still very low, mainly due to numerous side reactions. An alternative solution could come from the use of isoeugenol which provides better production rates, but natural isoeugenol is not available in large volume,

Table 16.6
Principal natural flavoring substances produced by biotechnological means

Compounds	Aromatic Note	Estimated Market T/Yr (1997)	Precursor	Biocatalyst (Not Exhaustive)	Process	Concentration g/l	Commercial Availability	Ref.
Vanilline	Vanilla	5000	Ferulic acid	*Amycolatopsis sp.* *Pycnoporus sp.*	Liquid	11	Yes	(42,129, G. Feron, personal data, 1997)
γ-decalactone	Fruity/peach	5–10	Ricinoleic acid	*Yarrowia lypolitica* *Sporidiobolus sp.*	Liquid	10–15	Yes	(131)
δ-decalactone	Nuts/milk/ coconut/fruity	3.5	Massoia lactonez Other ?	*Saccharomyces cerevisiae* Various filamentous fungi	Liquid	>1	Yes	(132,133, G. Feron, personal data, 1997)
γ-dodecalactone	Peach/musk	0.5	Oleic acid	Strain 458 + *Saccharomyces cerevisiae*	Liquid	>5 ?	Yes	(56,57, G. Feron, personal data, 1997)

Pyrazine	Roasty, nutty	?	Threonine	*Bacillus subtilis*	Solid	2–3	?	(29)
Methyl-ketones	Blue cheese notes	?	Coconut fat	*Aspergillus niger*	Solid	? (Yield = 42%)	yes	(4)

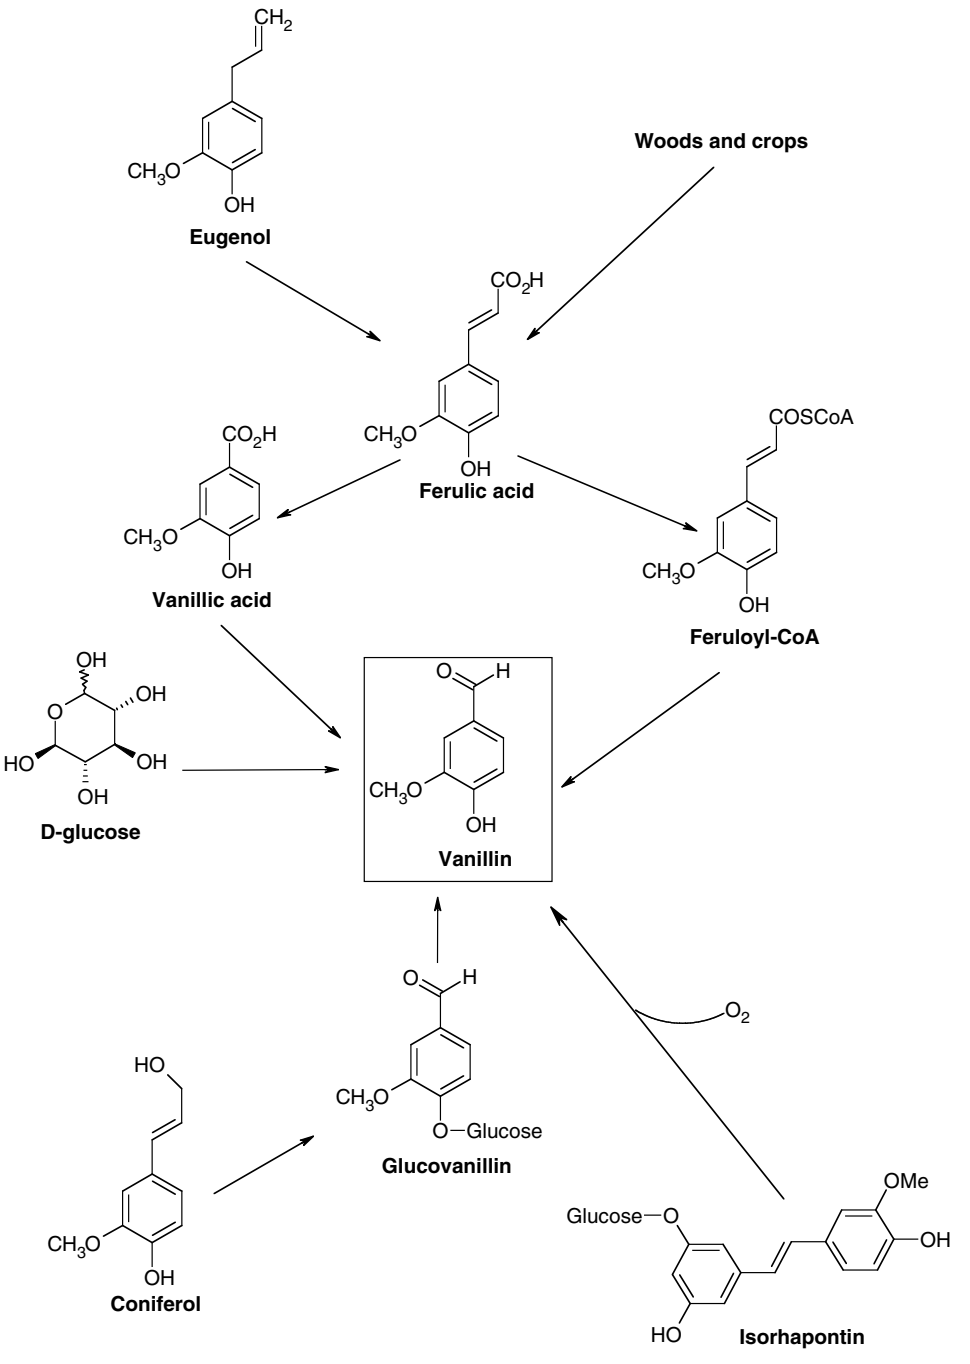

Figure 16.8 Proposed metabolic pathways for the biotechnological synthesis of vanillin (adapted from Feron, G., P. Bonnarme, A. Durand,*Trends Food Sci. Technol*. 7:285–293, 1996; Priefert, H., J. Rabenhorst, A. Steinbüchel, *Appl. Microbiol. Biotechnol*. 56:296-314, 2001; and Walton, N.J., A. Narbad, C. Faulds, G. Williamson, *Curr. Opinion Biotech.* 11:490–496, 2000).

which limits its use for vanillin production. In the 1990s, studies tended to focus on the direct use of ferulic acid. This acid is one of the constituents of various grasses and crops, and is also a product of the microbial oxidation of lignin. For these reasons it constitutes

an excellent precursor. However its recovery as pure precursor was difficult, which was one of the main limits for its use. The first and most important advance in the field was published in 1997 with the work of Rabenhorst (for H&R company) (44) that described a two step process, one step for the bioconversion of eugenol to ferulic acid by a novel *Pseudomonas* species and the second step describing the conversion of ferulic acid to vanillin by *Amycolatopsis* species. The yield of the bioconversion attained was 78% with a final concentration of 11.5 g/L. In parallel with Rabenhorst's work, the development during the ame decade of molecular tools and genetic engineering opened the possibility of overcoming the different drawbacks mentioned, and led, very recently, to the development of industrial processes (Section 16.4.6.1).

16.4.2 Raspberry Ketone or Frambinone

Raspberry ketone (para-hydroxyphenyl-butan-2-one) is the key compound of raspberry flavor. It is present in very low concentration in the berry (from 0.1 to 2.0 ppm). Its threshold of detection is around 1 to 10 ppb. As an additive in food products, it is used at concentrations from 5 to 50 ppm. Unlike vanilla flavor, natural raspberry ketone is not available because of the high price of extracting it from the corresponding fruit (45). From a financial point of view, natural raspberry ketone occupies the second place after vanillin with a total theoretical market comprising between 6 and 10 millions euros.

If biovanillin was considered as the Holy Grail for some biotechnologists, frambinone (raspberry ketone) is more like the Lost Ark. The difficulty comes principally from the absence of a natural cheap precursor close to the final product and available at enough quantity. However, in spite of these limits, some attempts to produce bioframbinone have been described in the literature. They are summarized in Figure 16.9. The first one concerns the bioconversion of betuligenol, the chosen precursor of frambinone, and betuloside, its glucoside. The later is found in rhododendron, birch, alder, yew, maple, and fir. In the patented processes (46,47), the chosen betuloside source was silver birch, especially the bark. After extraction from the bark, the betuloside was hydrolyzed with a β-glucosidase and then oxidized using yeast alcohol dehydrogenase, which appears to be an elegant and innovative bioprocess. To our knowledge there is not an industrial application yet, mostly due to technological constraints and costs.

Another interesting route was proposed by Whitehead in 1998 (48). The approach consists of exploring the possibility of developing a process close to the chemical pathway of synthesis, that is, condensation of 4-hydroxy-benzaldehyde with acetone. The main difficulty results in the finding of a biocatalyst able to condense, via an aldolase reaction, acetone and a phenol compound. However, some aldolases of biological origin are capable of acting on a large spectrum of substrates, but with variable catalytic constants (49).

16.4.3 Other Phenolic Compounds

As described in the Figure 16.6 and in section 3.1.3, phenylalanine is the source of different flavor compounds in traditional fermented products. As phenylalanine is an abundant and cheap compound, it can be also used as natural substrate for the biosynthesis of natural benzaldehyde and natural β-phenethyl alcohol.

16.4.3.1 Benzaldehyde

In quantity, benzaldehyde is the second most important molecule, after vanillin, for its use in the flavor and fragrance industries. Natural benzaldehyde is used as an ingredient in cherry and other natural fruit flavors. It is generally extracted from fruit kernels such as

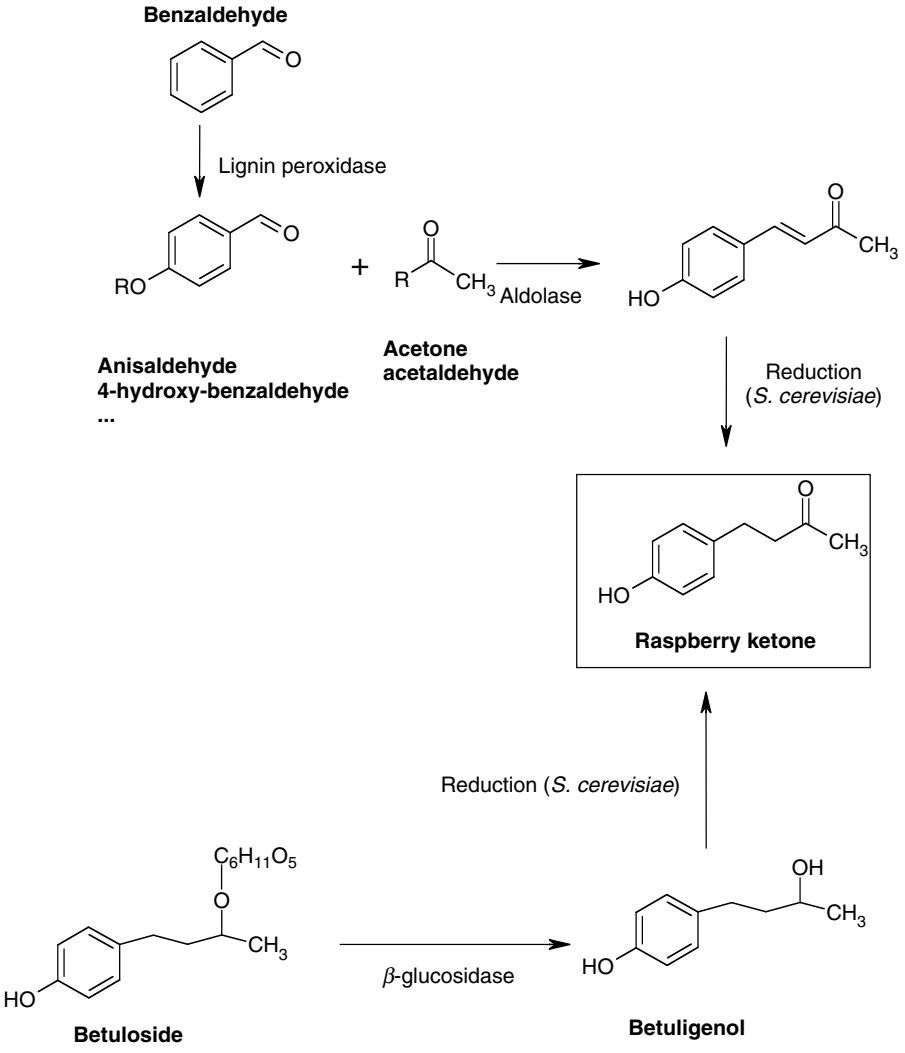

Figure 16.9 Proposed metabolic pathways for the biotechnological synthesis of raspberry ketone (adapted from Dumont, B., P. Hugueny, J.M. Belin, French Patent Applications FR 2 724 666 A1, 1994; Whitehead, I.M, *Food Tech*. 52:40–46, 1998; and Hugueny, P., B. Dumont, F. Ropert, J.-M. Belin, *Bioflavor 95*: INRA Editions, 1995, pp 269–273).

apricots. Natural benzaldehyde has a market of ~20 t/yr and a price of ~240 €/kg. Benzaldehyde obtained from natural cinnamaldehyde can be purchased for 100 €/kg with an estimated market of more than 100 t/yr. However its classification as "natural" remains questionable in view of European Union rules.

The fermentation of phenylalanine offers an alternative route for the biosynthesis of natural benzaldehyde. This route has been studied in a mutant of *Pseudomonas putida* (50) and in the white rot fungi *Polyporus tuberaster* (51). However, production via a fermentation process could become commercially acceptable only if sufficient yields can be obtained, which is not the case as yet. One limitation to scaling up the process is the toxicity of the product (52).

16.4.3.2 2-phenylethanol

After vanillin and benzaldehyde, 2-phenylethanol shows a sizeable market. Its bioproduction is of industrial interest because its price is ~1000 €/kg with an average market of 0.5–1 t/yr (53,54). The production of 2-phenylethanol can be done by harnessing the Ehrlich pathway of different yeast species by bioconversion of L-phenylalanine. As observed for the production of benzaldehyde, above a certain concentration attained, 2-phenylethanol is highly toxic for the biocatalyst. *In situ* product removal appears to be necessary to overcome toxicity and inhibition of the reaction of bioconversion.

16.4.4 Lactones and Methyl Ketones

Lactones constitute an important class of value added bioflavoring additives (from 6000€ to 1200€ with an average market of 5T/yr). They are used in many flavoring preparations like butter or fruit. The general strategy used for the production of biolactones consists of the reduction of the aliphatic chain of hydroxy fatty acids carried out via the β-oxydation system as described in Figure 16.10 with the catabolism of castor oil. After a number of cycles of β-oxydation, the CoA ester of the reduced hydroxyl fatty acid is released from the β-oxidation complex. Usually, the precursor used for the production of a lactone is a hydroxy fatty acid. Depending upon the position of the hydroxy group on the aliphatic chain, this acid could lead to the formation of a γ-lactone or a δ-lactone. In fact, the only natural precursor available in sufficient quantity and at a cheap enough price is ricinoleic acid [(*R*12)-hydroxy-(Z9)-($C_{18:1}$)], the major fatty acid (90%) of castor oil, which is obtained from the plant *Ricinus communis*. In this case, the added value obtained by bioconversion of the product (γ-decalactone) is sufficient for commercial exploitation of the bioconversion system, as is evident from

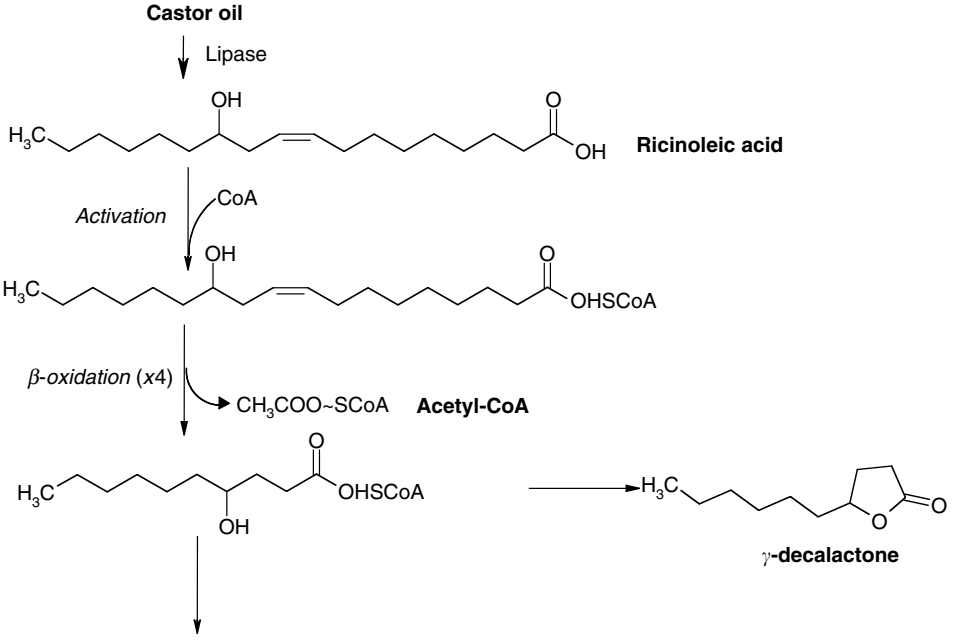

Figure 16.10 β-oxidation of ricinoleic acid and 4-hydroxy-decanoic acid lactone synthesis. Original pathway as deduced from the works of Hutton and Stumpf in plant (Hutton, D., P.K. Stumpf, *Arch. Biochem. Biophys.* 142:48–60, 1971) and Okui *et al.* in *Candida sp*. (Okui, S., M. Uchiyama, M. Mizugaki, *J. Biochem.* 54:536–540, 1963).

the numerous patents on this production system (33). To a lesser extent, 4-decanolide can be obtained from coriolic acid and δ-decalactone can be produced by *Saccharomyces cerevisiae* from 3,11-dihydroxymyristic acid, which is present in Jalap resin (55).

Because there are few natural sources of natural hydroxyl fatty acids, processes have been developed for their biotechnological production, such as the microbial production of 10-hydroxystearic acid for the synthesis of γ-dodecalactone (56,57). Another promising possibility for the future might be the use of isolated enzymes that act on natural polyunsaturated fatty acids, as has been successfully applied using lipoxygenases (58). In this case it might be possible to obtain new lactones. However, in some cases, the production yield is closely related to the structure of the hydroxy fatty acids used as precursors, and this selective affinity has not yet been explained. As described in § 4.6.1., novel knowledge obtained with genetic engineering on producing species can help to understand these physiological particularities.

Methyl ketones are synthesized from the β-oxidation of short chain fatty acids (Figure 16.3, Section 16.3.1.2), with their typical blue cheese aroma and they are commonly used for the flavoring of many dairy products, but are also used in soups, meat products, cooked food, and dressings (59). The major studies have focused on the use of spores of *Penicillium* spp. or *Aspergillus* spp. with oil and fats from plant origin, essentially coconut. The innovative aspect of the work was the development of solid-state fermentation (SSF) processes that are particularly adapted to filamentous fungi cultures. This technique was developed at an industrial and commercial level by the British company, Stafford Specialty Ingredients (4). To our knowledge, this is the only example of the production of bioflavor by SSF at an industrial scale. The production of pyrazine from threonine (29) has recently been reported with the same mode of culture, but industrial exploitation of the results is not mentioned.

16.4.5 Green Notes

Volatile aldehydes and alcohols are key compounds in the fresh and green sensorial notes of vegetables and fruits (60). They are produced by plants in response to various stresses, and they play a major role in plant defense mechanisms (61). The pathway is summarized in Figure 16.11. Polyunsaturated octadecanoic acid is oxidized to 9-, 10-, or 13-hydroperoxides depending on the specificity of the lipoxygenase catalyst, and these compounds are then cleaved by hydroperoxide lyase into C6- C9- or C10-aldehydes, which can be reduced to the corresponding alcohols by yeast alcohol dehydrogenase. This metabolic pathway is a typical plant pathway, which has been mimicked in order to produce natural aldehydes and alcohols (62–65). The highest demand from the flavor industry concerns *cis*-3-hexenol and *trans*-2-hexenal (66).

The worldwide market for natural green notes is estimated to be 5–10 metric tons per year with an average price of 3,000 €/kg. With the growing demand for these natural flavoring compounds, efficient and viable industrial scale processes have been developed, starting from readily available polyunsaturated fatty acids (oleic, linoleic, and linolenic acids) and using plant and microbial systems, essentially soybean lipoxygenase and hydroperoxyde lyase from different plant origins, then alcohol dehydrogenase from *S. cerevisiae* (67). Presently, some flavoring companies produce up to 50% of their green notes compounds by these biotechnological processes.

16.4.6 Prospects

The previous paragraphs illustrate different approaches and processes that have been developed for the production of natural bioflavor. However, in spite of many advances in this field, many applications have shown some limits for commercial exploitation. This is

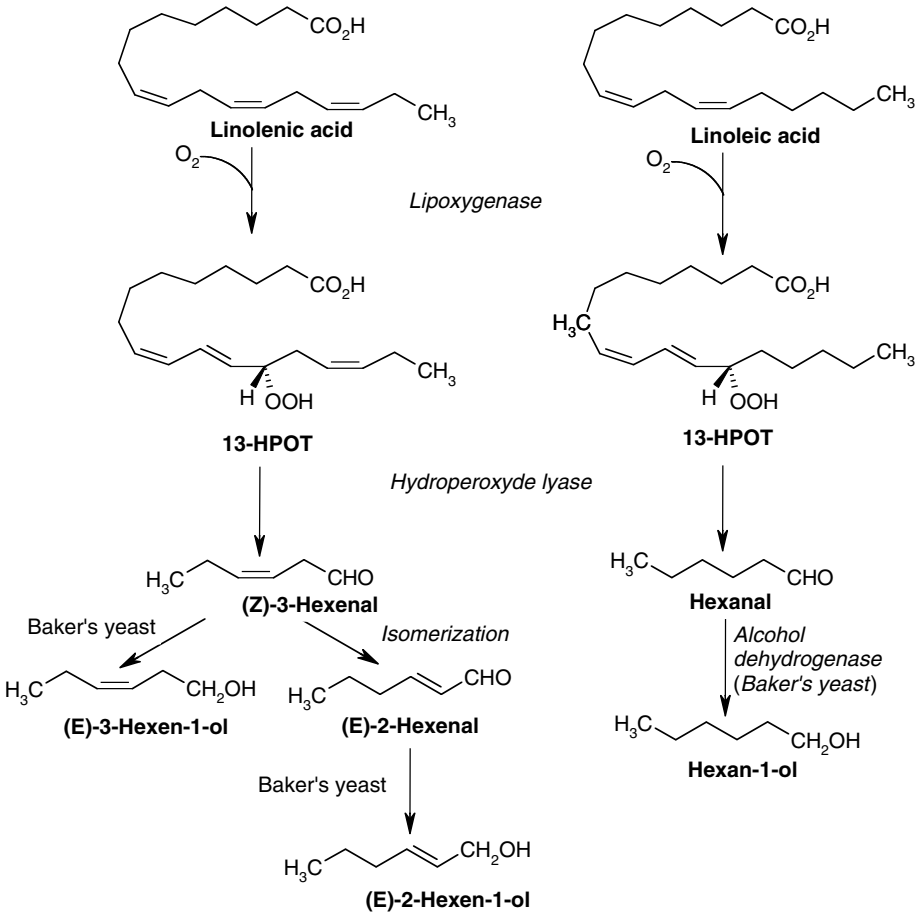

Figure 16.11 Degradation of polyunsaturated C18-acids in the lipoxygenase/hydroperoxide lyase pathway and synthesis of green notes (adapted from Muller, B.L., C. Dean, I.M. Whitehead, *Bioflavor 95*: INRA Editions, 1995, pp 339–344).

mainly due to the lack of basic information on the metabolism of the related compounds. Nowadays, research tends to focus on better control of the different metabolic pathways in order to preferentially orient the fluxes of these pathways to the desired compounds. The following sections present some recent and innovative studies that have been used for this purpose and that could appear as new prospects for the development of the field.

16.4.6.1 Genetic Engineering

Natural synthesis of flavor compounds occurs in tissues where both low concentrations of substrates and weakly active enzymes are present. As described above, biotechnologists try to mimic Nature by mixing tissues or cells possessing high concentrations of substrates and very active or highly specific enzymes. In the genetic era it is expected that they also propose to increase the substrate concentration or the catalyst activity, or even to modify this activity through genetic engineering. As a matter of fact, Nature itself continuously modifies genomes of all species, resulting in the diversity present on Earth. For instance, ricinoleic acid, the substrate for the synthesis of γ-decalactone, is only present at trace levels in most species, but it constitutes 70 to 80% of hydrolyzed castor oil. To explain this

specificity, it can be noted that the substitution of only four amino acids can change a 12-desaturase activity into a 12-hydroxylase one (68).

However, genetic engineering is not so easily understandable by consumers, and the public perception of biotechnology and especially of genetic engineering is, particularly in Europe, rather weak (69). It is true that this perception is partly due to the lack of understanding (69) but also to the philosophical, social, and economical dimensions of the subject. When a gene from an equatorial plant (produced by the third world agriculture) is added to a microbial cell to enable production of exotic flavors in developed countries' reactors, two different questions arise; one about the unnaturalness of the obtained product, and the other about the behavior of rich countries toward poor ones. However, the use of microorganisms to produce aroma compounds in closed reactors is not comparable to open air culture and the resulting flavor, which contains no genetically modified DNA or protein, may not even require specific labeling in the new European rules. Nevertheless, except for the production of specific compounds, genetic engineering in the production of aroma compounds is not significantly booming. This can be explained by the still developing legislative framework in Europe [firms dare not yet utilize genetically modified organisms (GMOs) as catalysts to produce natural products] and the fact that rules are not so constraining in North America. In the USA, for a product to be labeled "Natural" often only requires one "natural" step, which can be completed by the use of classical (nonmicrobial) chemical techniques. In this moving context, it is obvious that many aroma producers develop genetic engineering processes without publishing them (although some processes are patented). This part of the chapter will focus on the production of some compounds that will illustrate the various approaches employed. The main strategies will be summarized in the conclusion of this section.

16.4.6.1.1 Diacetyl Diacetyl is derived from pyruvate through an α-acetolactate degradation pathway (Figure 16.12). Although the oxidative decarboxylation can be catalyzed by enzymes, it occurs mainly spontaneously in media in the presence of metallic catalysts or with a suitable electron acceptor (70,71). In *Lactococcus lactis* strains, the main pathway results in the accumulation of lactic acid (homolactic). Other pathways can convert pyruvate to other end products including acetic acid, ethanol, diacetyl, acetoin, and 2,3-butanediol (heterolactic or mixed acid fermentation). As the acetolactate decarboxylase enzyme (coded by *aldB*) converts acetolactate to acetoin without enabling the production of diacetyl, this enzyme was the first target to increase production (72). However, production with the *aldB* mutant strain was not so high because the homolactic pathway was dominant. To significantly increase the yields required a rerouting to the heterolactic pathway. As shown in Figure 16.12, the homolactic pathway consumes $NADH,H^+$. The first step of the heterolactic pathway is redox neutral (produces NAD^+). The importance of the redox balance of cofactors led Lopez de Felipe et al. (73) to modify it by adding an $NADH,H^+$ oxidase coding gene in order to direct the fluxes into the mixed acid pathway. This was done with success giving rise to a high amount of acetoin, but required the combined disruption of *aldB* to significantly increase the production of diacetyl (74) as, in adequate conditions, oxidative decarboxylation could take place giving rise to diacetyl instead of acetoin (75). A similar strategy could be followed using a classical mutagenesis approach selecting mutants deficient in acetolactate decarboxylase and possessing a low lactate dehydrogenase activity. With that two step mutagenesis approach, mutants of *Lactococcus lactis* subsp. *lactis* biovar Diacetylactis were obtained by Monnet et al. (76) in a nongenetically modified way, but the resulting strains were very sensitive to aerobic conditions and required catalase or yeast extract to grow in the presence of oxygen. In all these cases, the objectives were not so much the production of the aroma compound diacetyl, but the utilization of dairy strains overproducing it in milk products.

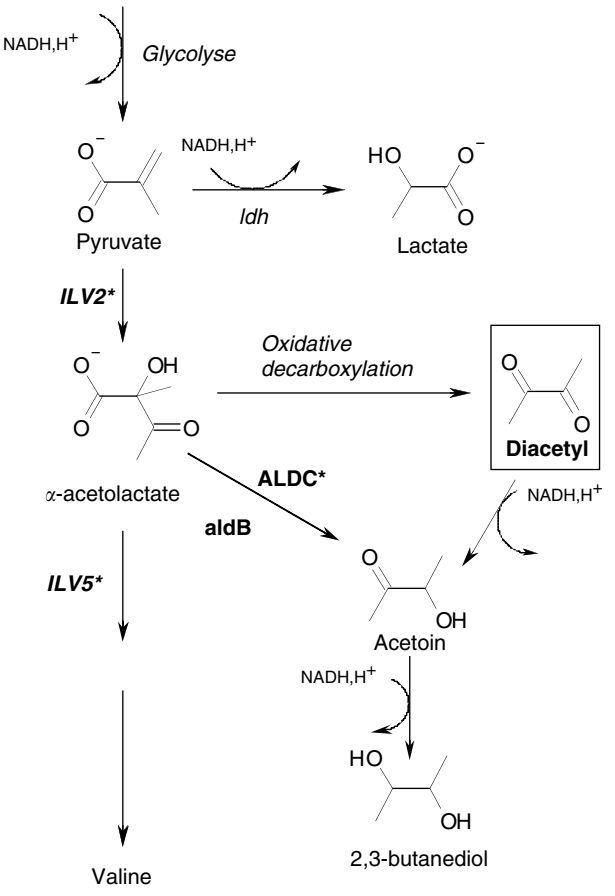

Figure 16.12 Schematic representation of pyruvate metabolism in *L. lactis* (a) and *S. cerevisiae**(b). (a): Pyruvate resulting from the glycolysis pathway can be converted into lactate or into α-acetolactate which is readily decarboxylated into diacetyl (through an oxidative decarboxylation) or, after catalysis of acetolactate decarboxylase (encoded by *aldB*) into acetoin and 2,3-butanediol. (b): Pyruvate is converted to the unstable acetolactate by an acetohydroxyacid synthetase (encoded by *ILV2*) and later to valine (using the reductoisomerase *ILV5*). Some acetolactate can be degraded into diacetyl and therefore, an heterologous acetolactate decarboxylase (ALDC) can be added to favor the pathway leading to acetoin.

It can be noted that in other products such as beer, diacetyl is an important off flavor which can be detected at rather low concentrations (below 0.02 to 0.10 mg/L). Genetic engineering tools have been used to decrease its production in brewer's yeast. In yeast, the metabolic pathways are different from what they are in lactic acid bacteria, and α-acetolactate is an intermediate in the biosynthesis of valine (Figure 16.12). Diacetyl, when formed, can be reduced in yeast into acetoin and 2,3-butanediol, but this requires sometimes several weeks (77). The various strategies have been described by Hansen and Kielland-Brandt (78). Approaches interfering with the valine pathway have been attempted through *ILV2* inactivation or *ILV5* overexpression (79,80). Rerouting from α-acetolactate to acetoin was also tried through the expression of *E. aerogenes* α-acetolactate decarboxylase gene (81).

16.4.6.1.2 Vanillin and Precursor Compounds The production of vanillin or its precursors is probably the field that gave rise to the highest number of patents for genetically

modified strains. Several strategies are used to increase the synthesis of vanillin or of its precursors, and to decrease degradation with genetic manipulations or natural mutations. Most are derived from the microbial pathways described previously, but some authors have also proposed genetic construction enabling new pathways (from glucose) (82).

Because vanillin is very reactive, it exhibits a toxic effect to most microorganisms, which convert it rapidly to less toxic compounds (43). The first approach was to select mutants from the producing strain that are unable to degrade vanillin. The genetic approach of disrupting a target gene such as the one encoding vanillin dehydrogenase (83) resulted in the realization that many nonspecific dehydrogenases were able to convert vanillin (43). Thus, more classical strategies consisting in the isolation of strains on a screening medium were used to select strains unable to grow on vanillin (84), or unable to degrade coniferyl aldehyde (85). Transposon mutants were also used to identify the disrupted genes (86). It was thus observed that mutants disrupted for *vanA* and *vanB* were unable to degrade vanillic acid. These genes code for components of the vanillate-*O*-demethylase which catalyzes the first step of vanillate catabolism.

Other strategies using heterologous DNA were also used with the expression of a phenolic stilbene dioxygenase from *P. paucimobilis* in *E. coli* (87), of a ferulic acid decarboxylase from *S. cerevisiae* W3 in a strain used in the production of shochu, a Japanese distilled liquor (88), or even of the pathway from glucose to vanillin in *E. coli* KL7 (89).

16.4.6.1.3 Biotransformation of Methyl Ricinoleate into γ-decalactone Fewer patented processes have been disclosed for the genetic engineering of γ-decalactone, but several approaches have been attempted, mainly with the yeast *Yarrowia lipolytica*, an organism possessing several families of lipid degrading enzymes (90) for which genetic tools have been developed. The use of this species to produce lactones has been reviewed recently (91).

As shown previously (Section 16.4.4), the biotransformation pathway includes the introduction of a C18 hydroxy acid into the β-oxidation pathway and its exit at the C10-level for the lactonization step (spontaneous). Two main reactions can cause a decrease in the yields: the further β-oxidation of the C10-precursor, or the degradation of the lactone through the same pathway and the exit of the pathway at another stage of the β-oxidation cycle resulting in 3-hydroxy-γ-decalactone.

16.4.6.1.3.1 Acyl-CoA Oxidases of Y. lipolytica Conserved nucleotides blocks from acyl-CoA oxidases encoding genes of *S. cerevisiae* (*POX1*-M27515), *C. maltosa* (*AOX1* and *POX1*-X06721 and D21228) and *C. tropicalis* (*PXP4*, *PXP5* and *PXP2*-M12160, M12161, and P18259) were used to amplify fragments of the genes encoding *Y. lipolytica* acyl-CoA oxidases. Five genes (*POX1* to *POX5*) coding for five acyl-CoA oxidases (Aox1p to Aox5p) have been detected in the yeast *Y. lipolytica* (92). Aox2p and Aox3p are respectively long and short chain specific, whereas Aox1p does not exhibit any activity and Aox4p and Aox5p are active on a wide range of substrates (93).

16.4.6.1.3.2 Blockage of β-oxidation on Short Chain Compounds For yeast species possessing several forms of acyl-CoA oxidases (*C. tropicalis, C. maltosa,* and *Y. lipolytica*), chain length specificities have been observed. The strategy then consists in deleting genes encoding short chain specific enzymes to maintain good activity between C18 and C10 and to block it for shorter acyl-CoA. This requires a good knowledge of the characteristics of the enzymes, which is not always easy to acquire. For *Y. lipolytica*, these characteristics have been obtained by studying how mutant strains grow on methyl ricinoleate, and how γ-decalactone accumulates (94,95). This resulted in the construction of a Δ*pox2pox3pox5* strain with a multicopy insertion of *POX2* (96) but, as this construction was still able to degrade γ-decalactone, the *pox4* gene was also deleted giving rise to a strain able to produce 10 times more γ-decalactone than the wild type and unable to degrade it (97).

16.4.6.1.3.3 Decreasing Acyl-CoA Oxidase Activity in Order to Modify the Fluxes Knowledge of how the global acyl-CoA oxidase was targeted to the peroxisome (where the β-oxidation takes place) was necessary to improve the construction. This was explained by Titorenko et al. (98) who observed that acyl-CoA oxidase was targeted as a heteropentamer including each Aoxp and that Aox2p or Aox3p was necessary for a good assembly of the polymer. Without these Aoxp, the acyl-CoA oxidase activity was weak.

Because *Y. lipolytica* was able to produce more 3-hydroxy-γ-decalactone than γ-decalactone, it was proposed that the acyl-CoA oxidase activity was higher in the β-oxidation flux than the 3-hydroxyacyl-CoA dehydrogenase. Attempts to decrease the acyl-CoA activity in order to increase the production of γ-decalactone were made with success (99). A similar strategy of decreasing β-oxidation fluxes have been carried out with a completely different approach. A process has been proposed using high cell concentrations of a nongrowing Po1d, a *leu⁻ura⁻*derived strain (100).

16.4.6.1.3.4 Acyl-CoA Oxidase Activity Design The current work on acyl-CoA oxidases and lactone production deals with the selectivity of these enzymes. The activity of Aox2p and Aox3p have been characterized with *pox2* and *pox3* genes expressed in *E. coli* (101,102) and protein shuffling experiments between these two forms are being carried out (103).

16.4.6.1.4 Aldehydes (Green Notes) Although biotechnology uses the natural pathway utilizing naturally concentrated sources of substrate (vegetable oil) and enzymes (e.g., soy bean flour) (Section 16.4.5), there is a scaling up problem resulting from the instability of hydroperoxide lyase. Whether this enzyme is sensitive to hydroperoxides or to the reaction products is not known, but its activity rapidly decreases when employed, suggesting a suicidal behavior of the enzyme (65). Moreover, crude extracts are often associated with isomerase activities converting *cis*-3-hexenal into *trans*-2-hexenal (60). As many hydroperoxide lyase encoding genes have been characterized, cloned, and expressed in microorganisms, new processes involving lipoxygenase produced hydroperoxides and microorganisms containing plant hydroperoxide lyase and alcohol dehydrogenase have been proposed. Hydroperoxide lyase exhibits specificities resulting in the production of the highly desired hexenal from the hydroperoxide of linolenic acid or to the more common hexanal from the hydroperoxide of linoleic acid. However, expression in a microbial cell may modify the activity. In a mixture of hydroperoxides, recombinant hydroperoxide lyase from alfalfa expressed in *E. coli* results in a good ratio of *cis*-3-hexenal whereas the expression of this enzyme from green bell pepper in *Y. lipolytica* gives rise to high ratios of hexanal (104), although its specificity in green bell pepper or when expressed in *E. coli* results in the unsaturated aldehyde (105).

Other hydroperoxide lyases have been cloned and expressed in microorganisms: from tomato fruits (106), *Arabidopsis thaliana* (107), melon (108), guava (109). This resulted in several processes of production of green notes which were disclosed very recently (110–113). The wound responding regulation system of the hydroperoxide lyase can be used (114) or, more conveniently, another expression system such as the lipid inducible *POX*-promoter of *Y. lipolytica* (104).

16.4.6.1.5 Conclusion From the set of examples described above, the approaches can be divided into three main strategies (Table 16.7). The first one consists in stopping a degradation pathway in the producing strain. This can require a thorough knowledge of the pathway or simply a good screening medium. In this case, the simple deletion of a target gene often shows that another degradation pathway can be active: the inactivation of the gene coding for vanillin dehydrogenase decreases vanillin dehydrogenation only slightly, showing that several enzymes can catalyze this reaction; and the disruption of *pox3* and *pox5* showed that another acyl-CoA oxidase enzyme (encoded by *POX4*) was active on

γ-decalactone (96,97). This step can usually be overcome using traditional mutation procedures that do not give rise to "genetically modified organisms" (76).

A second strategy, which necessitates a good global knowledge of the metabolic fluxes, consists in modifying these fluxes. Lopez de Felipe et al. (73,115) had the original approach to modify the cofactor redox equilibrium inside the cell by expressing a gene coding for an $NADH,H^+$ oxidase thus changing the metabolism of lactococci from homolactic to heterolactic. Once again, Monnet et al. (76) had a similar result by blocking the homolactic pathway through a classical mutagenesis strategy, rerouting substrates to the mixed acid pathway showing that a lot can be done within the nongenetically modified framework, as long as adequate screening conditions can be used. Another attempt to modify the flux inside a metabolic pathway consisted in decreasing the acyl-CoA oxidase activity within the β-oxidation pathway to favor the exit of the pathway at this stage and decrease the exit at the dehydrogenase step (99).

Eventually, the third possibility is to add a heterologous enzyme or pathway inside an organism that is well known and for which genetic tools have been developed. Some examples (see Table 16.7) have been described for the production of vanillin from glucose in *E. coli* or the production of hexenal from hydroperoxides in various organisms. These strategies are often more complex than initially thought, and problems of expression or of interference with other pathways are common.

Table 16.7
Examples illustrating the main approaches used in the genetic engineering of aroma compounds biosynthesis

Compound	Target	Organism	Mutation	Ref.
Blockage of the degradation of the compound of interest				
Diacetyl	*aldB*	*L. lactis*	GMO	(72,74)
	combined with redox balance		GMO	
Diacetyl	acetolactate decarboxylase	*L. lactis*	mutagenesis	(76)
γ-decalactone	*pox3pox4pox5*	*Y. lipolytica*	GMO	(97)
Vanillin	*vdh*	*P. fluorescens*	GMO	(83,138)
Vanillin	*vanA, vanB* (transposon	*P. fluorescens*	GMO	(86,138)
	mutant)	BF13		
Vanillin	degradation of coniferyl aldehyde	*Pseudomonas* sp.	mutagenesis	(85)
Vanillin	growth on vanillin	*Pseudomonas* sp.	mutagenesis	(84)
Modification of fluxes/rerouting				
Diacetyl	redox state: NADH oxidase	*L. lactis*	GMO	(73)
γ-decalactone	β-oxidation fluxes/*ura⁻, leu⁻*	*Y. lipolytica*	GMO	(100)
γ-decalactone	β-oxidation fluxes/*pox*	*Y. lipolytica*	GMO	(99)
diacetyl	rerouting	*L. lactis*	mutagenesis	(76)
Heterologous gene or pathway				
green notes	hydroperoxide lyase	*E. coli, S. cerevisiae,*	GMO	(104,110-
		Y. lipolytica		113)
Vanillin	ferulic acid decarboxylase	*S. cerevisiae* W3	GMO	(88)
Vanillin	stilbene dioxygenase	*P. paucimobilis*	GMO	(87)
		to *E. coli*		
Vanillin	pathway from glucose to vanillin	*E. coli* KL7	GMO	(89)
Directed evolution/protein shuffling				
γ-decalactone	acyl-CoA oxidase L7	*Y. lipolytica*	GMO	(103)

In conclusion, genetic engineering of the production of aroma compounds is often complex and requires not only a thorough knowledge of the pathway but also of the fluxes inside the cell. For that reason, genetic tools can be completed by the use of flux modelling systems such as Metabolic Control Analysis strategies (116).

16.4.6.2 Biocatalyst Environment

16.4.6.2.1 Oxydoreduction Potential Considerable efforts have been made to understand how cellular metabolism reacts to variations in pH, temperature, pressure, and osmotic pressure. However, little information is available on the response of microorganisms to changes in external oxidoreduction potential (ORP). Early studies suggested that each species or strain has a preferred redox potential range, within which growth is possible (117,118). Certain enzymes activities are controlled by ORP, and modification of this parameter can alter metabolic balances during anaerobic growth of *Escherichia coli* (119). This is also true for the synthesis and the proportion of amino acids synthesized by *Clostridium glutamicum* (120). More recently, Bespalov et al. (121) have shown that *E. coli* can sense the medium's ORP and swim to a preferred ORP niche by means of redox taxis.

As for the pH, ORP is an intrinsic parameter of all media, because they contain at least one molecule able to move from one redox state to another. Oxidoreduction potential can be considered as the average electron availability of a medium. Biochemical reactions are often redox reactions occurring in an aqueous environment, and protons play important roles in electron exchange reactions. Consequently, pH and ORP are not independent parameters. Each medium has its own ORP value, and the different redox coupling system equilibria depend on this value. Moreover it is possible to manipulate this value by the addition of molecules (such as cysteine and ascorbate) as well as by gas mixing (O_2 and H_2).

This control of ORP was first performed to increase the rate of production of some metabolites, such as xylitol in the yeast *Candida* (122). Very recently it has been shown that this physicochemical parameter also affects the functioning of yeast for the production of some flavors. In particular, in view of the importance of ORP in the regulation of β-oxidation flux (123,124), the sensitivity of the genus *Sporidiobolus* to a modification of external ORP by using gas (O_2 or H_2) or molecules {DTT, $K_3[Fe(CN)_6]$}, with regard to their ability to synthesize 4-decanolide, was studied in our laboratory [125]). Results indicated that the synthesis of lactone was highly improved under an ORP reduced to 50 mV. This production is 4 times higher than that of control (ORP 300 mV). However, when the ORP dropped to –150 mV, no lactone production was observed (Figure 16.13). This was directly related to the functioning of the β-oxidation system via a modification of the cofactor level (NAD^+:NADH ratio) and the enzyme activities of the yeast (126). To our knowledge, this was the first example of the effect of external ORP modifications on the production of a flavoring substance.

Basically, these different studies led to the question of the defining of an optimal ORP (as it is already done for pH) for the functioning of major enzymatic systems and metabolic pathways (Figure 16.14), and especially those leading to the synthesis of flavor compounds. Moreover, in terms of application, ORP seems to appear also as an essential environmental parameter that has to be taken into account during fermentation processes as well as in traditional fermented food technology.

16.4.6.2.2 Polarity Flavor compounds are mainly hydrophobic compounds. For this reason, their toxicity is often one of the limits encountered in the scaling up of the process. Above a certain concentration of aroma, the biocatalytic activity is strongly inhibited. To minimize the disadvantage of substrate and product toxicity, studies based on solvent resistant organisms have been developed. In particular, some investigations have focused

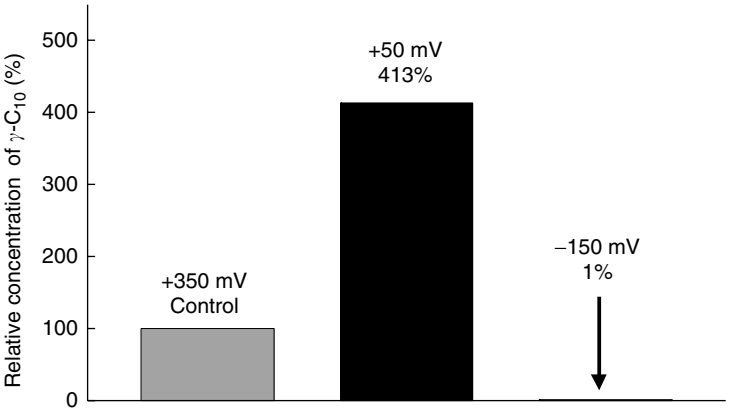

Figure 16.13 Relative maximum amount of γ-decalactone produced by yeast (*Sporidiobolus ruinenii* in this example) under different oxydo-reduction potential conditions (from Feron, G., X.-D. Wang, C. Viel, C. Perrin, G. Mauvais, R. Cachon, C. Diviès, *Proceedings of the 10th Weurman Flavor Research Symposium*, Beaune, 2002, pp 389–392).

on the biotransformation of terpenes by a particular strain of *Pseudomonas alcaligines* able to growth on limonene. From different mutants obtained on this strain, it is possible to better understand the enzymes involved in terpenes biotransformation (127) for the production of food grade flavoring products such as α-terpineol or carvone, for example.

Beside the toxicity aspect, the hydrophobicity of flavor compounds frequently implies their channeling through enzymatic complexes, making their recovery difficult when they are not the terminal product of a metabolic pathway. Based on the works of Spinnler et al. (128), the possibility to modify extracellular polarity by the use of organic solvents and lypophilic compounds can be an interesting way to modify catalytic and equilibrium constants inside a pathway and, as a consequence, the recovery of interesting intermediaries that are not released generally outside the biocatalyst (Figure 16.14). The feasibility of such a strategy was demonstrated by studying the catabolism of ricinoleic for the recovery of γ-decalactone with the yeast *Sporidiobolus ruinenii* grown in the presence of decane (128). As a result, the corresponding 4-hydroxy-acid intermediates released during the β-oxidation of (*R*)-ricinoleic acid have been detected with a final accumulation of γ-decalactone up to 1 g/L.

In spite of the difficulty to find and select microorganism able to growth on organic solvents, these results open a very innovative area particularly adapted to the production of "bioflavor".

16.5 GENERAL CONCLUSION

As a general conclusion, one must considered that the biotechnological production of microbial flavors is an industrial reality that will tend to be further developed in the future. In fact, the exponential progress of results acquired on the understanding of metabolic pathways involved in the synthesis of the desired compounds will permit better control of the flavoring metabolism of the biocatalysts, either in biotechnological or in traditional fermentation processes. The sole limits that could occur on this development might come from legal considerations, but also from food consumer acceptance of genetically modified microbial (GMO) products. Presently, as it was observed for the vague chemophobia of the past, the use of flavor from GMO is totally avoided in the food industry, especially in Europe.

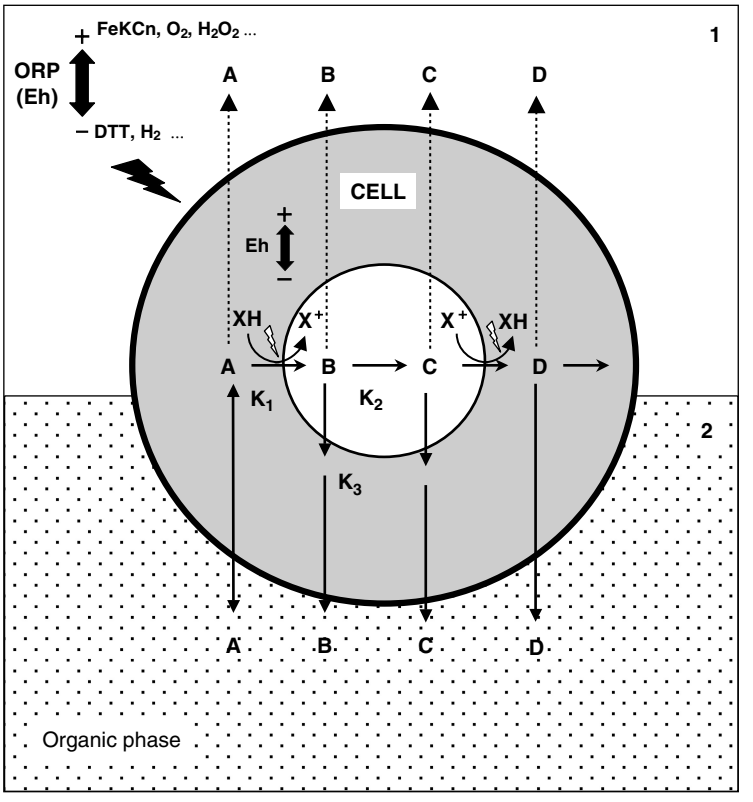

Figure 16.14 Strategy to orientate metabolic pathways leading to flavor compounds in a cell with the modification of external ORP (Eh) [Figure 16.14(1)] or extracellular polarity/hydrophobicity [Figure 16.14(2)] by the use of organic solvents. In the first case, external modification of Eh would affect internal Eh, modifying internal redox balance and metabolic flux. In the second case, hydrophobic intermediates (flavors B, C, and D), formed by a sequence of intracellular reactions, would cross the cell membrane and partition favorably in the organic phase, where they should accumulate (adapted from Spinnler, H.E., C. Ginies, J.A. Khan, E.N. Vulfson, *Proc. Natl. Acad. Sci. USA* 93:3373–3376, 1996).

Even questioning the character "natural" and "safe" of GMO, especially in the case of interspecies transfers, genetic engineering still constitutes one of the most promising possibilities either as a tool for production of novel and safe additives or creating material for discovering new biocatalytic capacities.

1.17

Microbial Production of Oils and Fats

James P. Wynn and Colin Ratledge

CONTENTS

17.1 INTRODUCTION

17.1.1 The Concept of Single Cell Oils

Human beings have used microorganisms as sources of foods and food ingredients since ancient times. We have been consuming a wide variety of fermented beverages, including beers and wines, and numerous fermented foods, such as cheeses, yogurts, salamis, sauerkraut, and tempeh, since almost the very beginnings of civilization. Extensive use of microorganisms for food production has occurred in many civilizations, and the safe consumption of microorganisms themselves, as well as the foods that they have produced, is now well established as a global activity.This is evidenced by the many chapters in this volume that deal with the various aspects of microbial technologies in the production of a wide variety of foods.

The use of isolated components from microbial cultures in foods also has a long history. These range from vinegar (i.e., acetic acid, which is, of course, a product again almost as old as civilization) to citric acid, numerous amino acids, and polysaccharide gums. Of more recent appearance has been the advent of microbial proteins in which the whole organism (or almost so) is the object of consumption. The first uses of this technology came in the development of food yeast (the Torula process), which was devised as a means of converting surplus sugar and molasses in the West Indies in the 1940s and 1950s to a biomass that could be used as an animal feed supplement. (The nutritional value added to the biomass was derived by the yeast converting the sugar and ammonia, supplied as the sole nitrogen source, into proteins, which then were eaten by the animals.) Of major significance in the use of microorganisms for food was the advent of various Single Cell Protein (SCP) processes that further developed the original concept of the Torula process for use with other microorganisms and other substrates. In particular, alkanes were (and are) produced by the petroleum industry in vast amounts almost as a waste material during the refinement of crude petroleum oil. This led to major advances in the technology of large scale microbial cultivations with, eventually, fermentors up to 1500 m^3 being built to produce large amounts of SCP. Such fermentation plants could easily generate upward of 5000 tons (dry weight) of biomass per year on a site about the size of three or four football fields. With the use of such large scale production facilities came economies of scale: yeast biomass derived from alkanes could be produced for as little as $150–200 per ton in the 1970s.

Against this background of being able to produce large amounts of microbial biomass as a source of protein food, the current ideas of producing oils and fats using microorganisms were conceived (1). The name Single Cell Oils (SCO) was coined (2) to be in keeping with the concept of SCP and to indicate the distinctiveness of this material. The term SCO was meant to denote those oils that could be extracted from a microorganism, which would approximate an animal or plant oil and be suitable for use in foods or in other products where oils and fats from more conventional sources were normally used.

The concept of producing SCOs as alternatives to plant oils, though, was far from novel and the quest to produce them has a long history [see (3–5) for reviews covering this period]. Initial attempts to use various yeasts and filamentous fungi as potential sources of oil were probably started in the first two decades of the twentieth century. By the 1930s, serious attempts were being made in Europe and the U.S. to develop these processes. During World War II, the first attempts to produce microbial oils on an industrial scale were developed in Germany, with Henkel, as one of the major oils and fats companies, being a key instigator. Production details are somewhat scant, but it appears that the fat-containing yeast produced was only used as a feed material for army horses! But as the German army at the time had over a million horses, this may not have been an inconsiderable amount or an insignificant contribution to animal nutrition. However, the oil within the yeast does not appear to have been extracted, though technically it could have been. Clearly, if the entire material was only going to be used for animal nutrition, then there was no point in extracting the oil and then feeding it together with the residual high protein microbial biomass to the horses; rather, just feed the entire high fat biomass.

The importance of this early research in Germany and elsewhere is not to be underestimated. It laid down several important principles that hold good today and that can be summarized as follows:

1. Not all microorganisms can accumulate lipid. Those that do so above an arbitrary limit of about 20% of the dry cell biomass are termed oleaginous (6).

2. The main organisms that accumulate lipid are yeasts and fungi. Bacteria are not good producers.
3. Some microorganisms can accumulate more lipid than others.
4. Oil contents of a few microorganisms can reach up to 70% (w/w) of the dry biomass.
5. Lipid accumulation in a microorganism is triggered when a nutrient (usually nitrogen) in the growth medium becomes exhausted and the surplus carbon source (usually glucose) continues to be assimilated by the microorganism, which is converted into a storage oil or fat.
6. The oils that are accumulated by microorganisms are the same type as are found in seed oil plants (i.e., predominantly triacylglycerols and the esterified fatty acids).

17.1.2 Oleaginous Microorganisms and Lipid Accumulation

The range of fatty acids that microorganisms produce is extensive (7) and is almost as diverse as those from plant sources. However, if we restrict ourselves to the oleaginous organisms, that is those accumulating more than about 20% (w/w dry wt) oil, then the range of fatty acids is much more restricted and, almost without exception, are the same as those found in plant and animal oils and fats. A selection of fatty acids from various oleaginous yeasts, molds, and some algae is given in Tables 17.1–17.3. More complete lists of fatty acids found in the oleaginous microorganisms can be found in previous reviews of the authors (8–10).

As can be seen from the tables, the composition of these fatty acids covers the type and range of fatty acids seen in many of the commercial plant oils though some microorganisms, particularly species of molds and algae, clearly produce some polyunsaturated fatty acids (PUFA) that are of a longer chain length and are even more unsaturated than those that occur in plants. It is these microorganisms that have become increasingly of more interest as the demands for PUFAs as dietary supplements have increased over the past decade. These aspects of microbial oil production have then become the cornerstone for the very recent developments in this area and therefore form the main focus of this chapter.

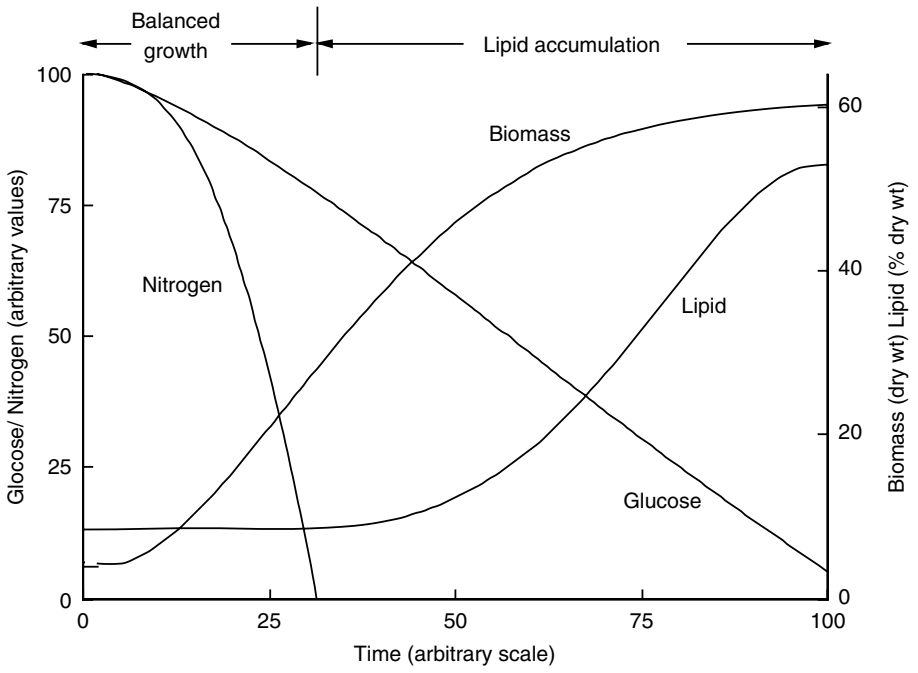

Figure 17.1 The course of lipid accumulation by a typical oleaginous microorganism. The concentration of nitrogen (usually NH_3) in the medium is adjusted in the initial formulation so that it becomes exhausted after about the first 24 to 36 hours' growth.

In most cases, though not in every one, the accumulation of lipid in an oleaginous species of microorganism follows a similar pattern (Figure 17.1). In essence, the microorganism of choice is grown in a culture medium that is high in carbon (usually glucose or sucrose) and low in nitrogen (usually this is an ammonium salt though urea is used occasionally) so that after the initial phase of balanced growth, where all nutrients are in excess, the organism exhausts the supply of nitrogen but continues to assimilate the carbon source. The absence of nitrogen from the growth medium stops cells from dividing and continuing to grow as the nitrogen is obviously needed for both protein and nucleic acid synthesis, both of which are essential for the creation of new cells. The continued assimilation of the carbon source, however, means that the cells must do something with it; oleaginous microorganisms convert it into oils and fats, though other organisms might convert it into other storage materials, such as polysaccharides (11), or even produce large amounts of metabolites, such as citric acid (12). The process of lipid accumulation (see Figure 17.1) continues until the cells reach a personal limit of obesity. Some cells may continue to produce oil until they are physically unable to accumulate any more (Figure 17.2). Other microorganisms, still being classed as oleaginous, stop lipid accumulation at some apparent limit that may vary from 20 to 25% (w/w dry wt) up to 60% or so. This limit is evidently genetically predetermined and is a characteristic of each individual organism. The reason why microorganisms accumulate lipid but then limit their production of it resides in the complexities of the biochemistry and genetics of these cells. This area has recently been reviewed by the present authors (13), and that article should be consulted for further information regarding the biochemistry and molecular biology of lipid accumulation in microorganisms and for an explanation for the limits to lipid production by individual microorganisms.

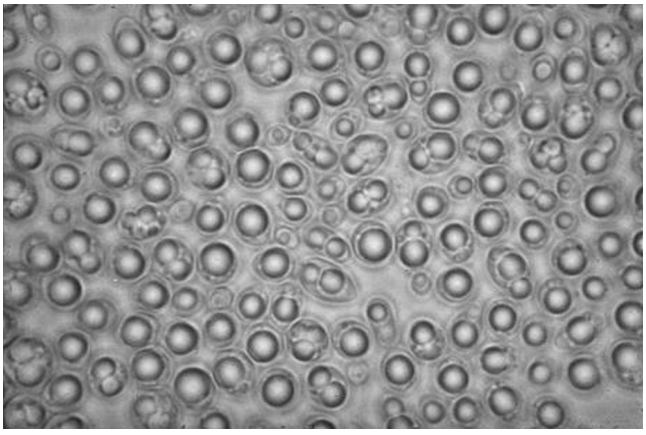

Figure 17.2 Cells of an oleaginous yeast, *Cryptococcus curvatus* (formerly *Candida curvata* D), showing the accumulation of lipid in the form of discrete intracellular droplets.

17.2 GENERAL PRINCIPLES, ECONOMICS AND PROCESSES FOR SCO PRODUCTION

The intrinsic cheapness of the commodity oils and fats obtained from agriculture, where the costs are usually between $400 and $800 per ton (see www.fas/usda/gov/oilseed), means that any potential biotechnology SCO process must aim at producing speciality oils and fats that would be valued at considerably higher prices. The biochemical efficiency of converting sugar into triacylglycerol indicates that to produce one ton of microbial oil, three tons of sugar substrate will be needed. A further one to two tons of sugar will also be needed to provide the remainder of the (oil free) biomass. As sugar costs about $300 per ton at world prices, the costs of substrate alone will be about $1500 to produce one ton of SCO. Add to this the cost of fermentation, which even on the largest scale will cost a minimum of $2000 per ton of oil generated, we already have a production cost that greatly exceeds the price of all commodity plant oils. Further costs will be incurred in the extraction and refining that must be done to produce a high quality, food grade oil. Hence even the cheapest SCO is not likely to cost less than $5000 per ton and, if a slow growing microorganism is used with fastidious growth requirements or with a low oil yield, then these costs could easily double or triple.

The exact costs of SCO production by fermentation technology, though, are difficult to calculate in general as there are so many variables that need to be taken into account. Apart from the costs of the process itself (Figure 17.3) and the costs of the substrate and other direct costs, there could also be other costs incurred, for example, in the disposal of the waste fermentation broth. Further revenue must be included in the eventual selling price of the SCO to cover all the capital outlay that will have been needed to customize the fermentation plant, or even to build a new one on a green field site, and also to cover the costs of all the research that will have been done to develop the process, as well as the final marketing, sales, and distribution of the oil.

While it may be difficult to estimate the cost of producing an SCO beyond the ballpark figures indicated above, we nonetheless can indicate the type of process that will be used. Figure 17.3 shows a typical large scale fermentation process of the type that would be used for SCO production. An appropriate microbial culture is initially grown through shake-flask culture, then placed into small (10–100 L) stirred fermentors, and finally

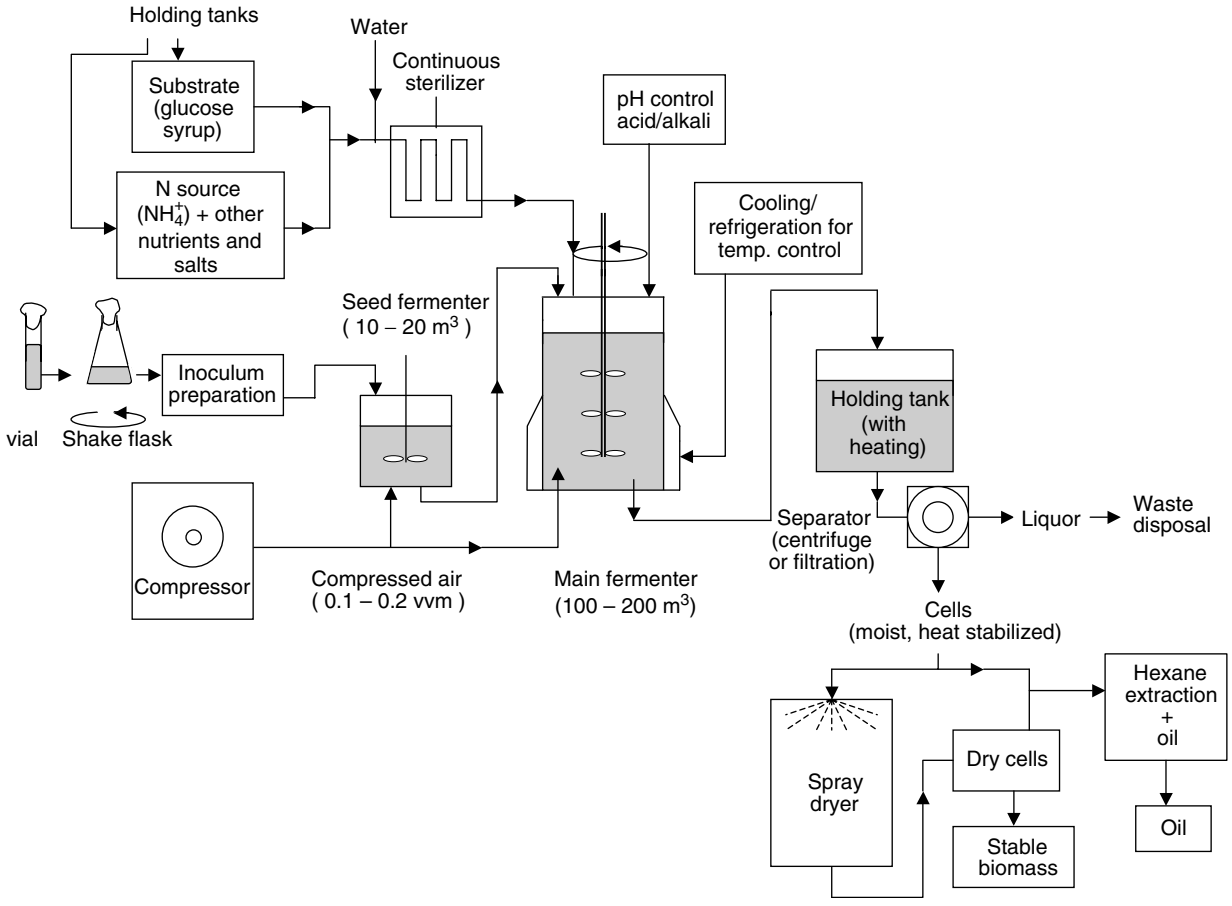

Figure 17.3 A diagrammatic presentation of a fermentation system used for the production of Single Cell Oils. (see text, Section 17.2).

placed in a large seed fermentor that is usually about 10% of the volume of the final fermentor to be used. The use of a large inoculum volume means that the growth time of the organism in the final fermentor is minimized; that is, the productivity (measured as g oil produced per unit time per unit volume of fermentor) is maximized.

Growth of the SCO-producing organism will probably follow the pattern given in Figure 17.1. All the major parameters, such as temperature, pH, and dissolved oxygen, are carefully measured and controlled during the fermentation process. Temperature control is critical and in most fermentations which, of course, are exothermic, this requires continuous cooling using a water supply rather than expensive refrigeration. For this reason, fermentations that run at 30°C or higher are usually preferred.

The sterility of the systems is also of paramount importance, and there are frequent checks at all stages of both the inoculum preparation as well as the final fermentation process itself that the culture remains axenic. Contamination usually means that the individual production run has to be aborted but, fortunately, this is usually a rare event.

In the final hours of the fermentation, when the oil content of the cells is reaching its maximum, the amount of residual substrate (e.g., glucose or sucrose) may be exhausted. Although this may seem to be good practice, in that all the added substrate will have been consumed, this situation can stimulate the cells to use the lipid that they have just accumulated. What happens is that oil accumulation occurs as a means of the cells storing excess carbon as a reserve material. However, when the substrate is exhausted, the cells then sense that they are starving and instigate a survival mechanism in which the stored reserve of oil is now mobilized for the cells' own benefit. Consequently, if this happens in the fermentation process, not only will the final oil yield diminish but, more importantly, the switch from the cells using glucose to using oil as a substrate induces the formation of lipases. Lipases are induced as the first step in oil utilization, and their presence can be detrimental to the final quality of the oil.

Even if the glucose or other substrate is not completely exhausted at the end of growth and at the time of harvesting the cells, the final process of cell harvesting (Figure 17.3) means that any residual substrate will be removed from the cells at this stage. The cells in the absence of glucose, whether they are being harvested by filtration or centrifugation, still respond to the stress of there being no carbon source by inducing the formation of lipases; they still sense the starvation stress and begin to utilize their oil reserves. If the activity of the induced lipases is not checked, this will inevitably lead to loss of valuable oil but will also cause free fatty acids to be liberated. These will not be easily removed and, indeed, may remain in the final oil to detract from its final appearance, flavor, and general characteristics. Induction of lipases in the cells, either during the final hours of the fermentation process, or during the harvesting of the cells, therefore has to be prevented. This is most easily achieved by heating the fermentation broth in the final hours to a point where the lipases are destroyed or the mechanism of inducing the lipases is prevented by heat denaturation of the protein-synthesizing ribosomes. In practice, heating the fermentation broth to no more than 60°C is normally regarded as sufficient.

It is usually more economical if the final fermentation broth is removed as quickly as possible from the fermentor as this speeds up the turnaround time before the fermentor can be cleaned, refilled, and reinoculated, and the process repeated. To achieve this fast turnaround, the fermentor is usually discharged into a holding tank (see Figure 17.3) which can, as an alternative to heating the fermentor, be heated to inactivate the lipases and stabilize the oil. Harvesting of the cells from the holding tank can then take place over a much longer period than harvesting directly from the fermentor itself — perhaps taking up to 48 hours depending on the size of the centrifuges or rotary drum filtration units available.

The harvested cells are still moist. They can be completely stabilized by flash drying (e.g., spray drying) in which case the dry cells can be either stored until required or sold if there is a market for an oil-rich microbial biomass. Alternatively, the moist cells can be directly extracted using hexane (which is a permitted solvent for oil extraction). The process of oil extraction either from the moist cells, or from the spray dried cells, is the same as is used with the extraction of oils from plant seeds.

Usually for SCO extraction, a small scale extraction unit either must be built or a suitable existing commercial unit has to be identified. Such small extraction units are used commercially in the extraction of various high value, low volume, speciality oils or in the extraction of essential oils from various plants seeds and tissues. A final deodorizing step together with a refinement step then completes the oil extraction and production. [Further information regarding the extraction of various SCOs from organisms being grown commercially is given in (14).]

The overall aim is to produce a clear, bright oil with a minimum of coloring; though some yellowness is acceptable, a dark, brown oil would not be regarded as desirable. The various characteristics of the oil need to be carefully evaluated, chief among them being the overall stability of the oil. Some food grade, antioxidant material can be added to ensure a high stability of the oil, though in practice many microbial oils have been found to be very stable to oxidation because of the presence of natural antioxidants that have been co-extracted with the oil.

17.3 SCO PRODUCTION PROCESSES

Because of the high cost of producing microbial oils, most recent work has concentrated on the production of various oils rich in polyunsaturated fatty acids (PUFA) as these are the most expensive oils. There is, however, one exception, and that has been the pursuit of producing a possible cocoa butter equivalent fat using yeasts.

17.3.1 Process for the Production of a Cocoa Butter Equivalent Fat

In the mid 1980s the price of cocoa butter reached an all time high of more than $8000 per ton. This made the possibility of producing a facsimile fat — known as a cocoa butter equivalent (CBE) fat — using yeast technology somewhat attractive. However, cocoa butter is a triacylglycerol in which the three component fatty acyl groups are palmitic acid (16:0), oleic acid (18:1), and stearic acid (18:0) (Table 17.4). Unfortunately, most microbial oils are low in their contents of stearic acid (see Table 17.1) and therefore modification of the composition of the yeast fat was necessary if a CBE was to be produced. Several approaches were tried to achieve this end, and these have been reviewed in four separate chapters in ref. 15. The most successful work was led by Henk Smit of the Free University of Amsterdam, Netherlands, using *Cryptococcus curvatus* D and involving the deletion of the gene that codes for the Δ9–desaturase, which converts stearate into oleate (16). This genetic deletion led to the mutant accumulating 50% of its total fatty acids as stearic acid (Table 17.4) and a greatly diminished amount of oleate. So complete was the genetic deletion that, for the yeast then to grow, it was necessary to include a small amount of oleic acid in the growth medium. Subsequent modification of the mutation led to the isolation of a partial revertant that could now grow without the addition of oleate but which nevertheless still accumulated a large amount of stearic acid. Unfortunately significant amounts of linoleic acid (18:2) still occurred in the final fat, which detracted from the final quality of the yeast CBE. Also it was found that when this final mutant (R22.72) was grown in

large scale fermentations, it was not particularly stable and the quality of the final fat was now below that achieved in small laboratory cultivations.

The simplest and possibly the most successful approach to achieving an increase in the stearate content of the yeast fat was that used by Julian Davies in New Zealand, which was to grow the yeast with a deficiency of oxygen (17). This required trials to be done in 100 m^3 fermentors in order to decrease the aeration rate sufficiently to cause the desaturases to stop working. (All fatty acid desaturases require molecular oxygen for their reaction.) When this was done, the content of stearate was increased to 24% of the total fatty acids (Table 17.4). The low aeration rate in the fermentor also diminished the contents of 18:2 and 18:3 in the yeast fat thus adding to the overall attractiveness of the product.

The properties of the final yeast CBE produced in this manner were sufficiently good for it to be considered suitable for use alongside more conventionally produced CBEs. However, by the time the work had been completed the price of cocoa butter had fallen to about $3000/ton forcing down the price of the CBE fat to under $2000/ton. Even though the proposed process intended to use the waste lactose arising from cheese creameries in New Zealand, where there are vast amounts of it available throughout the year, and could therefore almost claim to be using a substrate of zero cost, the process was still deemed to be uneconomical.

Although this work was ultimately unsuccessful, it did show that SCOs could be tailor-made to a desirable specification by appropriate genetic manipulations of an amenable organism, such as *C. curvatus*. Furthermore, careful manipulation of the fermentation conditions, in this case using a very low aeration rate, could also help change the fatty acid profile of the organism toward the most desirable configuration. These principles would therefore apply to other organisms being used for other SCOs and illustrate one of the strengths of the biotechnological approach to oil production, namely to take an individual organism and then to optimize both oil quality and production by careful selection of the organism and control of its growth conditions.

17.3.2 Polyunsaturated Fatty Acids (PUFAs)

Before covering the present SCO processes for the production of various PUFAs, we thought that it would be helpful if we explained the reasons behind the current upsurge of interest in these lipids.

PUFAs are now in considerable demand mainly as dietary supplements and are regarded as nutraceutical materials. The major sources of these fatty acids are given in Table 17.5 together with their biological roles. PUFAs fall into two main categories: the ω-6 or n-6, (sometimes given just as n6), and the ω-3 (n-3 or n3) series, depending on the position of the final double bond in the acyl chain relative to the terminal methyl group (Figure 17.4).

17.3.2.1 Dietetic Significance of Long Chain Polyunsaturated Fatty Acids

Although fat in general is very much seen as a harmful element in the human diet of course, in moderation, fat is a perfectly healthy food component and certain dietary fats are actually dietetically essential for human health. Biological membranes are composed of a lipid bilayer and several groups of cell signalling molecules (prostaglandins, leukotrienes, and eicosanoids) that are essential for cell function are synthesized from lipid precursors. Although animal cells are capable of synthesizing fat *de novo* from glucose certain specific fatty acids (the basic building blocks of lipids) cannot be produced *de novo* by animal cells. This is a result of cells lacking certain enzyme activities involved in polyunsaturated fatty biosynthesis.

The biosynthesis of the two major groups of polyunsaturated fatty acids, the n-6 and n-3 series, are shown in Figure 17.4. These two groups are synthesized, respectively, from linoleic acid [18:2(n-6)] and α-linolenic acid [18:3(n-3)]. Both linoleic acid and α-linolenic acid are essential fatty acids, as they cannot be synthesized *de novo* in animals which lack the Δ12 desaturase required for 18:2 biosynthesis from oleic acid and the Δ12 and Δ15 desaturases required for 18:3(n-3) biosynthesis from oleic acid. As a result of this metabolic deficiency, animals require sources of both 18:2 and 18:3(n-3) in their diet. Fortunately, both these essential fatty acids are synthesized by plants, which almost without exception possess a Δ12 desaturase and a Δ15 desaturase. As a result, a dietary deficiency of either of these fatty acids is unheard of in nature and difficult to obtain even under laboratory conditions. (Even if one eats a minimum of plant derived oils, these essential fatty acids are still present in animal fats as, invariably, the animals that we eat are herbivores and will have derived their own linoleic and linolenic acids from their plant diet.)

Once taken up by animal cells, both 18:2 and 18:3(n-3) can be further elongated and desaturated to the full compliment of long chain polyunsaturated fatty acids (LC-PUFA), i.e., fatty acids containing 20 or more carbon atoms and three or more double bonds, (Figure 17.4). It should be noted that although animal cells can synthesize LC-PUFA from the essential fatty acid precursors, plant cells are unable to produce LC-PUFA and so dietary sources of LC-PUFA are traditionally animal oils (especially fish oils).

Several of the LC-PUFA, of both the n-3 and n-6 class, play important roles in cell function. LC-PUFA are key components in cell membranes, playing a role in regulating the fluidity of membranes and therefore the activity of many membrane associated processes. Indeed two LC-PUFA, arachidonic acid [20:4(n-6)], and docosahexaenoic acid [DHA, 22:6(n-3)] are highly enriched in mammalian brain and nervous tissue where they play an important role in brain and neural development, especially in neonates (19). The role of DHA in brain development has been highlighted by reports that a diet rich in fish oils containing high levels of DHA may have played a defining role in the evolution of mankind in terms of brain size and therefore intelligence (19).

Certain LC-PUFA are the precursors of a number of cell signalling compounds that are vital for many vital processes from inflammatory response to blood clotting. Arachidonic acid [20:4(n-6)] and dihomolinolenic acid [20:3(n-6)] are key n-6 precursors of the group 2 and group 1 series of prostanoids while eicosapentaenoic acid [20:5(n-3)],

Table 17.5
The Major Sources and Biological Functions of the Major PUFAs* and Their Applications

	n-6 Family		n-3 Family		
Sources	**GLA (18:3; 6,9,12)**	**ARA (20:4; 5,8,11,14)**	**ALA (18:3; 9,12,15)**	**EPA (20:5; 5,8,11,14,17)**	**DHA (20:6; 4,7,10,13,16,19)**

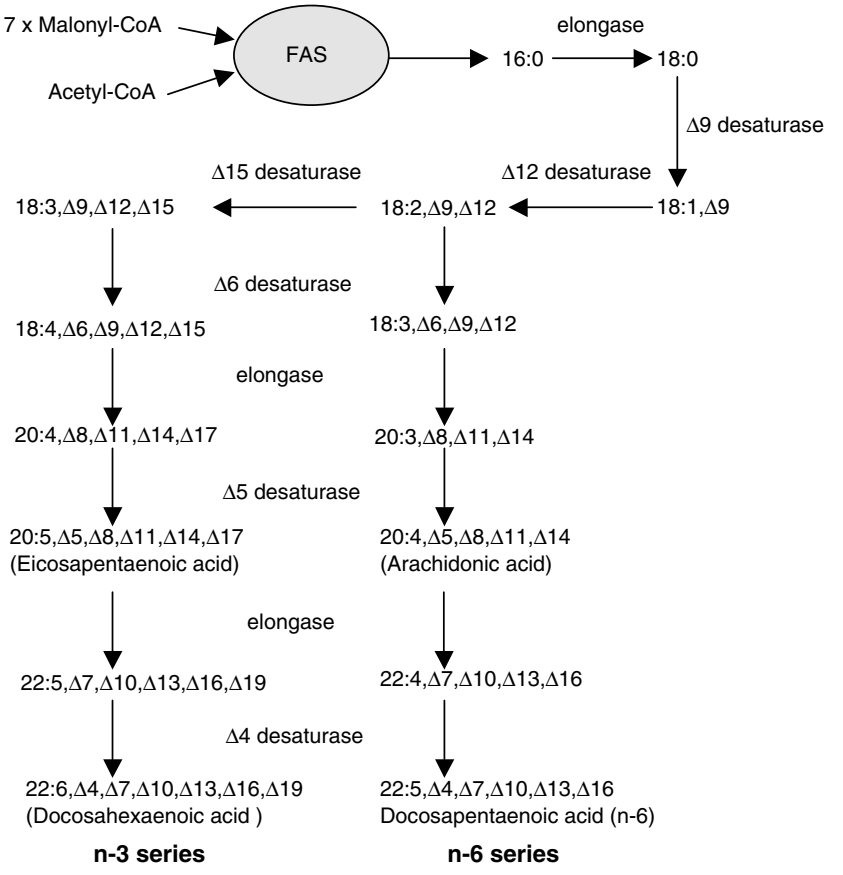

Figure 17.4 Diagram showing the routes of *de novo* biosynthesis of polyunsaturated fatty acids of the n-3 and n-6 series.

another n-3 LC-PUFA, is the precursor of the group 3 series of prostanoids (20). As the group 3 series of prostanoids often act antagonistically to the group 1 and 2 series and, because the enzyme activities that produce the prostanoids from their respective n-3 and n-6 precursors are the same, the ratio of n-3 and n-6 fatty acids in the diet can have far reaching physiological implications.

The current Western European/USA-type diet is becoming increasingly deficient in LC-PUFA of the n-3 class. This is a result of the decline in the consumption of food types rich in these fatty acids. Good sources include oily fish and certain animal organs (e.g., liver) that are losing favor with today's consumer. As a result there is an interest in fortifying foodstuffs with n-3 fatty acids and various attempts have been made to this end either by direct addition to foodstuffs (such as bread) or by feeding farm animals on a diet rich in n-3 fatty acids in the form of LC-PUFA themselves (fish oil) or as α-linolenic acid (flaxseed oil). Neither of these approaches is completely satisfactory, however. The inclusion of fish oil in animal diets or in food products directly can impart a distinct fishy taste that is generally not well received by consumers and has been noted to cause farm animals to go off their feed (21). Flaxseed oil is not associated necessarily with off-flavors and, although it increases the n-3 fatty acid content of the food, it does not boost the n-3 LC-PUFA levels which is the desired outcome. Although animals, including man, can synthesize

n-3 LC-PUFA from α-linolenic acid, the rate at which this occurs is generally slow (20) and several factors, including age, and hormonal balance, can decrease these conversions further still. Therefore additional supplementation of these key fatty acids is frequently thought to be desirable.

17.3.2.2 Processes for the Production of Various PUFAs

Of particular importance are: γ-linolenic acid [GLA, octadecatrienoic acid, 18:3 (6,9,12), or abbreviated to 18:3(n-6)], arachidonic acid [ARA, eicosatetraenoic acid, 20:4 (5,8,11,14), 20:4(n-6)], eicosapentaenoic acid [EPA, 20:5 (5,8,11,14,17), 20:5(n-3)], and docosahexaenoic acid [DHA, 22:6 (4,7,10,13,16,19), 22:6(n-3)]. Of these four PUFAs, only GLA can be obtained from plant sources (Table 17.5); all the others must either be obtained from animal sources or by using SCO technology. When animal sources are used for PUFA production, the source material is often in short supply or extensive purification is needed as with the production of purified EPA and DHA starting with fish oils that contain a mixture of these PUFAs. Consequently, the overall costs to production are very high thereby making the microbial route to their production an attractive and economic alternative.

17.3.2.2.1 γ-Linolenic Acid-rich SCO The first commercial microbial oil was produced in 1985 and was rich in γ-linolenic acid [GLA, 18:3(n-6)]. The oil was aimed at being an alternative source of the oil from seeds of the evening primrose (*Oenothera biennis*). Evening primrose oil was, at that time, considered to be useful in the treatment of multiple sclerosis though these claims have since been discounted. The oil was also useful for the treatment of a number of other disorders and today is still sold as an over-the-counter nutraceutical for the relief of premenstrual tension. It is also thought to be useful for the treatment of eczema, especially in children. A considerable amount of clinical and medical interest still exists with this PUFA and further information regarding the current roles of GLA can be found in two recent monographs on the topic (22,23).

Against this background, the search for an alternative source to evening primrose oil began in one of the present authors' (CR) laboratory in the late 1970s by examining fungi belonging to the class known as the *Mucorales*. Prior work (24,25) had indicated that GLA occurred in most, if not all, species in this group and, after a search of more than 300 species and strains, one organism was identified as being the most productive. This was *Mucor circinelloides*, also known as *Mucor javanicus*. Initial toxicity trials of the oil showed that it was without any detrimental effect on a variety of cells and whole animals. Furthermore, as the fungus itself has a long association with the fermented food known as tempeh, clearance for the use of the oil, coming from what was a Generally Recognized As Safe (GRAS) organism, quickly followed. Sales of the oil began in 1985 and lasted until 1990. It was sold under the trade name of Oil of Javanicus and a small market for it was quickly established. Approximately 5 to 8 tons a year of the oil was produced using fermentors up to 220 m^3. The company producing the oil was J. & E. Sturge Ltd at Selby, North Yorkshire, UK. This company normally produced citric acid by fermentation technology and, for the production of the GLA-SCO, one of the existing fermentation vessels was employed without modification although the medium being used was one with a high C:N ratio in order to engender lipid accumulation (Figure 17.1). The production process is shown in broad outline in Figure 17.3.

The specifications of the oil were superior to those of evening primrose oil in almost every respect (Table 17.6). With 18–20% GLA, the SCO had more than double the content of GLA of evening primrose oil, it has less residual herbicide and pesticide materials (though the amounts found in evening primrose oil were much less than the maximum permitted levels) and had exceptional long term stability due to the presence of natural

antioxidants that were coextracted with the oil from the fungal cells. The fermentation process could, moreover, guarantee an unchanging specification of the oil which could be available at any time of the year. However, and perhaps not too surprising, the oil was difficult to market as there was an obvious reluctance on behalf of the public to purchase what was a microbial oil. Marketing strategies therefore very carefully avoided using words such as "fungus", "mold", or even "microorganism," though "biotechnology" was considered to be acceptable.

The arrival of this "new" oil in the market place had an immediate effect in decreasing the price of evening primrose and thus the initial, apparent profitability of the biotechnology process was therefore not fully realized. Further, another plant source of GLA had been developed during the second half of the 1980s which was borage (*Borago officinalis*). This oil, which was sold under the name of starflower oil, had an even higher content of GLA than Oil of Javanicus (Table 17.6) and could be produced for less than the cost of evening primrose oil as this plant was an annual crop and not a biennial crop like evening primrose. It was thus an immediate and strong competitor to the GLA-SCO.

Of telling significance in the final economics of oil production was the status of the various oils in the eyes of the European Union Agricultural Committee. Both evening primrose and borage were regarded as non-food crops and, as such, then enjoyed financial subsidies from the EU for their cultivation. (Round 1 to the plants.) Next, the fermentation process had to buy the sugar being used in the production of the GLA-SCO at European prices and not at World price, which was about half the EU price because of trade tariffs being imposed. With approximately 10 tons of sugar being needed to produce one ton of oil, this was Round 2 to the plants and, indeed, it was "game, set, and match." Production of Oil of Javanicus ceased in 1990 as it could no longer compete against borage oil.

Another process for the production of GLA using fermentation technology was developed in the late 1980s by Idemitzu Ltd in Japan. While the process in the UK had used a species of *Mucor* that contained 18–20% of its total fatty acids as GLA, the Japanese process, which used *Mortierella isabellina* another member of the Mucorales group, settled for a species that had only about 8% GLA in its oil (Table 17.6). However, the oil content of the Japanese organism was about 50% of the biomass whereas that of the UK organism was only 25%. Thus although more oil was obtained in the Japanese process, the GLA content was not sufficiently high to compete against the two major plant sources. Sales of the Japanese oil did not achieve a significant part of the market and the oil no longer appears to be available. Some details of the process have appeared (26) but information as to the size of the production system and the amounts produced has not been disclosed.

Although no longer in production, Oil of Javanicus still represents one of the best sources of oil from which to purify GLA itself, if such a pure fatty acid should ever be needed. The very low content of linoleic acid (18:2) in the oil (Table 17.6) means that fractionation of the fatty acids, using a technique such as urea adduct formation, would be relatively simple in comparison with trying to purify it from either evening primrose or borage oils which have much higher contents of 18:2. However, at the time of writing, no such demand for a high purity GLA has been expressed and thus the fermentation process must now languish until some favorable economic circumstances arise that would justify its resurrection.

17.3.2.2.2 Arachidonic Acid (ARA) rich SCO The prospect of producing an oil rich in ARA from a microbial source was first investigated in the mid 1960s. Initial interest was due to a misapprehension that this fatty acid was a potential chicken flavor additive. With this as the driving force, a small research group led by Bob Shaw at Unilever Ltd, UK, initiated a study of ARA production by microbial sources (24,25) thereby identifying a number of potentially useful organisms. Another early, and nondietetic, application for a microbial oil rich in ARA was as a cosmetic additive with the Lion Corp of Japan developing and patenting a process in 1988 for the production of an ARA-rich oil (27).

17.3.2.2.2.1 Microbial Sources of ARA-rich SCO Many different micro-organisms have been examined for their capacity to synthesize ARA, however, only two – both fungi (*Mortierella alpina* and *Pythium* sp) have been seriously considered for commercial production (28). Subsequent development has, though, concentrated solely on *Mt. alpina* as this organism is now widely considered the most productive species (29,30). *Mt. alpina* is the fungus used in all the current commercial ARA-rich SCO processes.

Mortierella alpina is a ubiquitous soil fungus that has been isolated from soils all over the world. There are at least 37 different isolates of *Mt. alpina* that have been deposited in the world's major culture collections (though there maybe some overlap in these collections). All the off-the-shelf strains have been exhaustively examined for their capacity to synthesize arachidonic acid and the most productive strain is reported to be ATCC 32222 (31,32). However the production organisms used commercially are proprietary strains that have been isolated either directly from the environment or via strain selection (30,33). It should be noted that strain selection with *Mt. alpina* is far from straightforward as stimulating sporulation in this fungus, which is a prerequisite to strain improvement, is difficult if not impossible for many strains. One notable exception is the 1S-4 strain, which sporulates freely, and was isolated by Prof. S. Shimizu's group. It is now used commercially by Suntory Corp. in Japan.

17.3.2.2.2.2 Commercial Production of ARA-Rich SCO There are currently at least three commercial processes operating to produce ARA-rich SCOs. Two are operating in the Far East. In Japan, Suntory Corp., one of the pioneers of ARA-rich SCO technology continues to produce ARA-rich SCO using technology developed by the group of Prof. S. Shimizu. The process employed by Suntory is relatively well documented and basically follows the steps outlined in Figure 17.3. In China, Wuhan Alking Bioengineering Co. Ltd. (Wuhan City) have been producing ARA-rich SCO since 2001 using a process that is far less well reported. Both of these processes, while operated on a commercial basis providing ARA-rich SCO for infant formula supplementation and as health supplements, do not constitute a major global source of ARA-rich SCO. That honor goes to the ARA-rich SCO produced by DSM Co. (formerly Gist-brocades) in Italy under contract for Martek Biosciences Corp. Their process is responsible for >95% of the current ARA-rich SCO produced and will be even more important when a second plant (in Belvidere, NJ, USA) comes on-line to meet the current demand for ARA-rich SCO which cannot be met by the Italian plant alone.

This ARA-rich oil (sold under the trade name ARASCO™ as part of the infant formula additive Formulaid™) is produced using *Mortierella alpina* (Table 17.7) in a process that shares many features with the process operated by Suntory. However, the strains used in the two competing processes differ and, so inevitably, do the details of the processes, which are optimized for the specific production strain employed. Both though approximate to the production outline given in Figure 17.3.

A cryovial of a certified stock of the production organism (a proprietary strain) is thawed and cultivated in shake flasks, the medium used is relatively simple containing simple salts, glucose and yeast extract. After the cells have grown to a designated density, cultures are used to inoculate a set of increasingly large fermentation vessels so as to maintain an inoculum volume of approximately 5–10% (v/v). The final vessels are in the region of 50 to 100 m^3 and are nitrogen fed, as the amount of total nitrogen needed to support the final cell density cannot be added into the initial medium without suppressing the mass transfer capacity of the fermentation vessels and creating problems maintaining the dissolved O_2 concentration above a critical value (PUFA biosynthesis being an aerobic process). The nitrogen feeding regimes allow very high biomass concentrations to be achieved. Cell densities in excess of 50 g/l have been reported (34) and it must be assumed that the commercial process exceeds this value. Very high cell densities are, of course, required for all SCO processes as the product is intracellular. As a consequence, the fermentation has to support these high cell densities and maintain sufficiently high oxygen transfer rates within the tank to support not only growth but also the O_2-dependent desaturase enzymes that are required for PUFA biosynthesis.

A key factor in obtaining very high cell densities, while not exceeding the O_2 transfer capacity of the fermentation vessel, is culture morphology. As a filamentous fungus, *Mt. alpina* is capable of growth as either dispersed hyphae yielding a culture that resembles porridge (oatmeal) or as discrete pellets (of varying sizes). The morphology observed is interdependent on a number of factors including strain, nitrogen source, dissolved O_2, and metal ion concentrations (34,35). While dispersed hyphae are most productive at low cell densities, due to the ease of O_2 transfer to the hyphae, at high cell densities the viscosity of the medium becomes problematic (in terms of mass transfer and physical mixing of the broth). As a result, dispersed biomass is not suitable for commercial production. In contrast, pellet formation can be suboptimal for ARA production as the interior of the pellet can rapidly become nutrient and O_2-limited. The optimum biomass morphology is a compromise between different factors and appears to be very small pellets. Small pellets minimize the problems associated with nutrient transfer across the pellet radius whilst having the benefit of reducing culture viscosity to promote high final cell densities.

Once the cell density has reached a suitable level (and the cell lipid is of adequate quantity and quality – the total fatty acids contain in excess of 42% ARA) the biomass is removed from the fermentation vessel and harvested. The harvesting involves dewatering the biomass, using either a continuous centrifuge and a screw press, or a filter press, and then drying the biomass prior to extraction of the cell oil. Drying of the biomass is a critical step as drying must be achieved rapidly to avoid spoilage of the cell lipid (either due to contamination of the wet cake with other microorganisms or breakdown of the oil, *via* β-oxidation by the fungus itself). However, heating the biomass to a substantial degree (see also Section 7.2) also compromises the quality of the oil obtained due to oxidation of the highly unsaturated lipid.

Early attempts to remove oil from the fungal biomass (and those still used by Suntory) involved a disruption step designed to release the cell lipid and make it more accessible to hexane extraction (36). Although disruption increased extraction efficiency, the downside was the retention in the extracted oil of colloidal particulate

matter which complicated the downstream treatment of the oil. A more recent adaptation has been an extrusion process that yields pelletized biomass (37) that allows relatively efficient oil extraction without the need for extensive cell disruption and the problems associated with this. The biomass pelletization process also contributes significantly to oil stability.

Another process that can greatly increase the quality of the crude oil obtained is pasteurization of the culture broth at the termination of the fermentation (see Section 17.2). Pasteurization has two benefits, it decreases the risk of a fast growing microbial contaminate (bacteria or yeast) becoming established in the culture broth during harvest and it also ensures that the *Mt. alpina* biomass is non-viable and that all enzymatic activity has ceased (37). Non-viable *Mt. alpina* biomass is advantageous as it minimizes the risk of triacylglycerol hydrolysis by endogenous enzymes during the harvest period (21,37).

The extracted oil is refined, bleached, and deodorized using methods developed for vegetable oils, resulting in translucent yellow oil with a distinctive but not strong flavor (the authors' personal experience). Despite the high level of unsaturation the oil is remarkably resilient to oxidation suggesting the presence in the extracted and processed oil of naturally occurring antioxidants.

17.3.2.2.2.3 DHA-rich SCO Once the beneficial properties of DHA, in terms of neonate neural and visual development, were realized a clean fermentable source of DHA was an obvious target for biotechnologists. Although fish oils were commonly available containing significant quantities of DHA, these oils had certain disadvantages that made their inclusion in infant formula unadvisable. Most significant of these was the occurrence in fish oils of another n-3 LC-PUFA, eicosapentaenoic acid [EPA, 20:5(n-3)]. Although this LC-PUFA has certain potentially attractive therapeutic properties (see below) it is contra-indicated for infant nutrition as it is associated with growth retardation (38). As a result of this (and due to many fish oils now containing low levels of environmental pollutants) the inclusion of fish oil in infant formula is not considered advisable and has not obtained GRAS status from the Food and Drug Agency (FDA) of the USA for this application, thereby barring its inclusion in infant milk formulae in the USA.

A number of marine microorganisms that produce DHA are known (Table 17.3) but these were considered little more than of academic interest as they were hard to cultivate to the high densities with substantial lipid reserves (39–41) as would be required for commercial SCO production. Two competing American companies, OmegaTech (Boulder, CO), and Martek Biosciences (Columbia, MD), which became a single company in 2002 when Martek acquired OmegaTech, did, however, develop high density cultivation systems for some of these marine microbes and these cultivation systems are the basis for the current DHA-rich SCOs (see Table 17.7).

17.3.2.2.2.4 DHA Production Organisms As mentioned, a number of marine microorganisms are known to produce DHA (substantial DHA biosynthesis is strongly associated with marine environments for reasons yet to be fully explained). These organisms include both microalgae and, surprisingly, bacteria (Table 17.5). Bacteria for a long while were considered unable to synthesize PUFA (42) but this property is now found in many marine bacteria and in bacteria isolated from intestines of fish. (Indeed, many people would consider that the LC-PUFAs of fish are derived either from these intestinal bacteria or are derived from ingested algae and are not synthesized by the fish themselves.)

Two heterotrophic microalgae, a dinoflagellate (*Crypthecodinium cohnii*), and a stramenopile (*Schizochytrium* – formerly classified as a "fungoid protist") have been selected as production organisms for commercial DHA production. Both of these organisms produce the majority of their LC-PUFA as DHA (Table 17.7). In *C. cohnii*, DHA (up to 50% of total fatty acids) corresponds to >95% of all PUFA with only 28:8(n-3) being

detectable at >1% of total fatty acids (43). The fatty acid profile of *Schizochytrium* is also relatively simple [one of the criteria on which this strain was selected, see (21)] but does contain detectable amounts of other PUFA belonging to both the n-3 and n-6 pathways. Of most significance was the presence of the n-6 PUFA, docosapentaenoic acid [DPA n-6, 22:5(n-6)], at approximately one third the level of DHA (43). As the appearance of this fatty acid in humans was associated with a deficiency of DHA (and of n-3 PUFA in general), it was thought that this was a fatty acid that should be avoided in infant formula. Although the evidence to support this assumption was far from unequivocal, this doubt was sufficient to preclude the DHA-rich SCO from *Schizochytrium* from being considered for inclusion in infant formula. As a result, while the *C. cohnii* oil was developed as an infant formula additive, the *Schizochytrium* oil was developed as a general food additive and as an animal food ingredient aimed at increasing the amount of DHA in the human diet in the form of meat and eggs (21). Since April 2002, Martek and OmegaTech have been a single company (the former acquiring the latter) and both DHA-rich oils remain under development.

A third production organism is now being employed by Nutinova, a subsidiary of Celanese, in Germany to produce other DHA-rich SCO. This oil has a fatty acid composition similar to the *Schizochytrium* oil (see Table 17.7) although the phylogeny of the production organism is the subject of some conjecture and debate. The commercial significance of this oil is likewise unclear though the indications are that the product will be launched in 2004 under the trade name of DHActive. A similar oil is also thought to be near commercialisation in Japan by Nakase-Suntory.

17.3.2.2.2.5 Commercial Production of DHA-rich SCO Although many microalgae that produce DHA are photosynthetic (Table 17.3) the species selected for industrial development are heterotrophic. This is a key attribute as it allows cultivation in large fermentation tanks (up to 200 m^3) at high cell density. A photosynthetic production system would be hindered by the requirement for cellular access to light which severely limits cell densities and causes such processes to be many times more expensive to operate than heterotrophic systems. A recent economic analysis calculated that photosynthetic cultivation of microalgae for LC-PUFA production was at least an order of magnitude too expensive to compete with highly purified fish oils (45).

Both the *C. cohnii* and *Schizochytrium* processes operate in a similar fashion (as shown in general outline in Figure 17.3). In both cases, a cryopreserved stock of the production organism, a proprietary strain obtained by classical strain selection to have a range of desirable attributes, is thawed and cultivated in shake-flask culture. As with the ARASCO™ protocol, the culture is scaled through a seed train to maintain a suitable inoculum volume of about 5–10% for each step in the scale up process. The culture medium throughout the seed train is kept constant so as to avoid stressing the culture and slowing culture growth. The culture media used have been extensively modified and bear very little resemblance to the high chloride-containing seawater-based media that appear in the literature and are used in academic studies (39,46). One reason for this is the corrosive nature of the high chloride concentrations in sea water.

The marine ancestry of the DHA-producing microalgae was a problem for large scale production as these organisms would only grow in high salt (NaCl) conditions. High Cl^- concentrations, while not a problem in glass shake-flasks or even laboratory scale glass fermentation vessels, is a major concern in production scale stainless steel fermentors. Seawater contains 18–19000 ppm Cl^- whereas standard stainless steel (type 304) can withstand high Cl^- concentrations for a short while it is corroded at relatively low Cl^- concentrations if exposure is prolonged. A more resistant, and expensive, stainless steel (type 316) is often used for industrial fermentation tanks but this can only

withstand Cl^- concentrations up to 1000 ppm. To avoid problems with corrosion of fermentation tanks and downstream equipment, strains capable of growth in low saline conditions have been selected (21) and media formulations have been developed with other ions replacing Cl^- (and containing a Cl^- concentration of >250 ppm) that sustain growth of these organisms (47).

Although previously thought to be difficult to grow at high density, a combination of strain selection and media optimization means that these production organisms can now be cultivated at densities in excess of 100 g/l (44,46). These cultures also are high in oil (>20% w/w dry wt) and rich in DHA (>25% total fatty acids). Once optimal biomass and oil yields have been obtained, the biomass is harvested by continuous centrifugation and the cake spray dried to yield a powder that, after disruption, can relatively efficiently be extracted with hexane (Figure 17.3). As with ARA-SCO, the crude oil is then processed by refining, bleaching and de-odorizing in a process similar to that used by the vegetable oil industry. Although the resultant translucent orange oil is stable (the color is a result of β-carotene content that probably contributes to the oil stability), vitamin E is added to further increase the stability of the oil to a level where it is stable at room temperature for a minimum of 12 months. Again, as one of us (JPW) can attest through personal experience, the DHA-rich SCO (both DHASCO™ from *C. cohnii,* and the *Shizochytrium*-derived DHA-rich SCO) are remarkably palatable oils that lack the fishy taste associated with purified fish oil unless they are very badly abused.

17.4 SAFETY OF SINGLE CELL OILS

The arrival of SCO on the food scene is a relatively recent event – the first commercial SCO (Oil of Javanicus) not being produced commercially until 1985 (see Section 17.3.2.2.1) – well after regulations and regulatory bodies relating to food safety were in place. Therefore the safety of these food products had to be determined and proven to the regulatory authorities and the general public. The safety of Oil of Javanicus was relatively easy to confirm as both the producing organism (*Mucor circinelloides*) and the active ingredient (γ-linolenic acid) have long been part of the human diet and were therefore deemed safe by historical association with food products.

γ-Linolenic acid was the PUFA responsible for the therapeutic activity of evening primrose oil, the high value plant oil that Oil of Javanicus was developed to compete against. Evening primrose oil has been taken for centuries as a folk remedy for a number of ailments, the most well documented of which is premenstrual syndrome. Indeed, its reputed efficacy against general illnesses was such that it was also known as "King's Cure All."

The filamentous fungus *Mucor circinelloides* (the production organism for Oil of Javanicus) has a long documented association with human foods, being the organism used in the fermentative production of the oriental food tempeh. This historical connection and evidence of long term (hundreds if not thousands of years) human consumption without reported adverse effects was instrumental in proving the safety of Oil of Javanicus, and was one of the major factors (other than γ-linolenic acid productivity) involved in selection of *Mucor circinelloides* as the production organism of choice. Having a whole organism that was historically demonstrated non-toxogenic made it fairly easy to argue that a cellular constituent of that organism (the oil) would also be safe for human consumption. Likewise, as the methods used to extract and process the oil from *Mucor circinelloides* were essentially identical to those used to prepare vegetable oils for human consumption (14), it was evident that the processing of the fungal biomass to release the oil would not introduce any deleterious qualities to the final product.

Unlike Oil of Javanicus, the safety of ARA-rich SCO from Mt alpina could not be inferred by the association of the producing organism with any traditional foodstuff. Furthermore, there were even reports suggesting the potential harmful effects of an increase in the dietary intake of arachidonic acid (48). As a result extensive safety data had to be generated before ARASCO™ could be considered safe for human consumption, especially as its primary application is as an ingredient in baby formula. As a result ARA-rich SCO, along with DHASCO™, are probably the most extensively safety tested edible oils currently on the market. The safety of ARASCO™ has been reported by numerous authors who have assessed this oil from a number of different perspectives. The safety of ARASCO™ (the ARA-rich SCO produced by Martek Biosciences Corp) was even the topic of an entire symposium at the AOCS meeting in Indianapolis in 1996 (49).

For some years the inclusion of high levels of ARA in the human diet was considered undesirable, due to potential adverse effects on blood clotting (48). However the apparent lack of toxicity in animal models prompted a major study at the Western Human Nutrition Research Center, San Francisco, USA, of the effect of dietary supplementation with ARASCO™. During an intensive and prolonged study (in which human volunteers lived in a "metabolic ward" to decrease the effect of external influences) the inclusion of 1.5 g ARA/day (3 g ARASCO™/day) did not cause any significant adverse effects on any of the test individuals. Factors examined included blood coagulation, immune response, and the production of arachidonic acid derived signal molecules. The conclusion of the study was that the inclusion of 3 g/day ARASCO™ did not have any toxic effects on adult humans and that this oil should be considered safe as a human food ingredient (50–53).

Further studies have been undertaken in Europe to determine the safety of ARASCO™ as a nutritional supplement specifically in relation to its intended use in infant formula. A review of the literature was carried out to determine if the production organism (*Mort. alpina*) was, or had ever been, associated with human disease (33). This study concluded that this fungus had never been unequivocally linked to human disease (due largely to the fact it is unable to grow at human body temperature) and that there were no reports of mycotoxin production. As *Mt. alpina* is a ubiquitous soil fungus and therefore in common contact with humans it was argued that it was clearly a completely benign organism and should be considered safe for the production of human food material.

Animal studies employing rats as a mammalian model system have failed to demonstrate acute toxicity of ARASCO™ at levels up to 20 ml/kg body weight, (corresponding to a 75 kg human taking 1.5 l of ARASCO™ in a single dose). The only negative finding was that test animals experienced diarrhea the day following administration! Likewise, subchronic studies using a range of ARASCO™ doses in the rat model found that while >2 g/kg body weight/day caused some physiological changes in terms of blood lipid composition and organ weights. These changes are associated with high-lipid diets in general and are not specific to ARASCO™ consumption in particular. No obvious pathological changes were seen (i.e., none of the animals became ill). Furthermore, reproductive function was unaffected and the pups from the ARASCO™-fed group did not demonstrate any ill effects (54,55).

This detailed examination of ARASCO™, in terms of the producing organism and the SCO derived from it, demonstrated unequivocally that this SCO presents no greater danger to infant and human health than any other typical vegetable oil. It should also be pointed out that most of today's commodity and speciality plant oils have never undergone the extensive scrutiny to which SCOs have been subjected. We assume that such esoteric oils as walnut oil, macadamia oil, and sesame seed oil are intrinsically safe, as

indeed they probably are; but these have never gone through the extensive examination that SCO have had to.

The DHA-rich SCO from *C. cohnii*, like Oil of Javanicus, does not contain a LC-PUFA with questionable toxicological effects. Diets very rich in DHA are documented for several human populations – this DHA is invariably derived from ingestion of sea fish and sea mammals and has never been associated with any adverse effects. Indeed it was the supposed health benefits of the diets enjoyed by populations of Iceland and Japan (who have a very low incidence of cardiovascular disease, despite a high fat diet, and a low incidence of premature infant deliveries) that first highlighted the potential therapeutic effects of DHA. Ironically, the high intake of sea fish is now being suggested to represent a health risk to these same populations due to the presence in fish meat and especially oil of pollutants released into the marine environment by man (56,57).

As a result of the accepted inherent safety of an oil rich in DHA, the safety issues related to DHA-rich SCO were restricted to a demonstration of the safety of the microbially derived oil. In many studies, fish oils have been used as a negative control (i.e., "safe" oil) with which to compare DHA-rich SCO. The safety of DHASCO™, the DHA-rich SCO that is used on a commercial scale as a infant formula additive as part of the DHASCO™/ARASCO™ blend, has been comprehensively studied both by the manufacturer (Martek Biosciences Corp.), and by formulae manufacturers. These studies have looked at the possible *in vitro* effects of DHASCO™ to test for mutagenic and clastogenic (chromosome damaging) effects, animal studies and human feeding studies (Tables 17.8, 17.9). Animal studies using rats as a model system have checked acute toxicity at doses up to the maximum dose physically possible to administer (~20 g/kg body wt). Additionally, sub-acute studies, where DHASCO™ was fed at several times the anticipated human doses for prolonged periods (up to 90 days), have also studied the effect of DHA supplementation of female animals prior to and during pregnancy as well as to the offspring. None of these studies found any indication of toxicological problems and the LD_{50} for DHASCO™ (if one exists) was found to exceed the maximum possible dose.

Table 17.8
In Vitro and Animal (*in Vivo*) Studies on the Safety of DHASCO™ Produced by Martek Biosciences Corporation

Study	Max DHASCO™ Dose	Model System Employed	Conclusion	Ref.
Ames mutagenicity test	5 mg/plate	Salmonella typhimurium	Not mutagenic	58
Forward mutation test	5 mg/plate	Mouse lymphoma cells	Not mutagenic	58
Chromosomal aberration test	5 mg/plate	Chinese hamster ovary cells	Not clastogenic	58
Acute toxicity	20 g/kg body wt	rat	No deaths	59
Subchronic toxicity				
28 day	1.25 g/kg body wt/day	rat	Not toxic	59,62
90 day	1.25 g/kg body wt/day	rat	Not toxic	60
90 day, *in utero* exposure	3 g/kg body wt/day	rat	Not toxic	61,62
Developmental toxicity test	1.25 g/kg body wt/day	rat	Not toxic	58

Table 17.9
Human Safety Studies on the Safety of DHASCO™ Produced by Martek Biosciences Corporation

Dose (g/day)	Duration (weeks)	No. of Subjects per Group (Experimental and Control)	Conclusion	Ref.
4	15	14	No effect on platelet aggregation/homeostatic factors	63
4.5	6	12 vegetarians	No effect on thrombogenic factors	64
15	13	6	No change in blood clotting or immune paramters	65,66
1.5 – 7.3	2	8	No significant adverse effects	67
0.75 – 1.5	4	12–15	No serious adverse effects	68

Human studies (Table 17.9) comparing DHASCO™ alongside equivalent doses of DHA from fish oil or meat likewise have failed to detect any adverse effect associated with ingestion of DHASCO™; the most serious reported adverse effect being "fishy burps."

The safety assessments carried out on DHA-rich SCO from *Schizochytrium,* ingested either as extracted oil or as intact microbial biomass, have been similarly rigorous to those carried out on DHASCO™, i.e., from *C. cohnii* (69–73). Likewise these studies have observed a lack of toxicity at the genetic level when administered at either single high (acute) or prolonged lower (sub-acute) doses.

The extensive safety evaluation of both DHA-rich SCO and ARA-rich SCO was a necessary prerequisite to the release of these "novel" foods on to the open market, particularly as their major application was infant nutrition. However, as the intrinsic safety of microbe-derived oils has now been demonstrated, it seems likely that the next generation of SCOs will not have to undergo the same high level of toxicological testing. As microbial oils have been shown to be no more toxic than oils from traditional sources it should be sufficient in the future to demonstrate the lack of pathogenicity and toxigenicity of the producing organism. This should decrease the development costs of future products significantly.

One of the first beneficiaries of being a second generation SCO looks to be the DHAactive™ product developed by Celanase/Nutrinova. The safety of their product has been evaluated to a large degree by confirming its equivalence to previously available microalgal oils (i.e., DHASCO™ and DHAGold™) (74).

Whilst discussing the safety of SCO it is worthwhile noting that the safety of traditional high PUFA oils should not be tacitly accepted – although it often is. Fish oils (a major source of EPA and DHA-rich oil) have potential hazards themselves, these include the potential for contamination with environmental pollutants (dioxins, heavy metals), which have to be carefully removed by manufacturers prior to sale. Furthermore, fish oils can be very rich in the oil-soluble vitamins A and D (21) which, although beneficial in low doses, can lead to liver and kidney problems with excessive or prolonged exposure. Finally, while any possible microbial contamination of the biomass used for SCO production is closely monitored (sterility checks are made daily in production fermentors and any contaminated batches are discarded), no such monitoring (as far as the authors are aware) occurs with the fish bodies and livers that are extracted for fish oils. As fish livers have undoubtedly been handled and exposed to the atmosphere for a considerable time between harvesting of the fish and oil extraction, the microbial contamination of this material can only be guessed at!

17.5 COMMERCIAL SIGNIFICANCE OF SCOS

Although the first SCO appeared on the market in 1985 it was not until the twenty-first century that SCO have really become a successful commercial commodity. This commercial success has been based on the inclusion of a mix of ARA-rich SCO (ARASCO™), and DHA-rich SCO (DHASCO™) in infant formulae in many countries in Europe, Australasia, and the Far East. However, the market was somewhat limited due to the inclusion of the DHA/ARA-SCO blend in only formula designed for premature babies, and to the initial refusal of the FDA to allow inclusion of the DHA/ARA-SCO in infant formulae in the U.S. The breakthrough came in May 2001 when the FDA finally gave GRAS status to the DHA/ARA-SCO for its inclusion in infant formulae in the USA. Since February 2002 when the first formulae containing SCO were available in the US market, the SCO-fortified formulae have captured over 50% of US formulae sales. As a result of this success, >95% of all SCO production globally is destined for formula use; the size of the market is now limited by the supply, rather than demand, of both DHA-rich, and ARA-rich SCOs. Martek Biosciences acquired a new fermentation plant in October 2003 in an attempt to keep up with demand and DSM, the producers of ARASCO for Martek, have also exceeded the capacity of their first production plant and have recently commissioned a new plant in Belvidere (NJ, USA).

It is calculated that the production of SCO in 2003 will exceed 500 tonnes (Figure 17.5), equalling or even exceeding the total SCO produced cumulatively between 1985 and 2002 (75). Production and consumption of ARA-rich SCO, and DHA-rich SCO should continue to expand for at least the next five years based solely on the increased use of these products in infant formula. It should be noted that although the current use of SCO is rapidly expanding, this expansion represents, to a very large degree, the success of a single product, a DHA/ARA-SCO blend (Formulaid™) for one specific application (infant formula). If SCO production is to continue to grow beyond the next 5 to10 years, then new products and new markets must be developed to sustain this growth.

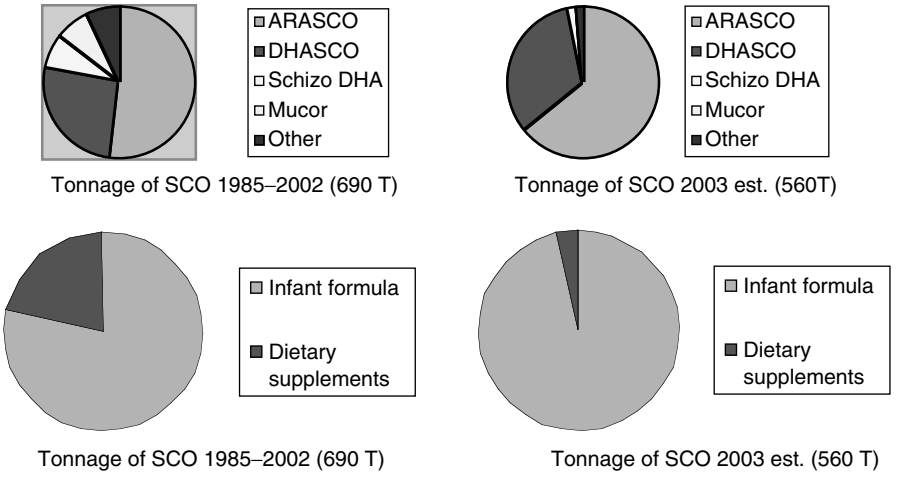

Figure 17.5 Production and usages of Single Cell Oils (SCO), 1985–2003. Top diagrams (left and right): production tonnages of the various SCOs; bottom diagrams (left and right): proportion of SCOs used for infant formulae and as dietary supplements (75).

Potential Uses of Cyanobacterial Polysaccharides in the Food Industry

Xue-Jun Liu and Feng Chen

CONTENTS

18.1 INTRODUCTION

In the past two decades, algal biotechnology has successfully employed advanced techniques matching economic development in the exploitation of novel biochemicals in algae. Humankind has benefited from the progress of algal biotechnology in alleviating the problems resulting from a phenomenal increase in world population and the concurrent scarcity of food resources to meet surging demands. This is witnessed in the application of microalgae (including cyanobacteria) and algae-like organisms in myriad areas of agriculture, aquaculture, environmental management, and pharmaceutical and food industries. The use of algal biotechnology for the production of a number of valuable biochemicals has become a firm reality, including the commercial production of β-carotene from the halophilous green algae *Dunaliella*, biomass as health food from *Spirulina* (*Arthrospira*), polyunsaturated fatty acids (PUFAs) from certain flagellates and diatoms,

phycobiliproteins from certain red algae and cyanobacteria, and astaxanthin from *Haemotococcus* (1,2).

The tendency of market demand to switch from synthetic to natural production has been recognized as the driving force for this vigorously developing biotechnology area (3). Some mature technologies have been applied directly to industry, while the others (e.g., recombinant DNA techniques, modern separation techniques) have been blended with conventional biotechnology, resulting in the birth of new research areas, new processes, and new products. Among them, the production of polysaccharides from the microalgae cyanobacteria is of significant importance, as reflected by the steadily increasing number of scientific publications concerning current research and progress pertinent to their huge potentials in various food and biotechnological industries (Table 18.1).

Polysaccharides are extensively used as gelling agents, stabilizers, thickeners, and emulsifiers, mainly in food products as well as in paints, photographic films, and pharmaceuticals, and in tertiary oil recovery (3–5). Traditionally, seaweeds, especially the red macroalgae, are the main sources of algal polysaccharides. However, seaweeds are usually harvested from their natural habitats (3), and production of seaweeds is extremely susceptible to seasonality and improper harvesting, which lead to inconsistent supply. This phenomenon has indicated the need to search for new and constant sources of algal polysaccharides. As a result, cyanobacteria have been widely investigated for the production of polysaccharides due to their high contents of the products and versatility in industry.

This review summarizes current knowledge of cyanobacterial polysaccharides with special emphasis on the properties pertinent to their applications in food, and explores commercial potentials of cyanobacterial polysaccharides in the food industry. Extensive information on the ecological implications and the application in wastewater treatment of cyanobacterial polysaccharides can be found in Guiseley (6), Adhikary (7), and Vilchez et al. (8). Red and brown algae, the main source of polysaccharides and their polysaccharide production potential have been reviewed by Arad (3), and Siddhanta and Murthy (9). The application of algal polysaccharides in medicine has been reported and discussed by Witvrouw and DeClercq (10), and Schaeffer and Krylov (11).

18.2 THE ALGAE CYANOBACTERIA

Cyanobacteria are conventionally called blue-green algae. Cyanobacteria are a diverse group of obligate photoautotrophs (~2,000 known species), as reflected by their widespread occurrence (except for those environments at lower pH), frequent abundance, and morphological diversity. These O_2-producing photosynthesizing prokaryotes are ultrastructurally and biochemically similar to both eubacteria and the chloroplasts of microalgae or higher plants (12,13), and thus possess both bacterial and algal attributes with high flexibility in their metabolisms. Typically, water acts as the electron donor during photosynthesis, leading to the production of oxygen, although several species are able to shift between H_2O and H_2S as electron donors (14). The cells of cyanobacteria contain only unstacked photosynthetic lamellae (thylakoids), where the electron transport reactions of photosynthesis and respiration occur. Cyanobacteria possess the ability to synthesize chlorophyll *a* and certain types of hydrophilic phycobiliproteins, including phycocyanin, phycoerythrin, and allophycocyanin (15). Nucleotide base sequence data of 16S and 5S rRNA have suggested that cyanobacteria are phylogenetically coherent with the Gram-negative eubacteria (16).

Much of the success of cyanobacteria, in view of their ecological and physiological adaptation to their corresponding environments, is undoubtedly a consequence of a number of features widespread in the group, in comparison to their counterparts in other taxa (13). First, cyanobacteria show considerable morphological diversity. They may be unicellular (e.g., *Chroococcus, Microcystis*) or filamentous (normally composed of vegetative cells, e.g., *Anabaena, Nostoc*), and they may form macroscopic or microscopic colonies. Unicells may divide in one, two, or three planes. Filaments may branch or not. Maintenance of their diverse colonial structures is aided by the presence of exopolysaccharides, such as slimes or a firm sheath. During their life cycle, cyanobacteria form highly specialized cells, namely, heterocyst and akinete, which help the organisms in the process of nitrogen fixation and to adapt to stress environments, respectively. Different cell forms (i.e., vegetative cells, proheterocysts, heterocysts, akinetes, germlings) alternate in a regular manner during their life spans. The discrepancy of these characteristics in different taxa provides the basis for morphologically based taxonomy. For instance, the presence or absence of a heterocyst is an important feature separating genera (17). Cyanobacteria exist in a wide range of ecological habitats because of several traits that allow them to survive in marginal environments. These include their tolerance to high temperature, high UV irradiance, desiccation, and free sulfide, as well as their ability to utilize low photon flux density and low levels of inorganic carbon, and to fix molecular nitrogen (18).

Given their diversity in ecophysiology and their obvious importance in a wide variety of ecosystems, cyanobacteria show a metabolic diversity while acclimatizing to the environments. Consequently, from a biotechnological point of view, they are a group of organisms that produce a wide spectrum of fine chemicals, or renewed energy, naturally or artificially. Indeed, cyanobacteria are nature's gift to mankind. First, their oxygenic photosynthesis provides a unique means to utilize cheap substrates (e.g., CO_2, H_2O) and solar energy for the primary production of organic compounds and many biotechnological products. Meanwhile, N_2-fixing cyanobacteria can utilize sunlight as their sole source of energy for the fixation of carbon and nitrogen, and thus make potential biofertilizers. There is renewed interest in the role of biological N_2 fixation by cyanobacteria. Recently cyanobacteria have been utilized as a source of nitrogen fertilizers in some developing countries to reduce the dependency of agriculture on fossil fuel, which, on the other hand, would lead to the reduced emission of CO_2 into the atmosphere (19). Cyanobacteria, like other microalgae, provide O_2 for BOD removal and incorporate nutrients such as nitrogen and

phosphorus into biomass, thereby reducing the eutrophication potential of receiving waters. The immobilized cyanobacteria can also remove heavy metals, nutrients, and toxic organic compounds due to their affinity for these contaminants (13). Cyanobacteria serve as a food source in various parts of the world; in the past, the main focus has been on the production of single cell protein (SCP), although other applications that require mass cultivation are apparent. For instance, the cyanobacterium *Spirulina platensis* is grown commercially and the biomass is used as a health food worldwide. It is also reported that cyanobacteria are a rich source of type II restriction endonucleases, some of which are currently marketed. Other products from cyanobacteria include amino acids and pigments that can be used as food colorants and diagnostic probes (13). It is worth noting that some hydrophilic pigments have been marketed. Phycobiliproteins, especially phycoerythrin, are stable pigments that can be stored for a long period of time, and show high fluorescence which is not quenched by a number of biomolecules, and so could be used as fluorescent probes (20). Other biochemicals may include animal cell growth stimulants, anti-HIV pharmaceuticals, and cyanobacterial toxins (13).

Recently, cyanobacterial polysaccharides have received much attention of bacteriologists, phycologists, and biotechnologists for the purpose of industrial-scaled applications of this fascinating and promising food ingredient. They stand out among fine chemicals not only for multiple functions in their habitats but also for huge commercial potentials.

18.3 POSSIBLE ROLES OF CYANOBACTREIAL POLYSACCHARIDES

In Bergey's classification system, the polysaccharide-producing cyanobacteria belong to all 5 subsections (17). In totality, 33 genera in 5 subsections have demonstrated the ability to release polysaccharides during their life cycles (Table 18.2).

The terminology associated with mucilaginous layers in cyanobacteria is quite dubious and confusing. As pointed out by Bertocchi et al. (21), the structural and functional differences between different sublayers of those mucilaginous layers are very arbitrary, and thus are often not evident in the literature. These structures are defined by Bertocchi et al. (21), further confirmed by De Phillipis and Vincenzini (22), and slightly modified by Adhikary (7). In general, the external envelope layers are divided into three structured or unstructured layers or zones (sheaths, slimes, and capsules), and can be observed under the microscope using Nomarski differential interference contrast photomicrography. The sheath is defined as a thin, electron-dense layer that loosely surrounds cells or cell groups, The layer is usually visible by light microscopy without staining. The capsule generally consists of a thick and slimy layer intimately associated with the cell surface, with sharp outlines, and is structurally coherent to exclude particles. Slime refers to the mucilaginous material dispersed around the organism but not reflecting the shape of the cells (22). The schematic diagram is shown in Figure 18.1.

The functioning of cyanobacterial polysaccharides has been extensively studied for both the ecologically and biotechnologically relevant purposes. The obvious function is to serve as a protective boundary between the cell and its immediate environment (22). For some species of the genus *Nostoc*, these mucilaginous layers equip them to overcome environmental stresses due to desiccation or low water activity in arid or semiarid regions and saline environments. It is known that the secreted glycan provides a repository for water, thereby acting as a buffer between cells and the atmosphere, and representing the key component of the mechanism to tolerate desiccation (23). Likewise, a role as buffer compounds for accumulation and slow release of water has been suggested for polysaccharides

Table 18.2
Polysaccharide-producing cyanobacteria in Bergey's classification system (17)

Subsections (No. of Genus)	No. of Polysaccharide-producing Genera	Genus Names
I (14)	10	*Chamaesiphon, Chroococcus, Cyanobium, Cyanotheca, Gloeobacter, Gloeocapsa, Gloeotheca, Microcystis, Synechococcus* (including former *Anacystis*), *Synechocystis* (including former *Aphanocapsa*)

produced by *Chroococcidiopsis* strains (24). It is suggested that for *Phormidium autumnale*, the release of extracellular polysaccharides enables the algal cells to survive very strong grazing pressure, thus making themselves less preferred foods than other microalgae, which

are devoid of capsules (25). In some species of *Nostoc*, the outermost slimy shrouds that trap trichomes have been suggested to facilitate the homogeneous dispersion of trichomes into the culture broth for improving light utilization and nutrient uptake, which results in the decrease in metabolic energy (26). It is also proposed that cyanobacterial polysaccharides can take a special role in certain important metabolic processes. In *Nostoc cordubensis*, the thick mucilaginous envelope surrounding the heterocysts appears to be essential for the protection of nitrogenase activity from inactivation by oxygen during the process of nitrogen fixation (27). In addition, because of their anionic substituents, cyanobacterial polysaccharides play an important role in handling metal ions when exposed to environments with high concentrations of metallic ions. They help increase the availability of essential metals (e.g., Fe, Mn) by binding to these metals to accumulate and release them slowly to be taken up. For the case of nonessential or toxic heavy metals (e.g., Ag, Pb, Hg), cyanobacterial polysaccharides have a tendency to sequester the metals in order to alleviate toxicity (28,29). For terrestrial or symbiotic species, it is suggested that polysaccharides may act as an adhesive for cyanobacterial cells. For some desert species, microbial crust cohesion is mainly attributed to algal aggregates, which is supposed to be due to the vigorous secretion of polysaccharides to survive wind force, as well as both high relative air humidities and low moisture content (30,31). The release of polysaccharides by the cyanobiont *Anabaena azollae* has been considered essential for the attachment of this cyanobacterium to the earth surface and to the cavities of the host plant *Azolla filiculoides* (32). It has been discovered that the synthesis of extracellular polysaccharides, UV-absorbing compounds, and antioxidants is a unique strategy to counteract UV damage on proteins, DNA, and membranes (33).

From an ecological point of view, polysaccharide-releasing cyanobacteria can tolerate high concentrations of heavy metals by binding them with living cells or dry cells, and consequently mitigating the toxicity of the heavy metals. One recent study shows the nontoxic cyanobacterium *Gloeotheca magna* can be used to remove cadmium and manganese (34).

Increasing attentions have focused upon the application of cyanobacterial monosaccharides and polysaccharides in medical antiviral therapy (10,11). Experiments have proved that the presence of a sulfate group is necessary for multiple antiviral activities (such as anti-HIV and anti-HSV), and the efficacy increases with the degree of sulfation. Studies using both sulfated and nonsulfated homo- and heteropolysaccharides isolated from algae or other sources, or synthesized, have revealed the mechanisms of binding of drugs to the viron, and the mechanisms of viral binding to host cells. Given the few classes of compounds investigated, however, the pharmacology of most compounds from algae and cyanobacteria with antiretroviral activity is still unknown (11).

18.4 CORRELATION BETWEEN CHEMICAL COMPOSITION AND PHYSICAL PROPERTIES OF CYANOBACTERIAL POLYSACCHARIDES

In general, cyanobacterial polysaccharides fall into the category of heteropolysaccharides; they possess repeating units in which several different monosaccharides are present. Ten of 15 different monosaccharides have been found in the polysaccharides of the thermophilic cyanobacterium *Mastigocladus laminosus* (35), which can be further divided into 4 categories according to their chemical structures: (1) the hexoses (glucose, galactose, and mannose); (2) the pentoses (ribose, xylose, and arabinose); (3) the deoxyhexoses (fucose and rhamnose); and (4) the acidic hexoses (glucouronic and galactoronic acids) (22). In a few cases, some monosaccharides with methyl or amino functional groups have been

reported, such as amino sugars (e.g., N-acetyl-gluco- and galactosamine), methylated sugars (e.g., 3-0-methyl-pentose, 3-0-methyl deoxyhexose, 4-0-methyl hexose), and other rare sugars (e.g., 4-0-[1-carboxyethyl] mannose) (35). Glucose is the most frequently found monosaccharide (in more than 90% of cyanobacterial polysaccharides), followed by galactose, mannose, and rhamnose, respectively and xylose is the most common among the pentoses (21). The molar ratio varies from species to species; and at times within the same species if the growth conditions are altered. In most cases, glucose is also the most abundant monosaccharide. Sometimes, arabinose, galactose, or fucose are also reported to be present at higher concentrations than glucose. Ribose has only been found in small number of polymers (~9% of the polysaccharides analyzed). Furthermore, in most cyanobacteria, uronic acids are the important constituents. The presence of acidic sugars in the macromolecules accounts for the anionic nature of almost all the polysaccharides studied so far (4,36). The possibility of simultaneous presence of two acidic monosaccharides is about 50% (22). Quantitatively, the relative contribution of glucouronic acid and galactouronic acid to total acidic sugars differs among species (7,22). Comparison of monosaccharide composition (in terms of molar ratio) between several intensively studied cyanobacterial polysaccharides is shown in Table 18.3.

Polysaccharides in cyanobacteria differ markedly from those of bacterial origin. First, most cyanobacterial polysaccharides are characterized by an anionic nature and many of them contain two different uronic acids, a feature rarely found in the polymers released by strains belonging to other microbial groups (42). Second, most polysaccharides synthesized by cyanobacteria are quite complex, either in the number of the monosaccharides or monomers, or in diversity of linkage types, resulting in even more complex repeating units and a broad range of possible macromolecular structures (42,43). As emphasized by De Philippis and Vincenzini (22), the qualitative and quantitative analyses of the monosaccharides are strongly affected by the conditions employed for hydrolysis of the polymers, and thus the moderate hydrolysis should be applied to the analytical practice of cyanobacterial polysaccharides. The most accessible carbohydrates are uronic acids. Briefly, incomplete hydrolysis due to the glycosidic linkage stabilized by the carboxyl group may result in an underestimate of the contents of constituent sugars, while excessive hydrolysis may lead to degradation or lactonization to some extent (44,45,46).

The presence of sulfate groups has been found in some prokaryotic polysaccharides (4). However, the occurrence of phosphate residues, frequently found in polysaccharides of many other bacterial groups, has never been investigated in cyanobacterial polysaccharides, although phosphate-containing polysaccharides are attracting much interest because of their possible immunological significance (42).

Another important feature that contributes to the physico-chemical properties of the polysaccharides is the presence of a polypeptide moiety or other nonsaccharidic components such as organic substituents (e.g., acetyl, pyruvyl, succinyl groups), or inorganic ones (e.g., sulfate or phosphate groups) (42). However, systematic investigations of the presence of these nonsaccharidic components in cyanobacterial polysaccharides have only been undertaken recently, and as a result, data available are very limited (22). Large amounts of the same amino acids have also been found in polypeptide moiety of the polysaccharide produced by *N. calcicola*, which are found to contribute significantly to the hydrophobicity of the macromolecule (47). On the other hand, the removal of the proteinaceous moiety drastically reduces the viscosity of aqueous solutions and the adhesive capacity of the polysaccharides produced by some microalgae. A significant presence of ester-linked acetyl groups, as well as deoxy-sugars like fucose and rhamnose, may give an appreciable contribution to the emulsifying properties of polysaccharides, owing to a certain lipophilic character introduced by these small molecules in the macromolecules which

otherwise would be highly hydrophilic. However, some polysaccharides containing high levels of rhamnose do not show any particular emulsifying activity. Acetyl groups may hinder cation binding, but may also facilitate gel swelling, as in the case of alginate gel beads, which contribute to the stabilization of the ordered form of the polymers as reported for the xanthan structure (42). The charge on these molecules is conferred either through the presence of uronic acids residues (frequently glucouronic acid or pyruvate), linked as a ketal to a neutral sugar (36). Polysaccharides characterized by high concentrations of charged components (e.g., uronic acids, sulfate or phosphate groups, pyruvate ketals) usually form stable gels in the presence of metallic ions, and are most promising for the removal of toxic metals from polluted waters. However, the mere determination of charged groups is not enough for anticipating the actual metal binding capacity of a polymer, because depending on the conformational structure of the macromolecules, some of the charged groups are hardly accessible for the ions. Indeed, the ion uptake depends on both charge density and charge distribution on the polymers (42). Charged groups also significantly contribute to polysaccharide solubility in water and improve the ability of the macromolecules to bind water molecules. Consequently, the viscosity of their aqueous solutions increases, closely related to the effective volume occupied by the macromolecules (48). On the other hand, the protective role against desiccation suggested for microbial polysaccharides is particularly effective as the presence of acidic components in the macromolecules increases their water retaining capacity (49).

A large number of studies are available on the rheological properties of aqueous solutions of cyanobacterial polysaccharides, most of which consider that the viscosity of polysaccharides would depend on shear rate. All the polysaccharides show pseudoplastic behavior. However, if their viscosity dependence on shear rate is compared with that of xanthan solutions at the same concentration, many differences become evident. The polysaccharide produced by *Synechococcus* BG0011 shows a more marked shear thinning behavior but lower values of viscosity than xanthan gum at the same concentration (50). Polysaccharides of *Spirulina platensis* show pseudoplastic behavior at very low concentrations and are also characterized by a significant decrease of viscosity with increasing ionic strength of the solution (51). A rather wide range of rheological behaviors has been observed in aqueous solutions of the polysaccharides produced by *Cyanotheca* strains or *Cyanospira capsulata* (22). Indeed, flow properties highly differentiate these polymers, some of which show a behavior quite similar to or even better than xanthan gum, while some others show a more marked shear thinning behavior, a property that could be of particular interest for certain special applications (4). Other comparative data between xanthan gum and the polysaccharide from *Cyanospira capsulata*, with regard to the dependence of viscosity on pH, NaCl concentration, and temperature, have been demonstrated (22), suggesting a very promising behavior of these cyanobacterial polymers.

18.5 FACTORS INFLUENCING PRODUCTION OF CYANOBACTERIAL POLYSACCHARIDES

Researches have suggested that each algal strain should be carefully tested in order to envisage the right culture strategies aimed at optimizing polysaccharide production. Because most cyanobacterial strains have only been tested in small culture devices and in studies not oriented to maximizing its production, they attain only moderate levels of polysaccharides except *Cyanospira capsulata* and some *Cyanotheca* strains (52,53). The comparison of the biomass productivity between cyanobacteria and red microalgae in different culture systems are listed in Table 18.4.

Table 18.4
Comparison of productivity between cyanobacteria and red microalgae in different culture modes

Polysaccharide Sources	Flask	Column	Fermentor	Pond	Ref.
Cyanobacteria					
Cyanospira capsulata			116 mg L^{-1} D^{-1}	144 mg L^{-1} D^{-1}	37
Aphanocapsa halophytica MN11	32 mg L^{-1} D^{-1}				38
Nostoc insulare 54.79	47.0 mg L^{-1} D^{-1}		18.4 mg L^{-1} D^{-1}		39
Anabaena flos-aquae A37	36 mg L^{-1} D^{-1} (for 7 D culture), 20 mg L^{-1} D^{-1} (for 12 D culture)	46.4 mg L^{-1} D^{-1}			22
Red microalgae					
Porphiridium sp.				55-75, 133 mg L^{-1} D^{-1}	22
Botryococcus braunii	130-145 mg L^{-1} D^{-1}				40
Bacteria					
Xanthomonas campestris	7–10 g L^{-1} D^{-1}				41

There is seemingly an absence of a common behavior of polysaccharide release among the polysaccharide-producing cyanobacteria described so far. Gantar et al. report that the mucilaginous sheath of *Nostoc* 2S9B is mainly synthesized in the aseriate stage of the developmental cycle and then released as empty shells, at the same instance when homogonia are liberated (60). Some other species, *Cyanothece* sp. BH68K, *N. calciola*, and *Phormidium* sp. J-1, show a significant release of polysaccharides starting from the late exponential growth phase, suggesting that cyanobacteria produce polysaccharides as a typical secondary metabolite (22). On the contrary, the polysaccharides released may be regarded as a primary metabolite evident in the fact that polysaccharide production parallels biomass production (51). This result is consistent with that of Mehta and Vaidya (61), in which the highest rates of polysaccharide synthesis and release are achieved by young cultures in a *Nostoc* strain. The kinetics of polysaccharide release have been considered as a complex dynamic equilibrium among different processes, i.e., trichome elongation and akinete germination (62). It has been concluded that the polysaccharide synthesis is mainly directed toward the formation of the capsule, and as opposed processes, i.e., trichome fragmentation and akinete differentiation, which causes the release of the polymer into the culture medium. There are also reports that the sugar composition varies quantitatively as well as qualitatively with the age of the culture (56).

In cyanobacterial cultures, the production of polysaccharides appears to depend on the C:N ratio. A change in light intensity, temperature, and the concentrations of sulfur, iron, phosphate, and potassium also affect polysaccharide production (22). By means of nutrient starvation, especially under nitrate and sulfate limitations, *Synechococcus* produce a large amount of exopolysaccharides (7). However, the exudation of polysaccharides under special culture conditions is demonstrated only for phycocyanin-rich cultures, suggesting different metabolic pathways for phycocyanin and phycoerythrin-rich *Synechococcus* species. More important, the formation of substituents of the polysaccharides, which may play a crucial role in determining the physicochemical properties of the cyanobacterial polysaccharides, can be manipulated by changing the growth conditions (35,46).

Available studies on enhancing polysaccharide release by means of optimizing the culture conditions mainly focus on the effect of nitrogen limitation or starvation. The response to nitrogen starvation, however, is species-specific in many cases and depends on the nitrogen sources used (63,64). In some nitrogen-fixing species, the production of polysaccharides is reported to be associated with carbon metabolic flux or an impairment of balanced growth both from a nutritional point of view and from physicochemical parameters (35,52). Nicolaus et al. reports that the dramatic decrease in polysaccharide yield occurs when the strain *Phormidium* sp. is grown with a light–dark cycle, in the absence of aeration and phosphorus (65). Likewise, the increase in P and N in the medium, and the absence of combined nitrogen, have a similar effect on the yield, giving rise to a one third decrease with respect to the amount obtained under standard growth conditions. For *Spirulina*, on the other hand, lowering the nitrogen content and nitrogen deprivation causes a strong increase in the total amount of polysaccharides even in the absence of phosphate (65). This finding has been confirmed in polysaccharide analyses of three species of *Nostoc* (59), indicating that combined nitrogen in the media has qualitative influence on the composition of extracellular polysaccharide, but not on intracellular polysaccharides. It is noticeable that the conclusions drawn from different researchers working on different species or strains are often confusing and sometimes even contradictory (65). The ambiguity in polysaccharide production is explained as the differences in physiological roles played by the exocellular polysaccharides in different strains (22). For instance, when the shortage of metallic ions stimulates the enhanced secretion of polysaccharides, the function of the polymer as a chelating agent for cations essential for cell life may be more

pronounced. Likewise, when nitrogen limitation or starvation stimulates polysaccharide release, the polymer may act as a product of overflow metabolism which is exuded to allow cells to get rid of the carbon excesses (66). Another explanation is that nitrogen starvation or limitation causes a decrease in photosynthetic pigments, leading to the decrease in photosynthetic efficiency, and meanwhile, the response of microalgae to nitrogen deficiency is to degrade N-containing compounds inside the cells, giving rise to the decrease in nitrogen content and increase in carbohydrates and fatty acids (35).

Another approach to increasing the amount of polysaccharide release is to supplement the algal culture with intermediate metabolites such as glyoxylate in glycometabolism. This approach has proven promising when applied to *Cyanospira capsulata*, leading to the net enhancement of the final yield of cyanobacterial polysaccharide without affecting the growth rate (52).

18.6 PERSPECTIVES FOR COMMERCIALIZATION OF CYANOBACTERIAL POLYSACCHARIDES IN THE FOOD INDUSTRY

Polysaccharides are derived primarily from the red and brown algae, and higher plants, which have been widely employed in the food industry. These polysaccharides serve as emulsifying agents, gelling agents, thickening agents, and stabilizers (4). Microorganisms are a highly promising renewable source for the production of polysaccharides. Microbial polysaccharides offer greater advantages over the polysaccharides derived from other sources because they are obtained from cultures of selected microbial strains with a high and stable yield in a controllable environment. Some cyanobacterial polysaccharides even possess a superior property to *Xanthomonas* polysaccharides (Figure 18.2). Recent studies have indicated the interesting properties of these polymers, which make them suitable for forming stable gels, fibers, films, and liquid crystals; stabilizing suspensions and emulsions; enhancing viscosity of aqueous solutions; and serving as flocculants. All these features make them particularly suitable for use in the food industry, although they can be used equally well in the other industries (Table 18.5). The assessment of their potential use for various industrial purposes or specific application is quite an arduous task. In order to envisage the possible applications of these polymers, one should refer to some recent reviews on properties and uses of polysaccharides from the other microbial sources (4,5).

One of the most important prerequisites of a polysaccharide, which determines many of the properties generally considered useful for its industrial utilization (i.e., high viscosity of its aqueous solutions, capability of forming gels with good tensile strength, stabilizing emulsion), is that it possesses, together with an adequate composition and structure, a high molecular weight (MW) (69). In this respect, only seven cyanobacterial polysaccharides have been tested, five of which show MWs higher than 1000 kDa. The highest MW values, in the range of 1400–1900 kDa, have been recorded for the polysaccharides produced by C*yanospira capsulata* (46,62).

Physical properties of certain polysaccharides must be seriously considered before putting them into use in the food industry. The important properties of cyanobacterial polysaccharides include high viscosity at a low concentration, high pseudoplasticity (shear thinning), yield value and suspending power, and stable viscosity toward salts, and a wide range of temperature and pH (70). In order to provide a scientific basis for industrial applications, future research should focus on the following: (1) alteration of rheological properties in different aqueous solutions, the change in texture of the products, and the correlations between chemical composition and physical properties, especially the ability

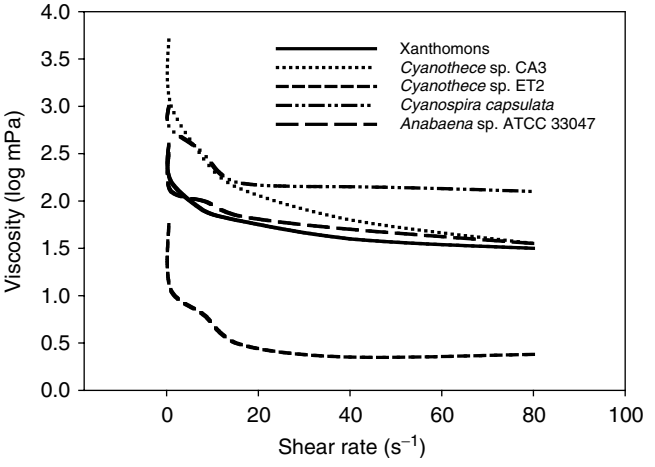

Figure 18.2 Comparison of viscosity dependence of aqueous solutions of polysaccharides produced by *Xanthomonas* and some cyanobacterial species/strains (0.2% w/v ratio for *Anabaena* sp., for other strains, 0.1%). Sources: De Philippis et al. (54,67), Moreno et al. (68).

Table 18.5
Potential applications of cyanobacterial polysaccharides

Applications	Physico-chemical Properties
Thickening agents	Excellent viscosity stability
Dietary fiber	The ability to stabilize suspensions and emulsions
Antiviral drugs	S-containing and thus inhibition of virus infection
An essential ingredient to formulate new functional foods	P-containing and thus improvement of immune systems
Food additives to improve texture and water-holding capacity of other foods	Rheological properties
Toothpaste and cosmetics as suspendants and emulsifiers	Pseudoplasticity
Environmental engineering, such as the removal of contaminants	Charged components
Textile industry	Flocculating activity

to thicken or to cause gel formation; (2) mixtures of several polysaccharides to exhibit synergistic gelling; (3) possible interaction of polysaccharides with food components such as proteins, lipids, and metallic ions, and (4) the stability over a wide range of physical factors, such as pH, temperature, and light (42). However, judging from the limited information available, it is still not possible to generalize an overall picture in physical attributes, either based on taxonomy or morphology or ecological habitat of the cyanobacteria of interest. The reason is that these physical characteristics are highly species or strain specific (22).

From culturing, harvesting, and processing to final marketing of biotechnological products, many procedures are involved, and thus there is room for improvement. As a

first step in the production of cyanobacterial polysaccharides, development of a cost effective cultivation process is vitally important. Although the use of a tubular photobioreactor system has high capital costs, they may be offset by significantly high productivities and reduced costs for harvest due to high cell density (71). Major improvement in cultivation techniques is needed to ensure the maximal conversion of substrate to biotechnological products. It is desirable to develop a heterotrophic fermentation process for polysaccharide production because light is no longer required (i.e., not a limiting factor) in heterotrophic culture, and consequently the cell density and productivity can be greatly enhanced on a large scale (1). The use of heterotrophic fermentation to produce xanthan gum by other bacteria has been well established, and much of the expertise and knowledge on fermentation production of xanthan gum can be adopted for developing an industrial fermentation process for polysaccharides using cyanobacteria as producing organisms. Equally importantly, complementary to basic researches on structure–function investigation, physicochemical properties, and the condition of optimal polysaccharide production, the improvement of the intrinsic capacities of the cultivated strains may lead to significant future developments in exploitation of cyanobacterial polysaccharides for industrial applications. This can be achieved either by the isolation and selection of spontaneous mutants displaying appropriate characteristics, or by modification of some physico-chemical attributes through genetic engineering using genomic information implicated in polysaccharide production (35), because for some polysaccharide producing cyanobacteria, most genes controlling the enzymatic syntheses have been decoded and published (Tanaka, Cyanobase, http://www.kazusa.or.jp/cyano/). Some cyanobacteria (e.g., *Synechocystis*) have been regarded as model organisms in genetic manipulation. A recent study of an obligate photoautotrophic fatty-acid-producing microalga has demonstrated the possibility of introducing a human glucose transporter gene into the microalga so that the alga can grow heterotrophically on glucose, indicating conventional fermentation technology may be used for growing microalgae on a commercial scale (72).

The present knowledge of cyanobacterial polysaccharides suggests that these polysaccharides may cover a broad range of complex chemical structures and physical properties. It is reasonable to anticipate that further studies on polysaccharide-producing cyanobacteria will lead to the discovery of new polymers possessing properties different from those of existing available polymers.

In the future, the relations between structures and properties of most cyanobacterial polysaccharides still have to be elucidated in detail in order to determine proper application for each polysaccharide. It has to be stressed that the development of any microbial polysaccharide into a viable biotechnological product requires a multidisciplinary effort, which combines many different areas of expertise (i.e., microbiology, biochemistry, chemistry, genetics, engineering). There is a pressing need to fill the existing gap between current knowledge and exploiting cyanobacteria for the production of useful polysaccharides (67).

18.7 SUMMARY

Cyanobacteria are a diverse group of prokaryotes performing oxygenic photosynthesis, which are widely distributed in different habitats (from aquatic to terrestrial environments and to Arctic and Antarctic environments). Due to their physiological adaptation to the environments, cyanobacteria exhibit a great diversity in metabolic pathways during growth. Therefore, they are versatile in the production of a wide range of bioactive materials as both primary and secondary metabolites, among which polysaccharides have received much attention both in academia and industry. Technically, cyanobacterial polysaccharides are

readily recovered from the culture solutions. In view of their chemical composition and conformational structure, cyanobacterial polysaccharides are heteropolysaccharides, being composed of 6–10 monosaccharides (e.g., neutral sugars, deoxy sugars, uronic acids, amino sugars, methylated sugars). The peculiar features of these polymers in comparison with those of other microbial origin are characterized by an anionic nature, many possessing two different uronic acids and are complex either in the number of the monosaccharides or monomers or diversity of linkage types, resulting in even more complex repeating units and a broad range of possible macromolecular structures. Another important feature that contributes to the physico-chemical properties of cyanobacterial polysaccharides is the presence of a polypeptide moiety or other nonsaccharidic components such as organic (e.g., acetyl, pyruvyl, succinyl group) or inorganic (e.g., sulfate or phosphate groups) substituents, which modify or determine important physical properties in food. These structural and conformational features give rise to a great variety of physical and chemical properties of cyanobacterial polysaccharides. Previous studies have revealed that cyanobacterial polysaccharides possess unique physico-chemical properties compared with the existing polymer source (xanthan), of primarily bacterial origin. There is an increasing appeal from both the scientific community and the food industry to introduce these biopolymers into the market. In the future, concerted efforts are needed to fill the existing gap between current knowledge and that is needed in order to scale up the production of cyanobacterial polysaccharides, making them comparable to existing commercially available polysaccharides. Studies on cyanobacterial polysaccharides under diverse environmental or cultural conditions will enable an enhanced understanding of cyanobacterial metabolic processes which is necessary to develop new industrially profitable products for human uses. In conclusion, the use of cyanobacterial polysaccharides for the food industry is still in its infancy, the opportunity is enormous, and once scale up procedures are successfully developed, the opportunity will become a reality.

ACKNOWLEDGMENT

The authors are grateful to the support of CRCG (The University of Hong Kong Committee on Research and Conference Grants). The authors would also like to extend their special thanks to Dr. R. De Philippis at the Universita' degli Studi di Firenze (Italy) for providing valuable references, and Mr. S. C. Chang for improving the early draft of this review.

Food Applications of Algae

G.A. Ravishankar, R. Sarada, B. Sandesh Kamath, and K.K. Namitha

CONTENTS

19.1 HISTORICAL PERSPECTIVES

Algae have been long recognized as a heterogeneous group of organisms, ranging from prokaryotic blue greens to distantly related eukaryotic lines. Their growth modes range from phototrophy through photoheterotrophy to heterotrophy. Each growth mode in turn can be either obligate or facultative (1). The genetic diversity of microalgae is evident still further in their ecological diversity and ubiquitous distribution. Different species can grow in water ranging from fresh water to hypersaline environments; from the water surface to the limits of photic zone, which is often 200–300 meters; either free floating or attached (2).

This great genetic diversity of algae leads to a great variety of products. Microalgae have a wide range of physiological and biochemical characteristics, many of which are rare or absent in other taxonomic groups. For example, unlike higher plants and animals and most prokaryotic microorganisms, some algae synthesize long chain polyunsaturated fatty acids (LC-PUFAs), such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) (3). Some species of microalgae can efficiently synthesize intra- or extracellular polysaccharides, some of which contain unusual monomer sugars. For example, some algae synthesize extracellular polysaccharides containing substantial quantities of D-galactose, while others use L-galactose or a mixture of the two isomers (4).

Microalgae such as *Spirulina* have also had a long history in human nutrition. *Spirulina platensis* was consumed by the native population of the subSaharan region of Kanem, northeast of lake Chad and Belgium (5,6). The dried mats of *S. platensis* in the shape of biscuits or flakes were sold as djhe in the markets of the capital city of Fort Lamy (known as N'Djamena today). Djhe was used to prepare the sauces for the millet meal eaten by the Kanembou population. The spiral shape of the trichomes and the presence of abundant gas vacuoles resulted in the formation of large floating mats of *S. platensis* that the wind brought to the shores and sun dried (7).

The potentiality of *Spirulina* as a food for humans was exploited in ancient Mexico as well. Historical records reveal that at the time of conquest of Mexico by Spain, biscuits analogous to djhe were sold in the Mexican markets (8). The biscuits were prepared, as in the case of djhe, by sun drying mats of microalgae (*S. maxima*) that grows abundantly in the highly alkaline waters of Lake Texcoco near what is now Mexico City where first large scale factory for the production of *Spirulina* operates.

Since the 1950s, microalgae have been a major focus of attention as potential sources of protein, liquid fuels, and fine chemicals (9–12). Although initial work with microalgae focused mainly on protein production for human and animal nutrition (13), economic realities have meant that the emphasis today is on high value fine chemicals. There are now well established microalgae production plants in various countries, processing several different species of microalgae, including *Chlorella* (Taiwan, Australia), *Spirulina* (U.S., China, India, Mexico), *Dunaliella* (U.S., India, Australia), and *Haematococcus* (U.S., India).

Marine macroalgae (seaweeds) are grouped under three broad groups, brown, red, and green, based on pigmentation. These are referred to as Phaeophyceae, Rhodophyceae, and Chlorophyceae respectively. They have a long history of exploitation and cultivation. They are used directly as food or are processed to yield products used as food additives, pharmaceuticals, and industrial chemicals (14).

Over the last 50 years, the main products from macroalgae have been the phycocolloids, mainly agar and carrageenans (15,16). These phycocolloids have been essential to the development of modern microbiology and biotechnology (17). Since prehistoric times coastal human populations must have collected and eaten a variety of seaweeds. What is known about previous and existent uses of algae as sea vegetables has been compiled by Levring et al. (18) and by Chapman and Chapman (14). For example, a green sea lettuce (*Ulva lactuca*) was consumed in Brittany and elsewhere and esteemed for curing scurvy. The red alga, *Chondrus crispus* (Irish moss), is still commercially available as food in Ireland and is used by the people living in the folk coasts of Latin America, where it is not uncommon to find red algae such as *Gracilaria* as cushuro on the menu. Only in Japan, however, has human consumption of seaweeds developed into a real cult. Seaweed fishing has been described in the literature since 274 A.D (14). Approximately 20 kinds of sea vegetables are normal items on the Japanese shopping list. They provide up to 5–10% of Japanese food requirements.

Seaweeds have been used as food since the fourth century in Japan and the sixth century in China. Today these two countries, along with Republic of Korea, are among the largest consumers of seaweeds as food. In the past, the requirements were met by harvesting the supply of seaweeds from natural (wild) stocks. However, increasing demand over the last fifty years and a better understanding of the life cycle of these seaweeds has led to the development of cultivation industries, which produce more than 90% of market demand today. China is the largest producer of edible seaweeds, growing about 5 million tons, followed by the Republic of Korea with about 800,000 wet tons and Japan with about 600,000 wet tons. The main edible seaweeds include *Laminaria*, *Undaria*, and *Hizikia* in the brown seaweed category; *Porphyra* and *Palmaria* in the red seaweed category; and *Monostroma* and *Enteromorpha* in the green seaweed category. These seaweeds are being extensively farmed in countries such as China, the Philippines, Indonesia, Japan, the U.S., France, and Chile, to meet the ever-increasing demand (19–21).

19.2 NUTRITIONAL VALUE OF MICRO- AND MACROALGAE

Micro- and macroalgae are rich in protein, polysaccharides, carbohydrates, lipids, amino acids, trace elements, and vitamins (22). Table 19.1 gives the chemical composition of *Spirulina, Chlorella,* and *Scenedesmus*.

Table 19.1
Chemical Composition of Algae

Component	*Spirulina* (Percentage Dry Weight Basis)	*Chlorella*	*Scenedesmus*
Protein	50–60	40–50	50–55
Lipids	2–3	8–12	8–14
Carbohydrates	15–20	12–16	10–15
Fibre	5–8	6–8	10–12
Ash	10–12	8–10	6–8
Nucelic acid	5–7	6–8	4–6
Moisture	5–8	5–8	5–7

Source: Reference 23

19.2.1 Proteins

Various studies on the chemical composition of the biomass of *S. platensis* and *S. maxima* document an unusually high protein content, comprising up to 62–65% of its dry weight; *Chlorella* has been found to contain 58% protein. Such a high level of protein in *Spirulina* is uncommon even in the microbial world, being surpassed only by certain bacteria like *Cellulomonas*, which are recorded to have protein levels above 80% of their dry weight (24,25). However, the high protein content in these bacteria is accompanied by high nucleic acid content, which is medically undesirable. Excess nucleic acids (26,27) result in uric acid accumulation due to purine catabolism, which may in turn lead to pathological conditions such as gout. In *Spirulina* the concentration of nucleic acid is always below 5% of the dry weight and is thus advantageous.

Research conducted on *Spirulina* by the World Health Organization and scientists in the United States, France, West Germany, Mexico, Vietnam, and Japan confirm that it has a blend of nutrients that no other single plant source can provide. The protein content of *Spirulina* is higher than that of any other food (28,29). The net protein utilization (NPU) value of *Spirulina* is comparable to that of other vegetarian sources, indicating good amino acid composition, digestibility, and biological value. The amino acid profile of *Spirulina* protein is impressive. Indeed, with the exception of cysteine and lysine, which are present in quantities somewhat lower than in standard proteins, all the other essential amino acids are present in adequate concentrations (30–34). The potential use of *Spirulina* as a source of protein for human consumption has been widely recognized (35). The essential amino acids which it produces (Table 19.2) are of value in designer foods. The recommended intake of *Spirulina* based on the recommended daily allowance (RDA) requirements is given in Table 19.3. The protein content of seaweeds varies. Protein comprises 5–11% of the dry matter of brown algae. Red algae have a higher protein content ranging from 30–40% of dry matter; green algae can have up to 20%.

19.2.2 Minerals

The mineral makeup of *Spirulina* is attractive, as well. The iron level of *Spirulina* is 12 times higher than that of any other food. *Spirulina* is also rich in magnesium, potassium (Table 19.4), and other trace elements (29). *Spirulina*, being particularly rich in iron and calcium, is good for blood rejuvenation and the healthy functioning of bones and teeth.

Seaweed contains enormous amounts of mineral elements, which account for up to 36% of its dry mass. The mineral macronutrients include sodium, calcium, magnesium

Table 19.2
Amino-Acid Profile in *Spirulina*

Essential Amino Acids	Per 10 gms	% Total
Isoleucine	350 mg	5.6
Leucine	540 mg	8.7
Lysine	290 mg	4.7
Methionine	140 nmg	2.3
Phenylalanine	280 mg	4.5

potassium, chlorine, sulfur, and phosphorous. The micronutrients include iodine, zinc, copper, selenium, molybdenum, fluoride, manganese, boron, nickel, and cobalt (36).

Among the micronutrients, seaweeds have a high proportion of iodine content. The iodine content in brown algae ranges from 1500–8000 ppm in dry kelps and 500–1000 ppm in dry rockweed; in red and green algae, the iodine content ranges from 100–300 ppm in dry seaweeds. The recommended daily intake of iodine is 150 mg/day. One gram of dried brown algae provides 5–8 mg of iodine and one gram of red algae (purple nori)

Table 19.4
Different minerals found in *Spirulina*

Minerals	Per 10 gms	RDA	% RDA
Calcium	100 mg	1000 mg	10
Iron	15 mg	18 mg	83
Zinc	300 µg	15 mg	2
Phosphorous	90 mg	1000 mg	9
Magnesium	40 mg	400 mg	10

provides 1–3 mg of iodine. Besides iodine, seaweed is one of the richest sources of calcium, the content ranging from 4–7% of dry matter (37).

19.2.3 Vitamins

Seaweeds, like green vegetables, contain all kinds of vitamins and are a natural source of vitamins to humans. Among the group B vitamins, seaweeds contain vitamin B_{12}, which is particularly recommended for treatment of the effects of aging, chronic fatigue syndrome, and anemia. *Chlorella* contains vitamins C, E, B, and A. *Spirulina* is the richest source of B_{12} and the daily ingestion of 1 g of *Spirulina* would be enough to meet the daily requirement of B_{12} (29,38). Apart from vitamin B_{12}, *Spirulina* has an excellent blend of other vitamins, including vitamins A, B_1, B_2, B_6, E, and H (biotin) (Table 19.5). It contains 21% of the RDA of thiamin and riboflavin (29). *Spirulina* has a β-carotene (provitamin A) content (0.1% of the dry weight) which is 20 times higher than that of carrots. Its folic acid and Vitamin B_{12} contents make it a good therapeutic food for anemia.

Algae provide a good source of vitamin C (39). The levels of vitamin C range between 500–3000 mg/kg of dry matter for green and brown algae, whereas red algae contains 100–800 mg/kg. Vitamin C is of interest in human nutrition because it strengthens the immune defense system, activates the intestinal absorption of iron, controls the formation of conjunctive tissue, acts in trapping free radicals, and regenerates vitamin E (37).

The brown seaweeds contain higher levels of vitamin E than the green and red seaweeds. Vitamin E is important in human nutrition, because, due to its antioxidant activity, it inhibits the oxidation of low density lipoproteins. It also plays an important role in the arachidonic acid chain, by inhibiting the formation of prostaglandins and thromboxan. Brown algae also contain alpha, beta, and gamma tocopherol; the green and red algae contain only alpha tocopherol. Gamma and alpha tocopherol have been shown to increase the production of nitric oxide and nitric oxide synthase activity and also help in prevention of cardiovascular disease (40).

19.2.4 Lipids

Microalgae contain significant quantities of lipids, with a composition similar to that of vegetable oils (Table 19.6). Under certain conditions, microalgae have been reported to contain lipids up to 85% of their dry weight (41,42). The lipid content in general ranges between 20 and 40% of the dry weight. At least one microalga, *Botryococcus braunii*, produces large amounts of C_{15} and C_{33} hydrocarbons (43).

Table 19.5
Different Vitamins present in *Spirulina*

Vitamins	Per 10 gms	Recommended Daily Allowance	% RDA
Vitamin A (β-carotene)	23000 IU	5000 IU	460
Vitamin B_1 (Thiamine)	0.31 mg	1.5 mg	21
Vitamin B_2 (Riboflavin)	0.35 mg	1.7 mg	21
Vitamin B_3 (Niacin)	1.46 mg	20.0 mg	7
Vitamin B_6 (Pyridoxine)	80.00 µg	2.0 mg	4
Vitamin B_{12} (Cyanocobalamine)	32.00 µg	6.0 µg	533
Vitamin E (α-tocoferol)	1.00 IU	30.0 IU	3
Folacin	1.00 µg	400.0 µg	0.04
Panthothenic acid	10.00 µg	10.0 mg	1
Biotin	0.50 µg	-	-
Inositol	6.40 mg	-	-

Table 19.6
Lipids from Microalgae

Microalgae	Lipid	Ref.
Porphyridium cruentum	Eicosapentaenoic acid	49
	Arachidonic acid	59
Porphyridium aeruginosa	Arachidonic acid	53
	Palmitic acid	
	Oleic acid	
	Linoleic acid	
Ochromonas danica	γ-Linolenic acid	60
Monodus subterraneous	Eicosapentaenoic acid	61
Euglena gracilis	α-Linolenic acid	62
Ulothrix aequalis	α-Linolenic acid	63
Lauderia borealis	Eicosapentaenoic acid	64
Phaeodactylum tricornutum	Eicosapentaenoic acid	65
Chlorella minutissima	Eicosapentaenoic acid	61
Nannochloropsis oculata	Eicosapentaenoic acid	65

The lipids of microalgae are generally esters of glycerol and fatty acids with a chain length of C_{14} to C_{22}. They may be either saturated or unsaturated. Some blue green algae, especially the filamentous species, tend to have large quantities of polyunsaturated fatty acids (25–60% of the total) (44–48).

The lipids of some algal species are rich in essential fatty acids such as the C_{18} linoleic (18: 2ω3) and γ-linolenic (18: 3ω3) acids and their C_{20} derivatives, eicosapentaenoic acid (20: 5ω3), and arachidonic acid (20: 4ω6). These fatty acids are an essential component of the diet of humans and animals and are becoming important feed additives in aquaculture.

The eukaryotic algae have a predominance of saturated and monosaturated fatty acids (49). Triglycerides are the most common storage lipids and may constitute up to 80% of the total lipid fraction (50,51). Besides the triglycerides, the other major algal lipids are

sulphoquinovosyl diglyceride (SL), monogalactosyl diglyceride (MGDG), digalactosyl diglyceride (DGDG), lecithin, phosphatidyl glycerol, and phosphatidyl inositol (52).

The red unicellular *Porphyridium cruentum* and *P. aeruginosa* have high levels of arachidonic acid (20:4) as well as palmitic, oleic (18:1), and linoleic acids (Table 19.6) (49,53). The chrysophytes have relatively high contents of 22:6 and 22:4 acids (54,55) and the dinophytes have significant quantities of highly unsaturated 18:4 and 22:6 acids, as well as the saturated 16:0 and 20:0 acids (54,56). The major unsaponifiable lipid in the *Chlorophyceae* and *Cyanophyceae* is n-heptadecane (57,58), with sterols being more common in the green algae.

Spirulina has yet another merit in its lipid composition, being cholesterol free and rich in polyunsaturated essential fatty acids (66), which is desirable for treating or preventing conditions like atherosclerosis, obesity, and blood pressure. Additionally, this alga is rich in γ-linolenic acid (Table 19.7), a precursor for prostaglandin biosynthesis, and thus has even further medical implications (29). In short, the composition of *Spirulina* makes it a low calorie, low fat, cholesterol free source of protein.

Although seaweeds have a low fat content, ranging from 1–5% of dry weight, they have a higher proportion of essential fatty acids than the green plants (land plants). Green algae have a higher oleic and α-linoleic acid content and red and brown algae are rich in EPA and arachidonic acid content (67).

19.3 ALGAE AS A SOURCE OF NUTRACEUTICALS

The very great diversity of the microalgae is also reflected in their chemical composition, and the microalgae are, therefore, potential sources of an almost unlimited range of chemicals (Table 19.8). The main chemicals currently being commercialized or under consideration for commercial extraction are carotenoids, phycobilins, fatty acids, polysaccharides, vitamins, sterols, and biologically active molecules for use in human and animal health (43,68–70). Selection of promising algae and their products requires evaluation of the suitability of the alga for mass culture, the value of the product, its concentration in the alga, the size of the market for the products, and existing and future alternative sources.

19.3.1 Carotenoids

The carotenoids, β-carotene and astaxanthin, are attractive algal products because they command a high market price (\$600 kg^{-1} for β-carotene; \$3000 kg^{-1} for astaxanthin)

Table 19.7
Essential fatty acid composition of *Spirulina*

Fatty Acids	mg/10 gms	% Total
C14:0 Myristic	1 mg	0.2
C16:0 Palmitic	244 mg	45.0
C16:1 Palmitoleic	33 mg	5.6
C17:0 Heptadecanoic	3 mg	0.3
C18:0 Stearic	8 mg	1.4

(121, www.healthfoods.com) and they are present in high concentrations in some algal cells. Carotenoids are powerful antioxidants. Recent studies have shown a correlation between a diet rich in carotenoids and a diminishing risk of some diseases. For example, a diet rich in β-carotene and lycopene helps diminish cardiovascular disease and cancers; one rich in lutein and zeaxanthin helps reduce opthamalogical diseases. Brown seaweeds are particularly rich in carotenoids, especially in fucoxanthin, β-carotene, and violaxathin. The main carotenoids of red algae are β-carotene and α-carotene and their dihydroxylated derivatives, lutein and zeaxanthin. The carotenoid composition of green algae is similar to that of higher plants; the main carotenoids are β-carotene, lutein, violaxathin, antheraxanthin, zeaxanthin, and neoxanthin. The antioxidant properties of algal carotenoids, and the role they play in preventing many pathologies linked to oxidative stress, have been demonstrated by Okuzumi et al. (72) and Yan et al. (73).

19.3.2 Fatty Acids

Apart from the carotenoids, the long chain polyunsaturated fatty acids — arachidonic acid (AA; 20: 4n-6), eicosapentaenoic acid (EPA; 20: 5n-3), and docosahexaenoic acid (DHA; 22: 6n-3) — are of great interest. For example, the red unicellular *Porphyridium cruentum* can contain more than 30% of its total fatty acids as AA and equally high concentrations

of EPA (74,75); in the diatom *Phaeodactylum* more than 35% of the total fatty acids can be EPA (76). DHA, on the other hand, is more abundant in prymnesiophytes such as *Isochrysis*, *Pavlova*, and in the cryptomonad *Chroomonas salina* (77).

Not only are there very great variations in the fatty acid composition of different species, but the total fatty acid content also varies. Furthermore, the fatty acid content and composition can be manipulated by altering culture conditions (78,79). Genetic enhancement of the production of desirable fatty acids also remains a possibility for the future.

A major barrier to the commercialization of algal fatty acids is the fact that no single species is a distinctly better producer than another, although *Phaeodactylum tricornutum, Porphyridium cruentum*, and *Nannochloropsis salina* are the most likely candidate organisms. The production of pure fatty acids or algal lipids for pharmaceutical use requires the ability to extract the lipids and purify the fatty acids effectively.

These fatty acids, especially the omega-3-fatty acids EPA and DHA, have a function in the prevention of cardiovascular disease and rheumatic arthritis, and are also apparently essential in infant nutrition (80–82). They are also important in the treatment of atherosclerosis, cancer, rheumatoid arthritis, psoriasis, ocular diseases, hypertension, and diseases of old age such as Alzheimer's disease and age related macular degeneration (83,84). Estimates of the potential U.S. market for these fatty acids range up to $790 million and, although fish oil is presently the main source of EPA and DHA, the supply of suitable fish oils is limited and the quality variable. Cultured microalgae could be a more reliable source.

These essential fatty acids are also important in the nutrition of aquaculture species (85), and the demand for high quality algal feed for this purpose is increasing. Most hatcheries grow their own algae on site, because live feeds are preferred. This small scale cultivation is generally unreliable, and the cultures often collapse. This is mainly due to the very primitive culture systems used, and the lack of experience of the hatchery staff. If a preserved microalgal product of reliable composition could be produced at a reasonable cost, this could overcome some of these problems. One such product of heterotrophically grown *Tetraselmis* was available for some time and was effective as a feed (86). The main problem with this product was the cost, and the fact that the composition of the alga was not optimal for the nutrition of the aquaculture species.

19.3.3 Phycobilins

Phycocyanin and phycoerythrin can be easily isolated from red or blue green algae (87). Highly purified phycobilins are being used in immunofluorescent labeling (88,89). Although the value for these high purity phycobilins is very high ($3.00–17.00/mg) (www.phycobiliprotein.com), the overall market size is small and unlikely to increase significantly. An alternative use for the phycobilins is as a natural food color. This is obtained as protein extract and marketed as Lina Blue (a brand name) (90), as an edible dye especially for food products such as ice cream and yogurt. Phycocyanin is used for this purpose in Japan. In recent years (91,92) the hepatoprotective, antiinflammatory, and antiarthritic properties of phycocyanin have been reported. Phycocyanin is also used as natural dye by the cosmetics industry. There is a potentially large market for the phycobilins; however, it will require extensive marketing and the compounds will have to be registered with the appropriate regulatory authorities in various countries. Unfortunately, this will take some time and will be an expensive process.

19.3.4 Bioactive Compounds

One area of interest in recent years is the production, by microalgae, of biologically active substances, with possible applications in human and animal health. Although screening of

microalgae has been limited so far, compounds with antineoplastic (93,94), antibacterial (95–97), antifungal (98–100), and antiviral (101,102) activities have been isolated from microalgae, mainly blue green algae, and also macroalgae (Table 19.9). Other pharmacologically active substances have also been found. If eventually found to be suitable for medical use it is likely that many of these will be manufactured by synthesis. However, the complexity of some of these molecules makes production by algal culture a potential possibility.

19.4 INDUSTRIAL PRODUCTION PROCESSES

19.4.1 *Chlorella*

Chlorella is a unicellular, fresh water, green microalga, one of the earliest organisms used in applied research. Its potential use as a source of single cell protein was realized early by the Taiwanese. In 1951 the first *Chlorella* pilot plant was constructed and operated for the Carnegie Institution by Arthur D. Little, Inc. at Cambridge Mass. In 1960s, the large scale production of this alga was started in Taiwan (10). Another series of laboratory and pilot plant studies followed in Japan under the guidance of Dr. Himoshi Tamiya after his stay at Stanford. His strong working group at the famous Tokugawa Institute in Tokyo concentrated on *Chlorella* research, as did a study conducted in Israel. The results of this first boom of applied research on microalgae were published in the classic and still fascinating report edited by Burlew (9), which contains an interesting article on the use of natural algal suspension consisting mainly of *Chlorella* for the nutrition and apparently successful treatment of leprosy patients (113).

19.4.1.1 Nutritive Value

Chlorella is considered a nutritional powerhouse. It is richer in chlorophyll than *Spirulina* or other blue green algae, contains nearly 60% protein, and contains all of the essential

Table 19.9
Bioactive compounds from seaweeds

Seaweed	Bioactive Compound	Application	Ref.
Eucheuma	Carrageenan	Anticonstipation agent	103
Digenia simplex	Kainic acid and its isomer allokainic acid	Antihelminthic compounds	104
Phyllophora nervosa	An alkaloid hordenine	Sedative	105
Laminaria angustata	Aminoacid Laminine	Antihypertensive compound	106
Porphyra yezoeusis	γ-butyrobetaine	Hypocholesterolemic compounds	107
Fucus vesiculosus	Fucans	Blood anticoagulant compounds	108
Porphyra tenera	Porphyrosin	Antiulcer compound	109
Enteromorpha and *Ulva*	Acrylic acid	Antimicrobial	110
Dictyopteris zonaroides	Tetrabromoheptanone	Antimicrobial	111
Bonnemaisonia hemifera	4 polymers of polyhalo 3-butene-2-one	Antimicrobial	111
Discodermia kiiensis	Discodermin A-D	Cardiac activity	112

amino acids. It contains β-carotene, B complex, vitamin C, E, and K, minerals, carbohydrates, fatty acids, and lipoic acid. The major *Chlorella* production in the world is achieved in Taiwan; 10–15% of the total is produced in green houses in Japan. The main products of *Chlorella* available in the health food market are in the form of biomass dry powder, compressed pills, and *Chlorella* extract, marketed under different brand names. The cost of production of *Chlorella* extract ranges from $10 to $15/kg dry weight biomass (114). Over the last 20 years, there has been no significant breakthrough in the technology utilization, probably because of the knowledge of diversified uses of *Spirulina* (29).

19.4.1.2 Beneficial Effects

Chlorella is known for its ability to stimulate the growth of beneficial bacteria in the intestines and detoxify chemicals and heavy metals from the body. It has been reported to stimulate interferon production and increase the activity of B and T cells, thus enhancing the body's natural defense system. It has also been found to accelerate healing, improve digestion, protect against radiation, prevent degenerative diseases, help in the treatment of fungal infections such as *C. albicans*, relieve arthritis pain, and, due to its nutritional content, aid in the success of numerous weight loss programs.

19.4.2 *Spirulina*

Spirulina is a multicellular, filamentous blue green alga recognized as a unique health food throughout the world because of its nutrient density. The nutrient medium used for cultivation is simple and highly alkaline (pH 9.5–11). Growing in high alkaline media where other microorganisms do not survive is a great advantage in allowing mass production of *Spirulina* under outdoor conditions. The production centers of *Spirulina* are spread throughout the world including India (114).

19.4.2.1 Nutritive Value

Besides its high protein content (55–65%), *Spirulina* has also been reported to be a good source of β-carotene (precursor of vitamin A), B vitamins, pigments-phycobilins, chlorophyll, minerals, and γ-linolenic acid, an important nutraceutical.

19.4.2.2 Beneficial Effects

Spirulina has shown to possess cholesterol-reducing effect. The Harvard University School of Dental Medicine showed reduced oral cancer cells when *Spirulina* extracts were used (115). In Japan, the reports showed that *Spirulina* reduced kidney nephrotoxicity from mercury and three pharmaceutical drugs in experimental rats (116). *Spirulina* may also have positive effects against diabetes and may help to reduce high blood pressure (117). Research in Japan showed that *Spirulina* increased *Lactobacillus* in rats threefold over a control group (118). In France, pharmaceutical compounds containing *Spirulina* accelerated wound healing (30). A study in Mexico also hinted at the beneficial effect when *Spirulina* was incorporated in the diet of undernourished children and adults. In Togo, rapid recovery of malnourished infants through the use of *Spirulina* was reported in a village clinic. In India, large scale studies with preschool children showed carotenes in *Spirulina* helped the children recover from symptoms of vitamin A deficiency (119). In Romania, studies by Fica et al. (120) showed that when *Spirulina* tablets were prescribed to patients with nutritional deficiencies, the patients gained weight and their health improved. In China, *Spirulina* has been prescribed as a baby-nourishing ingredient in baked barley sprouts. When given *Spirulina*, 27 out of 30 children aged from 2 to 6 years

recovered in a short period from bad appetite, night sweats, diarrhea, and constipation. In 1989, the National Cancer Institute announced that chemicals from blue green algae were found to be remarkably active against the AIDS virus and 100 types of cancer (101). The sulfolipid portions of the glycolipids in *Spirulina* can prevent viruses from either attaching to or penetrating into cells, resulting in prevention of viral infection.

19.4.3 *Dunaliella*

β-carotene from the alga *Dunaliella salina* was the first high value algal product commercialized (121) and there are now major producers in Australia (Western Biotechnology Ltd; Betatene Ltd), the U.S. (Microbio Resources Inc; Cyanotech), India (Parry Agro), and Israel (Naturebeta). The Australian producers use very large (5 ha or greater) shallow ponds without any means of mixing (122,123), whereas in the U.S., India, and Israeli, producers use paddle wheel mixed raceway ponds to grow the algae. The β-carotene is sold mainly as an oil extract, as a suspension in vegetable oil, or as a dried algal powder (121).

The *Dunaliella* β-carotene process has several advantages:

1. *Dunaliella salina* is the most halophilic eukaryote known, with an optimum salinity of about 22% w/v NaCl for growth, and an ability to withstand NaCl concentrations >30% and high temperatures. This means that extensive open air culture of the alga is possible.
2. The cells contain up to 14% of dry weight as β-carotene.
3. This β-carotene has a high sale price and a large and growing market.

In the market, *Dunaliella* products are available in dried form or extracted form. *Dunaliella* is harvested by different means of concentration and centrifugation, followed by spray drying. The final product in powder or pill form is considered to be of highest quality (124). The product in this form is mainly aimed at the health food market for direct human consumption. The price of the product is based on the β-carotene content; it can be as high as $2000/kg of β-carotene. The extracted form of the product is obtained from *Dunaliella* wet biomass harvested by flocculation. The β-carotene is extracted into vegetable oil and the product thus obtained can be applied as a food dye and a provitamin additive for human consumption, for fish and poultry feed, or in the cosmetics industry as an additive to sunscreen products. The price of this product will be comparatively lower and depends on the β-carotene concentration. The size of the market for natural β-carotene from *Dunaliella* is difficult to estimate, but the trend and demand globally is increasing.

The disadvantages and threats to the algal process are:

1. The biomass in the growth ponds rarely exceeds $1 g^{-1}$ and the algal cells have a density almost identical to that of the growth medium; this makes harvesting a complicated and expensive process.
2. Most of the world markets are supplied by synthetically manufactured β-carotene, and the production capacity of the synthetic product could be increased relatively easily.

The major competitive advantage of *Dunaliella* β-carotene over the synthetic product is that the algal product is natural. There are also some suggestions that the natural algal mixtures of the cis and trans isomers of β-carotene are more biologically active than the synthetically produced pure trans β-carotene (125–127). Furthermore, the increasing

evidence for a preventive action of β-carotene against certain cancers, particularly epithelial cancers (128–130) should lead to an increase in the demand for β-carotene.

The algal β-carotene producer still needs to continue improving the algal culture process, so as to increase the β-carotene productivity by increasing growth rate and reliability, and by improving the β-carotene content of the cells. This requires improvements in the design of the production plants, a better understanding of *Dunaliella* physiology, and better algal strains, which can be obtained by either strain selection or by mutagenesis (131) and by genetic engineering.

19.4.4 *Haematococcus*

The production of the ketocarotenoid astaxanthin using the freshwater alga *Haematococcus pluvialis*, is also very attractive, but has fewer advantages than the *Dunaliella* β-carotene process. First, *H. pluvialis* is a freshwater alga, and thus open air culture is extremely difficult due to contamination by many other undesirable algal species. *Haematococcus pluvialis* culture will require closed culture systems such as tubular photo bioreactors. Although some pilot scale units have been tested (132,133), these systems require further refinements. However, recently completely closed photo bioreactors with artificial light, and a combination of closed photo bioreactors and open culture ponds are being used for *Haematococcus* cultivation (134,135). Second, unlike *Dunaliella, H. pluvialis* changes from a motile, flagellated cell to a nonmotile, thick walled aplanospore during the growth cycle (136,137); the astaxanthin is contained in the aplanospore. This means that the physical properties (density, settling rate, cell fragility) and nutrient requirements of the cells change during the culture process, and this alters the optimum conditions for growth and carotenoid accumulation during the growth cycle (138). Third, the content of astaxanthin in the aplanospores is about 1–2 % of dry weight and their thick wall requires physical breakage before the astaxanthin can either be extracted or be available to organisms consuming the alga (139).

On the other hand, the high value of astaxanthin, and the rapid growth of its main market, the aquaculture industry, means that the potential markets are very promising. The main competing product is synthetic astaxanthin, and once again, the algal process has the advantage of producing a natural product. The only natural alternatives are crustacean meal, which is in limited supply and only has low astaxanthin content, and the yeast *Phaffia rhodozyma,* which also has much lower astaxanthin content than the alga (140).

The development of a commercially viable algal astaxanthin process requires the development of an effective closed culture system and the selection (either from nature or by mutagenesis) of strains of *Haematococcus* with higher astaxanthin content and an ability to tolerate higher temperatures than the wild strains.

19.4.4.1 Astaxanthin as a Nutraceutical

Most of the microalgae products like *Spirulina* sp. and *Aphanizomenon flosaquae* are used as nutraceuticals. The medicinal benefits of nutraceuticals depend upon high quality manufacturing and effective control of production environments. Astaxanthin, a powerful bioactive antioxidant, has demonstrated efficacy in animal or human models against Alzheimer's and Parkinson's diseases, and macular degeneration (141), a cause of blindness in the U.S. Astaxanthin also ameliorates the effects of LDL, protects against cancer, and repairs cell damage caused by lack of oxygen, hence a potent nutraceutical.

19.4.4.2 Astaxanthin as Antioxidant

Astaxanthin has been shown to be a powerful quencher of singlet oxygen activity in *in vitro* studies (142,143). Astaxanthin has stronger antioxidant activity (10 times higher

than β-caroten e) and is more than 500 times as effective as α-tocopherol. Astaxanthin has been purported to be the super vitamin E (134,143–146). The antioxidant property has been demonstrated in a number of biological membranes (147–149). Astaxanthin has preventive effects against aflatoxin B1 carcinogenicity (150). Kobayashi and Sakamoto (151) showed antioxidative activity of astaxanthin under both hydrophobic and hydrophilic conditions, while Kobayashi et al. (152) reported *in vivo* activity against super oxide anion radicals using a whole cell assay system. Astaxanthin also has strong activity as an inhibitor of lipid peroxidation mediated by active forms of oxygen (143,153). The strong antioxidative activities of astaxanthin suggest its potential as a photoprotectant against UV irradiation (154,155). Preparations containing Astaxanthin for the prevention of light induced aging of the skin have been developed by Suzuki et al. (156,157).

19.4.4.3 Astaxanthin for Health

Mammals lack the ability to synthesize astaxanthin, or to convert dietary astaxanthin into vitamin A. Unlike β-carotene, astaxanthin has no provitamin activity in these animals (158). Astaxanthin has been shown both *in vitro* and in a study with human subjects to be effective for the prevention of the oxidation of low density protein (159), suggesting that it can be used to prevent arteriosclerosis, coronary artery disease, and ischemic brain development. A number of astaxanthin health products are under study (159,160). Studies on rats have shown no toxicity of astaxanthin even in diets containing 400 ppm astaxanthin (161). Dietary administration of astaxanthin has proved to significantly inhibit carcinogenesis in the mouse urinary bladder, rat oral cavity, and rat colon (162–164). In addition, it is reported to induce xenobiotic-metabolizing enzymes in rat liver (150). Astaxanthin has been shown to enhance *in vitro* antibody production by mouse spleen cells stimulated with sheep red blood cells (145,165) and in human blood cells *in vitro* (158,166). Further it has not exhibited any mutagenicity in *in vitro* study at doses up to 14.4 mg/day for two weeks (159). Yamashita (167) has reported an antiinflammatory effect of astaxanthin when administered together with aspirin. An oral preparation has been developed by Alejung and Wadstroem (168) for the treatment of helicobacter infections of the mammalian gastrointestinal tract. There is strong evidence to suggest that astaxanthin modulates the humoral and nonhumoral immune system. It enhances the release of interleukin-1 and tumor necrosis factor α in mice, with greater effect than canthaxanthin or β-carotene, and has the greatest cytokinin inducing activity (169). Astaxanthin has a significant enhancing action on the production of immunoglobulin A, M, and G, and on T-helper cell antibody production, even when suboptimal amounts of antigen are present (158,166). Consequently, at the initial stage of a pathogen invasion, doses of a particular antigen may be suboptimal for eliciting an effective immune reaction; astaxanthin appears to enhance this response. Astaxanthin might also be useful in preventing age related macular degeneration that causes irreversible blindness.

19.4.4.4 Astaxanthin for Salmon and Trout Feeds

The predominant source of carotenoids for salmonids has been synthetic astaxanthin, which has been used for pigmentation for the last 20 years, since FDA approval in 1996. Natural sources of astaxanthin for commercially raised salmonids have been utilized, which include processed crustacean waste from krill, shrimp, crab, and crawfish. However, crustacean waste products contain high amounts of moisture, ash, and chitin, which limits the use in salmonids feeds. Another natural source, *Phaffia rhodozyma,* requires a large amount of feed for sufficient pigmentation, leading to higher ash contents. The efficiency of dietary astaxanthin using microalgae for flesh pigmentation of Atlantic salmon and rainbow trout has been demonstrated by Torrison et al. (170) and Storebakken (171). For

salmon, astaxanthin is even considered a vitamin that is essential for the proper development and survival of juveniles (172). Choubert and Heinrich (173) showed that feeing rainbow trout with algae up to 6% of the diet had no major effect on growth or mortalities. Thus, the algae was concluded to be a safe and effective source of pigment. Astaxanthin has been used to enhance the immune response of fish and shrimp for maximum survival and growth. Natural microalgal astaxanthin has shown superior bioefficacy over the synthetic form. Full approval in Japan has been received for the use of astaxanthin as a pigment in feeds and foods; registration for approval is in progress for the United States, the European community, and Canada. An amount of 25–100 ppm of carotenoids in the final feed has been considered to give desired pigmentation in various salmonid species (173).

In poultry astaxanthin has shown to reduce the mortality of chicks by 50%, and to reduce *Vibrio* infections in eggs, thereby improving the nutritional value of eggs, especially among European consumers. However, the livestock feed market for astaxanthin, which is presently small, may grow to a size comparable to the market for synthetic pigments, which is estimated at $185 million. The largest market for astaxanthin, aquaculture, constituting 24% of total global fisheries production, is currently valued at $35 billion per annum and is expected to grow to $49 billion by 2010.

Limited studies have been carried out on dietary astaxanthin intake by humans. In a study reported by Miki et al. (159), astaxanthin was tested to protect low density lipoprotein from oxidation; 3.6–14.4 mg/day of an astaxanthin-containing drink was administered over a period of 2 weeks. Progressively slowed LDL oxidation with increasing doses of astaxanthin was observed and no ill effects were reported.

Sterlie et al. (174,175) reported that when 100 mg of synthetic astaxanthin in olive oil containing meal was given to male volunteers, maximum plasma concentration of 1.24 mg/L astaxanthin was observed in the first 6 hours postprandially. The relative concentration of total astaxanthin in HDL decreased compared to the other lipoprotein fractions in the 72 hour study.

Based on a study conducted with 40 healthy volunteers, Lignell (176) reported the effect of astaxanthin on mammalian muscle function. Volunteers received 1 capsule of 4 mg astaxanthin each morning in association with food. No significant difference was observed between the treatment and placebo group in any physical parameters measured.

The effect of dietary astaxanthin on the health of humans as studied by Aquasearch (177) on 33 volunteers consuming daily 3.85 mg (low dose) and 19.25 mg (high dose) for a period of 29 days indicated no ill effects or toxicity due to consumption of astaxanthin as analyzed by medical and clinical parameters.

Tso and Lam (146) suggested astaxanthin could be useful for the prevention and treatment of neuronal damage associated with age related macular degeneration, and it may also be effective at treating ischemic reperfusion injury, Alzheimer's disease, Parkinson's disease, spinal cord injuries, and other types of central nervous system injuries. Astaxanthin was found to easily cross the blood–brain barrier and did not form crystals in the eye.

19.4.5 *Porphyra*

Porphyra, commonly known as nori or purple laver, is the largest source of food from red seaweeds in the world. Nori has been a staple in the diet of most Asian countries, such as Japan, China, and the Republic of Korea.

19.4.5.1 Nutritive Value

Porphyra contains significant amount of proteins, vitamins, and minerals. The vitamin C content in *Porphyra* is greater than in raw oranges. It has vitamin A content comparable to

spinach. The free and proteinaceous amino acids in nori are similar to that of vegetables. *Porphyra* contains high amount of arginine, which is generally present in animal protein. The characteristic taste of nori is caused by the large amounts of three amino acids: alanine, glutamic acid, and glycine. It also contains an abundant amount of taurine, which is essential for liver activity in preventing the occurrence of gallstone disease and to control blood cholesterol levels. Nori also contains large amounts of essential trace elements, such as zinc, needed for certain enzyme functions (20,178).

19.4.5.2 Cultivation Methods

Porphyra cultivation dates back as far as 300 years ago, when it was collected by hand from natural resources. Actual cultivation began during the 1960s when the life cycle of *Porphyra* was clearly understood. Detailed information on its life cycle and methods of cultivation can be found in Oohusa (179) and Mumford and Muira (180).

19.4.5.3 Food Uses

Porphyra is dried and processed into thin purplish black sheets. Nori is mainly used as a luxury food. It is commonly used in Japanese sushi, wrapped around a small handful of boiled rice topped with a slice of raw fish. Nori can be incorporated into soy sauce and can be used as a raw material for jam and wine. In China, it is mostly used in soups and for seasoning fried foods. In the Republic of Korea, it has similar uses to Japan, except that the popular snack with beer is Hoshinori, which is nori quickly fried in a pan with a little oil (181).

19.4.6 *Enteromorpha*

Enteromorpha is commonly known as aonori or green laver. Its life history involves an alternation of generations, both generations having the same appearance of long, tubular filaments.

19.4.6.1 Nutritive Value

Enteromorpha contains about 20 percent protein, little fat, low sodium, and high iron and calcium. Its vitamin B group content is generally higher than most vegetables, and while its vitamin A is high, it is only half of that found in spinach.

19.4.6.2 Cultivation Methods

Enteromorpha is cultivated in Japan and the Republic of Korea. It is also found in other parts of the world including Europe and North America. For cultivation, rope nets are seeded with spores by submerging them in areas where *Enteromorpha* is growing naturally, usually attached to rocks. Harvesting can be done 2–3 times during the growing period, either by hand picking from the nets or by machine (182). The quantities of *Enteromorpha* harvested in Japan and the Republic of Korea are 1400 and 1038 tons/yr respectively (www.surialink.com).

19.4.6.3 Food Uses

Enteromorpha is lightly roasted to improve the flavor and powdered. The powder can be used as a condiment in soups and foods. The algae can be crushed into small pieces and used as a garnish. More information on its life cycle and cultivation methods, along with descriptions and useful illustrations, can be found in Ohno (183).

19.4.7 *Eucheuma*

Eucheuma is a red algae belonging to the family *areschougiaceae*, mainly used as a source of carrageenan. The Philippines is the leading producer and exporter of *Eucheuma* raw material. It accounts for more than 70% of the world's production of carrageenan (184). In India, experimental field cultivation of *Eucheuma* has been successfully done by the Central Salt and Marine Chemicals Research Institute, Bhavnagar (185). The cultivation methods of *Eucheuma* and the uses of carrageenan are explained in the next section.

19.5 ALGAE BASED INDUSTRIAL PRODUCTS OF FOOD PROCESSING

Seaweeds have been commercially exploited for hydrocolloids since 1658, when the gelling properties of agar, extracted with hot water from red seaweed, were first discovered in Japan. Various red and brown seaweeds are used to produce three hydrocolloids, namely agar, alginate, and carrageenan (Table 19.10). A hydrocolloid is a noncrystalline substance with very large molecules which dissolves in water to give a thickened (viscous) solution. Industrial uses of seaweed extracts expanded rapidly after the Second World War, which were subsequently limited by the availability of raw materials. Research into seaweed life cycles has led to the development of cultivation industries that now supply a high proportion of the raw material for some hydrocolloids. Today, approximately 1 million tons of wet seaweed are harvested and extracted to produce these three hydrocolloids. Total hydrocolloid production is about 55,000 tons, with a value of $585 million (181).

19.5.1 Agar

The main seaweeds used for agar extraction are *Gelidium* and *Gracilaria*.

19.5.1.1 Cultivation Methods

Gelidium is a small slow growing plant; cultivation in ponds and tanks is possible but not economically feasible. One exception is a Canadian company in Vancouver, Marine Bioproducts International Corp., which claims to be growing consistent, high quality *Gelidium* from which high grade agar and agarose products are obtained (www.marbio.com).

Table 19.10
Sources of Seaweeds for Hydrocolloids

Hydrocolloids	Seaweeds
Agar	*Gelidium*
	Gracilaria
Alginate	*Ascophyllum*
	Durvillaea
	Ecklonia
	Lessonia
	Laminaria
	Macrocystis
Carrageenan	*Kappaphycus alvarezii*
	Eucheuma denticulatum
	Chondrus crispus
	Betaphycus gelatinum

Source: Reference 181

Gracilaria cultivation is widespread and several methods are used. It can be grown vegetatively in open waters on the bottom of bays, estuaries, or reef flats; on lines, ropes or nets; in ponds; or in tanks (186–188). The harvesting methods for *Gelidium* and *Gracilaria* are given in Table 19.11.

19.5.1.2 Extraction of Agar

Agar is used because of its ability to form gels, and the unique properties of these gels. Agar dissolves in boiling water and when cooled, forms a gel between 32° and 43°C, depending on the seaweed source of agar (189). The procedure for the extraction of agar from seaweeds is shown in Figure 19.1.

19.5.1.3 Food Applications

- About 90% of the agar produced is used for food applications. The U.S. Food and Drug Administration has classified agar as GRAS (Generally recognized as safe).
- Agar can be used as a stabilizer and thickener in pie fillings, icings, and meringues in the baked goods industry.
- Some agars, especially those extracted from *Gracilaria chilensis,* are used in confections with very high sugar content like fruit candies.
- Agar is a popular component of jellies in Asian countries and is used in gelled meat and fish products because of its high melting temperature and gel strength.
- Agar has been used to stabilize sherbets and ices in combination with other gums.
- Agar is used to improve texture of dairy products like cream cheese and yogurt and to clarify wines.

Further information on the uses of agar in food applications can be found in Armisen (190) and Armisen and Galatas (189,191).

19.5.2 Alginate

The main seaweeds used for alginate production are given in Table 19.10.

19.5.2.1 Cultivation Methods

None of the alginate producers are cultivated, since the costs of harvesting and transporting are expensive compared to alginate production. The harvesting methods used for alginophytes are given in Table 19.12.

Table 19.11
Harvesting methods for Agarophytes

Agarophytes	Harvesting Methods
Gelidium	A high percentage of harvest is by gathering of storm-cast seaweed by dragging a net.
Gracilaria	Fully grown Gracilaria resists water movement and eventually break off. These broken pieces drift and are collected by nets or picked up after they wash onto the shore.

Source: Reference 181.

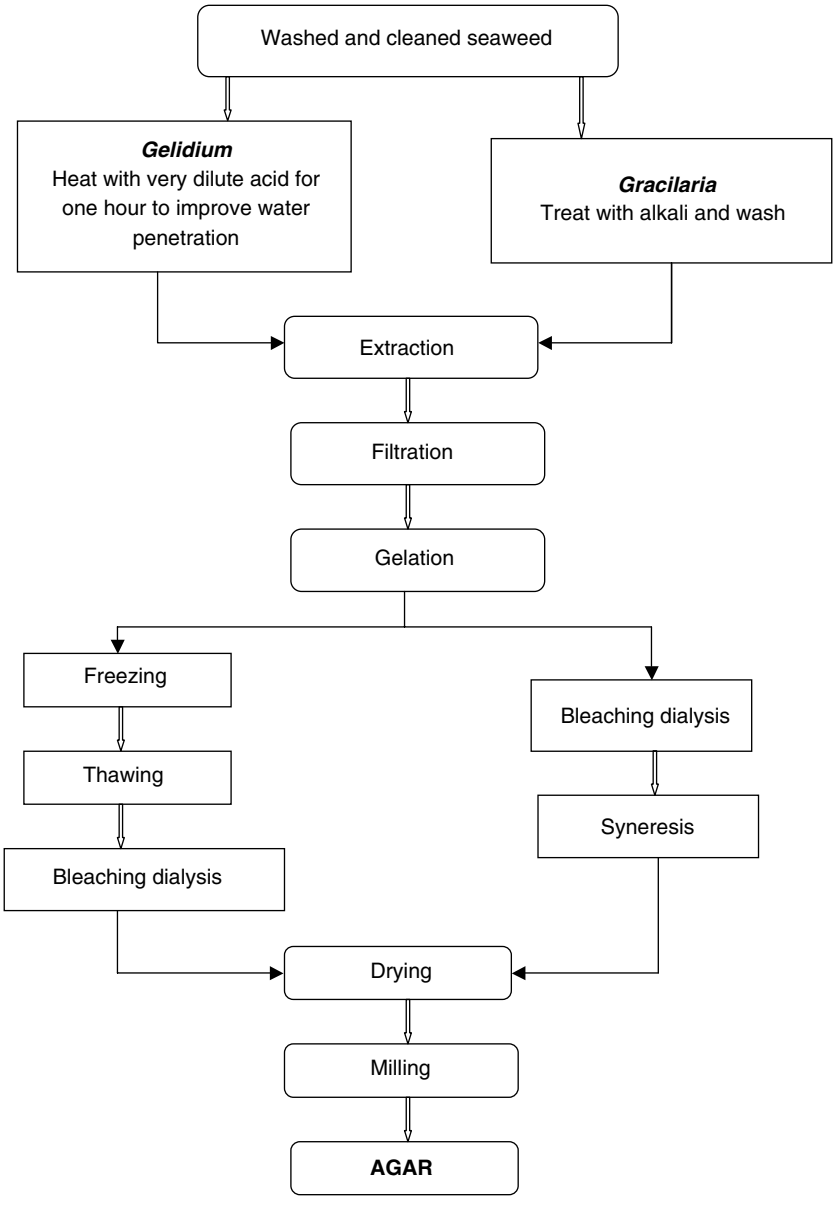

Figure 19.1 Flow chart for the production of agar (Source: Reference 181)

19.5.2.2 Extraction of Alginate

Alginate is present in the cell walls of brown seaweeds and is partly responsible for the flexibility of the seaweed. The methods used to extract alginate (192) from seaweeds are shown in Figure 19.2. The main applications of alginate are in thickening aqueous solutions and forming gels.

19.5.2.3 Food Applications

- Alginates are used to stabilize ice cream; addition of alginate reduces the formation of ice crystals during freezing and gives a smooth product.

Table 19.12
Harvesting methods for wild Alginophytes

Alginophytes	Harvesting Methods
Ascophyllum	Mechanically harvested using a flat-bottom vessel, which has rotating cutters to cut the seaweed. These are then collected with the help of nets.
Durvillaea	Collected only from storm-cast material.
Ecklonia	Collected from beach-cast seaweed.
Laminaria	Harvested using a mechanical device, the scoubidou, mounted on a boat

Source: Reference 181

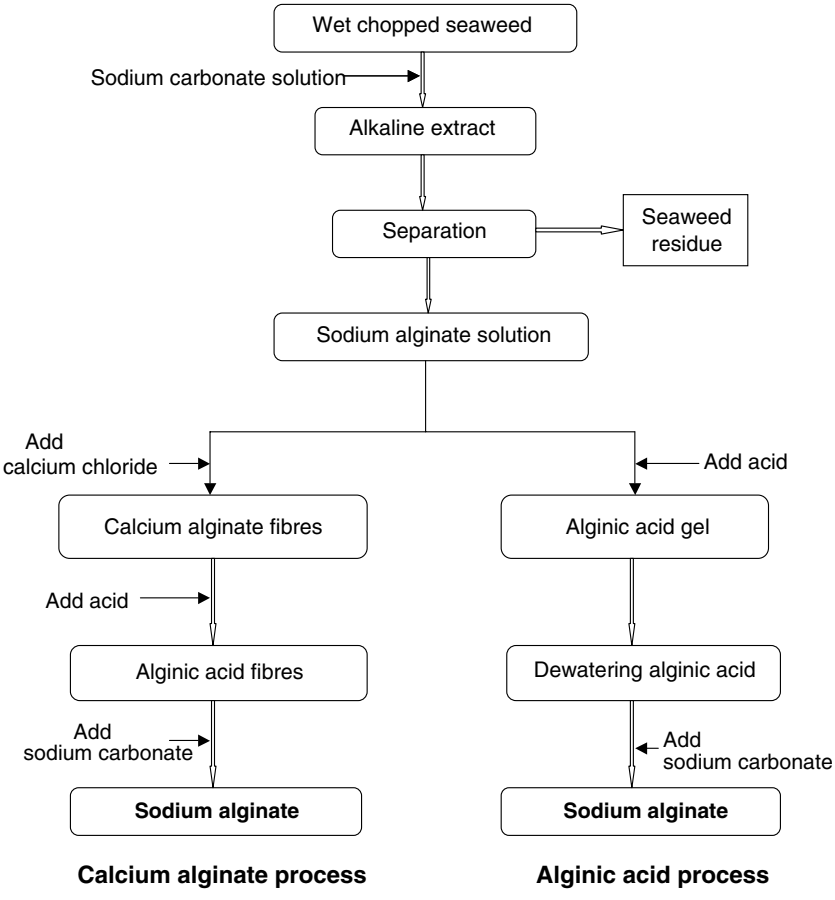

Figure 19.2 Flow chart for the production of sodium alginate (Source: Reference 181)

- Propylene glycol alginate at low concentrations provides stable, long lasting beer foam.
- Even though a large number of agents are used for the removal of off colors and to clarify wine, addition of sodium alginate is found to be effective in more difficult cases.
- Alginate–calcium mixtures are used to make edible dessert jellies; because they do not melt, alginate jellies have a different, firmer mouth feel when compared to gelatin jellies.

- Alginate gels are used in restructured or reformed food products such as restructured meat.
- Calcium alginate films and coatings have also been used to preserve frozen fish, which protects the fish from air.

19.5.2.4 Other Uses

- Calcium alginate is used to immobilize enzymes or cells.
- Good quality stable fibers produced from mixed salts of sodium and calcium alginate and processed into nonwoven fabric are used in wound dressings as they have wound healing and haemostatic properties.
- Alginic acid has also been used in some dietary foods, such as biscuits.
- Recently, oral controlled release systems involving alginate microspheres sometimes coated with chitosan to improve mechanical strength have been tested as a way of delivering various drugs.
- Crude alginate is used as a binder in salmon and other fish feeds.

19.5.3 Carrageenan

The main seaweeds used for carrageenan production are *Kappaphycus alvarezzi*, *Eucheuma denticulatum*, and *Betaphycus gelatinum.* About 120,000 dry tons/yr of *K. alvarezzi* and 30,000 dry tons/yr of *E. denticulatum* are harvested, mainly from the Philippines, Indonesia, and Tanzania.

19.5.3.1 Cultivation Methods

Kappaphycus and *Eucheuma* are cultivated by the same methods, the most popular being the fixed, off bottom line method and the floating raft method (193).

The fixed, off bottom line method is the simplest one. A suitable site is chosen and two wooden stakes are driven into the bottom about 5–10 m apart. A monofilament nylon line or a polypropylene rope 20–30 cm above the sea bottom is stretched between the stakes. Seaweed pieces (50–100 g) are tied to the line. If the site is suitable and the farming is maintained regularly, seaweed reaches 10 times its original size in 6–8 weeks, when it can be harvested.

The second method of cultivation is the floating raft method. It is suitable for protected areas where water current is weak or where water is too deep for fixed bottom lines. A floating construction is used to suspend the seaweed about 50 cm below the surface. A timber frame made of bamboo or mango timber is used with 3 mm polypropylene ropes stretched parallel in one direction between the timbers. The seedlings are tied to ropes and the raft is anchored to the bottom. Regular maintenance is required. At the time of harvest, the entire raft is removed and used as a drying rack. The harvesting methods for other carrageenophytes are given in Table 19.13.

More information on *Kappaphycus* and *Eucheuma* cultivation with useful illustrations can be found in Foscarini and Prakash (194).

There are several carrageenans, differing in their chemical structure and properties. The carrageenans of commercial interest are called iota, kappa, and lambda (Table 19.14). Their uses are related to their ability to form thick solution or gels and they vary, as will be seen.

19.5.3.2 Extraction of Carrageenan

The procedure for the extraction of carrageenan is given in Figure 19.3.

Table 19.13
Harvesting methods for other carrageenophytes

Carrageenophytes	Harvesting Methods
Chondrus crispus	Collected by hand rakes using small boats.
Betaphycus gelatinum	Harvested during may to September, where it is pulled by hand during low tide.
Gigartina canaliculata	During low tide, seaweeds are pulled from rocks by hand.
Sarcothalia crispata	Hooks are used to drag the seaweeds off the rocks.

Source: Reference 181

Table 19.14
Properties of different Carrageenans

Carrageenan	Properties
Iota	Elastic gels formed with calcium salts.
	Clear gel with no bleeding of liquid.
	Gels freeze/thaw stable.
Kappa	Strong, rigid gel, formed with potassium salts.
	Brittle gel forms with calcium salts.
	Slightly opaque gel becomes clear with sugar addition.
Lambda	No gel formation, forms high viscosity solutions.

Source: Reference 181

19.5.3.3 Food Applications

- Kappa carrageenan at 0.01–0.04% added to cottage cheese and to ice cream prevents separation of whey.
- Lambda carrageenan or a mixture of carrageenans helps improve liquid coffee whiteners by preventing separation of fat at 0.2–0.3% levels.
- Combining various carrageenans with locust bean gum, konjac flour, and starch provides a variety of melting and nonmelting gels and gel textures which can be used as suitable substitutes for gelatin.
- Mixtures of kappa and iota carrageenan are used in low or noncalorie fruit jellies.
- A combination of carrageenan and xanthan gum can be used in low oil or no oil salad dressings to help suspend herbs.
- Adding phosphates and carrageenan to low fat products helps prevent the loss of tenderness, juiciness, and flavor of such products.
- Seaweed flour (kappa carrageenan) and locust bean gum are used with meat pieces in canned pet foods.
- Apart from these applications, carrageenan gels provide a good medium for immobilizing enzymes and whole cells.

More information on applications of carrageenan can be found in Stanley (195), Therkelsen, (196) and Nussinovitch (197).

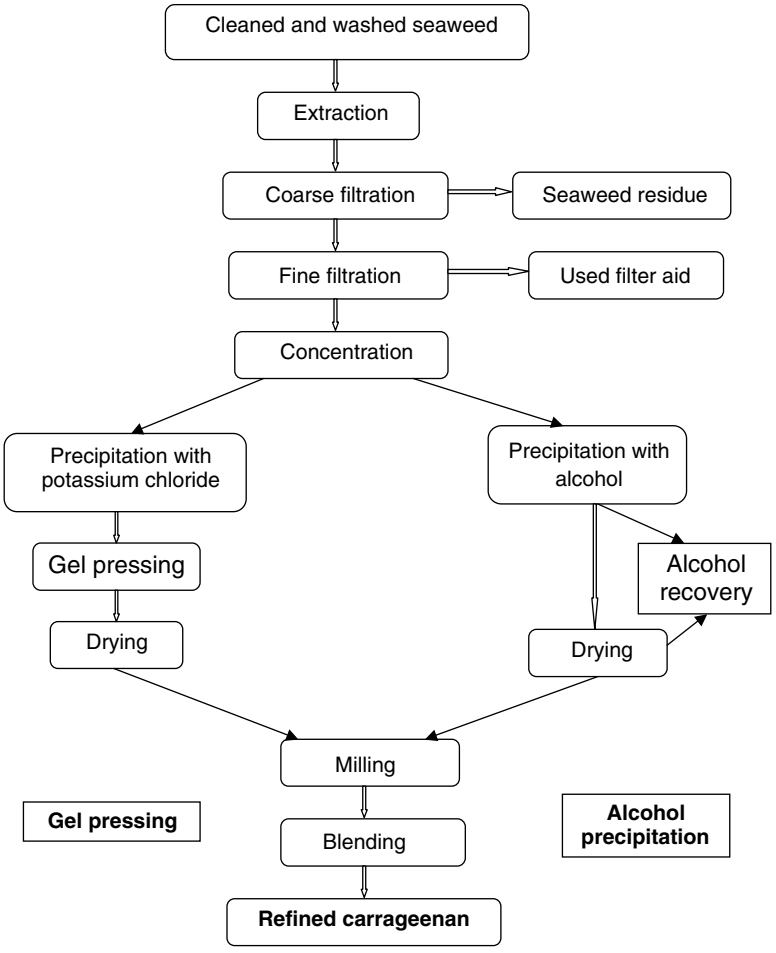

Figure 19.3 Flow chart for the production of refined carrageenan (Source: Reference 181)

19.6 SUMMARY AND FUTURE PROSPECTS

Forms of algae have been used from time immemorial as an alternative source of food. Several civilizations have adopted this efficiently, and developed recipes, which helped human beings in meeting the nutritional needs for their wellbeing. Algae were often used as a famine food by virtue of its availability under drought conditions. Persistent consumption from generation to generation established the safety of such algal food materials. The need for ensuring nutritional security has lead to the evaluation, from the point of view of essential micro- and macronutrients, of algal resources, both from fresh water and marine forms. The uniqueness of algae as a source of protein, vitamins, minerals, and essential fatty acids and health promoting substances, as well as the advancement of food science and nutrition, have thrown light on the versatility of algal forms in meeting nutritional and nutraceutical requirements of the human beings. The food chain in the ecosystem involves utilization of algal forms, which are primary producers, by the depending animal forms for their food needs. This has been extrapolated to develop a number of feed formulations for fish, crustacean, and poultry farming, which is now a flourishing industry providing fortified feed ingredients mainly in the fish and meat farming sector. From the 1970s it was

recognized that the large scale cultivation of micro and macro algal forms could lead to controlled production systems, with high quality and safety, that would provide standard food material in abundant quantity for human needs. This lead to the development of large scale production ponds for the microalgae *Chlorella*, *Spirulina*, *Dunaliella,* and *Haematococcus,* leading to the annual production of over 20,000 tons of biomass which have been used as food supplements. While *Chlorella* has been mainly used in health foods, *Spirulina* is used both as a health food and as a source of nutraceuticals such as β-carotene, vitamins, and minerals in therapeutic formulations. The health promoting qualities of algae are also being exploited for developing newer beneficial formulations for targeted applications. Microalgae such as *Dunaliella* and *Haematococcus* are also cultivated as a rich source of carotenoids, especially β-carotene and astaxanthin. Undoubtedly these algal forms are the richest source of these important dietary carotenoids, which are essential for human physiology and disease prevention. Macroalgal forms such as *Porphyra*, *Enteromorpha,* and *Eucheuma* are directly used as food, and their potential applications have not been fully exploited. Their cultivation is restricted to certain regions of the world, mainly in East Asian countries. However, the use of macroalgae for gums and thickening agents is well recognized and utilized by the food processing industries.

The newer potentials of algal forms are in the area of health foods, designer foods, and functional foods. There is need for continued effort to unravel the health benefits of algal constituents and to develop standard specifications for the products derived from them. including scientific validation of their efficacy. Designer foods for specific needs such as pediatric or geriatric formulations, including specialty foods for women and children, may be looked at from the point of view of nutritional security, especially in the developing world, where there is a demanding nutritional need. Foods for various human disorders and for the prevention of disease such as cancer, atherosclerosis, hypertension, and immunological disorders are being addressed through algal supplementation. It is necessary to ensure the quality and quantities of such identified algae and algal products. Therefore, there is need for continued research from the biochemical, nutritional, nutraceutical, pharmaceutical, and medical oriented angle. Also there is need for development of large scale production systems with the involvement of engineers for both biomass production and downstream processing. Despite the potential of algae, adequate attention has not been given for their utility and their exploitation for food uses. Future years will certainly witness tremendous advancements in both algal cultivation and utilization, especially for the health food sector.

1.20

Butanol Production from Agricultural Biomass

Nasib Qureshi and Hans P. Blaschek

CONTENTS

20.1 INTRODUCTION

The process of producing butanol by fermentation was first discovered by Pasteur in 1861 (1). Butanol fermentation, also called acetone butanol ethanol (ABE) or solvent fermentation, is one of the oldest fermentation processes, second only to ethanol (1). The typical ratio of acetone to butanol to ethanol in the final product is usually 3:6:1 with maximum concentration of total solvents being 20 g L^{-1} when using traditional strains and traditional batch fermentation processes. The low concentration of solvents is caused by end product inhibition and results in a high cost for solvent recovery using distillation. During the early part of the twentieth century this fermentation was commercially viable. However, in the 1950s and 1960s butanol and acetone produced by fermentation were unable to compete economically with petrochemically produced solvents.

Butanol, being an important industrial chemical, is produced chemically. Currently, it is produced using either the oxo process starting from propylene (with H_2 and CO over a rhodium catalyst) or the aldol process starting from acetaldehyde (2). Acetone, a coproduct of the butanol fermentation, is produced chemically either by the cumene hydroperoxide process, or the catalytic dehydrogenation of isopropanol (3). In either case, these synthetic routes have proven to be economically advantageous in comparison to the fermentation-based processes. For this reason all butanol/acetone fermentation facilities around the world have ceased operation.

In 1996 the worldwide annual production of butanol and acetone was 2.49×10^9 kg and 2.10×10^9 kg, respectively. The total production of acetone and butanol was achieved by chemical processes using petroleum-based raw materials. Since 1990, production of butanol has been constant in the USA at 1.17×10^9 kg, while worldwide butanol production has fluctuated slightly. Acetone and butanol production by regions of the world is shown in Table 20.1 (4).

Butanol has several applications in the chemical industry and as a fuel (Table 20.2). When used as a fuel butanol can contribute to clean air by reducing emissions such as

Table 20.1
World production of butanol and acetone by region

Region	Butanol (kg)	Acetone (kg)
United States	1.17×10^9	1.20×10^9
North America (Total)	1.17×10^9	1.20×10^9
South America	5.12×10^7	8.52×10^7
Europe	8.43×10^8	3.31×10^8
Asia	4.30×10^8	4.76×10^8
Total	2.49×10^9	2.10×10^9

Table 20.2
Applications of butanol and acetone

Butanol
Manufacture of dibutyl phthalate (precursor), butyl acetate (precursor), butyl acrylate (as a latex), glycol ethers, methyl butanol, and amine resins. Is an excellent fuel; used in plastic industry as a feedstock chemical; a solvent in the manufacture of oil, pharmaceuticals, and perfumes; as a solvency enhancer in the formation of nitrocellulose lacquers.
Acetone
Solvent for paints, lacquers, resins, nitrocellulose, varnishes, various processing, and cellulose acetate. Use in the manufacture of: methyl isobutyl ketone, methacrylates, methyl butanol, methyl isobutylcarbinol, isophorone, and diacetone alcohol.

Reproduced with permission from Springer-Verlag GmbH & Co. KG. (N Qureshi, HP Blaschek. ABE production from corn: a recent economic evaluation. *J. Ind. Microbiol. Biotechnol.* 27:292–297, 2001; Table 2)

unburned hydrocarbons in tail pipe exhaust. Butanol has research and motor octane values of 113 and 94 compared to 111 and 92 for ethanol (5). Some of the advantages of using butanol as a fuel have been reported in the literature (5), including a vapor pressure for pure butanol of 0.63 psi as compared to 2.25 psi for ethanol, and a heat of vaporization of 141.3 k cal kg^{-1} for butanol as compared to 204.1 k cal kg^{-1} for ethanol. Additionally, the high boiling point (118°C) and comparatively low vapor pressure of butanol may enhance cold starting. Butanol is more miscible with gasoline and diesel fuel and is less miscible with water, than ethanol. It is currently used as a feedstock chemical in the plastic industry and as a food grade extractant in food and flavor industries (Table 20.2). Because of the potential for carcinogen carryover, the use of petroleum-derived butanol is not desirable for food-based applications (6).

Oil price increases in early 1970s resulted in a revival of research activities on a number of fermentations, including butanol, ethanol, and 2,3-butanediol, with a long range view toward reducing dependence on foreign oil. As a consequence, research has focused on developing technologies to produce fuels and chemicals from easily and widely produced renewable resources including agricultural biomass. A mixed degree of success was achieved in various countries when bioconversion programs involving alcohol fuel production were examined. This resulted in partially depressed crude oil market prices, which made it clear that fuel alcohol process development research should now be directed toward resolving problems associated with the efficiency of both new and traditional processes. By 1975, Brazil had introduced its ethanol production program (7) followed in 1977 by the USA (8). By 1982 many countries had introduced similar programs, but the subsequent reduction in oil prices led to diminishing interest in fermentation derived ethanol.

In order to make butanol fermentation an economically viable option, various laboratories around the world identified the following factors to impact the economics of butanol fermentation: high cost of substrate; low product concentration (<20 g L^{-1}); low reactor productivities (< 0.5 g $L^{-1}h^{-1}$); low ABE yields (0.29–0.33); and an escalated cost for butanol recovery by distillation, which is the classical approach for solvent recovery. Additional factors such as bioreactor costs, interest rates on borrowed capital, and the rate of return on the investment were also identified as factors which affect the price of fuels derived from renewable resources (9–13).

Because corn is a major crop in the Midwest region of the United States, *Clostridium beijerinckii* BA101 (previously called *C. acetobutylicum*) was developed to hydrolyze and

utilize corn starch, and accumulate higher concentrations of butanol in the fermentation broth (6,14,15). *Clostridium beijerinckii* BA101 was developed from *C. beijerinckii* 8052. The developed culture is able to hydrolyze starch into glucose faster than it is able to utilize the glucose (16). Although most butanol producing cultures secrete amylases (starch hydrolyzing enzymes), *C. beijerinckii* BA101 has an enhanced capability to hydrolyze starch. In addition, *C. beijerinckii* BA101 produces a higher concentration of total solvents (25–33 g L^{-1}) under optimized fermentation conditions (15). In addition to corn, other renewable and economically viable substrates such as agricultural wastes, including food and fruit processing industry wastes, soy molasses (17), starch-based packaging materials (16), corn fiber hydrolysate, molasses, whey permeate, and cellulosic biomass hydrolysate can potentially be used with *C. beijerinckii* BA101 and *C. acetobutylicum* in order to produce solvents. In addition to the development of new microbial strains, techniques for improved production rates, energy efficient solvent recovery, and continuous fermentations have been developed. These developments have occurred with an eye toward using butanol in internal combustion engines (18,19). With these developments in butanol fermentation and downstream recovery we have reached a stage where fermentation derived butanol is able to compete economically with petroleum-based and chemically manufactured butanol. While the reader may be surprised to find a chapter on butanol production in a text on Food Biotechnology, the fact that agricultural food crops and derived carbohydrates obtained from those crops can be used to produce this valuable chemical by fermentation making this an appropriate topic of this book. The various problems and solutions which have been associated with this fermentation will be discussed in this chapter.

20.2 SUBSTRATES

20.2.1 Corn/Degermed Corn

Of the many substrates outlined here, two have been used on an industrial scale: corn (also called maize) and molasses. Corn contains approximately 71% starch which can be easily hydrolyzed by the butanol producing cultures. The molecular biology and genetics of substrate utilization, including starch, in *Clostridia* has been published elsewhere (20). This capability on the part of the cultures eliminates the need for a hydrolysis step which is essential for ethanol producing strains. The composition of corn is shown in Table 20.3 (21). During the ABE fermentation starch and glucose are utilized while corn fiber, protein, and oil are left behind depending on the process used for processing the corn. Pentosans and cellulosic fibers can be utilized only after hydrolysis, either by enzymatic

Table 20.3
Average composition of corn

Components	Average Composition (%)
Starch	71.1
Total sugars as glucose	2.6
Protein	9.5
Oil	4.3
Pentosans (in corn fiber)	6.2
Cellulose (in corn fiber)	3.3
Ash	1.4

Source: Reference 21

treatment, or dilute acid treatment, or a combination of both. The use of corn as substrate for this fermentation is well documented (1,22–24).

Degermed corn is obtained after removal of the germ, which contains oil. The oil content of corn is approximately 4.3% and its recovery results in substantial byproduct credit for this fermentation. However, a number of extra processing steps (soaking, grinding, fine grinding, sieving, and centrifugation) are involved in the germ recovery process as compared to the dry milling process (25). For this reason, capital costs associated with producing degermed corn are higher, which offsets the byproduct credit. Hence, corn dry milling is preferred over wet corn milling. This is consistent with the current trend in the USA toward establishment of more dry mills. Another drawback of corn wet milling is that during soaking of the corn nutrients are leached out, making the corn mash deficient in nutrients for fermentation. Hence, nutrient supplementation is required in order to produce butanol from degermed corn (26).

20.2.2 Molasses

Molasses as a fermentation substrate has many advantages over corn including easy handling and processing. Molasses contains approximately 50% sucrose. Sucrose can be hydrolyzed by solventogenic cultures during the fermentation to produce butanol. There are several types of molasses, namely blackstrap, invert (high test), and beet molasses (27). Until the early 1980s a butanol fermentation plant was operational in South Africa [National Chemical Products (NCP) Germiston, South Africa]. The process was terminated due to a shortage of molasses which was caused by drought.

20.2.3 Whey Permeate

In the past, whey permeate was considered to be a waste product of the dairy industry; however, new uses for whey permeate have changed that impression so that now whey permeate is considered a byproduct. Whey permeate has numerous applications in the fermentation industry which have been documented in the literature (28). The lactose content in whey permeate, which is the carbon source for fermentation, varies from process to process. Typically, the lactose content in whey permeate is in the range of 44–50 g kg^{-1}, making it a suitable substrate for the butanol fermentation. This is because butanol fermentation limits substrate concentration to < 60 g L^{-1} due to product toxicity. For fermentations other than butanol (i.e., ethanol or 2,3-butanediol) supplementation with additional carbohydrate is required. For details on the composition of whey permeate see Maddox et al. (28). Various types of whey permeates have been used for the production of butanol using *C. acetobutylicum,* suggesting that it is a good substrate for this fermentation. Both *C. acetobutylicum* P262, and *C. beijerinckii* BA101 have been used for butanol production from whey permeate. It should be noted that this substrate is a rich source of minerals and hence further supplementation of minerals to the fermentation medium is not required.

20.2.4 Other Butanol Fermentation Substrates

The high cost of substrates, including corn, molasses, and whey permeate, has been identified as a major factor affecting the economic viability of butanol production by fermentation (1,12,29). In order to find a solution to this problem a number of carbohydrate containing alternative substrates have been investigated. Butanol producing cultures are able to utilize a wide variety of carbohydrates such as sucrose, glucose, fructose, mannose, lactose, dextrin, starch, pentoses (xylose, arabinose), and inulin (1). Use of these carbohydrates by butanol producing cultures makes it possible to ferment byproducts and agricultural wastes to butanol. The details of some of these substrates are presented in what follows.

20.2.4.1 Soy Molasses

Spray dried soy molasses (SDSM) is a byproduct of the soy processing industry and contains 746 g kg^{-1} of carbohydrate, of which 434 g kg^{-1} is fermentable (17). The sugars that are present in soy molasses include glucose, sucrose, fructose, pinitol, raffinose, verbascose, melibiose, and stachyose (17). The fermentable sugars include glucose, sucrose, fructose, and galactose. It was determined that *C. beijerinckii* BA101 was not able to ferment raffinose, pinitol, melibiose, verbascose, and stachyose due to its inability to hydrolyze the α 1-6 glycosidic bond present in these sugars. In order to be able to use these sugars, a strain of *C. beijerinckii* BA101 should be developed with a capability of hydrolyzing α 1-6 glycosidic bonds. Development of such a strain would result in the more complete utilization of sugars present in SDSM. Figure 20.1 shows a diagram of an oligosaccharide present in soy molasses.

20.2.4.2 Agricultural Wastes

Examples of agricultural wastes include waste corn or contaminated corn, and fruit industry waste such as apple and pear drops, and apple pomace (1,16,30). A mixture of cracked corn, apple drops, and starch-containing packing peanuts (peanut shape packing material) was successfully fermented without adjusting the pH or supplementing with nutrients (16). The fruits used in this study showed significant signs of decay suggesting that such orchard wastes can be used. Apple pomace contains approximately 10% sugars which can be fermented to butanol (1). The residue which is obtained after sugar fermentation can be hydrolyzed and subsequently fermented to butanol as well. Another source of fermentation substrate is corn fiber, which can be hydrolyzed, using either enzymes or acid or both, into simple sugars followed by fermentation. Approximately 4.7×10^6 dry tons of corn fiber are produced in the USA annually (31). At the time of preparation of this manuscript authors were examining the hydrolysis of corn fiber and fermentation to butanol. Other agricultural biomasses such as corn stover (corn stalk), wheat straw, rice husks, and various grasses can become substrates for this fermentation as well. It should be noted that sugars derived from the hydrolysis of these lignocellulosics can be utilized by the solventogenic *Clostridia* (1).

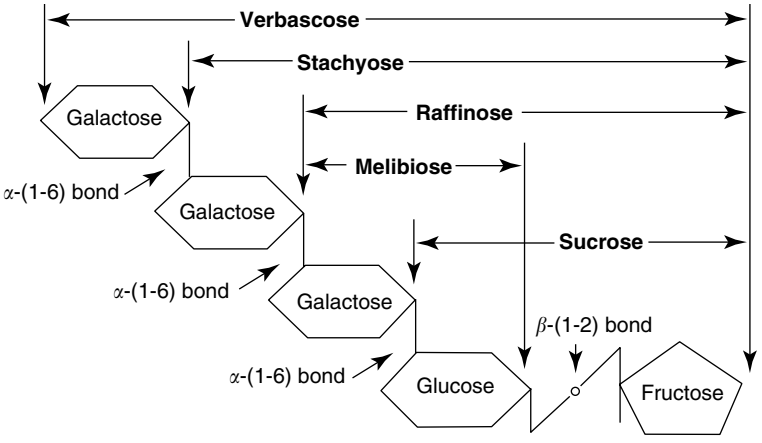

Figure 20.1 Predominant soy molasses oligosaccharides. [Reproduced with permission from Springer-Verlag GmbH & Co. KG (N Qureshi, A Lolas, HP Blaschek. Soy molasses as fermentation substrate for production of butanol using *Clostridium beijerinckii* BA101. *J. Ind. Microbiol. Biotechnol.* 26: 290–295, 2001; Figure 1)]

In the USA a significant amount of such wastes is available, which could become potential substrates for butanol fermentation and could replace conventional substrates such as corn. Direct utilization of cellulosic waste using single or mixed cultures is another possible approach for utilizing these economically available substrates for butanol fermentation. However, keeping in view the size and objective of this chapter, it is not possible to describe those processes or cultures here. For preliminary information on such processes and cultures, see Jones and Woods (1).

20.2.4.3 Jerusalem Artichokes

Jerusalem artichoke is an agricultural crop which contains the carbohydrate inulin. Use of inulin requires hydrolysis using either dilute acid or the enzyme inulinase prior to fermentation (1). Following hydrolysis, Jerusalem artichokes have been used as a fermentation substrate for producing solvents (32). The hydrolysates were prepared using inulinase and fermentation resulted in the production of 23–24 g L^{-1} solvents in 36 h.

20.2.4.4 Potatoes

Because *Clostridia* possess strong amylolytic activity (33), substrates other than corn have been considered for this fermentation. Potatoes and potato wastes are economically viable substrates which could be used for butanol fermentation. Although it has been suggested that this substrate has viscosity problems (34), both hydrolyzed and unhydrolyzed potato waste has been successfully used for butanol production using *C. acetobutylicum* or *C. beijerinckii* strains (35). An initial potato starch concentration of 45–48 g L^{-1} was used in the fermentation thereby producing up to 12 g L^{-1} ABE (35). These results were obtained with unhydrolyzed potatoes. Potato starch hydrolysis with α-amylase and amyloglucosidase prior to the fermentation resulted in the production of 11.4 and 10.4 g L^{-1} total ABE, respectively. This suggested that hydrolysis prior to fermentation was not beneficial to the fermentation. Other examples of successful butanol production from potato include that of Grobben et al. (36) who used *C. acetobutylicum* DSM 1731.

Various additional substrates that can be used for the production of butanol include sulfite waste liquors (a byproduct of the paper industry), sugar beet, wheat, rye, and oats. Sulfite waste liquor contains glucose, xylose, and arabinose which are fermentable by *Clostridia*. At the time of preparation of this chapter research is being planned on the use of other economically viable substrates such as CO_2 and distillers dry grain solids (DDGS). CO_2 is a byproduct of the ethanol and butanol fermentations. Similarly, DDGS is obtained as a byproduct of the corn dry milling ethanol industry and could be used as a substrate for butanol fermentation following hydrolysis of the cellulosics. In the USA approximately 5.10×10^9 kg of DDGS is produced each year, from which 1.93×10^9 kg of hexoses and pentoses can be obtained following hydrolysis.

20.3 UPSTREAM PROCESSING OF SUBSTRATES

The raw materials mentioned previously may require upstream processing depending upon the process being used for fermentation. Molasses requires dilution and removal of insoluble solids; whey permeate requires concentration, possibly by reverse osmosis; and corn requires removing bran, germ, and oil; milling; sieving; centrifugation; and saccharification. Table 20.4 shows the upstream process steps which may be required for the production of butanol from various substrates. The most economically viable substrate is cellulosic biomass, which requires prior hydrolysis either by dilute acid treatment or

Table 20.4
Upstream processing steps that may be required for butanol production from various substrates.

Corn
Wet Milling (germ removal): Steeping, grinding, fine grinding, sieving, and centrifugation
Dry Milling: Grinding, mash cooking
Molasses
Dilution and sediment removal by centrifugation
Whey Permeate
For batch fermentation no upstream processing is required
For integrated fermentation and product removal process: lactose concentration possibly by reverse osmosis is required
Soy Molasses
Dilution, removal of sediment and supplementation with additional carbon source is required
Jerusalem Artichokes
Cooking, mashing, sediment removal, hydrolysis with inulinase and dilution
Corn Fiber
Steam explosion, acid or enzymatic hydrolysis and possible removal of inhibitors
Potato
Cooking, mashing, sediment removal and dilution
Agricultural Waste/Biomass
Steam explosion, hydrolysis by dilute acid or enzymatic method
CO_2
Due to slow dissolution rate in aqueous solutions, rate of reaction would be slow
Distillers Dry Grain Solids (DDGS)
Steam explosion, hydrolysis with dilute acid or enzymes

enzymatic treatment or both. The acid hydrolysis method is comparatively faster than the enzymatic method; however, acid hydrolysate contains sugar degradation products which may inhibit the fermentation. Removal of these inhibitors is essential for good productivity in the fermentation. Jerusalem artichokes require hydrolysis prior to fermentation by using the enzyme inulinase.

20.4 MICROBIAL CULTURES

There are a number of cultures capable of producing significant amounts of solvents from various carbohydrates. The strain that was used for the production of solvents in large scale was *Clostridium acetobutylicum* P262. Unfortunately the plant (South Africa) was shut down due to molasses shortages caused by drought. The other strains that have been studied in the past include *C. acetobutylicum* ATCC 824, *C. acetobutylicum* NRRL B643, *C. acetobutylicum* B18, *C. beijerinckii* 8052, *C. beijerinckii* BA101, and *C. beijerinckii* LMD 27.6.

Various different species of butanol producing *Clostridia* are recognized based on the ratio and type of solvents produced. *Clostridium butylicum* produces isopropanol rather than acetone. It has been reported that *C. aurantibutyricum* produces all three solvents including

acetone, isopropanol, and butanol. *Clostridium tetanomorphum* produces equal amounts of ethanol and butanol. This culture does not produce any acetone or isopropanol 1).

A significant amount of research efforts has been made to genetically improve some of the existing cultures or isolate new solventogenic strains. Montoya et al. (37) isolated strains that produced 24.2 to 29.1 g L^{-1} total solvents. *Clostridium beijerinckii* BA101 is a strain developed from *C. beijerinckii* 8052. *Clostridium beijerinckii* BA101 has been reported to accumulate 23.5-33 g L^{-1} solvents (15,38). Attempts have been made to enhance solvent production capability of *C. acetobutylicum* ATCC 824. The newly developed strain is reported to produce 25.6 to 30 g L^{-1} solvents (39). Note that none of the parental strains produced $>$ 20 g L^{-1} solvents.

20.5 GENETICS OF CLOSTRIDIUM BEIJERINCKII

The hyper-amylolytic *C. beijerinckii* BA101 mutant was generated using N-methyl-N-nitro-N-nitrosoguanidine (MNNG), together with selective enrichment on the nonmetabolizable glucose analog 2-deoxyglucose (14). Amylolytic enzyme production by *C. beijerinckii* BA101 was 1.8- and 2.5-fold higher than that of the parent strain grown in starch and glucose, respectively. Dramatically elevated levels of butanol and acetone resulted in higher butanol and total solvent yields for hyper-amylolytic *C. beijerinckii* BA101 relative to the NCIMB 8052 parent strain when grown in P2 medium containing either 6% glucose or STAR-DRI 5 maltodextrin (6). The *C. beijerinckii* BA101 strain consistently produced on the order of 19 g L^{-1} butanol in 20 L batch fermentations. This represents an increase of more than 100% in butanol concentration by the BA101 strain when compared to the parent NCIMB 8052 strain. The kinetics of butanol production over time also indicated a more rapid rate of butanol production by *C. beijerinckii* BA101 in semidefined P2 medium containing glucose or maltodextrin. The lower levels of butyric and acetic acids produced over the course of the fermentation carried out by *C. beijerinckii* BA101 is consistent with an enhanced capacity for uptake and recycling of these acids. A low acid producing mutant of *C. acetobutylicum* designated B18 was generated following ethyl methyl sulfonate treatment (40). This mutant utilized glucose (up to 8%) more completely and accumulated less acid in batch fermentations. Enzyme assays indicated that the B18 mutant has twofold higher butanol dehydrogenase and butyraldehyde dehydrogenase activities. *C. beijerinckii* BA101 also appears to more completely utilize carbohydrate when compared to the *C. beijerinckii* NCIMB 8052 strain (6). This corresponds with the higher total butanol and solvent production by the *C. beijerinckii* BA101 strain when grown in either glucose or maltodextrin. Carbon balance following fermentation by *C. beijerinckii* NCIMB 8052 and BA101 indicates sufficient carbon is available for the twofold increase in butanol concentration observed during *C. beijerinckii* BA101 fermentations (6).

Two reports have suggested that the instability of certain solventogenic genes (*ctfA*: acetoacetyl-CoA; ctfB: acetate/butyrate CoA transferase; *aad*: aldehyde/alchohol dehydrogenase; and *adc*: acetoacetate decarboxylase) may be the cause of strain degeneration in *C. acetobutylicum* (41,42). Specifically, the genes for butanol and acetone formation in *C. acetobutylicum* ATCC 824 were found to reside on a large 210-kb (pSOL1) plasmid whose loss led to degeneration of this strain (42). Eight genes concerned with solventogenesis in *C. beijerinckii* NCIMB 8052 were found at three different locations on the genome (43). In *C. beijerinckii* NCIMB 8052, new evidence has demonstrated that the *ctfA* gene is localized on the chromosome in a solvent operon downstream from the *ald* gene and upstream from the *ctfB* and *adc* genes (44). Chen and Blaschek (44) reported that the degeneration of *C. beijerinckii* NCIMB 8052 does not involve loss of the *ctfA/B* genes, and

that degeneration is prevented by the addition of sodium acetate into the medium. It has also been demonstrated that the addition of sodium acetate increased levels of solvent production by *C. beijerinckii* NCIMB 8052 and BA101 (15,44).

Chen and Blaschek (45) also demonstrated that the specific activities and mRNA expression levels of Coenzyme-A transferase, acetoacetate decarboxylase and butyraldehyde dehydrogenase were elevated in *C. beijerinckii* BA 101 when compared to *C. beijerinckii* NCIMB 8052. Harris et al. (39) found that strain PJC4BK (pTAAD), a mutant that carries a second copy of the *C. acetobutylicum* alcohol dehydrogenase gene, produced more ethanol than the wild type strain. Similarly, increasing the dosage of *sol* operon genes in *C. beijerinckii* BA 101 may lead to increased butanol production.

Although these key enzymes in the solvent forming pathway of the hyper-butanol producing *C. beijerinckii* BA101 mutant have previously been shown to have elevated levels of activity and expression (15,44), these findings do not fully explain the metabolic activities associated with *C. beijerinckii* BA101. Because *C. beijerinckii* BA101 was produced using chemical mutagenesis (14), the molecular basis for why this strain produces enhanced levels of acetone and butanol (relative to the *C. beijerinckii* NCIMB 8052 wild type strain) is not fully understood.

Subsequently, much of the focus of our lab has been to characterize the hyper-solvent producing mutant *C. beijerinckii* BA101. Studies have shown that the mutant exhibits higher levels of expression and activities for *ptb* and the genes of the *sol* operon when compared to the wild type *C. beijerinckii* NCIMB 8052 (45). The *sol* operon and the *ptb/buk* operon from *C. beijerinckii* NCIMB 8052 and *C. beijerinckii* BA101 have been cloned and sequenced. The sequences of the structural genes from the *sol* operon, *ald*, *ctfA*, *cftB* and *adc*, have been compared and results show that the two strains are identical with respect to these genes. In addition, the regulatory regions of the *sol* operons from *C. beijerinckii* BA101 and *C. beijerinckii* NCIMB 8052 have been compared, and no differences have been found. It has been proposed that the *sol* operon is controlled directly by Spo0A (46), however, we have found no consensus sequences for Spo0A boxes in the upstream region of the *sol* operons in these organisms.

To investigate the expression of the cloned *sol* operon, constructs of the shuttle vectors pTJ1 and pTJ2 containing the *sol* operon from *C. beijerinckii* BA101 were introduced into the degenerate mutant *C. beijerinckii* SA2 (47) via electrotransformation. We have successfully restored butanol production in this strain with the constructs pTJ1*sol* and pTJ2*sol*. These plasmids were derived from the CAK1-based phagmid (48). However, southern hybridization data suggests that the replicative plasmids pTJ1*sol* and pTJ2*sol* have undergone integration events. To investigate the effect of downregulating the acidogenic enzymes phosphotransbutyrylase (PTB) and butyrate kinase (BK), we produced two nonreplicative plasmid constructs containing internal fragments of the acidogenic genes *ptb* and *buk* and electrotransformed *C. beijerinckii* BA101. Southern hybridization analysis of the putative integrational mutants showed that the constructs had not integrated at the *ptb* and *buk* target sites but elsewhere in the chromosome. Fermentation analysis is being carried out in order to see if these recombination-induced variants of *C. beijerinckii* BA101 show improved solvent production characteristics.

In addition to the study of the acidogenic and solventogenic genes in *C. beijerinckii* BA101, studies into the sugar transport by this strain have also been carried out. The increased glucose utilization by *C. beijerinckii* BA101 has been reported previously in our laboratory (6). It was observed that *C. beijerinckii* BA101 utilizes an ATP-dependent phosphorylation system to take up glucose at a rate double that of *C. beijerinckii* NCIMB 8052. This appears to allow *C. beijerinckii* BA101 to transport and utilize glucose during the solventogenic stage (49).

20.6 SUGAR TRANSPORT

Saccharolytic *Clostridia* have the capability of utilizing a wide spectrum of carbon sources for growth and are transported into the cell by a variety of mechanisms. Phosphoenolpyruvate (PEP) dependent phosphotransferase system (PTS) is the predominant transport mechanism for carbohydrates in *Clostridia* (50). The clostridial PTS has been shown to be functionally related to the PTS present in other bacteria. However, not all carbohydrates are accumulated by *Clostridia* via the PTS. By analogy with other bacterial transport systems, accumulation of some carbohydrates is likely to be driven by ion gradients or by ATP hydrolysis. Comparatively few studies examining non-PTS based transport systems have been undertaken with obligate anaerobes. Recent work in our laboratory provided evidence for an alternative glucose transport system in *C. beijerinckii* NCIMB 8052 and BA101 (49).

Glucose uptake and accumulation by *Clostridium beijerinckii* BA101, a butanol hyper-producing mutant, was examined during various stages of growth. Glucose uptake in *C. beijerinckii* BA101 was repressed 20% by 2-deoxyglucose (2-DG) and 25% by mannose, while glucose uptake in *C. beijerinckii* 8052 was repressed 52% and 28% by these sugars, respectively. We confirmed the presence of PTS associated with cell free extracts of *C. beijerinckii* BA101 by glucose phosphorylation by PEP. The PTS activity associated with *C. beijerinckii* BA101 was 50% of that observed for *C. beijerinckii* 8052. *Clostridium beijerinckii* BA101 also demonstrated lower PTS activity for fructose and glucitol (sorbitol). Glucose phosphorylation by cell free extracts derived from both *C. beijerinckii* BA101 and 8052 was also dependent on the presence of ATP, consistent with the presence of glucokinase activity in *C. beijerinckii* extracts. ATP-dependent glucose phosphorylation was predominant during the solventogenic stage when PEP-dependent glucose phosphorylation was dramatically repressed. A nearly twofold greater ATP-dependent phosphorylation rate was observed for solventogenic stage *C. beijerinckii* BA101 than for solventogenic stage *C. beijerinckii* 8052. These results suggest that *C. beijerinckii* BA101 is defective in PTS activity and that *C. beijerinckii* BA101 compensates for this defect with enhanced glucokinase activity resulting in an ability to transport and utilize glucose during the solventogenic stage.

Glucose uptake by both acidogenic and solventogenic stage *C. beijerinckii* BA101 was inhibited by proton conductors, ATPase inhibitors and non-PTS substrates in contrast with what was observed for acidogenic stage *C. beijerinckii* 8052. However, it was observed that these compounds were also potent inhibitors of glucose uptake by solventogenic *C. beijerinckii* 8052. ATP-dependent glucose phosphorylation was dramatically induced during solventogenic stage when PEP-dependent glucose phosphorylation was decreased. Approximately a twofold greater ATP-dependent phosphorylation rate was observed during all growth stages for *C. beijerinckii* BA101 versus *C. beijerinckii* 8052. These results suggest that an alternative glucose transport mechanism is present in *C. beijerinckii,* which is predominant during the solventogenic stage (51). The alternative transport mechanism together with enhanced glucokinase activity may allow *C. beijerinckii* BA101 to more completely utilize glucose in spite of a defective PTS being associated with this strain.

20.7 FERMENTATION

20.7.1 Batch Process

The most commonly studied process for butanol production is batch fermentation. As mentioned in the substrates section, a number of carbohydrates can be used for butanol

production. The upstream processing for fermentation depends upon the carbohydrate used for fermentation. The most commonly used substrates for butanol fermentation are molasses, corn, or glucose derived from corn.

The production of butanol on an industrial scale was carried out using large fermenters ranging in capacity from 200,000 to 800,000 L. The industrial process used 8–10% corn mash which was cooked for 90 min at 130–133°C. Corn contains approximately 71% starch. A schematic flow sheet for butanol production from corn is shown in Figure 20.2. Butanol production is a biphasic fermentation where acetic acid and butyric acid are produced during acidogenic phase followed by their conversion into acetone and butanol. During the acidogenic phase the pH drops due to acid production and subsequently rises during solvent production. Figure 20.3 shows the results of a typical batch fermentation process.

The use of molasses offers many advantages over using corn, including presence of essential vitamins and micronutrients (27). In industrial processes beet, invert, and blackstrap molasses were diluted to give a fermentation sugar concentration of 50 to 75 g L^{-1}, most commonly 60 g L^{-1}. The molasses solution was sterilized at 107–120°C for 15–60 min followed by adding organic and inorganic nitrogen, phosphorus and buffering chemicals. During cooling, nitrogen or carbon dioxide is swept across surface to keep the medium anaerobic. After inoculation the medium is sparged with these gases to mix the inoculum. The final solvent concentration ranged from 12 to 20 g L^{-1}. The yield of solvent is usually low, at 0.29–0.33. Distillation has been the method of choice to recover butanol; however, during the last two decades a number of alternative techniques have been investigated for the economical recovery of butanol, which will be discussed in the recovery section.

The solvent concentration that can be produced in a batch process depends upon the culture used. As mentioned in the Microbial Cultures Section, ABE on the order of 25–33 g L^{-1} can be produced in a batch process depending upon the culture used. Using newly developed *C. beijerinckii* BA101 an ABE yield of 0.45 can be obtained (6).

20.7.2 Fed-Batch Fermentation

The fed-batch fermentation is an industrial technique which is applied to processes where a high substrate concentration is toxic to the culture. In such a situation the reactor is initiated in a batch mode with low substrate concentration and low volume of medium (usually less than half the volume of the fermenter). As the substrate is utilized by the culture,

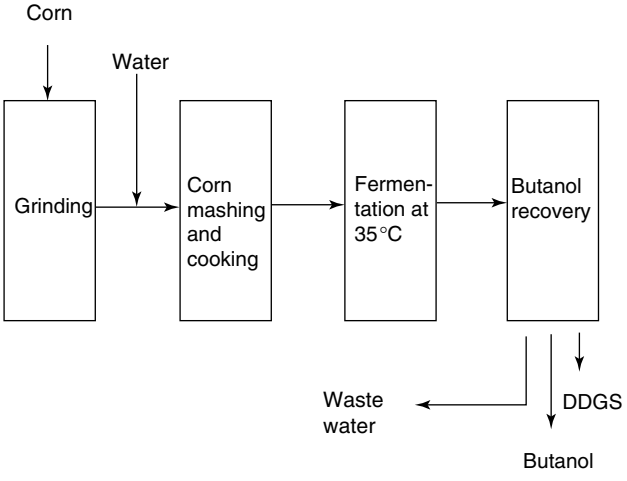

Figure 20.2 A schematic diagram of butanol production from corn by fermentation.

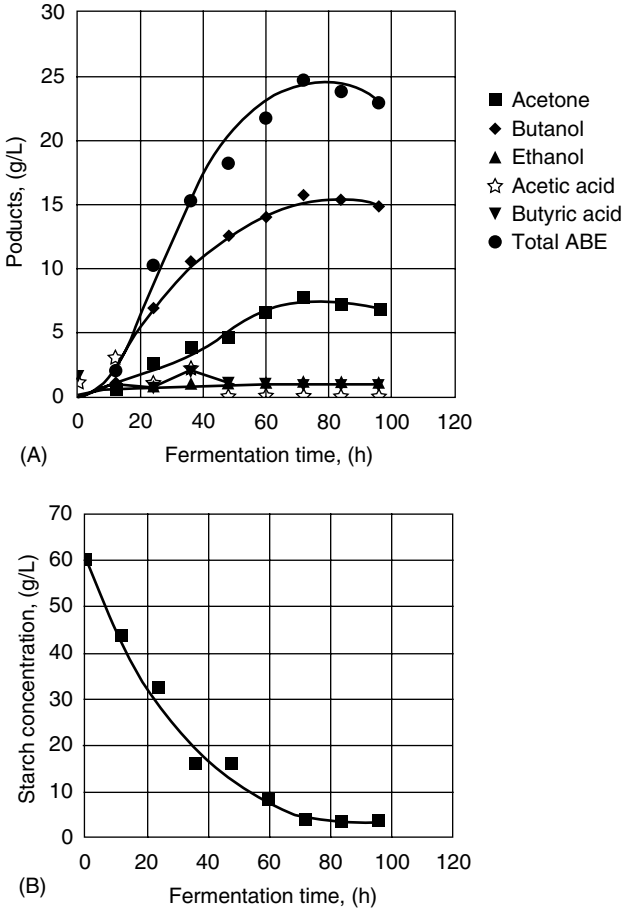

Figure 20.3 Production of butanol from corn starch by *C. beijerinckii* BA101. [Reproduced with permission from Springer-Verlag GmbH & Co. KG (TW Jesse, TC Ezeji, N Qureshi, HP Blaschek. Production of butanol from starch-based waste packing peanuts and agricultural waste. *J. Ind. Microbiol. Biotechnol*. 29: 117–123, 2002; Figure 1)]

it is replaced by adding a concentrated substrate solution at a slow rate, thereby keeping the substrate concentration in the fermenter below a level toxic to the culture. When using this approach, the culture volume increases over time. The culture is harvested when liquid volume is approximately 75% of the volume of reactor. Because butanol is toxic to *C. acetobutylicum* or *C. beijerinckii* cells, the fed-batch fermentation technique cannot be applied in this case unless one of the novel product recovery techniques is applied for simultaneous separation of the product.

20.7.3 Continuous Fermentation

The continuous culture technique may be used to improve reactor productivity and study the physiology of the culture in steady state. A number of studies exist for the continuous fermentation of butanol. Because of the production of fluctuating levels of solvents and complexity of butanol fermentation, the use of a single stage continuous reactor does not seem to be practical at the industrial scale. In continuous culture, a serious problem exists in that solvent production may not be stable for long time periods and ultimately declines over time, with a concomitant increase in acid production. In a single stage continuous

system high reactor productivity may be obtained; however this occurs at the expense of low product concentration when compared to that achieved in a batch process. In a single stage continuous reactor 15.9 g L^{-1} total solvents was produced at a dilution rate of 0.1 h^{-1} resulting in a productivity of 1.5 g L^{-1} h^{-1} (52). In order to improve the productivity the dilution rate was increased to 0.22 h^{-1}, increasing productivity to 2.55 g L^{-1} h^{-1}. However, the product concentration decreased to 12 g L^{-1}. In a more recent study a continuous fermentation was run in order to study the effect of fermentation gases and dilution rate on solvent production (53). In this system a productivity of 0.58 g $L^{-1}h^{-1}$ was obtained at a dilution rate of 0.07 h^{-1}, producing 8.3 g L^{-1} total solvents. In order to improve reactor productivity Mulchandani and Volesky (54) used a single stage spin filter perfusion bioreactor. In the perfusion bioreactor a maximum productivity of 1.14 g L^{-1} h^{-1} was obtained, however, solvent concentration fluctuated over time.

Two or more multistage continuous fermentation systems have been investigated in the attempt to reduce fluctuations and increase solvent concentration in the product stream (55–57). This is done by allowing growth, acid production, and solvent production to occur in separate bioreactors. In a two stage system, Bahl et al. (55) reported a solvent concentration of 18.2 g L^{-1} using *C. acetobutylicum* DSM 1731 which is comparable to the solvent concentration in a batch reactor. This type of multistage reactor system (7–11 fermentors in series) was successfully tested at the pilot plant and full scale plant level in Russia (then Soviet Union) (56).

20.8 IMMOBILIZED CELL BIOREACTORS

Highly productive immobilized cell bioreactors have been developed for the production of butanol. In these reactors productivities as high as 6.5–15.8 g L^{-1} h^{-1} have been achieved as compared to $<$0.50 g L^{-1} h^{-1} in batch reactors. Due to space limitations we can not describe further details of these reactors; however, a brief overview will be presented in section 11 (Butanol Fermentation Limitations).

20.9 RECOVERY

20.9.1 Distillation

The cost of recovery of butanol is high because its concentration in the fermentation broth is low due to product inhibition. In addition to the low product concentration, the boiling point of butanol is higher than water (118°C). The usual concentration of total solvents in the fermentation broth is 20–30 g L^{-1}, of which butanol is only about 13–18 g L^{-1}. This makes butanol recovery by distillation energy intensive. Phillips and Humphrey (13) evaluated the economics of butanol removal from the fermentation broth using distillation and demonstrated that, as the concentration of butanol is increased from 10 to 40 g L^{-1}, energy saving by a factor of several orders of magnitude may be achieved. At 10 g L^{-1} feed butanol the ratio of tons of oil used for fuel to the ratio of tons of 100% recovered butanol is 1.5, while at 40 g L^{-1} feed butanol concentration this ratio is 0.25. This suggests that tremendous energy savings can be achieved if the butanol concentration in the fermentation broth can be increased from 10 to 25 g L^{-1}.

In order to economize butanol recovery, a number of recovery techniques have been investigated including *in situ* gas stripping, pervaporation, liquid–liquid extraction, perstraction, and reverse osmosis. Details of these techniques have been described elsewhere (58–59).

Any of these techniques can be applied for *in situ* butanol removal, removing butanol simultaneously as it is produced. The objective is to prevent the butanol concentration from increasing above the tolerance level of the culture. The product is subsequently recovered either by condensation (gas stripping and pervaporation) or by distillation (extraction).

20.9.2 Gas Stripping

Gas stripping is a simple technique for recovering butanol (and acetone and ethanol) from the fermentation broth (60). Nitrogen or fermentation gases (CO_2, H_2) are bubbled through the fermentation broth followed by passing the gas through a condenser. As the gas is bubbled through the fermenter it captures solvents which are condensed in the condenser followed by collection in a receiver. Once the solvents are condensed the gas is recycled back to the fermenter to capture more solvents. This process continues until all the sugar in the fermenter is utilized by the culture. In some cases a separate stripper can be used to strip off solvents followed by recycling the stripper effluent that is low in solvents. Figure 20.4 shows a typical schematic diagram of solvent removal by gas stripping. Gas stripping has been successfully applied to remove solvents from batch (61), fed-batch (62), fluidized bed (63), and continuous reactors (64,65). In addition to removal of solvents, a concentrated sugar solution was fed to the reactor to reduce the volume of process streams and economize the butanol production process (62,63,65).

20.9.3 Pervaporation

Pervaporation is a membrane-based process which is used to remove solvents from fermentation broth by using a selective membrane (58,59). The liquids or solvents diffuse through a solid membrane leaving behind nutrients, sugar, and microbial cells. The concentration of solvents across the membrane depends upon membrane selectivity, which is a function of feed solvent concentration, and membrane composition. Application of pervaporation to batch butanol fermentation has been described by Groot et al. (66), Larrayoz and Puigjaner (67), and Qureshi and Blaschek (68). Pervaporation has also been applied for the removal of butanol from the fermentation broth in fed-batch reactors (69,70). In fed-batch reactors a concentrated sugar solution is used to reduce the process stream volume. It is interesting to note that acids did not diffuse through the membranes used by these authors. Qureshi et al. (71) used a polypropylene membrane through which acids diffused, though at high acid concentration in the fermentation broth.

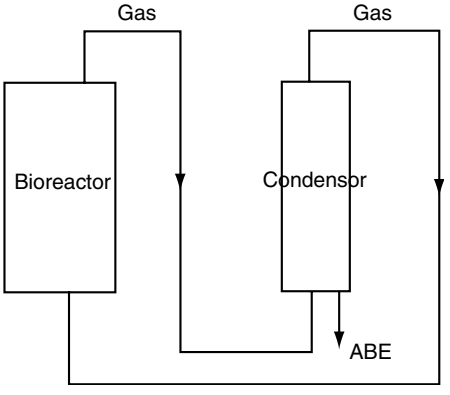

Figure 20.4 A schematic diagram of butanol production by fermentation and recovery by gas stripping.

The use of a liquid membrane, rather than a solid membrane, has been described by Matsumura et al. (72). The oleyl alcohol containing liquid membrane was supported on a microporous 25 mm thick flat polypropylene sheet. The liquids which diffused through the membrane showed a selectivity of 180 as compared to silicone membrane selectivity of approximately 45. It was estimated that if this pervaporation membrane was used as a pretreatment process for butanol separation, the energy requirements would be only 10% of that of conventional distillation. Unfortunately, this was not a stable membrane.

In order to develop a stable and high selectivity membrane, silicalite, an adsorbent was included in a silicone membrane (73). The selectivity of the silicone-silicalite membrane was improved from approximately 40 to 209. The working life of the membrane is 3 years. The membrane was used with both butanol model solutions and fermentation broths. A comparison of various membranes suggested that this membrane may be superior to other membranes (74).

20.9.4 Liquid–Liquid Extraction

Liquid–liquid extraction is another technique which can be used to remove ABE (acetone, butanol, and ethanol) from the fermentation broth. In this process an extraction solvent is in contact with the fermentation broth (58). Butanol, acetone, and ethanol are diffused into the extraction solvent and recovered by back-extraction into another extraction solvent or by distillation (75). The basic requirements have been presented by Maddox (58), Mattiasson and Larsson (76) and Ennis et al. (77). Some of the requirements for extractive butanol fermentation are:

1. Nontoxic to the producing organism
2. High partition coefficient for the fermentation products
3. Immiscible and nonemulsion forming with the fermentation broth
4. Inexpensive and easily available
5. Can be sterilized and does not pose health hazards.

An early report on the application of extractive butanol fermentation was that described by Wang et al. (78) who used corn oil as an extraction solvent and reported an increase in butanol production in repeated batch fermentations. Since that time there have been many reports on the use of various extraction solvents for extractive butanol fermentation (58). Of the many extraction solvents reported in literature, oleyl alcohol appears to meet some of the requirements, and it has been a subject of a number of investigations (75,79,80). Roffler et al. (80) were successful producing butanol in an extractive fed-batch fermentation using a sugar solution containing 339 g L^{-1} glucose.

Extractant toxicity is a major problem with extractive fermentations. In order to avoid the toxicity problem brought about by the extraction solvent, some investigators have used a membrane to separate the extraction solvent from the cell culture (81,82). Eckert and Schugerl (82) used a microfiltration unit in order to separate bacterial cells producing butanol from the extraction solvent (decanol). In this process, a continuous fermentation cell recycle system was used. The fermentation broth was circulated through the membrane and the cells were returned to the fermenter, while the permeate was extracted with decanol to remove the butanol. In this system a productivity of 3.08 g L^{-1} h^{-1} was achieved. In cell recycle systems, without extraction, productivities as high as 6.5 g L^{-1} h^{-1} have been achieved. Compared to this productivity a productivity of 3.08 g $L^{-1}h^{-1}$ is low, however, it is difficult to compare the two systems unless the biomass concentration and fermentation parameters are presented.

Another approach for reducing the toxicity and improving the partition coefficient has been to mix a high partition coefficient, high toxicity extractant with a low partition coefficient and low toxicity extractant (83). The resultant mixture is an extractant with a high partition coefficient and low toxicity. At this time research is underway in the authors' laboratory on the extractive recovery of butanol from the fermentation broth of *C. beijerinckii* BA101. In integrated extractive fermentations, oleyl alcohol forms an emulsion when agitated at high speed to improve rate of removal of butanol.

20.9.5 Other Recovery Techniques

The prominent recovery techniques that have been used in the ABE fermentation have been presented. In addition to these techniques, adsorption (58,84), reverse osmosis (85), and aqueous two phase extraction (58,76,86) have also been used; with, however, lower success due to limitations associated with these techniques.

20.10 BUTANOL FERMENTATION LIMITATIONS

The major problems with the butanol fermentation are product inhibition due to solvent toxicity, use of dilute sugar solutions, low ABE yield, low reactor productivity, and uneconomical product recovery. In the butanol fermentation a maximum solvent concentration of 25–30 g L^{-1} is rarely attained (69). The fermentation broth contains approximately 970–980 gL^{-1} water to be removed in order to separate the solvents. Therefore, simultaneous recovery should be an essential part of this fermentation process using one of the novel techniques mentioned. Use of one of the novel product recovery techniques allows for concentrated feed streams in addition to efficient product recovery, thus benefiting the fermentation process. An alternative approach would be to develop a superior culture which could produce solvents at higher concentrations. However, there has been limited success with this approach leaving *in situ* or in line removal as the only viable options. In addition, in line or *in situ* recovery techniques eliminate the use of dilute feed solutions. Those approaches have been applied in batch (68,87), fed-batch (69), and continuous (63,88) fermentations.

Another major problem associated with the ABE fermentation is low ABE yield. In most fermentations, an ABE yield of 0.3–0.45 g g^{-1} is achieved with the release of the rest of the carbon (approximately 53%) to the environment in the form of CO_2 gas. In addition, H_2 gas is also released, which is a loss of energy. It is suggested that H_2 be separated from CO_2 using a membrane and used as a fuel. Currently, the authors are investigating the conversion of CO_2 gas to butanol to improve solvent yield. Low butanol yield adversely affects butanol price (Figure 20.5).

Another problem with the ABE fermentation has been the low reactor productivity when batch fermentation is employed. In a batch reactor, productivity on the order of $<$0.50 g L^{-1} h^{-1} is achieved. In order to improve reactor productivity, continuous immobilized cell reactors (63,89–91) or cell recycle reactors (57) have been developed. In these reactors, productivities as high as 6.5 to 15.8 g L^{-1} h^{-1} have been achieved as compared to batch reactor productivity of approximately 0.50 g L^{-1} h^{-1} or less.

Substrate cost is another factor which significantly influences the price of butanol (Figure 20.6) (29). For this exercise a corn price of \$73 ton^{-1} was taken into consideration as a base case scenario. A cheaper substrate would likely reduce the cost of butanol. However, this also depends on upstream processing of the substrate and the processes that can be applied for fermentation and recovery.

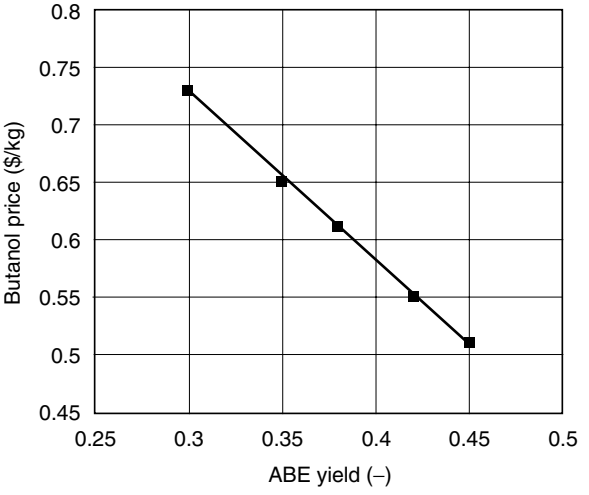

Figure 20.5 Effect of ABE yield on butanol price. [Reproduced with permission from Institution of Chemical Engineers (N Qureshi, HP Blaschek. Economics of butanol fermentation using hyper-butanol producing *Clostridium beijerinckii* BA101. Trans IChemE, Part C, 78:139–144, 2000; Figure 3)]

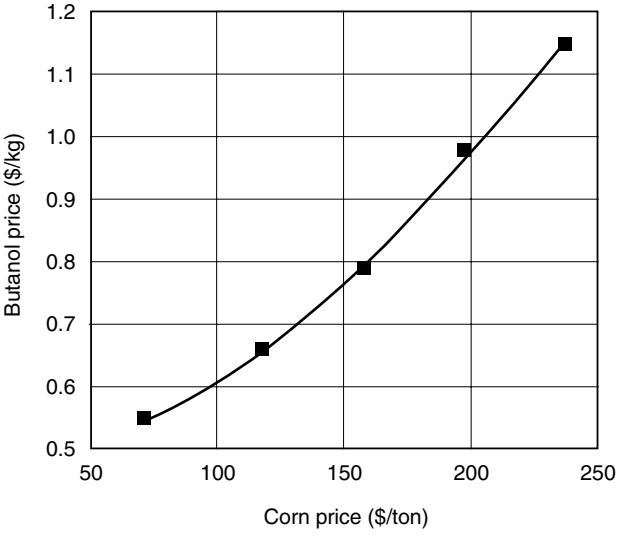

Figure 20.6 Effect of corn price on butanol price. [Reproduced with permission from Institution of Chemical Engineers (N Qureshi, HP Blaschek. Economics of butanol fermentation using hyper-butanol producing *Clostridium beijerinckii* BA101. Trans IChemE, Part C, 78:139–144, 2000; Figure 2)]

The economic recovery of butanol plays a major role in determining the price of butanol (29,92). However, at this stage it appears that integrated product recovery plays an important role in the economics of the butanol fermentation.

20.11 INTEGRATION OF FERMENTATION AND RECOVERY

The major problems associated with butanol fermentation have been uneconomical product recovery, and the use of dilute sugar solution (usually 60 g L^{-1} for batch fermentation),

which results in a large reactor and process stream volumes thereby making butanol fermentation noncompetitive when compared to butanol obtained from petrochemical sources. Simultaneous recovery and fermentation when using novel recovery techniques have solved these problems because concentrated sugar solutions (130–350 g L^{-1}) can be used in combination with economic product recovery systems (62,63,68–71). Product recovery techniques such as gas stripping, pervaporation, and liquid–liquid extraction have been applied to high productivity reactors (63,93,94) thereby making butanol fermentation and recovery much more attractive. These reactors offer the advantages of high productivity, use of concentrated sugar solutions, reduction in reactor size, and efficient recovery of product. With these developments only a few problems remain with the butanol fermentation (i.e., low ABE yield). It is anticipated that with the recent developments in integrated fermentation and recovery, the butanol fermentation would be closer to commercialization. Using batch fermentation and distillative recovery the butanol price is estimated to be \$0.55 kg^{-1}, while using integrated technology it is estimated to be \$0.12–0.37 kg^{-1} which is competitive to petrochemically derived butanol. Figure 20.7 shows a schematic diagram of integrated butanol fermentation and recovery process. In a continuous butanol fermentation and product recovery experiment 460 g L^{-1} (reactor volume) total ABE was produced from 1163g L^{-1} (reactor volume) total sugar as opposed to 20–25 g L^{-1} ABE from 60 g L^{-1} sugar in a nonintegrated batch fermentation. Integration of fermentation and product recovery makes the butanol fermentation economically more attractive.

20.12 PROBLEMS OF COMMERCIALIZATION AND FUTURE DEVELOPMENTS

In a recent independent study on butanol commercialization conducted at the College of Commerce at the University of Illinois (Urbana, IL), it was determined that fermentatively produced butanol is competitive with petrochemically derived butanol. This is because of the use of integrated process technology in combination with *C. beijerinckii* BA101 which can produce 25–33 g L^{-1} total ABE in batch process. However, it is anticipated that petrochemical industries would reduce price of butanol in an attempt to prevent the fermentative production of butanol from being successful. Currently, petrochemical industries have

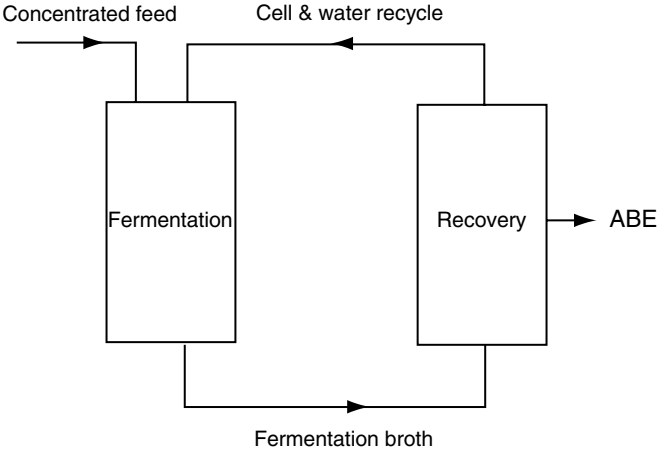

Figure 20.7 A schematic diagram of integrated production of butanol.

a monopoly with respect to butanol market. We suggest that researchers should focus on the following problems.

Although butanol fermentation is more economically competitive today than it was two decades ago, certain problems still remain to be resolved. These include the development of a superior culture that is able to produce elevated levels of butanol. Along these lines attempts have been made, but with limited success. *Clostridium beijerinckii* BA101 and *C. acetobutylicum* PJC4BK are examples of two strains that have been modified to produce elevated levels of solvents. However, the maximum level of solvents that these strains can produce is on the order of 25–33 g L^{-1} which is still low from a product recovery point of view. Another problem is the low ABE yield. Due to the release of CO_2 and H_2 approximately 53% of the substrate is lost in the form of these gases. An improvement in yield would further economize the production of butanol. Alternately, CO_2 could be captured and converted to acetone and butanol. At this time authors are studying the conversion of these gases to solvents.

Another problem with butanol fermentation is the inability of these cultures to use the sugars derived from economically available substrates such as corn fiber hydrolysate (95). As with corn fiber hydrolysate, it is anticipated that sugars derived from hydrolysed corn stalks, wheat straw, and rice husk could not be utilized without pretreatment of these substrates, which would add to the cost. In order to meet these challenges new strains capable of utilizing agricultural biomass derived sugars should be developed. Alternately, economic methods capable of removing inhibitors from the hydrolysates should be developed. Simultaneous saccharification and fermentation is another approach that should be considered.

20.13 BUTANOL FERMENTATION WASTE AND BYPRODUCTS

In the traditional butanol fermentation plants a number of byproducts and waste streams were generated, including a large waste water stream, waste cell mass, and CO_2 and H_2 gases. However, due to recent developments in bioreactor design, process integration, and recovery technology the size of some of these streams has been reduced significantly. As mentioned, the application of process integration allows for the use of concentrated sugar solutions thereby enabling the recycle of water and a reduction in waste disposal streams. Recycling the waste water stream allows for economic benefits in addition to being environmentally friendly. Use of highly productive reactors permits biomass (cell mass) reuse, thereby reducing waste biomass. However, the biomass that is generated can be used as an animal feed. Hydrogen gas can also be separated from the mixture of CO_2 and H_2 and used as an excellent fuel. CO_2 can be recycled either as a substrate (which is under investigation) or sold as a gas for other applications.

ACKNOWLEDGMENTS

N. Qureshi and H. Blaschek would like to thank Michael A. Cotta (United States Department of Agriculture, National Center for Agricultural Utilization Research, Peoria, IL) for reading this chapter and making valuable suggestions.

Methods in Plant Tissue Culture

Hector G. Nunez-Palenius, Daniel J. Cantliffe, Harry H. Klee, Neftali Ochoa-Alejo, Rafael Ramirez-Malagon, and Eugenio Perez-Molphe

CONTENTS

1.1 INTRODUCTION

For thousands of years people have benefited from the things provided by the higher plants, things such as food, building materials, dyes, fragrances, and medicines. As human beings domesticated plants, they were able to take advantage of plant genetic resources, leading to assorted varieties and cultivars of plants that helped feed, cloth, and shelter people. Nevertheless, world population has risen considerably during the last century, compromising worldwide food reserves. Agriculture is expected to feed an increasing human population, forecast to reach 8 billion by 2020 (1).

Plant biotechnology could present feasible alternatives which could greatly help overcome the risks of food shortages. Within the plant biotechnology discipline, plant tissue culture methods have played an essential role, allowing the development of transgenic plants with a number of desirable agronomic and food traits. What is plant tissue culture? The common understanding is that the term "plant tissue culture" generally refers to *in vitro* cultivation, on nutrient media, of any plant component, under a sterile environment. The plant component may be a single cell, tissue, or an organ. The result may be an entire *de novo* regenerated plant, or the utilization of the plant tissue culture technique to further research in plant biology.

1.2 HISTORY

The first recorded attempt at plant tissue culture was in 1902, when Haberlandt (2) placed epidermal, pith parenchyma, and palisade cells of monocotyledons in culture containing various sugars, inorganic salts, and amino acids. None of the cells divided. The first successful attempt at tissue culture was recorded in 1904, when Hannig (3), using similar media, was able to grow whole plants from embryos.

During the next two decades, work centered on improving embryo culture techniques. It was found that several complex additives, like yeast extract, coconut milk, and peptone, greatly stimulated growth. In 1934, White (4) placed excised tomato root tips in culture. When yeast extract was added to the medium, the roots were able to divide and grow indefinitely.

In 1936, Brown and Gardener found that tumors, similar to the tumors induced by crown gall bacteria, could be mimicked by exogenous auxin applications. This information was quickly applied to tissue culture. In 1939, Gautheret (5), Nobecourt (6), and White (7) each independently demonstrated that auxin indoleacetic acid, when incorporated into culture media, stimulated the production of undifferentiated callus. This was the first time hormones were added to tissue culture media. In 1956, Miller and others (8) discovered that the active ingredient in coconut milk and yeast extract which promoted growth in culture was a new class of hormones, called cytokinin. Skoog and Miller (9) further reported in 1957 that the auxin–cytokinin balance was very important for growth of cells in culture. If auxin levels were relatively high and cytokinin level relatively low, undifferentiated callus growth occurred. High levels of cytokinin relative to auxin induced the appearance of differentiated shoots. Thus, it became possible to regenerate a whole plant from a single undifferentiated cell.

In 1962, Murashige and Skoog (10) published the details of a distinct medium with high NH_4 levels, for tobacco cells; a paper most commonly cited in publications regarding tissue culture. This medium has given excellent results with both monocot and dicot species. A further advance came in 1964 when Guha and Maheshwari (11) placed Datura anthers in culture. From these anthers, embryoids formed which developed into haploid plants. Tissue cultures of haploid plants were a major advance for genetic studies. Vasil and Hildebrandt (12) were able to regenerate a whole plant from single tobacco cells, using a micro-culture method with fresh medium, enriched with coconut water.

In 1971, Takebe et al. (13) demonstrated that it was possible to regenerate whole plants from protoplasts. Protoplasts are plant cells without cell walls, usually produced by incubating tissue in crude cellulolytic preparations. The first somatic hybrid plant was produced in 1972, when Carlson and colleagues (14) fused protoplasts from two tobacco species and regenerated the hybrid cell into a whole plant.

In 1974, Zaenen et al. (15) discovered that a plasmid (Ti plasmid) in *Agrobacterium tumefaciens* was responsible for inducing tumors in crown gall-infected plants. Through the use of mutants, Ooms et al. (16) demonstrated that genes on the Ti plasmid affected a host plant's auxin–cytokinin balance, showing that one gene controlled auxin metabolism and other the cytokinin metabolism. In 1983, the first example of the expression of a foreign protein in a plant cell was demonstrated by Fraley and others (17). They inserted into the Ti plasmid a gene for kanamycin resistance. Resultant petunia and tobacco cells infected with this hybrid Ti plasmid were resistant to the bactericide kanamycin. In 1984 Horsch et al. (18) reported that the transformed cells were regenerated into whole plants and that the kanamycin-resistant gene was inherited as a single gene dominant trait. Genetic engineering was no longer a dream, thanks to plant tissue culture methods.

Throughout the last 70 years, plant tissue culture methods have evolved dramatically. Many techniques and methods have been developed since Haberlandt's early attempts. This technology has now been used for plant propagation, embryo culture, haploid production, germplasm conservation, mutant production, hybridization, or cell fusion, developmental studies, and metabolic studies, including secondary metabolites. Tissue culture technology has had a tremendous impact in both basic and applied plant science.

1.3 LABORATORY OPERATIONS

1.3.1 Laboratory Facilities

To design any type of facility for plant tissue culture operations, either small or large, the most important consideration must be organization and sanitation. The success of sanitation procedures requires proper work techniques by the operator as well as the correct design of the

facilities used for tissue culture. Street (19) has recommended that individual module facilities should be prearranged as in a production line. As Wetherell (20), and Kyte (21) pointed out, any plant tissue culture facility must have three main basic areas (laboratory, transfer room, and culture room) and must be designed to provide proper aseptic conditions. Windows and doors should be sliding, in order to avoid air currents that could carry spores, vegetative cells, or other reproductive structures of bacteria or fungi. On the other hand, several authors (22,23) have considered plant tissue culture facilities equipped with up to 10 different rooms. Explicit plant tissue culture laboratory designs, material, tools, and equipment can be found in Street (19), Wetherell (20), Kyte (21), George (23), and Gamborg and Phillips (24).

1.3.2 Sterile Techniques

As previously pointed out, the preservation of sterile conditions is critical for successful tissue plant culture procedures. All media, instruments, tools, and culture vessels must be sterilized to remove all contamination. Contamination may be due to bacteria, yeast, virus, or fungi. Nevertheless, in some cases even mites [(20), RM Rangel, personal communication, 1997] or thrips (24) can thrive in the moist environment of plant tissue cultures, causing disastrous contaminations.

Sterilized plant material, nutrient media, equipment, and tools must be handled using strict aseptic practices. Culture manipulation could be carried out on an open laboratory bench, but this is a very unsafe course of action because of increased chances for contamination. For this reason culture manipulations are done in a transfer room with air flow cabinets (Figure 1.1). The transfer room is an undersized space within the building, which is sterilized by ultraviolet irradiation lamps, used when workers are not present. Air is

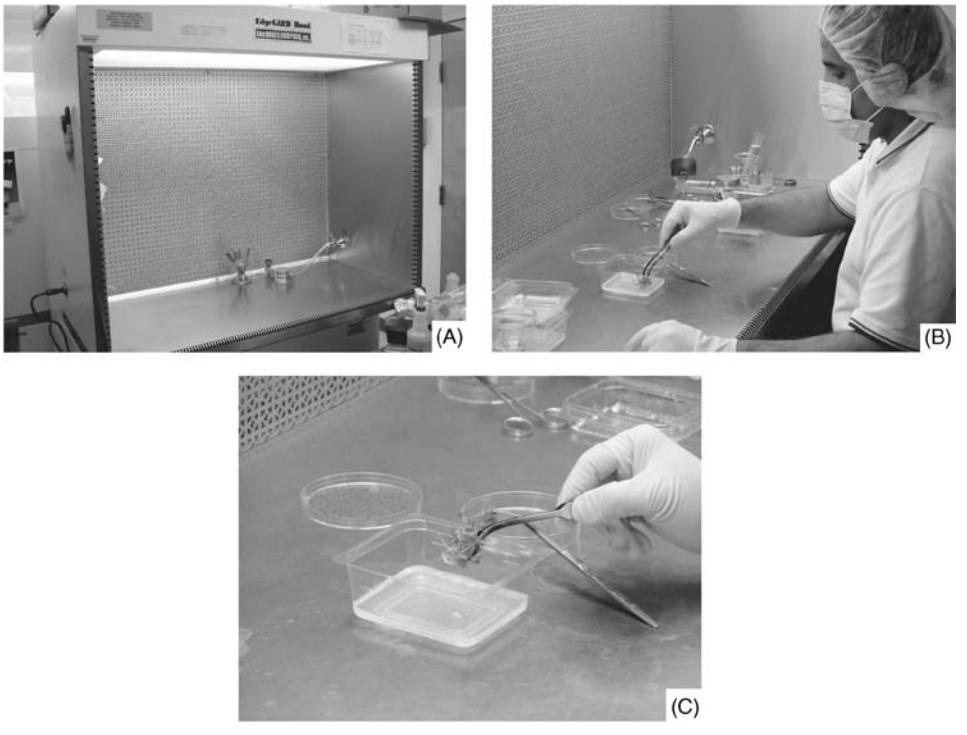

Figure 1.1 Laminar air-flow cabinet for *in virto* culture. **A**, ready for use. **B** and **C**, in use for strawberry micropropagation. (**B** and **C** courtesy of Yousef Dlaigan).

cleaned via a filter system. Laminar air flow cabinets are more common and more popular than transfer rooms, mostly because they are less expensive, easier to maintain, and safer, as they do not require UV lamps. There are two basic types of laminar air-flow cabinets, both equipped with a high-efficiency particulate air (HEPA) filter; vertical-air-flow and horizontal-air-flow. The former model seems to provide a better and more continuously sterile environment (25).

Methods of sterilization may be classified as dry heat, moist heat, radiation, microwaves, membrane filtration, and chemical. These sterilization procedures can be applied in sterilization of media and containers and in preparation of axenic or sterile explants (26).

Dry heat is used most with metal instruments, glassware, and other nonorganic materials able to tolerate high (180°C) temperatures, with no presence of moisture (Figure 1.2A). On the other hand, moist heat, steam sterilization, and autoclaving are commonly used to sterilize

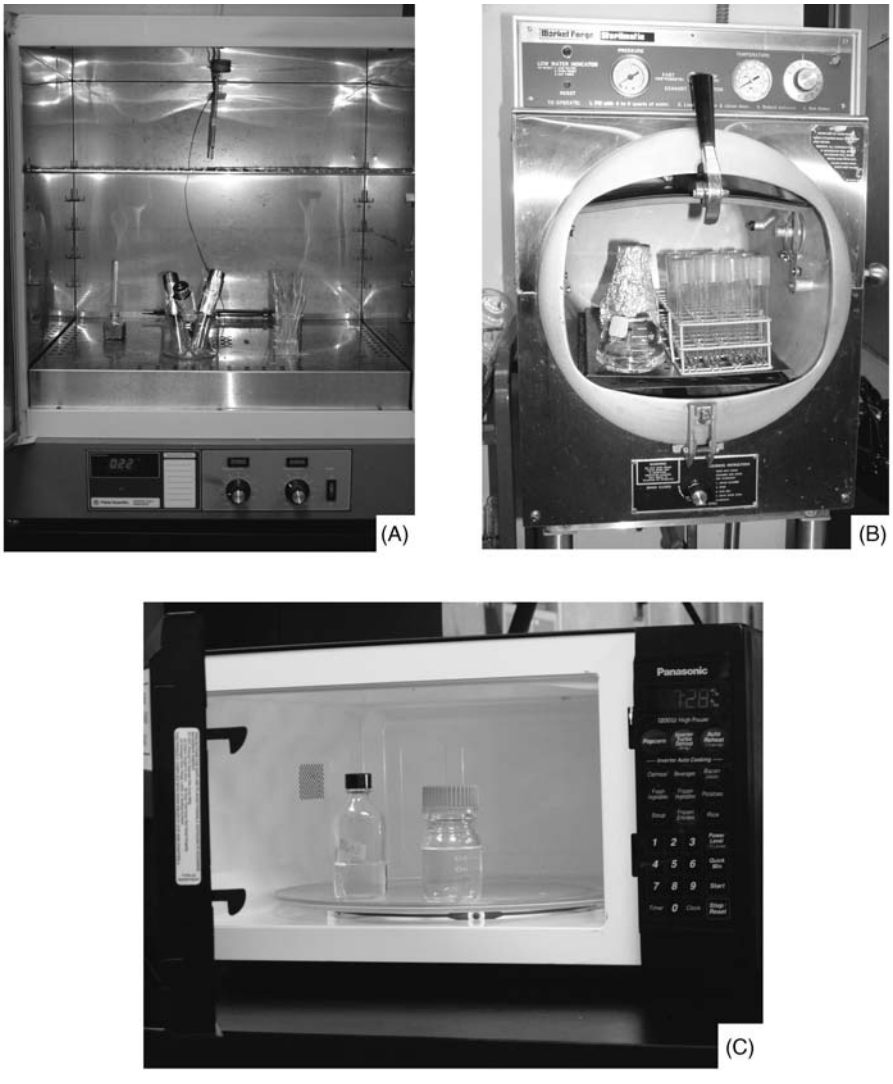

Figure 1.2 **A** Oven for dry-heat sterilization. **B** Autoclave for moist-heat sterilization. **C** Media-microwave sterilization.

nutrient media, distilled water, paper products, heat tolerant plastic ware, and contaminated material. A constant pressure of 1.06 kg cm^{-2} (105 kPa) and 121°C (250°F) for 15–20 minutes usually kills most living tissue (Figure 1.2B). Gamma (γ)-irradiation (radiation) is most frequently used with plastic materials, using a viable irradiation plant. Media microwave sterilization (Figure 1.2C) can be completed utilizing commercial microwaves, though the correct conditions for obtaining sterility have to be empirically obtained (27). Membrane filtration or microfiltration is a simple procedure easily achieved using Millipore membranes of 0.025–0.45 μm pore size and a syringe (Figure 1.3A). This method is generally useful for thermosensitive substances, such as vitamins, plant growth regulators, and complex organic additives, among others. Chemicals may be used on plant materials. Ethanol (70–80% concentration) is used for flaming metallic tools and to disinfect the air flow cabinet (Figure 1.3B).

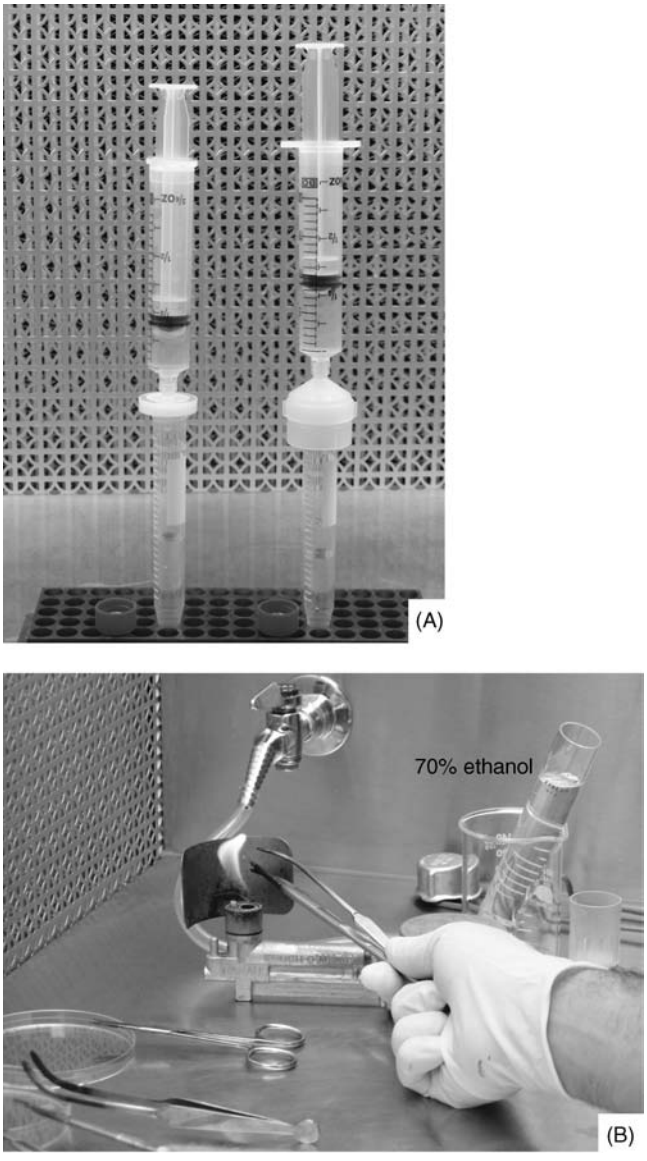

Figure 1.3 **A** Membrane sterilization by microfiltration. **B** flaming metallic tools.

Plant or explant surface sterilization may be achieved using a number of chemical substances. Table 1.1 depicts several chemicals regularly used in plant material surface sterilization, although the most appropriate chemical agent, its concentration, the sequential combination of agents, and the length of sterilization must be determined empirically for different plant materials.

1.3.3 Media Composition, Preparation, and Handling

Plant cells, tissues, and organs only have normal *in vitro* growth when supplied with nutrients and the appropriate environmental conditions. Moreover, different cells, tissues, and organs will have varying nutrient requirements: thus, there is no one single medium competent to sustain growth for all types of *in vitro* cultures. As a result, the best nutrient media for any specific cell, tissue, or organ generally has to be determined by trial and error. Nonetheless, related plant cell genotypes will have similar needs, reducing the size of preliminary experiments. Numerous formulations have been published for several types of tissues and are able to sustain good *in vitro* plant growth with diverse tissues.

A suitable plant culture medium must contain at least the known essential inorganic salts (macro- and micronutrients) in proper balance, as well as a carbon source for energy, frequently sucrose. In addition, the medium should contain water soluble vitamins and one or more plant growth regulators, because plant cells are heterotrophic when they are cultured *in vitro*. Organic nitrogen, organic acids, and complex extracts such as coconut water, casein hydrolysate, yeast extract, tomato juice, orange juice, or malt extract, are frequently added to the medium. But these substances are added for specific purposes, such as in ovule and

Table 1.1
Surface Sterilizing Chemicals for Plant Tissue Culture

Chemical	Concentration	Time Length (min)
Sodium hypochlorite[1]	0.9–4%	5–40
Calcium hypochlorite[1]	9–12%	5–40
Hydrogen peroxide	5–15%	5–30

anther cultures and plant specific media. The pH range for most plant tissue culture media is usually around 5–6. Maintaining proper pH is very important for *in vitro* culture because it determines the solubility and availability of the mineral ions and modifies gel properties of the agar. Any pH adjustments have to be done before adding the gelling agent (e.g., agar, agarose, gellan gum). These gelling agents are obligatory for semisolid media preparation. Owen et al. (29) claimed that culture medium pH is influenced by basal medium, carbohydrate source, gelling agent, activated charcoal, and medium storage method. When certain pH levels have to be kept constant through culture, a 2-Morpholinoethanesulfonic acid (MES) buffer can be added, following previously reported protocols (28).

Optimization for plant growth and regeneration of specific cell and tissues from diverse species might require adjustments to current media, rather than new formulations of nutrient media. Table 1.2 lists the composition of the most commonly used plant tissue culture media. Furthermore, Leifert et al. (30) has published an extensive and valuable review on mineral and carbohydrate nutrition of plant cell and tissues cultures.

Inorganic nitrogen is most commonly supplied as nitrate, but urea or ammonium ions may be used as well. Nitrogen, as an organic source, is provided as amino acid (glycine, asparagine, glutamine, aspartic acid, glutamic acid, and cysteine, among others), or casein-hydrolyzed. The nitrogen source has an important effect on plant cell metabolism and developmental response (26,31) For instance, an elevated level of ammonium and nitrate are used for callus culture, low concentrations of mineral salts are needed for shoot and root cultures, and a half strength medium favors cell differentiation and plant regeneration.

As previously pointed out, sucrose is the most commonly used carbon source in culture media. However, fructose and glucose can support similar or higher cell growth rates than sucrose in certain species such as *Catharanthus roseus* cells (32). Moreover, various lines and mutant rice cells are capable of using mannose, ribose, galactose, sorbitol, or even acetate as the only energy source (33).

Plants normally are competent to synthesize all required vitamins, but plant cells in culture are dependent on an exogenous source. Because of that, several vitamins may be included to the media. Thiamine is by far the most common vitamin added, because it is an essential cofactor in carbohydrate metabolism and is directly involved in the biosynthesis of some amino acids. However nicotinic acid, pyridoxine, folic acid, calcium pantothenate, choline chloride, *p*-amino-benzoic acid, and biotin are added as supplements, as well. *Myo*-inositol is an additional organic compound that functions as a vitamin (complex B) and it can be found in most of the media. Ascorbic acid (vitamin C) and citric acid, which are antioxidants, are added to media in certain cases in order to avoid excessive tissue oxidation or browning reactions.

Most plant *in vitro* cultures require exogenous plant growth regulators or plant hormones for differentiation and growth. Hormones can maintain or arrest growth *in* vitro. As growth begins, endogenous plant hormone levels of the explant will eventually start to be synthesized. As growth requirements change during culture, tissues are subcultured and hormone content can be altered. There are six main types of plant growth regulators: auxins, cytokinins, gibberellins, abscisic acid, brassinosteroids, and ethylene. Table 1.3 depicts some of most commonly used plant regulators in cell, tissue, and organ culture. Auxins and cytokinins are most widely used. An appropriate balance of these two hormones is required to induce either shoots (caulogenesis) or roots (rhizogenesis).

Plant tissue culture nutrient media can be obtained by preparing it from "stock solutions" or by buying basic commercial media from commercial companies. Once the medium is made, it is preferable to let it stand for 2–4 days at 25°C to watch for possible contamination. Media storage for long periods should be at 0–4°C, in order to avoid nutrient degradation and potential microorganism growth.

Ethylene inhibitors	
Silver thiosulphate	AgS_2O_3
Aminoethoxyvinylglycine	AVG
2,5-norbornadiene	NBD
Cobalt chloride	$CoCl_2$

As a general rule, nutrient media are sterilized in an autoclave (Figure 1.2B). Biondi and Thorpe (34) have recommended increasing sterilization time as media volume increases. For vessels having 10 to 20 ml of media, 20 min is adequate, while for flasks with 1 l of media, 40 min are needed because larger volumes heat more slowly. However, media oversterilization must be avoided, as this can result in degradation of media constituents and caramelization of sugars.

Sources of contamination for media may include the culture vessel, the medium itself, the explant, the environment of the transfer area, instruments and tools, and conditions in the culture room. All these sources have to be rigorously checked and meticulously sterilized to avoid contamination. All contaminated media have to be properly sterilized and then discarded.

1.3.4 Explant Selection and Culture Conditions

Any plant organ, tissue, and cell may be used as explant for *in vitro* culture. Nonetheless, some plant materials are more suitable to be used as explants, because they are naturally less contaminated and they have a higher propensity to induce sustained growth *in vitro*. Explants may come from either field grown or *in* v*itro* plants. Elite healthy young plants in a very active growing phase are the most suitable source of explant. Roots and underground tissues are highly likely to have contamination. Thus, these organs are not the best source for explants, unless they can be disinfected or grown in sterilized media. Adventitious or axillary buds and shoots, cotyledons, hypocotyls, and stems are common sources of explants.

Etiolated plants tend to give less contaminated explants, compared with normal plants. This could be because bacteria and fungi do not have appropriate conditions to reproduce in dark or dry conditions. Shoots from active growing plants are less contaminated than older tissues; in addition rough surfaces are more susceptible to contaminants. In summary, vigorous and healthy field- or greenhouse growing plants will give cleaner and less problematic explants. Undoubtedly, the best plant sources for explants are those which were grown in *in vitro* conditions, because plants are completely axenic. These *in vitro* cultures may be obtained from seeds. They are more easily sterilized under rigorous conditions without damage; mostly because they bear seed coats.

Plant cell and tissue cultures have several requirements for optimal growth and culture maintenance. The main physical necessities are temperature, light, and humidity. These factors can be accomplished using an incubator, plant growth chamber, or plant culture room. Temperature is frequently regulated between 22–30°C; nevertheless particular plant species and culture types will have specific temperature requirements. In general, tropical species will need higher temperatures than temperate-grown plants. Plant tissue light requirements may be affected by light irradiance, light quality, and photoperiod. Light conditions can regulate plant morphogenesis. Light irradiance is expressed as $\mu molm^{-2}s^{-1}$ and, in general culture growth is best between 40 and 110 $\mu molm^{-2}s^{-1}$. Light quality is related to the electromagnetic spectrum source, which can be different depending on the type of lamp used at the growth chamber. Finally, the length of light and dark periods (photoperiod) would generally be set at 6–18 hours of light, and the complementary dark period to give a total 24 h cycle. To achieve proper photoperiod, lights are attached to timers so that the length of the photoperiod can be controlled automatically. Normally, cool white or daylight fluorescent light lamps can provide the light irradiance and quality needed, although some specific plant cultures require incandescent lamps.

Relative humidity (RH) is a way to assess the amount of water vapor contained in a gaseous atmosphere. The RH is not easy to manage inside the plant tissue vessel or container, mostly because the container has to be sealed to avoid contamination, therefore reducing the gas exchange. Nonetheless, culture containers may be sealed with Parafilm™ or a wrapping film material, allowing gas exchange between the exterior and interior of the vessel. This prevents media contamination and desiccation. Temperature will determine the RH above the medium within the culture vessel. When air temperature is equal to media temperature, and the container is tightly sealed, RH will be approximately 98–99%. The type of closure will have an effect on intra-vessel RH. Short et al. (35) proved that a closed

screw-top lid gave 100% of RH, and a partially closed lid yielded 80% RH. A cotton wool plug gave 70% RH, cling-film wrap gave 60% RH, and filter paper led to 50% RH.

1.4 DIFFERENTIATION AND MORPHOGENESIS

Single plant cells can give rise to multicellular whole plants when they are cultured *in vitro* under proper conditions. This characteristic is known as totipotency. Schleiden (36) and Schwann (37) independently stated the basis of cellular theory and postulated that the cell is capable of autonomy and that it is totipotent. F.C. Steward (38) was the first to show totipotency of plant cells from tissue culture when he cultured whole carrot plants from single cells. Taking into account that all cells of a multicellular organism derive from an egg cell, theoretically they have the same genetic information and the same capacity to generate a whole organism. However, during the developmental process, different kinds of cells with different morphological and structured characteristics are generated, and each plays a specific function in the plant. This means that cells became differentiated, and the process by which they acquire function is known as differentiation. Plant cells undergo differentiation to generate tissues, organs, and eventually whole plants; this phenomenon is called morphogenesis.

1.4.1 Organogenesis (Direct and Indirect)

Plant cells can divide and dedifferentiate or redifferentiate when they are cultured *in vitro*. When plant cells are cultured, they can change their differentiated state or the developmental pattern to give rise to new forms and structures (morphogenesis). Two main pathways of morphogenesis can be recognized in *in vitro* cultures: organogenesis and embryogenesis. Organogenesis implies *de novo* organ formation (e.g., roots, buds, shoots, flowers, tubers) from cells, tissues, or organs. Organogenesis can occur from differentiated cells, tissues, or organs, and from non-differentiated cells or tissues (callus). In the first case, organ formation is referred as direct organogenesis, whereas organ formation in the second case is known as indirect organogenesis.

Organogenesis occurs in some cell or tissue cultures as a response to manipulation of exogenous levels of phytohormones or growth regulators. Skoog and Miller (9) demonstrated for the first time that the type of organogenesis was controlled by the balance of auxin and cytokinin in the tissue culture medium. Media relatively high in auxin and low in cytokinin induced roots, whereas media relatively low in auxin and high in cytokinin induced shoots. These results are very clear in the case of tobacco and many other plant species, but are not the rule, and for this reason, the *in vitro* multiplication of any plant usually requires special adjustment.

Organogenesis is the most common pathway to micropropagate plants. Micropropagation techniques allow the maintenance of characters and yield populations of plants identical to the individual used initially; in other words, this allows cloning elite material. Maintenance of genetic stability requires caution and care must be taken to avoid culture media inducing genetic variability.

1.4.2 Somatic Embryogenesis (Direct and Indirect)

The ability of somatic plant cells in culture to regenerate entire organisms, by a process resembling normal sexual embryogenesis, is one of the most remarkable features of plants. Somatic or adventive embryogenesis is the process by which somatic cells develop into differentiated plants through characteristic embryological stages without fusion of gametes. In contrast to organogenesis, a bipolar structure with a root–shoot axis is formed. This

process occurs naturally in a wide range of species. Embryogenesis can be induced directly from cells of an organized structure such as a stem, leaf, flower, tubers, or root segments, among others (direct embryogenesis), or from non-differentiated tissue cultures (callus), or cell suspensions (indirect embryogenesis).

The earliest published reports of *in vitro* somatic embryogenesis were in 1958 in carrot plants (38,39). Our current understanding of the process of *in vitro* somatic embryogenesis has arisen from a variety of experimental approaches, using a number of plant systems (40), of which the carrot (*Daucus carota*) has been the most important. In general, somatic embryogenesis can be divided into two phases: the induction of cells with embryogenic competence, and the subsequent development of the embryogenic masses into embryos. These phases are sometimes referred to as primary and secondary cultures, and the culture media used are similarly referred to as primary and secondary. Somatic embryogenesis has also been divided into the following stages: early growth, embryo maturation, and germination, or conversion.

The term embryogenic cell is restricted to those cells that have completed the transition from a somatic state to one in which no further exogenously applied stimuli, such as the application of growth regulators, are necessary to produce a somatic embryo (41). The cells that are in a transitional state and have started to become embryogenic, but still require exogenously applied stimuli, are identified as competent cells (42,43). During this somatic-to-embryogenic transition, cells have to dedifferentiate, activate their cell division cycle, and reorganize their physiology, metabolism, and gene expression patterns (44). Acquisition of embryogenic competence largely relies on dedifferentiation, a process whereby existing transcriptional and translational profiles are erased or altered in order to allow cells to set a new developmental program. The activation of cell division is required to maintain the dedifferentiated cell fate, as well as for embryogenic differentiation. This is not only true for those embryogenic systems with embryogenic callus (indirect somatic embryogenesis), but also for those where somatic embryos develop on primary explants without an intervening callus formation (direct embryogenesis).

Three factors have been shown to be important in the production of somatic embryos *in vitro*: the explant, the culture medium, and the culture environment (31,45). Although somatic embryogenesis can be induced from a range of tissues, immature or young explants are generally more responsive, with the developmental stage of the explant often being a prime factor. The genotype is also important. Although a wide range of basal media can be used for the induction of somatic embryogenesis, the MS medium (10) has been the most commonly used culture medium. Generally, primary culture requires an auxin, of which 2,4-dichlorophenoxyacetic acid (2,4-D) and naphthalene acetic acid (NAA) have been successfully used. During secondary culture, a lower level of auxin is needed, but there is sometimes the requirement for other hormones, particularly cytokinin and abscisic acid. The culture environment also influences somatic embryogenesis. It can occur under a variety of light dark regimes, but in general, darkness may be better. Osmotic stress can enhance somatic embryogenesis (46,47).

Somatic embryogenesis provides a unique experimental model to understand the molecular and cellular bases of developmental plasticity in plants (48). In the last few years, the application of modern experimental techniques has resulted in the accumulation of novel data on the molecular genetics and molecular biology of somatic embryogenesis (44,49,50). Genes differentially expressed during the early and late stages of somatic embryogenesis have been reported (50). The recent identification of genes that are markers of switch in cell fate or are themselves capable of inducing embryogenic development in somatic cells has opened up new approaches to the question of developmental flexibility and determination in plants (44).

1.4.3 Somaclonal Variation

Spontaneous genetic variation and mutation breeding have traditionally been used to develop new plant varieties. Spontaneous genetic variation usually occurs at a frequency too low to be used in most breeding programs. Mutation breeding, on the other hand, is difficult to control. Usually seeds, consisting of a shoot apex with hundreds of cells, are mutagenized. The resultant plants are usually mosaics and require several generations to stabilize. In addition, at mutation frequencies that are high enough to isolate useful traits, such modified plants usually contain additional deleterious changes and require significant breeding effort to generate new, improved varieties.

It was observed several decades ago that plants regenerated from cultured somatic cells were not genetically uniform but showed significant genetic variability. Larkin and Scowcroft (51) advanced the term "somaclonal variation" to denote such variation, and summarized many of its pertinent manifestations as they occur in cultured plant cells and regenerated plants. Evans et al. (52) extended the definition to somaclonal and gametoclonal variation to refer to those variations observed in regenerated plants from cultured somatic cells or from gametophytes, respectively. Variation has been detected in cultured cells for morphological and biochemical characteristics, and chromosome number and structure (53,54). The genetic variation observed in the regenerated plants appears to result from both preexisting variation in the explant donor tissue as well as from variation induced by the *in vitro* culture (55–57). The frequency of genetic change is significantly higher for somaclonal variation (1–3%) than that observed for spontaneous genetic changes (58). Therefore, this variation can be used to recover at high frequency natural genetic variability from existing crop cultivars.

Somaclonal variation can arise at the cell level by modification in the chromosomes, plastids, or mitochondria (59,60). Variation in regenerated plants can be genetic (heritable) or epigenetic. Genetic changes are stable and expressed in the progeny of regenerated plants after sexual cycle, whereas epigenetic changes are usually induced by culture conditions and are not useful for crop improvement because they are unstable even through asexual propagation (61). The term epigenetic has become used to indicate variation in phenotypic expression that is perpetuated by cloning but does not involve permanent changes in the genotype. All of the ontogenetic and phenological changes that occur in the development of an individual plant can be considered as epigenetic (62). Polyploidy is the most frequently observed chromosomal abnormality, but also chromosome rearrangements (translocations, deletions, inversions) can occur among regenerated plants (63,64). Mitotic crossing over could also account for some of the variation detected in regenerated plants. Single gene mutations and organelle gene mutations have also been detected in regenerated plants (64). Participations of retrotransposons as the mechanism for mutations induced by tissue culture has been proposed by Hirochika et al. (65). Gene amplification and changes in sequence copy number can also account for the observed *in vitro* genetic variation (66). Differences in DNA methylation in cell cultures or plant somaclones have been demonstrated (67–69). Molecular biology techniques have been used quite often to investigate genetic polymorphism in regenerated plants (70–74).

Somaclonal variation depends on the preexisting variation (mosaicism, chimeras) and on *in vitro* induced variation (culture medium composition, cultivar source of explants, age of the cultivar, length of time *in vitro*, proliferation rate, selection pressure, and cultural conditions) (58). Callus, cells suspensions, and protoplast cultures are the systems of choice for the recovery of mutants and variants. Growth regulators such as 2,4-D and benzyladenine (BA) have been implicated in the induction of variability (58).

In vitro genetic variation has been useful for the isolation of a number of variant cell lines resistant to different drugs, antibiotics, amino acid analogs, herbicides, and abiotic and biotic factors, among others (75,76). This genetic variation has also been used

to generate new plant cultivars (58) and somaclonal plants with interesting agronomic traits like resistance against pathogens (77).

In summary, somaclonal variation is an important source of genetic variation that can be used for the isolation and recovery of variant and mutant cell lines or plants with characteristics of interest.

1.5 PLANT CELL, TISSUE, AND ORGAN CULTURES

1.5.1 Initiation and Maintenance of Callus

Callus may be defined as an amorphous plant cellular aggregation, slightly differentiated, and attaining rapid proliferation. Almost all plant tissues response to callus induction, and it is known that successful callus initiation is largely dependant on genotype and the influence of exogenously supplied growth regulators. The type of growth regulator requirement and its concentration in the medium depend strongly on species and potential endogenous hormone content of the explant (78). In natural conditions, callus appears as a healing mechanism when the plant has been wounded, or after a tumour is induced by some phytopathogenic organisms like *Agrobacterium tumefaciens*. Natural development of callus tissue is a consequence of a change in the level of endogenous growth hormones, usually auxin and cytokinin. This type of callus may be easily cultured *in vitro* when suitable concentrations of needed growth regulators are applied.

Calli from all kinds of flowering plants have been induced with emphasis on dicotyledoneous materials, although monocotyledonous plant callus have been also induced and cultured (79–82).

Callus is composed of cells with similar characteristics to those of parenchyma cells, though cytological studies show that it is a heterogeneous tissue in cellular composition. When critically examined, callus culture is not a homogeneous mass of cells, because it is usually made up of two types of tissue: differentiated and nondifferentiated (78). The characteristics of a callus tissue *in vitro* depend on the type and quantity of growth regulators used; on organ, species, and source; and on the physical incubation conditions. One of the most important properties of the callus tissue is "friability." This is the ability of cells to break apart from clumps and to disperse. In general, high auxin concentrations favour callus friability, whereas presence of cytokinins tends to produce calli with hard consistency. Friability is desired for cell suspension culture.

With a suitable culture medium, almost any plant tissue with a high number of viable cells is able to produce callus tissue. It is known that only a few cells of the initial explant give rise to callus tissue; usually these are located on the inoculum surface or adjacent to wounds produced during explant handling. For the induction of callus tissue, culture medium such as described by Murashige and Skoog (10) or Gamborg et al. (83), generally semisolid, and with a suitable concentration of auxins and cytokinins, is needed. The induction of callus takes place when the amount of auxin is greater than cytokinin. It has been observed that auxins are callus inducers, whereas cytokinins only favor cell proliferation. Nevertheless, the requirements for growth regulators vary, depending on the tissue and species cultured. Auxins commonly used for callus induction are 2,4-D, which is usually active at 10^{-5}–10^{-7} M; indol-3-acetic acid, (IAA), at concentrations from 10^{-5} to 10^{-10} M; and naphthaleneacetic acid (NAA), that can be used at somewhat higher concentrations than IAA. The most common cytokinins are kinetin and benzyladenine (BA).

Callus proliferation has a high multiplication rate, thus subcultures every 3–8 weeks, depending on the species, are needed to maintain conditions suitable for callus growth. If

subcultures are not performed with the appropriate frequency, nutrient depletion and medium desiccation appears, as well as a potentially toxic metabolite accumulation that may induce tissue necrosis. For the callus subculture, only healthy tissue, with no dehydration or necrosis, should be taken and transferred to fresh culture medium. This media may be the same as used for induction medium, though in some cases it is desirable to reduce the concentration of auxin, and to add supplements such as hydrolysed casein and malt extract, which in several species help maintain the constant callus growth. Some calli need cytokinin to maintain cell proliferation, whereas with other calli this is not necessary, because natural endogenous cytokinin levels are sufficient to support proliferation. Additionally, complex additives such as coconut milk, yeast extract, or casein hydrolysate may be required.

In order to have more precise information about *in vitro* callus proliferation and the effects of the growth regulators or other additives, it is important to know callus growth rate. The simplest method is to measure fresh weight at the time of inoculation and at the end of culture. Weighing does not damage tissue; nevertheless, final weight may be influenced by callus hydration levels, and therefore it may not give precise biomass growth information. Alternatively, it is possible to use dry weight as a more precise measurement of biomass increment, unfortunately tissues are killed by this method. Other methods to determine the rate of tissue proliferation are determination of cell number per weight unit and mitotic index.

Callus of many species may be maintained indefinitely with appropriate subcultures; nevertheless, long term maintenance of callus may favor induction of genetic and epigenetic changes such as chromosomal aberrations, mutations, and different ploidy types that, as a whole, give rise to genetic variability in these cells, for what it is widely accepted that most long term callus cultures are chromosomally unstable (78). These changes generally cause a progressive loss in the ability of callus to be morphogenetically competent. Because of regeneration of organs or complete plants is arrested, it is necessary be aware that plant regeneration may not be achieved from long term callus proliferation. Therefore, for a callus maintenance program it may be best to control calli proliferation, and check frequently the morphogenetic competence by induction of plantlets (Figure 1.1C).

Callus tissues have several applications in plant tissue culture, due to their easy maintenance in controlled conditions and their rapid proliferation. Thus callus cultures are used for cellular metabolism studies, production of secondary metabolites, phytotoxicology, and cellular ultra structure. Callus cultures are useful to study cellular mechanisms that induce a response to different types of stress such as water deficit, salinity, extreme temperatures, and pathogen attack. Cell suspension cultures usually start from callus tissues and are intermediate steps for plant regeneration through organogenesis or somatic embryogenesis. Organogenic callus tissue can lead to the formation of adventitious shoots. This process is known as indirect organogenesis. Cell suspension as well as callus can give rise to embryogenic tissue, usually from auxin rich medium. Development of the somatic embryos starts as soon as the auxins are eliminated from the medium. Not every callus tissue has an organogenetic or embryogenetic potential; therefore, plant regeneration from a callus tissue is not always possible, mainly due to the genetic and epigenetic variations that take place in callus cells. It is possible to regenerate plants that are phenotypically different from the original plant material. This makes callus useful for breeding programs where natural genetic variability of some species is limited.

1.5.2 Initiation and Maintenance of Suspension Cultures

A cell suspension culture consists of dispersed cells and small aggregates growing in moving liquid media. It is normally initiated by transferring pieces of undifferentiated, friable calli to a liquid medium which is continuously agitated by a suitable device. Suspension cultures can be started from seedlings, imbibed embryos, or leaves by mechanical methods.

Leaves, soft tissues, or other plant segment can be gently ground and can be broken up in a hand held glass homogenizer. The homogenate, containing intact living cells, dead cells, and cell debris, is cleared by filtration and centrifugation and then transferred to a moving liquid medium. An enzymatic method for isolation of single cells by the use of pectinases, which digest the pectin wall, has also been employed for numerous plant species.

Cultures are initiated by placing freshly cut sections of plant organs on a solidified nutrient medium containing growth regulators. On this medium, the explant exhibits callusing, which is separated from the parent explant and transferred to a fresh medium to build up reasonable amount of callus tissue. This callus is transferred to a liquid medium and agitated to raise fine suspension of cells (78). The transferred callus initiates a fragmentation period forming small aggregates that produce free cells and new cell groups. However, it is almost impossible to establish a suspension culture formed by only individual cells. The plant cell culture requires a minimum size inoculum to be able to grow satisfactorily (84). An appropriate inoculum for chilli pepper (*Capsicum annuum* L.) cell suspensions is 5 mg dry weight per ml of culture medium (75).

In regard to culture growing, development is a sigmoid behaviour that includes five characteristic growing phases:

1. Lag phase: a preparation period before the starting of an accelerated division of plant cells
2. Log phase, or logarithmic phase: characterized by an exponential increase of the cell number due to an accelerated cell division
3. Linear phase: characterized by a linear increase of cell population, which increases fresh and dry weight of the culture
4. Deceleration phase: characterized by a gradual deceleration of cellular division rate, due to media depletion and cellular residues accumulation
5. Stationary phase: cellular division ceases

Cell suspension cultures usually require more frequent subcultures compared to callus culture and should be subcultured before they reach the deceleration phase to avoid loss of cell viability. Cell suspensions are grown in liquid media which has several advantages. All the cells are uniformly in touch with the media therefore, nutrient gradients are not formed. In theory, cell suspension culture may be initiated from any explant inoculated in a liquid agitated medium; nevertheless greater success is obtained when initiation is made from callus tissue. Cell cultures should be agitated or subjected to forced aeration to allow an adequate gas exchange (85,86). Container size and the liquid medium volume are important factors to obtain adequate aeration. Culture medium volume should be 20% of the flask volume. Generally Erlenmeyer flasks mounted on laboratory shakers are used for culturing. Specialized equipment has been designed for plant cell suspension cultures such as the platform orbital shakers, spinning cultures, stirred cultures, continuous culture systems, and airlift reactors (19,87,88). Platform (orbital) shakers are widely used for the initiation and serial propagation of plant cell suspension culture (Figure 1.4). They should have a variable speed control (30–150 rpm) and the stroke should be in the range of 4–8 cm/orbital motion. Besides aeration, agitation of media on a shaker serves two purposes: it exerts a mild pressure on cell aggregates, breaking them into smaller clumps and single cells, and agitation maintains uniform distribution of cell and cell clumps in the medium.

A number of bioreactor variables can easily be monitored on line, sensors for *in situ* monitoring of the two most critical variables for plant suspension cultures: biomass concentration and aggregate size are available (89–91). As pointed out previously there are

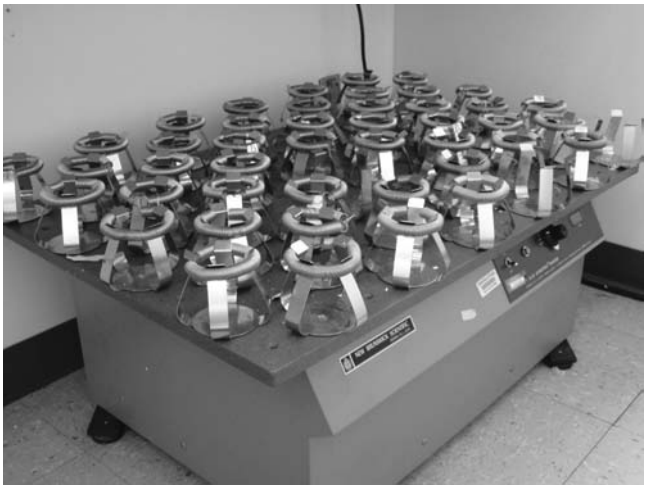

Figure 1.4 A platform orbital shaker for the aeration of liquid cultures. This shaker has clips for 250 ml culture flasks.

several ways to characterize biomass concentration in plant suspension cultures, but dry weight measurements are often considered to be the most meaningful and reliable. However this method requires sampling the bioreactor and takes 1–3 days to obtain a measurement, minimizing the measurement's usefulness for on line control. Similarly, aggregate size distribution is often measured by gently screening a sample from the bioreactor using a series of standard sieves and obtaining dry weight of the biomass retained on each screen. The mechanical sieving process has the potential to give size distribution. Thus, *in situ* techniques to monitor biomass concentration (dry weight l^{-1}) and aggregate size for plant suspension cultures need to be developed.

When small reactors or shaking flasks are used to grow cell suspension cultures, routine operations are relatively easy. With large scale operations involving aerobic high cell density plant cells, maintenance becomes more complex. In many cases scale up of plant cell suspensions has been accompanied by a reduction in system productivity (92). The process has to be scaled up in one or more steps, because shake flasks and bioreactors have completely different geometry, mixing, and gas regime characteristics (88). Problems, such as non uniform mixing, hydrodynamic shear damage of fragile plant cells, and low rates of oxygen to cell mass transfer, are potential barriers to process development. Cell damage can be avoided by operating the stirred tank bioreactor at low mixing speeds.

Despite the fact that oxygen requirements of plant cells are comparatively lower to microorganisms, high cell densities may lower the oxygen mass transfer coefficient, which in turn may cause oxygen starvation at low mixing speeds. Oxygen supply is known to affect both cell growth and the production of metabolites (93,94). Generally, growth rate increases when oxygen supply rise until it reaches a maximum. However, further increase of oxygen supply by increasing aeration rate or stirrer speed can decrease growth rate. This is not due to an oxygen increase *per se*, but to an increase in hydrodynamic shear and carbon dioxide stripping (95).

Oxygen starvation may be overcome using techniques proposed by Farrés and Kallio (96), who, using the binary vector pBVHb, on an LBA-4404 *Agrobacterium tumefaciens* strain, overcame oxygen starvation in tobacco suspension cultures by making cells capable of expressing active Vitreoscilla-hemoglobin protein (VHb). VHb-expressing cultures do not have a significant lag phase and can grow to higher cell densities relative to controls.

No significant differences in growth rate, biomass yield on sucrose, or ethanol production between VHb-expressing cell lines and controls were found.

Calli from a wide range of explants (cotyledons, hypocotyls, and leaves) and different media composition [Murashige and Skoog (10), Gamborg et al. (83), and Linsmaier and Skoog (97)] have been used with success for cell suspension induction. Vitamins, inositol, sucrose, and growth regulators, especially auxin (2,4-D at concentrations of 1–5 μM), should be added for ensuring cell division. The addition of 1 μM kinetin may be beneficial. The culture medium for suspension culture should be such that it maintains superior growth of cells (78).

Ozeki and Takeda (98), studying the regulation of phenylalanine ammonia lyase genes in carrot suspension cultured cells, established that plant cell cultures are often used as model systems to investigate regulation of secondary metabolism by environmental and developmental stimuli, because the cells can be grown in a stable and homogenous environment with respect to temperature, light, and nutrients. This reduces the complexity of the experimental system as compared to intact plants, and facilitates analysis of regulatory mechanisms.

1.5.3 Bioreactors, Immobilized Plant Cells, and Secondary Metabolites

The relevance of a bioreactor culture technique for plant micropropagation either via organogenesis or somatic embryogenesis has previously been established (91,99). This is a way to reduce production cost by scaling up and automation. For instance, Harrell and Cantliffe (100) developed a machine vision based measurement system which noninvasively quantifies the population characteristics of a heterogeneous plant tissue culture suspension grown in a bioreactor. Likewise, Harrell et al. (90) demonstrated the aseptic and automated harvest of somatic embryos from a bioreactor packed with *Ipomoea batatas* suspension culture. Using a machine vision system, which emulated the selection criteria of an experienced biologist, these authors were capable to classify somatic embryos as harvestable or nonharvestable, without affecting the aseptic conditions of the culture. The efficiency rate of this system was as high as 99%. On the other hand, periodic immersion liquid culture using ebb and flood system and column-type bubble bioreactors were found to be suitable for micropropagation of plants via the organogenetic pathway. Whereas balloon-type bubble bioreactors proved better performance for micropropagation via somatic embryogenesis with less shear stress on cultured cells (99).

Plant cell and tissue cultures have enormous prospects as a substitute method for the production of secondary metabolites of commercial value, which normally are extracted from cultivated or wild plants. In general, *in vitro* cultures accumulate lower amounts of secondary metabolites than whole plants. Nevertheless, a number of *in vitro* cultures have been able to yield higher levels of phytochemicals than cultivated or wild plants (101,102). To overcome the low secondary metabolite yield several strategies have been suggested, such as optimization of culture conditions, selection and improving of high-producing strains, addition of bioprecursors, biotransformation systems, elicitor treatment, metabolic engineering, and cellular immobilization (102–110).

Rosevear (111) has defined the immobilization technique as an artificial system which confines a catalytically active cell or enzyme within a reactor, and prevents its entry into the mobile phase which carries substrate and product. In 1966, Mosbach and Mosbach (112) reported for the first time a plant cell immobilization process, using cells of the lichen *Umbilicaria pustulata* entrapped in polyacrylamide gel. After that achievement, extensive information on immobilized plant cells, describing characteristics, properties, techniques, and commercial potentialities of that system have been published (113).

In the last 18 years, the appearance of recombinant DNA technology has opened the opportunity to change the expression and repression of genes which are related directly to biosynthesis, transport, accumulation, and degradation of secondary metabolites (114–117). In other words, it is now possible to regulate pathways that lead to phytochemical substance accumulation. Bailey (118) has defined metabolic engineering as the improvement of cellular activities by manipulation of enzymatic, transport, and regulatory functions of the cell with the use of recombinant DNA technology. This metabolic engineering approach can be used either in a plant or plant cell culture, and successful examples have been reported for monoterpene, lignin, carotenoid, flavonoid, and alkaloid biosynthesis (102,106,119).

As previously pointed out, a number of approaches have been developed to improve the use of the bioreactor culture technique for plant micropropagation, as well as to increase the secondary metabolite accumulation in plant cell cultures. However, not all of those approaches have been completely successful. Possibly that goal may be the result of the combination of improved bioreactor technologies, enhanced cell, tissue, and organ culture protocols and an exceptional metabolic engineering approach.

1.5.4 Root Cultures

Roots are very important organs for plant survival, because they have vital functions for absorption, and transport of water and nutrients. Plant roots have been valuable economically as food sources and medicines. *In vitro* culture of isolated roots was one of the most important successes within plant tissue culture. The advances were made by White in 1934 (4), who successfully cultured tomato roots in completely artificial conditions. The original radicle lines obtained by White were grown for 25 years in a liquid chemically defined medium, and were the initial *in vitro* cultures of plant organs (120).

In vitro culture of roots is a system of great interest for the study of metabolic processes that take place in those organs, as well those that are related to the metabolism of carbohydrates, vitamins, growth regulators, nutrient absorption, and translocation (121,122). Likewise, these types of cultures have been used in studies of differentiation, root development, and in the interaction of these organs with other organisms, such as Rhizobium, and parasitic nematodes. Another very interesting application of root culture is the synthesis of a large number of secondary compounds of interest that are produced by this tissue, and the potential production of them (123,124).

The response of roots to *in vitro* culture depends on factors such as species, culture medium, and environmental conditions of the culture. Roberts and Street (125) have classified root cultures into three different classes, depending on their response to exogenously applied auxins. In a group, which includes those of tomato, the addition of auxins has an inhibitory effect on growth or at best no effect. In the second group, auxins stimulate growth when they are added in suitable concentrations. In the last group, radicle cultures are entirely dependent on an external auxin source to be able to grow. Later, Butcher and Street (126) compiled a list with all root cultures published, and concluded that auxins are needed to support a suitable growth of radicular tissues. On the other hand, variation has been observed related to the time during which the roots may be growing *in vitro*.

Three groups of species are defined:

1. Roots that may be cultured indefinitely *in vitro*, needing only the medium and the appropriate subcultures. The roots of tomato, Datura, and other species have this type of behavior.
2. Roots that grow and develop *in vitro* during variable periods of time, but that do not achieve indefinite growth. In all cases, sooner or later, the rate of growth

gradually decreases, lateral root formation is inhibited, and finally the culture dies. This is the case with some leguminous and cereal roots.

3. Roots that up to now have not been cultured *in vitro*. To this group belong many woody species.

Related to the nourishing medium to the *in vitro* root cultures, several have been tested with a different degree of success, but the most widely used are those derivatives of the original White's medium, although some species responded better to Murashige and Skoog (10) or Gambor et al. (83) media. Sucrose is the principal carbon source used; nevertheless, some cultures of monocotyledons plants have a good response to glucose. Carbohydrate levels are between 1.5 and 2% (w/v), because major concentrations cause metabolic root alterations. Liquid media is used more frequently, stationary, or under agitation, though in some cases it is possible to use a semisolid culture medium.

In general, exogenous application of growth plant regulators must be carefully done, because some auxins combined with cytokinins may induce a rapid root dedifferentiation to turn into cellular suspensions. In certain cases, it has been observed that gibberellins strengthen growth (122).

A variant of root culture that has recently reached enormous importance is the root culture transformed by *Agrobacterium rhizogenes*. This subject is widely covered in section 1.6.3.2 of this chapter. The future work of *in vitro* transformed root culture should be based on the *Agrobacterium rhizogenes* genetic knowledge, and on the biochemistry and genetics of plants, in order to spread the range of plants that may be transformed and to increase both the rates of growth and the production of useful substances.

1.5.5 Shoot Cultures

Plant tissue culture techniques include the culture of any type of organ plant; but, among them, shoots are the organ preferred for commercial micropropagation. In general, herbaceous plant species are more amenable for micropropagation than woody plants because the latter may be more dramatically affected by seasonal changes that may have a profound effect on the physiology of tissues and organs. For example, dormant tissues or organs dissected from winter plants do not respond to *in vitro* culture as well as those collected during the spring. Shoot propagation is a general term used, but it includes apical and lateral meristems, as well as apical and lateral apexes. *In vitro* clonal propagation means the production of a plant population derived from a single individual by asexual reproduction. Plant propagation is derived from the plant's ability to attain a constant grow. However, not all plant cells are able to achieve steady division under normal conditions. As a result, plant growth requires the presence of a special type of tissue that always preserves the dividing capacity. This type of tissue is named meristem or meristematic tissue, and is made up of small, spherical, nondifferentiated cells, with a high relation of nucleus to cytoplasm, very small vacuoles, thin cellular walls, and nondifferentiated plastids.

The axillary and apical meristems inside the lateral and terminal buds are the natural vegetative growing points with capacity of new shoot formation. That capacity is maintained when they are established and cultured *in vitro*. Thus, the culture of terminal or lateral buds is an easy way for obtaining new shoots, which can be rooted to produce new healthy and vigorous plants. Therefore, this propagation system is based on a new shoot formation system from preexisting meristems, which does not imply cellular dedifferentiation, redifferentiation phenomena such as those that take place in the organogenesis, and somatic embryogenesis. The meristem and bud culture is a regeneration system less complex than organogenesis or somatic embryogenesis.

Shoot tips or meristem *in vitro* culture, is an ideal system for clonal propagation, because it provides the maximum genetic stability, which does not always is obtained from organogenesis or somatic embryogenesis. The system is relatively simple, and is very similar for many species. Thus, suitable conditions needed for propagation can be easily found. Nevertheless, bud propagation is slower and less productive than organogenesis and somatic embryogenesis. As an advantage, the meristem culture system alone or combined with thermotherapy or chemotherapy, allows rapid development of pathogen- and virus-free plants. This has an enormous importance especially in vegetative propagated species, because this is the easy way to obtain healthy plant material.

This methodology has been successfully applied to *in vitro* germplasm conservation by means of cryopreservation. Meristem or bud culture facilitates the transport of plant material without regulatory phytosanitary problems.

Micropropagation has several disadvantages, including high tissue sensibility to surface sterilization methods, elevated amounts of phenolic compounds which are produced during cutting, mostly in woody plants, and induced tissue vitrification in some of the cultured species.

According to the type of explant used, shoot culture technique may be divided into apex, axillary bud, and meristem culture.

1.5.5.1 Apex Culture

For culture of apexes, apical explants of 4–10 mm length are used. Besides the meristem, they contain several bud primordia as well as vascular differentiated tissue. This method is simple due to the manipulation of bigger explants and to the higher probability of their survival. Nevertheless, this method is not appropriate when pathogen free plants are needed, for what it is important to start with clean material from donor plants cultured under greenhouse conditions. Regarding the culture media needed for this type of propagation, Murashige and Skoog (10) or Gamborg et al. (83) media normally are used. Cytokinins are used with concentrations from 0.5 to 10 mg l^{-1}, favoring a multiple shoot proliferation from a single bud; although auxins in a small amount (0.01–1 mg l^{-1}) are used as well. Figure 1.5 illustrates *Photinia* X *Fraseri in vitro* plants cultured in MS medium.

1.5.5.2 Axillary Bud Culture

Explant size is not critical in this system, because it carries one or more axillary buds, from which shoot production shall take place. This is the simplest method for plant micropropagation, and it may be coupled to other systems to increase the material (40). For example, once a pathogen-free plant is obtained, it may be propagated through axillary bud system and after several cycles, the number of plants will be increased exponentially (127). Figure 1.6 depicts axillary bud propagation of *Agave tequilana* cactus plant which is used to obtain the Tequila liquor.

1.5.5.3 Meristem

For meristem culture, explants must be isolated by dissection under a stereomicroscope. The isolated explant is very small, usually less than 1 mm in diameter, and consists of the apical dome and a small number of leaf primordia, excluding the vascular differentiated tissue. To work and isolate so tiny explant presents certain difficulties. The explant size reduces the possibility of its successful *in vitro* establishment, and it needs a more complex culture media. Nevertheless, as the explant size is smaller, the probability of being pathogen free is increased. The main use of this type of culture is the production of plants free of virus or any pathogenic agent (128). This method may be combined with some type of

Figure 1.5 *Photinia X Fraseri in vitro* plants. They were propagated by mean of apex culture. Supplemented with 5 mg l^{-1} BA, exhibiting a shoot propagation rate of eight plants per explant within a lapse time of 45 days.

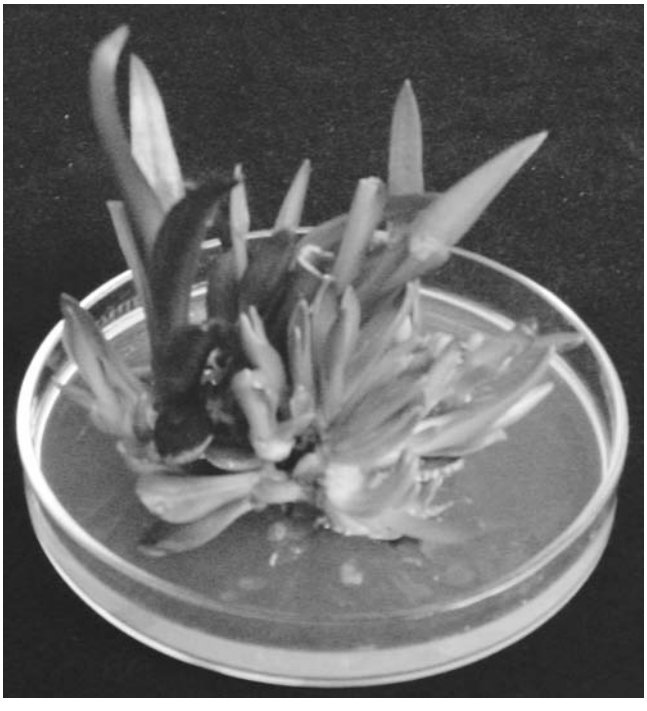

Figure 1.6 Axillary propagation of *Agava tequilana* depicting many axillary shoots (12 shoots per original explant).

thermo- or chemotherapy to assure pathogen liberation. Thermotherapy consists of incubation of whole plants or fragments to high temperatures before the isolation of meristem. Typical treatments are 7–9 days to 40°C, or 16–168 days to 32°C. After thermotherapy

treatments, plants must be analyzed by serological or molecular methods, or by electronic microscopy to confirm the absence of specific pathogens.

Ramírez-Malagón et al. (129) studied the elimination of viruses from two commercial garlic varieties using heat or chemical treatment and meristematic dissection. Growing explants were subjected to ELISA tests using potyvirus antisera. Thermotherapy killed 70% of explants; however, 64% of the surviving explants were seronegative. Chemotherapy treatment did not destroy the explants, but only 33% of them were seronegative. Field performance of virus-free plants was evaluated. *In vitro* plants had longer stems, higher fresh and dry weight per bulb, and increased yield in comparison with commercial lines (Figure 1.7).

Garlic plants and cloves harvested after virus elimination and field cultivation.

1.5.5.4 Acclimatization

Acclimatization is defined as the process by which an organism adapts to environmental changes. *In vitro* regenerated plants have several characteristics which complicated their adaptation to external environment. High relative humidity inside *in vitro* containers combined with a rapid cell proliferation by hormone action, induce formation of plants lacking of normal systems to avoid water loss. *In vitro* plants have a thin cuticle, wider stomata, and an atrophied closure mechanism. Therefore, the acclimatization process of *in vitro* plants must be done as gradual as possible, providing a slow reduction in relative humidity. In general, plants from *in vitro* propagation have to be cultured under greenhouse conditions provided with mist application system, with a different misting distance according to diverse species. Different antitranspirants have been tested to protect plants during this critical period, among them glycerol solutions or liquid waxes have been used, but the results not always have justified their use.

During *in vitro* culture plants do not perform a normal photosynthesis, and their carbon requirements are satisfied by the culture medium. Leaf anatomy from *in vivo* growing plants, differs from *in vitro* growing counterpart. The last ones are thinner, with less chlorophyll concentration. Therefore, transference of *in vitro* plants to soil must be done step by step, with slow light increments and slow relative humidity decrements.

In vitro plants are incubated under axenic environment consequently they have not developed their natural resistances against pathogens. During the first adaptation step, it is advisable to work under very clean conditions. Likewise, it is advisable to eliminate any culture medium residue adhered to the plant, because, due to its high sucrose content, it might favor microorganism growth. Evidence of successful plant adaptation is the development of new leaves after the transference to soil. At this time, watering should be reduced and light increased.

1.5.5.5 Current Approaches for Mass Clonal Propagation

Current micropropagation techniques require a large number of small containers, semisolid media, and aseptic division of plant tissues by hand. Also, plant micropropagation involves periodic transfers of plant material to fresh media due to exhaustion of nutrients in the medium and because of continuous tissue growth and proliferation, which is quickly limited by the size of the culture container. Gelling products are not inert and complicate automation. Labor generally accounts for 40–60% of production costs. Cutting and planting represent the most expensive part of micropropagation even in countries with low incomes. Furthermore, cleaning, filling, and handling of a large number of containers also adds to the final cost of the process. Other major costs result from losses during acclimatization and stem and root hyperhydricity, or vitrification. It has been concluded that commercial application of micropropagation for various species would only take place if new technologies were available to automate procedures, and if acclimatization protocols were improved (130). High production costs generally limit the commercial use of micropropagation to products with a very high unit value, such as ornamentals, foliage plants, and selected fruit crops.

In recent years, temporary immersion systems for plant micropropagation have been investigated as a means of overcoming some problems for *in vitro* mass propagation of plants (131). The positive effects of temporary immersion on micropropagation are recommended for shoot proliferation and microcuttings, microtuberization, and somatic embryogenesis. Immersion duration and frequency are the most decisive parameters for system efficiency. The parameters most involved in reducing production costs by temporary immersion systems include: the drastic reduction in work, reduction in shelving area, reduction in number of containers used, and better biological yields. Scaling up somatic embryogenesis

and shoot proliferation procedures involving temporary immersion systems in order to commercialize this process are now taking place for different plant species (131).

1.5.6 Isolation and Culture of Protoplasts

By definition, a protoplast is a plant cell coming from plasmolysed tissues and deprived of its cell wall. Protoplasts may be obtained by physical or enzymatic methods from almost any kind of plant tissue. For several species, it is possible to regenerate whole plants using just one single protoplast. Isolation and culture of protoplasts are made to pursue several different objectives, such as somatic hybridization, genetic transformation, and modelling systems for physiological and molecular studies (132,133). These cells, lacking a cellular wall, may easily allow the passage of organelles and different particles such as virus and naked DNA, by relatively simple methods like electroporation and microinjection. On the other hand, a naked plant cell may be the solution to harvest useful secondary metabolites, because cell walls limit the mass transfer to the culturing medium (134). Additional information on somatic hybridization and genetic transformation using protoplasts can be found in section 1.6 of this chapter (genetic manipulation).

Although protoplast isolation may be done by mechanical methods, the most important is the enzymatic one. This is based on the enzymatic degradation of the cellular wall components, which allows the protoplast obtaining without damaging the tissue. Enzymes that are used for this purpose belong to three different groups: cellulases, hemicellulases, and pectinases. In general mixtures of two types are used (135). Explicit and detailed protoplast isolation protocols can be found in Thomas and Davey (136), Gamborg et al. (137), Bhojwani and Razdan (138), Kyte (139), Collin and Edwards (140), Augé and Boccon-Gibod (141), and Dodds and Roberts (142).

A protoplast is the most unique system for whole plant regeneration from a single cell, presenting great potential involving several developmental pathways, such as suppression of events leading to cell death, active oxygen species generation, and induction of cell division (133).

1.5.7 Anther, Pollen, and Ovule Cultures

One of the most interesting applications of plant tissue culture is undoubtedly the generation of haploid and double haploid (DH) plants through anther, microspore, and ovule culture. Culture of these specialized organs was started by Guha and Maheswari (11) who were able to induced embryogenesis while culturing anthers from *Datura innoxia*. The successful culture of anthers and pollen of approximately 137 plant species belonging to 25 families, the majority of them solanaceae or gramineae have been achieved (143). Regeneration of complete plants in these systems is through direct or indirect embryogenesis induction.

If anthers or microspores are used as explants, the regeneration process is named androgenesis. Using this technique is possible to obtain homozygosity in one generation, reducing the numerous cycles of inbreeding necessary in conventional pure line breeding systems (144). The main applications of haploid plants generated *in vitro* culture are: studies of quantitative genetics and gene interactions, estimation of the gene number that take part in the polygenic characteristics, production of isogenic lines to be used in breeding programs, and isolation of homozygous recessive characteristics not easily achieved by conventional methods. By means of traditional breeding methods, to obtain one isogenic line can take from five to six generations, while by haploid plant systems followed by a dihaploidization process; it is possible to obtain isogenic lines in a very short period of time. There are additional advantages to this process: saving time from select plant material generation to marketing, selection efficiency increases due to an increment of additive

genetic variation, absence of variation among the segregating families, and decrease in effects of variation due to the environment (145).

The dihaploids obtained directly from the regenerated plants may be 30–60%, and the percentages of haploid plants up to 40–70% (146). The most frequent event is that the percentage of dihaploids obtained by breeders does not exceed 30% of the regenerated plants. Several workers are looking for increments of the number of DH plants by different treatments, such as increasing the concentration of mannitol in the culture media (147). Other authors consider more suitable treatments with colchicine to increase the number of DH plants (146,148,149).

Among the factors influencing haploid or double haploid regeneration are: physiology of donor plant, physical factors of culture, developmental stage of pollen, genotype, and culture media.

1.5.7.1 Physiology of Donor Plants

Age and physiology of donor plants have an influence on anther or microspore *in vitro* culture. Donor plants must be free of any type of environmental stress, phytopathological problem, or entomological problem. It is known that vigor of the donor plant is a requisite for a suitable response (150–156). For wheat anther culture, a temperature of 32°C is recommend if the donor plants are field cultivated, yet 30°C is an adequate temperature if donor plants are cultured in a greenhouse. Interestingly, anthers from field plants had a better *in vitro* regeneration response than those from greenhouse (150,154). Kristiansen and Andersen (153), working on *Capsicum annuum,* found that 26.4°C was the best temperature for incubation. Embryo formation was not affected by photoperiod, instead, age of the donor plant was important because a decline response was obtained when donor plant age was increased. Donor plant chemical pretreatments may affect anther response. Wassom et al. (156), on maize established different responses after abscisic acid (ABA), ancymidol, and gibberellic acid (GA) treatments. Other chemical pretreatment to donor plants might positively influence callus, and green plant formation. It consists in spraying the donor plant at different stages around meiosis with a chemical hybridization agent, such as hybrex™ or fenridazon–potassium, which have gametocidal effects (157–159).

1.5.7.2 Physical Factors of Culture

Cold or heat treatment to the anthers, either before or after *in vitro* culture has a main influence on regeneration response. Cold treatment induces a synchronous effect on pollen grain development, delays degeneration of microspores, and accelerates nuclear division during induction process. High temperature during early stages of embryogenesis is associated with protein synthesis. The effect of a temperature treatment has not been established yet, and available reports are contradictory (160). On the other hand, several reports about temperature androgenic response conclude that genotype, rather than cold or heat treatment is the response inductor (160–162).

1.5.7.3 Developmental Stage of Pollen

Pollen grain development stage is determinant for *in vitro* embryogenic response. Pollen grain must be collected before the dinucleated stage. Novák (163), and Heberle-Bors (158) established that the middle or late uninucleate stage are ideal for haploid and dihaploid embryogenesis.

1.5.7.4 Genotype

Genotype is the critical factor in anther *in vitro* culture, and it is considered the main factor that affects anther culture response and embryoid induction (160,164). These responses

are dependent not only on genetics, but also on the interaction of environment–genotype (158). Ouyang et al. (150) and Jones and Petolino (151) confirmed that interaction, and reported that even plants from the same genotype gave different culture responses if the donor plants are grown under different conditions. Moreover, anthers from the same genotype and grown in the same field conditions, but in different years, sometimes require different culture temperature. This complicates a single recipe for successful anther culture response, because for every genotype it is necessary to study its particular environmental, physical, and chemical requirements.

1.5.7.5 Culture Media

Media commonly used for anther and microspore culture are Murashige and Skoog medium (10), Nitsch medium (165), Potato-2 medium (166), and N6 medium (167). Media may be gelled by agar, gellan gum, or agarose. In order to prevent inhibitory substances from agar, liquid medium may be used or 10% Ficoll™ added, which avoids that anther sink into the medium (168–170). Trotier et al. (171) suggested the use of anther supports like membrane rafts. Different sucrose levels have been used in anther culture. Chu and Hill (172) and Saidi et al. (173) reported a concentration of 9% sucrose for wheat anther culture. Alemanno and Guiderdoni (146) established a sucrose addition of 60 g l^{-1} for *Oryza sativa*. Furthermore, Barnabás et al. (174) suggested a sucrose supplementation of 120 g l^{-1} in maize. Ferrie et al. (175) found for *Brassica oleracea* that the best sucrose concentration was 170 g l^{-1}. Culturing *Cucurbita pepo* anthers, Metwally et al. (176) recommended 150 g l^{-1} of sucrose.

Regarding plant growth regulators, 2,4-dichlorophenoxiacetic acid (2,4-D) is more frequently used, with concentrations from 1.5 to 2 mg l^{-1} mainly for anther or microspores from monocotyledon plants (151,152,169,172,173,177–179). For dicotyledon plants, 2,4-D concentrations are from 0.01 to 1 mg l^{-1}.

Other components included in the anther culture media are silver nitrate (180), copper sulphate at 10 mg l^{-1} (149), and activated charcoal (181). Beneficial effects of amino acids on androgenesis have been reported. Nitsch (165) attributes a positive effect of serine for *Nicotiana tabacum* anther cultures. Maheswari et al. (182) and Henry and DeBuyser (183) established that asparagine and glutamine are promoters of androgenesis. Nonetheless, Xu and Sunderland (184) and Hoekstra et al. (185) reported an inhibitory effect of glutamine on barley anther cultures.

1.5.7.6 Microspore Culture

Microspore culture may be considered just a variant of anther culture. In fact, several researchers (174,186,187) reported that anther culture is a microspore culture due to the fact that almost all dicots shed microspores into medium several days after anther incubation. All the factors reviewed for anther culture are applicable for microspore culture.

1.5.7.7 Ovule Culture

Another possible route for generation of haploid plants is culture of nonfertilized ovules. As for anther culture, gynogenesis depends upon genotype, physiological status of donor plant, type of explant, culture medium, and their interactions. Ovule culture has been much more complicated than anther or microspore culture process, and in spite of many efforts trying to improve the haploid induction technique, the yield of gynogenic embryos and haploid plants obtained is frequently low (188–190). In spite of that, several Cucurbitaceae ovule cultures have shown similar responses to those from anther culture. In *Cucurbita pepo,* Metwally et al (176) has produced 8.8 and 9.1 embryos per 100 cultured ovules

when 2,4-D was used, at a dosage of 1 or 5 mg l^{-1}. For *Cucumis sativus*, Gémes-Juhász et al. (191) have reported an 18.4% of gynogenesis frequency with 7.1% of plant regeneration. For *Cucumis melo*, Lotfi et al. (192) reported the regeneration of 175 haploid plants using gynogenesis, which were subjected to colchicine treatments, and induced 10 dihaploid and 100 mixoploid plants. These authors applied 0.05 mg l^{-1} α-naphtaleneacetic acid, and 0.2 mg l^{-1} benzyladenine as plant growth regulators.

1.5.8 Germplasm Storage

The main goal of constituting germplasm banks is to have easily available material for crop improvement, and to preserve local and introduced materials. Likewise, banks constitute an ideal means for maintaining useful lines for commercial hybrids, and for preserving valuable germplasm threatened by overcollection and severe perturbation of a habitat. There are many germplasm banks based on plant seed storage, although if genetic material is difficult to preserve as seed collection, botanic gardens or orchards are established as field gene banks. This system requires a large land area, considerable labor, and a sizeable capital investment. Because of this, the development of alternative conservation techniques is desirable. During the past few decades, different *in vitro* conservation methods have been developed as substitutes for field gene banks and have been widely employed depending on storage duration required (193). *In vitro* techniques compared to traditional methods, offer different germplasm storage based mainly on vegetative plant material preservation using cold storage, chemicals inhibitors, or cryopreservation techniques.

It is possible to preserve *in vitro* active collections by subculturing them with normal culture traits, but the success of that method depends greatly on plant species. Many species support a continued subculture for several years without any apparent change, such as strawberries, potato, *Photinia*, African violet, and gerbera (194). But others, such as cucumber, and maybe all cucurbits, lose their regeneration capacity through two to three years, and apparently it is not possible to use cold storage technique, because their survival depends on relatively hot temperatures (195). A number of advantages for *in vitro* preservation may be listed, such as the small space needed for storage, easy shipping, year round availability, maintenance of disease-free status, and quick propagation and distribution if materials are requested by users (196).

For several species there are *in vitro* conservation techniques based on modified incubation parameters. Strawberry preservation studies suggests that shoot culture storage has to be done under temperatures of 4°C, subculturing shoots over filter paper bridges in liquid medium and adding fresh medium every three months (197). Reed and Humer (194) studied in the strawberry the influence of benzyladenine in the storage medium, prestorage acclimatization, and exposure to a photoperiod during storage. They concluded that strawberry preservation at 4°C for 9–24 months intervals can be obtained before they require propagation.

Light is another physical factor studied for long term plant storage. It is important for plants to preserve photosynthetic capabilities and their absence implies a rapid elongation for many plants, nevertheless when this factor is combined with cold for plant material storage different responses are observed depending on genotype studied. Prune shoots had a positive and better response to a photoperiod of 16 h combined with a temperature of 4–8°C, compared with similar cold treatment in darkness (198). Romano and Martins-Louçao (199) were able to culture Cork oak (*Quercus suber* L.) explants on multiplication medium at 5 ± 1°C without a subculture for more than 22 months. They evaluated light and dark conditions for explant survival finding that light negatively affected culture viability. On the contrary, 50% of the cultures survived after two years of cold storage in dark incubation, and multiplication rate and rooting of cold storage plants was similar to controls.

It is important to asses the genetic stability of *in vitro* cultures, mainly after prolonged storage periods, because one of the objectives of germplasm storage is to preserve the genetical identity. A genetic stability study after one year of cold storage was conduced using apple plants tissues (193). These authors established that all stored apple shoots survived one year at 4°C, having a 12 h photoperiod of 11 μmol m^{-2} s^{-1} light irradiance. By means of an amplified fragment length polymorphism study (AFLP), they did not detect any differences in DNA fragment patterns using 20 primer combinations, while a methylation sensitive amplified polymorphism (MSAP) assay demonstrated that cold stored plants had developed methylation changes compared to controls. This methylation event is important because change in DNA methylation status may be a response to stresses associated with *in vitro* conservation, and further investigation is necessary to determine the physiology and genetic role of DNA methylation change for *in vitro* cultured species. This phenomenon has been found in several species such as potato, apple, and *Swietenia macrophylla*, (193,200,201).

Cryopreservation is a harder treatment to preserve *in vitro* plant cell, tissue, and organ cultures. When material to be preserved is a shoot apex collection, liquid nitrogen can be used as a suitable method to maintain viability and phenotypic and genetic stability, thereby ensuring long term germplasm storage. Many studies have emphasized that cold pretreatments of shoot cultures of hardy species improves the resistance of shoot tips to freezing in liquid nitrogen (202,203). Although high levels of shoot regrowth have been recorded with techniques such as vitrification and encapsulation–dehydration, none of them could suppress the deleterious effect of cold hardening pretreatment in shoot cultures (204). However, with similar encapsulation–dehydration technique, Sales et al. (205) successfully cryopreserved *Digitalis obscura* shoots. Their best treatment consisted in cold hardening of *in vitro* cultures before sucrose treatment, recovering up to 86% of the treated explants. Nevertheless, after applying the same treatment with diverse genotypes of the same spices, they found that cryopreservation responses mainly depend on genotype. More information on germplasm storage using *in vitro* techniques can be found in Westcott et al. (206), Kartha (207), Bhojwani and Razdan (208), Brennan et al. (209), Dodds and Roberts (210), Ashmore (211), Drew (212), and Collin and Edwards (213).

In vitro germplasm storage offers an alternative to traditional storage methods. It is a tool for different biological studies, and at same time it is a method to maintain for long time worthy research materials, mostly those which are vegetatively propagated. Although for commercial application, qualified personnel and minimal equipment is needed, undoubtedly plant tissue culture is offering an alternative to germplasm storage that is increasing as different techniques are developed, and many others are under study.

1.6 GENETIC MANIPULATION

Plant genetic improvement by conventional methods is mostly limited by narrow available genetic variability and by natural barriers of crossing. One of the most interesting applications of modern plant biotechnology is the possibility to genetically manipulate plants, in order to confer desirable agronomic traits, to carry out studies on genetics and metabolism, and to obtain plants with new characteristics.

This genetic manipulation can be made through two different methods: somatic hybridization and genetic transformation. The former is used to produce somatic hybrids which are produced by fusion of two protoplasts isolated from different plant sources. This technique allows mixing two genomes of diverse origin, and obtaining plant hybrids that could not be generated using traditional methods. The second method is the direct introduction of genes to the plant cell genome, also called genetic transformation. This process

requires first the delivery of foreign DNA to the nucleus of a plant cell, in a manner that minimizes damage using transformation methods. This includes the insertion, integration, expression, and inheritance of new foreign DNA. In a second step, fertile transgenic plants are regenerated starting from those transformed cells, using *in vitro* plant culture methods.

Plant genetic transformation is now a routine technique in numerous laboratories around the world, because it offers a valuable tool to accelerate crop genetic improvement, by transferring genes which confer resistance to pests, diseases, herbicides, and environmental stress, as well as quality traits such as improved postharvest storage, nutritional content, flavor, or color. Some examples of plant improvement using genetic transformation are depicted in Table 1.4. Additionally, genetic transformation can be used to study

Table 1.4
Examples of some Phenotypic Traits Improved by Plant Genetic Transformation.

Phenotypic Trait	Transgene(s)	Ref.
Altered lignification in forest trees	*COMT* (caffeic acid 5-hydroxyferulic acid O-methyltransferase gene,depressed)	(245)
Bacterial diseases resistance	Bacterial detoxification gene	(249)
	Antibacterial protein genes from insects	(250)
Cold tolerance	*gpat* Glycerol 3-phosphate acyltransferase gene for fatty acid unsaturation	(251)
	Anti-freeze gene from fish	(252)
	afp (carrot antifreeze protein)	(253)
Enhanced fruit quality	*Spe2* (yeast S-adenosylmethionine decarboxylase gene)	(254)
Enhanced growth	*vhb* (gene for *Vitreoscilla* hemoglobin)	(255)
Fungal diseases resistance	Bean chitinase gene	(256)
Herbicide resistance	EPSPS (glyphosate resistance)	(257)
High bioavailable iron-content plants	Soybean ferritin gene	(258)
Increased rooting capacity	*rolABC* from *Agrobacterium rhizogenes*	(259)
Insect resistance	*Bt* gene from *Bacillus thuringiensis*	(260)
	Cowpea trypsin inhibitor gene	(261)
Phytoremediation (use of plants for removal and detoxification of environmental pollutants)	Human cytochrome P450 (for oxidize a wide range of organic pollutants)	(262)
	merA9 (Bacterial organomercurial lyase for mercury phytoremediation)	(263)
	onr (PETN reductase for detoxification of explosives)	(264)
Rootstock transformation to alter scion growth habits	*rolABC* from *Agrobacterium rhizogenes*	(265)
Salt tolerance	*mtlD* Mannitol-1 phosphate dehydrogenase gene (mannitol metabolism)	(266)
Virus resistance	Viral coat protein genes	(267)
	Viral satellite RNA (cDNA copy)	(268)
	Pokeweed antiviral protein gene (a ribosome inhibiting protein)	(269)
Water stress tolerance	*p5cs* Δ^1-Pyrroline 5 carboxylate synthetase gene for proline biosynthesis	(270)

the organization, function, and evolution of plant genes, and their expression systems. Irrespective of the transformation method used, evidences indicate that foreign DNA is integrated at random into plant genome, and that the transgene is inherited according to established genetic rules. Foreign genes introduced to plant cells genome, also called transgenes, are usually chimeric assemblies of cloned DNA from diverse organisms.

A typical transgene consists of a coding sequence with 5´ and 3´ untranslated regions, including the promoter and the sequences for poly A addition that function in plants (214). In order to select and recover transformed cells, tissues, or plants, selective marker genes have been developed which confer resistance to an antibiotic or herbicide. Presence of these genes gives to transformed cells the ability to grow on media containing a toxic compound for untransformed cells. Examples of these marker genes are *nptII* that confers kanamycin resistance, *hpt* that confers hygromycin resistance, and *csr1-1* that confers chlorsulfuron resistance (215). In addition, a number of reporter genes are available, encoding enzymes or proteins that can be assayed or observed easily in plant tissues, facilitating the detection of transformation events during gene transfer experiments. The gene for the β-Glucuronidase (*uidA* or *gus*), which originates from *E. coli*, is the most widely used reporter gene in plant transformation protocols (216). Green fluorescent protein (GFP) is another interesting reporter gene, responsible for the jellyfish *Aequorea victoria* green bioluminescence. The intense fluorescence of GFP is due to the chromophore composed nature of modified amino acids within the polypeptide. Formation of fluorescent chromophore is species independent and apparently does not require any additional factors. Because the gene product is easily detectable *in vivo* in transformed tissues by its intense fluorescence, the GFP has become a unique reporter gene (217).

Usually, marker and reporter genes have no agronomic or nutritional value, and their presence in the plant genome can generate some plant grower and consumer concerns. For this reason, the development of transformation systems that produce marker free transgenic plants is desirable and has been intensely researched (218). Introduction of multiple genes for metabolic engineering applications that require simultaneous and coordinated expression of genes encoding multiple steps in a metabolic pathway is also under study (219).

1.6.1 Somatic Hybridization

Protoplasts are useful for a somatic hybridization technique, giving place for somatic hybrid cells, which are originated from the fusion of two protoplasts from different species. These somatic hybrids may be able to attain the posterior regeneration of a whole plant. Somatic hybridization enables the transfer of desired properties across species boundaries and avoids sexual incompatibilities. Protoplast fusion is not a spontaneous event, because they have a membrane with a negative peripheric charge, and thus they have the tendency to mutually repulse. Nevertheless, it is possible to use a chemical or physical fusion method to overcome that repulse. Chemical fusion consists on placing the protoplasts in medium that alter the characteristics of their membrane surfaces, such as $NaNO_3$, a high calcium concentration (Ca^{2+}), and polyethylene–glycol (PEG). These compounds change the plasma membrane's properties from having a negatively peripheric charge to a positively one. On the other hand, the most important physical method is electrofusion (220). A derivative of somatic hybridization technique is the production of cybrids. For the production of somatic hybrids or cybrids, is essential to have an efficient method for regeneration of whole plants starting from protoplasts.

In a comparative study of both methods using pea protoplasts, De Filippis et al. (221) reported that PEG induced about 15% of somatic hybrids, and that over 50% of the initial protoplast mix was lost or damaged. Additionally, PEG treated protoplasts had decreased viability and respiratory O_2 consumption. In presence of light, PEG also induced

a marked decrease in O_2 evolution, rate of CO_2 fixation, and protein and chlorophyll levels. Membrane damage was present in PEG treated protoplasts, as evident by large amounts of efflux of intracellular potassium (>70%) and CO_2 fixation products (>40%). On the other hand, electrofusion protocol produced 20–30% fusion products, lower protoplast membrane damage, and normal respiratory O_2 consumption. Under light, O_2 evolution and CO_2 fixation were close to, and in some cases higher than, freshly isolated protoplasts. Protein and chlorophyll content of electrofused protoplasts were close to the controls, and the loss of intracellular K was about 10%.

Nuclei fusion may also take place after protoplast fusion, and this is when true somatic hybrids are obtained. An interesting variation of protoplast fusion is when nuclei of one population of protoplasts to be fused are irradiated with x-rays or gamma rays. Resulting hybrids have the nuclei of one cellular line, and the cytoplasm of both lines, including mitochondria and plastid genomes. This type of cytoplasmic hybrid is called a cybrid.

In its beginning, somatic hybridization was considered as a technique that would revolutionize agricultural research. Nevertheless, difficulties in protoplast isolation, culture, and regeneration, and elevated ploidy levels in the resulting somatic hybrids, as well as the emergence of genetic transformation techniques, lead to limited use of this procedure. Despite this fact, this technique continues being an important tool in the improvement of some species. For example, citrus somatic hybridization and cybridization has become an integral part of several programs of citrus improvement (222). Applications of these techniques to citrus rootstock improvement include the production of allotetraploid hybrids that combine complementary diploid rootstocks, and to combine sexually incompatible or difficult to hybridize genera that possess traits of interest (222).

1.6.2 Direct Transformation

1.6.2.1 Gene Transfer to Protoplast

Uptake of exogenous DNA into plant protoplasts can be promoted by various treatments. Those more frequently used, as in somatic hybridization, are polyethylene–glycol (PEG) and electroporation (223). These methods do not require biological vectors and the DNA uptake is a physical process.

For regeneration of whole transgenic plants, it is essential an efficient regeneration system starting from protoplasts. This is one of the main obstacles for this transformation method, because plant regeneration from protoplasts always is a complex process that depends on many parameters and not easily achieved. Use of direct gene transfer to protoplasts as a method for production of whole transgenic plants is being taken over by biolistic or *Agrobacterium*-based transformation methods. However, this method maintains its importance in transient expression studies, which neither require integration of transforming DNA into genome nor regeneration of whole plants.

1.6.2.2 Gene Transfer Using Biolistics

Biolistics is a transformation method based on gene delivery into intact plants cells or organized tissues by high velocity micro-projectiles coated with DNA. These projectiles are tungsten or gold particles 1–2 μm in diameter. A number of devices for accelerating microprojectiles have been described (224). Acceleration is achieved either by gun powder charge, capacitance discharge through a drop of water, or the sudden release of compressed air, nitrogen, or helium. Development of this technique has allowed the transformation of many plant species considered recalcitrant, because the biolistic process appears to be effective regardless of species or tissue type (225,226).

Biolistic transformation process is influenced by several parameters such as origin and stage of the tissue; cell survival after bombardment; and the material, size, propulsion velocity, impact distribution, and DNA-carrying capacity of the particles. It is important to target cells that are actively dividing, as these have the greatest capacity for foreign DNA integration. Tissue culture conditions and media that induce the division of cells with high morphogenic competence will facilitate the transformation and recovery of transgenic plants (227).

Biolistic transformation is also possible for chloroplasts (228), and is a valuable method for transient gene expression studies. The disadvantages of the biolistic process are that it requires special instrumentation and the fact that it is a direct gene transfer method, and therefore has no direct effect on chromosomal integration mechanism. For this reason biolistics can not guarantee the stable transformation of bombarded cells.

1.6.2.3 Other Direct Transformation Systems

Microinjection, DNA introduction mediated by silicon carbide, and tissue electroporation are alternative direct transformation methods. Microinjection is a direct physical method for introducing DNA or any other kind of molecule into single plant cells using an optical microscope and micromanipulators. This is one of the most difficult gene transfer methods, but it has some advantages such as control of the quantity of DNA injected, and the possibility to observe and control the cells before, during, and after DNA transfer (229).

The direct delivery of DNA to plant cells using silicon carbide whiskers is a simple and inexpensive option for the production of transgenic plants. Cells are mixed abruptly with plasmid DNA in the presence of silicon carbide whiskers. The resultant collisions between cells and needle-like whiskers result in cell penetration and DNA delivery (230). Electroporation-mediated DNA transfer into intact plant cells and regeneration of whole maize transgenic plants were reported by D´Haullin et al. (231). This demonstrates that it is not indispensable to eliminate the cell wall to introduce DNA by electroporation.

1.6.3 Agrobacterium-Mediated Transformation

1.6.3.1 Agrobacterium tumefaciens

Agrobacterium tumefaciens is a Gram-negative soil bacterium that induces tumors called crown galls on many plant species. This is due to the natural capacity of this bacterium to introduce a DNA segment of its large tumor-inducing plasmid (Ti) into plant cells. The transferred DNA, called T-DNA, is integrated into plant cell genome via recombination. Products of virulence (*vir*) genes located on a nontransferred segment of the Ti plasmid are responsible for excision of T-DNA for transfer into a plant nucleus and for chromosomal integration in recipient cell. The *vir* genes are tightly regulated, so their expression occurs only in the presence of wounded plant cells, the targets of infection. This is because the product of *vir A* gene detects small phenolic compounds, like acetosyringone and others, released by wounded cells. Genes transferred to plant genome, located in the T-DNA, encoded enzymes involved in the production of plant growth regulators like auxin and cytokinin, and tumor-specific novel amino acid derivatives called opines. The first ones, called oncogenic genes, alter the development patterns of the plant tissue forming tumors, while the products of the second kind of genes are used by *Agrobacterium tumefaciens* as sources of carbon and nitrogen. The type of opine produced is used to classify the *Agrobacterium* strains.

Plant cells containing the T-DNA wild genes cannot regenerate whole plants. However, deletion of the oncogenic genes from the T-DNA does not interfere with the

transfer process to plant cells. This is because only two repeated regions of 25 bp, located in the ends of T-DNA, called border sequences, are indispensable for the transfer process. These border sequences are recognized by endonucleases encoded by *vir* genes and they are the only *cis* elements necessary to direct T-DNA transfer. Plant cells transformed with T-DNA lacking oncogenes are able to regenerate complete plants. Therefore, by using such disarmed Ti plasmids it is possible to obtain fertile transgenic plants. Genes of interest can be introduced into plants by linking them to the disarmed T-DNA via recombination or by cloning them between border sequences in an independent plasmid called a binary vector. Any DNA between the border sequences will be transferred to the plant cell genome.

Efficiency of T-DNA transfer by *A. tumefaciens* can vary dramatically for different plant species, cultivars, or target tissues, and the principal limitation of this genetic transformation system is the host range of the bacteria (232,233). A typical transformation protocol using *A. tumefaciens* involves a 24–72 h cocultivation of bacteria (containing the plasmid with foreign genes) with plant tissues. This is followed by culture of explants on shoot induction medium with the appropriate antibiotic or herbicide (234) to select transformed cells, and one antibiotic to eliminate residual *Agrobacterium*. Modifications of this approach have been adapted to several plant species.

1.6.3.2 Agrobacterium rhizogenes

Agrobacterium rhizogenes is a soil bacterium responsible for development of hairy root disease on a range of dicotyledonous plants. The hairy root phenotype is caused by transferring to the plant genome, a DNA sequence from the Ri plasmid that encodes functions which induce root formation, in a manner similar to the development of crown gall disease by *A. tumefaciens*. Transformed roots are easily distinguished by their rapid growth on hormone-free media and plagiotropic root development. These roots can be cultivated *in vitro* easily and are an important tool for the study and production of plant secondary metabolites. *Agrobacterium rhizogenes* will also transfer in *trans* the T-DNA of binary vectors, thereby enabling the production of hairy roots containing foreign genes. Tissues transformed by wild genes of *A. rhizogenes* are able to regenerate fertile plants, which is important because regeneration from tissues containing wild genes of *A. tumefaciens* is a very rare event. However, due to independent insertion of Ri T-DNA and binary vector T-DNA, segregation in subsequent generations can produce plants free of wild genes of *A. rhizogenes.* Therefore, *A. rhizogenes* can be used as an alternative transformation system for the generation of plants transformed with foreign genes, including agronomical useful traits.

Transgenic plants are usually obtained after transferring transformed roots segments to a shoot induction media (235,236). Sometimes plants regenerated from hairy roots exhibit an altered phenotype characterized by several morphological changes including wrinkled leaves, shortened internodes, reduced apical dominance, reduced fertility, altered flowering, and plagiotropic roots (237).

Protocols for hairy roots establishment have been created and described in detail (238,239). Frequently two types of problems may arise trying to establish hairy root cultures, one relates to the difficulty of transforming certain plant species, and another concerns specifically the complication presented as to when transformed roots should be removed from the original tissue to establish the appropriate cultures. The common range of *Agrobacterium rhizogenes* hosts is limited to dicotyledoneus plants (240), although within that group there are recalcitrant woody species difficult to transform. Fortunately, it is possible to increase the host range of different bacterial strains introducing additional copies of virulent active genes or carrying out a double plant material transformation (241,242).

The most important characteristics of roots transformed by *Agrobacterium rhizogenes* is their major growth rate in comparison to normal roots and their complete independence of exogenous growth regulators to induce growth. The major growth arises from several characteristics, such as main lateral root formation, high linear extension speed, secondary diameter increase as consequence of expansion and cellular differentiation, profusion of radical hair, and geotropism absence (238). Growing speed of *in vitro* transformed root cultures changes widely depending on plant species (243), and culture conditions as well (244).

Culture of transgenic roots is increasing especially in the field of study and production of secondary metabolites. As it was pointed out, White grew root cultures as early as 1934, but these culture systems were not used, mainly due to their poor growth rate. With the discovery of transformed roots, the disadvantage of scanty growth was overcome. Therefore, in this *in vitro* system of isolated plant organs, growth and expression of secondary metabolism biosynthetic route were compatible. On the other hand, root biosynthetic capacity is also maintained in transformed roots, consequently they become attractive as systems for the study and production of secondary metabolites that are synthesized and accumulated specifically in the roots. Plant tissue transformation protocols of *Agrobacterium rhizogenes* infection technique may be used for a wide number of industrial interest metabolite producing species (245,246). Transformed root cultures have certain characteristics that make them appropriated to be cultured in large fermenters to produce at commercial level several secondary metabolites (247).

1.7 CONCLUDING REMARKS

Plant cell, tissue, and organ culture methods have evolved considerably throughout the last 100 years, since Haberlandt's first attempts to culture *in vitro* plant fragments. It is interesting in this regard to note that these methodologies have conveniently been utilized as research systems to study at the molecular, genetical, biochemical, cellular, physiological, and morphological levels several processes that take place in plants. The outcome of those studies have helped enormously and complemented a better understanding of plant biology function. Therefore, *in vitro* culture of plants has had an important role in basic plant science. Alternatively, plant cell, tissue, and organ culture have also been applied to the commercial production and propagation (micropropagation) of elite plants, as well as to obtain pathogen-free plants. In addition, these *in vitro* systems have been used in the production of secondary metabolites at industrial stage.

On the other hand, not all plant tissue culture techniques have had the same success rate. Initial techniques and observable facts related to *in vitro* culture, such as somatic hybridization and somaclonal variation, were considered at first as powerful tools for plant improvement. However, ambiguous and unexpected results, as well as many drawbacks, such as lack of genetic control in those systems, have posed somaclonal variation and other tissue culture techniques' expectatives in a moderate context. Nevertheless, as previously noted in this chapter, numerous plant *in vitro* methodologies are still in use by scientists, and new technologies have recently emerged, increasing the role of *in vitro* tissue culture on plant science. Furthermore, plant cell, tissue, and organ techniques have played a key role in the advance of plant transformation protocols. Without plant *in vitro* regeneration techniques, GMO crop plants could not be obtained at all. It is important to emphasize that the combination of plant *in vitro* techniques and genetic engineering can make significant contributions to the development of food biotechnology.

In summary, tissue culture technology has had, and will have, a remarkable impact on and relevance to both basic and applied plant science. Consequently, it is expected that these plant *in vitro* methods will contribute to the advance and improvement of food biotechnology science.
